PARIS.

Academy of Sciences, October 6.—M. Léon Guignard in the chair.—H. **Deslandres**: Remarks on the constitution of the atom and the properties of band spectra. A continuation of communications previously made on the same subject. Band spectra may be considered as being formed of transversal and longitudinal vibrations, but the exact part of the spectrum which can be attributed to the one or the other of these cannot as yet be precisely determined.—G. **Charpy** and J. **Durand**: A cause of rupture of steel rails and a means of suppressing it. It has been proved by several observers that a frequent cause of breakage of steel rails, not possessing any local faults due to manufacture, consists in the formation of very fine fissures appearing on the surface carrying the wheel after a certain period of use, and it has been proposed that, after a careful inspection of the permanent way, these fissured rails should be detected and removed. The critical age of steel rails appears to be about ten years. The author has found that the incipient cracks are removed by annealing, and suggests a method by which it would be possible to anneal the rails without removal from the track.—E. **Ariès**: The equation of state of ethyl formate.—G. A. **Boulenger**: The genus Saphæosaurus, a Rhynchocephalian of the Kimmeridge formation of Cerin. The examination of the specimens at the Lyons Museum leads the author to agree with the views of L. Lortet as to the classification of this reptile, as opposed to the interpretation of D. M. S. Watson.—N. E. **Nörlund**: An extension of the polynomials of Bernoulli.—M. **Stoïlow**: The analytical representation of functions of several complex variables.—G. **Serf**: The transformations of linear partial differential equations with two independent variables.—J. **Rey**: The experimental predetermination in the laboratory of the characteristic of a lighthouse at the horizon. The distribution of the light intensity in the horizontal plane is studied by means of a series of metallic screens, pierced with a regular series of small holes of accurately known diameter. The results of such a study are shown in a graph.—Ch. **Boulin** and L. J. **Simon**: The action of stannic chloride on dimethyl sulphate. The products of the reaction at a temperature of about 114° C., the boiling point of stannic chloride, are methyl chloride and stannic sulphate.

SYDNEY.

Linnean Society of New South Wales, August 27.—Mr. J. J. Fletcher, president, in the chair.—W. W. **Froggatt**: A new species of wax scale (*Ceroplastes murrayi*) from New Guinea. The author describes a wax scale found on the wild mango in the forests fringing the Kikori River, Delta Division, British New Guinea. The scale, for which the name *Ceroplastes murrayi* is proposed, produces a solid mass of hard, white, wax-like secretion, forming a rounded dome over the resting gravid female coccid. The characters of the female are described. Male unknown.—G. F. **Hill**: Australian Stratiomyidæ (Diptera), with description of new species. Six new species are proposed, belonging to the genera Actina, Hermetia, Odontomyia, Sargus, and Wallacea, two of these genera (Hermetia and Wallacea) not having previously been recorded from Australia.—J. **Mitchell**: Two new Trilobites from Bowning, N.S.W. The Trilobite described in this paper under the name of *Dalmanites (Hausmannia) loomesi* was formerly joined with *Hausmannia (Dalmanites) meridianus*, Etheridge and Mitchell. The examination of additional and much better specimens has shown that the two forms are specifically distinct, and accordingly each of the two forms originally described under the name *H. meridianus* has now been given specific rank. The cephalic characters of the other Trilobite proved to be so unusual that the writer deemed it advisable to propose a new genus (Adastocephalum) of the Phacopidæ for its reception. The chief generic feature in the genotype is the absence of glabellar furrows and lobes.—A. A. **Hamilton**: An ecological study of the salt-marsh vegetation in the Port Jackson district.

DIARY OF SOCIETIES.

THURSDAY, NOVEMBER 6.

ROYAL SOCIETY (jointly with the ROYAL ASTRONOMICAL SOCIETY), at 4.30.—Sir Frank Dyson, Prof Eddington, and Others: Discussion on the Results of the Observations obtained at the Total Solar Eclipse on May 29, 1919.

LINNEAN SOCIETY, at 5.

ROYAL COLLEGE OF PHYSICIANS, at 5.—Dr. A. P. Beddard: Some Remarks on Chronic Arthritis (Bradshaw Lecture).

CHEMICAL SOCIETY, at 8.—F. G. Donnan and W. E. Garner: Equilibra across a Copper Ferrocyanide and an Amyl Alcohol Membrane.—R. R. Le G. Worsley and P. W. Robertson: The Peroxides of Bismuth.—T. M. Lowry and R. G. Early: The Properties of Ammonium Nitrate. Part I. The Freezing-point and Transition-temperatures.—R. H. Vernon: Organic Derivatives of Tellurium. Part I. Dimethyl-telluronium-di-iodide.—J. Reilly and W. J. Hickinbottom: Intramolecular rearrangement of the Alkylarylamine. Formation of 4-amino-*n*-butylbenzene.—H. Swann: A New Modification of 3:4-Dinitrodimethylaniline.—G. Le Bas: (1) The Refractivities of Unsaturated Substances; (2) The Molecular Refractions of Benzene and Aromatic Derivatives.—R. R. Baxter and R. G. Fargher: Some 1:3-Benzodiazolearsinic Acids and their Reduction Products.

ROYAL SOCIETY OF MEDICINE (Obstetrics and Gynæcology Section), at 8.—Dr. D. Robinson: The *Rôle* of the Cinematograph in the Teaching of Obstetrics (Cinematograph Demonstration).—Dr. H. Spencer: Nine Cases of Inversion of the Uterus.

FRIDAY, NOVEMBER 7.

ROYAL SOCIETY OF MEDICINE (Laryngology Section), at 4.

ROYAL ASTRONOMICAL SOCIETY (Geophysical Committee), at 5.—Col. Sir S. G. Burrard, Prof. A. E. H. Love, and Others: Discussion on Isostasy.

TECHNICAL INSPECTION ASSOCIATION (at Royal Society of Arts), at 7.30.—Prof. Baly: The Spectroscope in the Science of To-day.

ROYAL SOCIETY OF MEDICINE (Anæsthetics Section), at 8.30.—Dr. F. E. Shipway: Intratracheal Insufflation of Ether in Operations which involve Bleeding into the Air Passages.

MONDAY, NOVEMBER 10.

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, S.W.7), at 5.—Lt.-Col. G. A. Beazeley: Surveying in Mesopotamia during the War.

BIOCHEMICAL SOCIETY (at King's College), at 5.30.

ROYAL SOCIETY OF MEDICINE (War Section), at 5.30.—Surg.-Rear-Admiral Sir Robert Hill: Presidential Address.

INSTITUTION OF MECHANICAL ENGINEERS, GRADUATES' ASSOCIATION, at 8.—F. M. Green: Modern Steam Turbines.

SURVEYORS' INSTITUTION, at 8.—A. Young: President's Opening Address.

TUESDAY, NOVEMBER 11.

ROYAL COLLEGE OF PHYSICIANS, at 5.—Dr. E. G. Browne: The Origins and Development of Arabian Medicine. I. The Translations (VII.-IX. Cent.). (FitzPatrick Lecture.)

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—S. Hazzledine Warren: A Stone-axe Factory at Penmaenmawr.

WEDNESDAY, NOVEMBER 12.

CONJOINT BOARD OF SCIENTIFIC SOCIETIES (at Royal Society), at 5.—Discussion of Draft Report on the Metric System.

ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 8.—C. A. Swan: Some Physical and Psychical Effects of Altitude.

THURSDAY, NOVEMBER 13.

ROYAL SOCIETY, at 4.30.—*Probable Papers*: Prof. W. B. Bottomley: The Effect of Nitrogen-fixing Organisms and Nucleic Acid Derivatives on Plant Growth.—W. Robinson: The Microscopical Features of Mechanical Strains in Timber and the Bearing of these on the Structure of the Cell-wall in Plants.—Agnes Arber: The Vegetative Morphology of Pistia and the Lemnaceæ.—Lt. Col. R. McCarrison: The Genesis of Œdema in Beri-beri.—W. J. Young, A. Breinl, J. J. Harris, and W. A. Osborne: Effect of Exercise and Humid Heat upon Pulse Rate, Blood Pressure, Body Temperature, and Blood Concentration.

ROYAL COLLEGE OF PHYSICIANS, at 5.—Dr. E. G. Browne: The Origins and Development of Arabian Medicine: II. Four Great Medical Writers of Persia (IX.-XI. Cent.). (FitzPatrick Lecture.)

INSTITUTION OF ELECTRICAL ENGINEERS (At Institution of Civil Engineers), at 6.—Roger T. Smith: Presidential Inaugural Address.

OPTICAL SOCIETY, at 7.30.

FRIDAY, NOVEMBER 14.

ROYAL ASTRONOMICAL SOCIETY, at 5.

ROYAL SOCIETY OF MEDICINE (Clinical Section), at 5.

PHYSICAL SOCIETY, at 5.—S. Butterworth: The Self-Inductance of Single Layer Flat Coils.—Dr. N. W. McLachlan: An Experimental Method of Determining the Primary Current at Break in a Magneto.—F. H. Newman: Note on a Modified Form of the Wehnelt Interruptor. (With Demonstration.)

SATURDAY, NOVEMBER 15.

PHYSIOLOGICAL SOCIETY (at London School of Medicine for Women), at 4.30.

THE TURKS OF CENTRAL ASIA.

The Turks of Central Asia in History and at the Present Day: An Ethnological Inquiry into the Pan-Turanian Problem, and Bibliographical Material relating to the Early Turks and the Present Turks of Central Asia. By M. A. Czaplicka. Pp. 242. (Oxford: At the Clarendon Press, 1918.) Price 15*s.* net.

THIS small and closely packed book deals with a big and intricate subject which can be dealt with satisfactorily only on a much larger scale, and it is to be hoped that its talented and learned author will presently give us a larger monograph in which the earlier history of the Turks, with its dramatic ties with the fortunes of Asia and Europe, will be told in much greater detail. It is opportune that such a book should appear when the greatest and most powerful empire established by the Turkish race is passing away, and when the thoughts of many of us are turning with a good deal of interest to the period in its history when the race emerged from the prehistoric age and began its wider sphere of interest. It is not possible in the space which NATURE can spare to do more than give a bare outline of the subject.

The Nomadic peoples who occupy the great stretch of grassy steppes, barren lands, and stony plateaus of Asia from the River Ural to the Yellow Sea form a group which is closely united by physical ties and by language. Their speech, although mutually unintelligible, has a common grammatical structure and a large number of common words. They are divisible into two main branches, respectively known to the Chinese as the Eastern and Western barbarians. Each of these divisions is again separable into two sections, one of them including the Mongols properly so-called, and the Tungus, better known in the West from one of their tribes as Manchus, and occupying the eastern part of Central Asia, of which the great desert of Gobi and its borders form the kernel. The other section, comprising the Turks and Finns (each divided into various tribes), occupies the country west of Mongolia, and is grouped about the great mountain chains of the Urals and the Altai Mountains, and is often spoken of as the Uralo-Altaic section of the human family.

At the time when history first notices this group, they were probably nearly as much separated as they are now, the great distinguishing feature which separates these two branches being that, while the Finnish branch were at that time almost entirely hunters and fishermen, the Turks have always been nomad herdsmen, having been occupied chiefly with the rearing of cattle, horses, and camels.

In their early days one section of the Turks formed the "frontagers" of the Aryan peoples, who lived in the Persian provinces of Khorasan, Balkh, and Transoxisia, which they continually worried and attacked. The two lands, that of the nomads and that of the settled people, were respectively known to the Persian writers as Turan and Iran. This Western section is generally known as the Western Turks, and was perhaps the only portion of the stock specifically called Turks at that time.

Another great section occupied the frontiers of China and the greater part of what is now known as Mongolia, and in the earliest Chinese writers are known as *Hiong Nu*, or *Hiun Nu*. The Hiong Nu formed a very powerful empire, which fought on equal terms with China, and was a serious menace to the latter empire during the Chinese dynasties of the earlier and later Han. The power of the Hiong Nu was gradually sapped in their struggles with the Chinese, and they were eventually attacked and conquered by their Eastern neighbours, known to the Chinese as Yuan Yuan, who thus became the masters of all Nomadic Tartary, and were probably nearly related to the later Mongols. I argued in former years that they were identical with the Avars of the European writers, who appear in the West at the time when the power of the Hiong Nu was destroyed.

Presently, in the sixth century, the Yuan Yuan were themselves conquered and replaced by the true Turks, who then appear *eo nomine* for the first time in the Chinese annals. The Chinese, not having the letter "r" in their alphabet, represented the name "Turk" by that of Thukiu. These Turks were, I feel sure, the Western branch of the race above named. They in turn became the masters of all Tartary, and eventually were divided into two sections, a Western branch and an Eastern, the latter being in a large measure the descendants of the Hiong Nu above named.

It is with the advent of these true Turks into Mongolia that we first meet with signs of a settled community there, marked by many traces of civilisation, which are clearly traceable to the Iranian lands from the borders of which these Turks came. Among these the most notable relics are the remains of towns, and the existence of inscriptions, proving their knowledge of letters. They have left us a number of most interesting inscriptions, which have been studied and illuminated by several notable scholars. The names of the rulers mentioned on these inscriptions are also found in the Chinese annals, and are attributed by them to the Thukiu. We can therefore date them with the greatest precision. They are written in the well-known and widely spread Syriac script known as *estranghelo*, in which the Nestorian inscriptions of China were written, and which was afterwards used by the Uighur Turks and the Mongols for their writings. The capital of these early Turks was in Northern Mongolia, and, as stated above, they have left large traces there of their settlements.

Presently it would seem that the earlier Turks who lived in the East and had been known as Hiong Nu reasserted themselves and conquered and replaced the Turks just named, taking possession of their settlements and capital, and continuing their culture. They also adopted the new name of Uighurs, which the Chinese, having, as I have said, no letter "r," changed into Hoei Hoei and other distorted forms of the name Uighur.

These Uighurs became a highly cultivated people, with a considerable literature, which is still extant, and their dialect is known as Eastern Turki. They apparently inherited from the Western Turks an attachment for the Iranian or Zoroastrian religion, and traces of the Zoroastrian gods and ritual are found among their remains. On other sides their religion was affected by missionaries from other sources. Manicheism found numerous recruits among them, and we are now fast recovering from the buried cities of Eastern Turkestan most interesting remains of the religion of Manes, while the Nestorian clergy founded episcopal sees in their country, and made numerous recruits. Presently, and in the seventh century, Buddhism also made its way among them in the corrupt form, and mixed with the Tantra superstitions, which then prevailed in Tibet, and is known as Red Lamaism in contrast with the reformed Lamaism of the later Yellow Lamas.

At length, in the ninth century, the religion of Islam found its way into Central Asia, being disseminated from the Central Asiatic State governed by the Samanis, and the Western Turks became eager converts to it both in the frontier steppes of the Persian Empire and in Eastern Turkestan. The Eastern Turks or Uighurs continued to be the more cultivated of the race, but the Western were the more powerful warriors, and under the name of Turcomans overran Persia and Asia Minor, founding the famous empire of the Seljuki, which was presently (in the thirteenth century) overwhelmed by the Mongols.

I am conscious of the extremely meagre and arid nature of this epitome, and how little it does justice to the wide reading and sound judgment of the author. No one knows it better, for I have spent a large part of my life in writing four fat volumes on the Mongols, and two sets of papers on the westerly drifting of Nomads and the northern frontagers of China in the old Ethnological Society's Journal and the Asiatic Journal respectively. This may give me at least a claim to speak in terms of high praise of the work before me, in which the author, having the unusual advantage of knowing Russian, has employed it with generous profusion, much to our profit, and in which she describes with clearness the various divisions into which the Turks have been disintegrated, with their geographical, ethnographical, and religious features, and also tells the story of their doings. It is so well done that I cannot pay the book a greater compliment than to repeat my invitation to the learned lady who has written it to give us a much larger work on the subject. I may add that a most ample bibliography occupies 114 of the 242 pages comprised in the work.

HENRY H. HOWORTH.

THE LIVING PLANT.

Botany of the Living Plant. By Prof. F. O. Bower. Pp. x+580. (London: Macmillan and Co., Ltd., 1919.) Price 25*s*. net.

A GOOD deal of discussion has recently taken place among botanists on the subject of the reconstruction of elementary botanical teaching, and one of the main contentions of the originators of the discussion was that in order to secure improvement "comparative morphology should be reduced to a subordinate position." It has further been alleged that in modern botanical teaching the teacher has failed to present the plant as a living organism, thereby implying that morphology has been divorced from physiology. Prof. F. O. Bower has already expressed himself forcibly and with sound sense upon the question in the pages of the *New Phytologist* (vol. xvii., Nos. 5 and 6, p. 105), and has aptly summarised his views with the adage, "Physician, heal thyself."

In his book now under notice he has given so admirable a presentment of the plant as a living organism that instead of there being any antagonism between physiology and morphology, their fusion and interdependence are so impressed on the reader that he can see, not two entities, but "one flesh."

Prof. Bower concludes the article to which reference has been made with the following: "Finally, each teacher with a due sense of his responsibility, and of his opportunities and requirements, must form his own scheme to meet his own needs. If he cannot do this he is not fit for his position."

Prof. Bower has followed this very pertinent criticism with his book, "The Botany of the Living Plant," which is framed on the lines of the annual course of elementary lectures on botany given by him at Glasgow for more than thirty years. His main object has been to present the plant as a living, growing, self-nourishing, self-adapting creature, and he has very finely achieved his ideal.

In his method of treatment of the subject he has allowed the living plant to tell its own story, slowly and naturally unfolding itself stage by stage in such a manner that interest is aroused and observation stimulated. The book may very justly be regarded as an invaluable contribution to sound learning. It does not aim at being an exhaustive treatise, but deals with the fundamental facts of plant life, and is written in a remarkably clear style, so much so that anyone with only a slight acquaintance with plant life should be able to acquire a real knowledge of the science of botany from a careful study of these essays.

The opening chapter is occupied by a careful and comprehensive description of the seed and its germination. It is sometimes considered more reasonable to commence the study of botany with the lower forms of plant life, but it is obviously a better plan to set out with a familiar and easily handled object, such as the seed, which marks a definite starting-point, and can be examined and studied in detail without recourse to the microscope. It is pointed out that in the plan of construction of the higher plants the outstanding feature is the capacity for indefinite vegetative increase which may be termed "continued embryology."

The cellular construction of the plant and the various functions of the cell, cell-division, and protoplasmic continuity naturally follow, and then the tissues are dealt with in further detail. The sequence of events next leads to an account of leaf and root from the morphological point of view, followed by chapters on the relation of plants to water, and on nutrition, storage, and respiration. In the chapter on growth and movement due attention is paid to the statolith theory in connection with geotropism. Succeeding chapters deal fully with the mechanical construction of the plant body, modifications of form in the vegetative system, such as bulbs, tubers, climbing plants, etc., the irregular nutrition of parasitic, semi-parasitic, and carnivorous plants, and vegetative propagation, all of which aspects of plant life are fully discussed with a wealth of well-chosen examples.

The inflorescence and flower and the formation and development of the seed with all that is entailed occupy some eighty pages and bring this first division of the book to its logical conclusion. This portion is not a mere chronicle of well-known facts, but is illuminated by a consideration of flower colours, pollination, and the details of fertilisation, and closes with a description of the mode of dispersal of some of the better-known seeds and fruits.

The second part of the book is arranged in four divisions, dealing respectively with the Gymnosperms, Pteridophyta, Bryophyta, and Thallophyta, followed by two chapters, one on sex and heredity, the other on the alternation of generations and the land habit. These two essays very fittingly come at the end as a summary of the previous chapters dealing with the life-histories of the lower plants.

As in the earlier part of the book, these more specialised chapters on the ferns, mosses, fungi, and algæ are treated on broad lines, and there is no superfluity of detail to obscure the salient features.

The book concludes with two appendices, one on the types of floral construction in Angiosperms, the other on vegetable-foodstuffs, both of which considerably enhance the value of the volume. In the former a few types of flower are described, and notes are added on the natural families to which the particular examples belong. The plants chosen are easily accessible and also represent characteristic features of families the products of which are of economic importance. Further, they are of interest in connection with the production and dispersal of seeds, floral biology, etc. The illustrations in this appendix have been drawn for the most part by Dr. J. M. Thompson, and are particularly clear and useful.

The glossary-index, which completes the book, occupies thirty-two pages, and furnishes a further example of the thorough and careful manner in which Prof. Bower has carried out his object.

We have for so long been accustomed to rely on translations of German text-books for our elementary botanical students that it is very gratifying to find them superseded by so excellent and comprehensive a study of the living plant from one of the most eminent of our own professors and teachers.

A. W. H.

OUR BOOKSHELF.

Influenza: A Discussion opened by Sir Arthur Newsholme. Pp. 102. (London: Longmans, Green, and Co., n.d.) Price 3*s*. 6*d*. net.

The discussion on influenza at the Royal Society of Medicine in November last summarises very completely our knowledge of this obscure epidemic disease. Sir Arthur Newsholme, in his opening remarks, expressed the opinion that influenza is a specific disease recognisable in severe outbreaks, and pointed out that, with the exception of plague and cholera, it has on occasion travelled farther and more rapidly over the world than any other recognised disease, and that it is one over which preventive medicine so far has secured little or no control.

Dr. Stevenson directed attention to certain features of the 1918 epidemic which differed from those of the past twenty-seven years, viz. (1) its intensity was greatly in excess of that of any of its predecessors, and (2) the sudden and startling change which occurred in 1918 in the age distribution of influenzal mortality. In all previous years the majority of deaths—generally about 70 per cent.—occurred at ages above forty-five. But in July, 1918, only about 30, and in October about 20, per cent. of the persons dying were more than forty-five years of age, and only 5·5 per cent. of the deaths of this outbreak were at ages above sixty-five, as against an average of 37 per cent. for the years 1890–1917.

Several speakers dealt with the aspects of the epidemic in the Navy and in the Army, and in France, America, and South Africa, which correspond closely with those observed among the civil population here.

With regard to the bacteriology of the disease, most of the observers noted the presence of the influenza bacillus, the pneumococcus and the streptococcus, but no very definite opinion is expressed as to the nature of the virus. Prophylactic vaccination receives scant notice, probably because the data were insufficient at the time of the meeting.

As regards treatment, Mr. E. B. Turner claimed that large doses of salicin constitute a specific, and certainly his experience, based on the observation of 2500 cases, suggests that this drug deserves an extended trial.

R. T. Hewlett.

The "Daily Telegraph" Victory Atlas of the World. Part i. (London: "Geographia," Ltd., 1919.) Price 1s. 3d. net.

THIS is the first part of a new atlas to be completed in about forty-eight parts. Each part is to consist of three double-page maps, 20½ in. by 26 in. A gazetteer is to complete the work. The first part contains maps of Australia (physical), South-West Spain (political), and Germany (historical), besides several inset maps. The colour printing is good and the lettering particularly legible. The orographical map of Australia is layer coloured, and although it shows some small discrepancies from the recently published official orographical map of the Commonwealth it is an effective and useful sheet. The map of Spain, which we take to be the type of political map of the atlas, would be improved by the omission of the "caterpillar" relief, which is merely misleading and of no value. In this respect the map of Germany is better, for no attempt is made to show relief on it. The changes due to the Peace Treaty are incorporated, but a mistake is made in the area of the Slesvig plebiscite. The atlas promises to be a useful one for general reference purposes. Its low price is much in its favour.

The Mica Miner's and Prospector's Guide. By Archibald A. C. Dickson. Pp. viii+50. (London: E. and F. N. Spon, Ltd., 1919.) Price 4s. 6d. net.

THE mica industry is indebted to the author of this "Guide" for the current system of mining in Kodarma, the most prolific mica field in the world. His memoirs on that field are well known. Any contribution of his to the literature of the subject is therefore sure of careful consideration. The present booklet, which is high-priced—fifty pages for 4s. 6d.—was prepared to help the increased output of mica necessary during the war. It contains much valuable information, but does not cover all the ground that might be expected from the title. It consists mainly of descriptions of eight of the secondary mines of the Kodarma field and of notes on the mining methods there. It contains little information as to costs and values, and would not explain to a miner who had no previous experience of mica-mining how to estimate the probable profit or loss of a newly discovered deposit. The author's main thesis is that mica-mining must be guided by careful geological study, and he insists that all the facts observable during the working of a deposit should be systematically entered on a mine plan. This warning is especially useful with a branch of mining in which so much of the output is from small mines worked by parties of local labourers. Mr. Dickson points out that the mica lenses on the margin of a deposit are apt to be inclined to the shoot, and a miner who was guided only by the facts seen would be diverted from the main body of mica.

Scattering of Light by Resonating Molecules.

PROF. R. W. WOOD (*Phil. Mag.*, vol. xxiii., p. 689, 1912) found that mercury vapour, even at the small density corresponding to atmospheric temperature, when illuminated by the ultra-violet mercury radiation λ2536, re-emits this radiation laterally in considerable intensity.

Further, Wood and Kimura found after repeated examination that this radiation is *completely free from polarisation* (*Phil. Mag.*, vol. xxxii., p. 329, 1916).

I have been very much impressed with the contrast between this case, where there is resonance, and the behaviour of gases in general when illuminated by light which is not in resonance with the free period of the atoms. In the latter case the laterally emitted light usually approximates to complete polarisation (Proc. Roy. Soc., A, vol. xcv., p. 155, 1918). What happens as we gradually depart from exact resonance?

Prof. Wood's experiments were made with the exciting light polarised, and he observed the resonance radiation through the same window by which the exciting light entered. In this way the light examined comes chiefly from the very first stratum of vapour entered by the beam. This stratum gives by far the most intense emission.

As, however, the beam advances into the mercury vapour the light in exact resonance is absorbed, being, in part at least, re-emitted. The lateral emission further on is much fainter, and corresponds presumably to a less exact resonance.

It appeared to be of interest to examine this lateral emission from the deeper strata for polarisation. This I have done, and I give here a brief statement of results, leaving the experimental details for later publication.

After the unpolarised primary beam has traversed 0·4 cm. of mercury vapour at ordinary temperature, the lateral emission shows very perceptible polarisation, the component intensity vibrating parallel to the exciting beam having 90 per cent. of the intensity of the perpendicular component.

After passing through 2·5 cm., this ratio fell to 82 per cent.

After 27·4 cm., the value found was 60 per cent.

Thus it appears that the scattered light is unpolarised only when resonance is very exact. The breadth of the absorption band (reversal) produced by a few millimetres of mercury at atmospheric temperature and *in vacuo* must be extremely small, and probably beyond the range of any but the most powerful spectroscopes. Yet it is only within this narrow spectral range of the exciting light that the scattered light is sensibly unpolarised. When this component is filtered out, and such excitation as remains is by light nearer the edges of the exciting line, polarisation becomes conspicuous.

It need scarcely be said that there is very much more to be done in this direction. Further experiments are in progress.

Vertical-pipe Irrigation for Orchards and Market-gardens in Arid Climates.

IN the issue of NATURE for September 11, 1919 (p. 44), abstracting from the *Comptes rendus* of the Paris Academy (August 25, 1919, p. 391), mention is made of a new method, proposed by M. Paul Parmentier, for irrigating orchards and market-gardens in Syria, Palestine, and other countries subject to long summer droughts. The observations of M. Parmentier refer especially to the citrus gardens around Jaffa.

In arid climates economy in irrigation-water is obviously of the utmost importance. According to the method proposed by M. Parmentier, the water is applied direct to the roots of each tree by means of earthenware, cement, or iron pipes fixed vertically in the soil. The great losses by evaporation that always occur in open canals and in surface irrigation are thus avoided. M. Parmentier remarks that with vertical-pipe irrigation the water used in a citrus orchard was only 84 litres per hectare, as compared with 600 litres necessary for surface irrigation, applied every five to twelve days. At Jaffa there are 880 trees to 1 hectare ($2\frac{1}{2}$ acres) of citrus orchard, and 1100 plants in the banana gardens. These figures are very high, and imply a great consumption of water.

The method proposed by M. Parmentier is not new. Watering orchards by means of special drain-tubes sunk vertically in the soil is an old practice at Messina, in Sicily, where it is chiefly applied to young plantations. This method of irrigation was first described long ago by Prof. Giuseppe Inzenga, the well-known Sicilian agronomist and botanist, in the *Annali di Agricultura Siciliana*; and again by F. Alfonso-Spagna in his "Trattato d'Irrigazione" (Palermo, 1877, p. 502). In my book of agricultural chemistry ("Chimica Agraria, Campestre e Silvana," Napoli, 1902) this special method of drainage-irrigation is again described. The *catuso* used by the Messina gardeners is a conical earthenware pipe, about 1 metre long, open at both ends. The diameter of the upper opening is 15 cm. and that of the lower 10 cm., the pipe thus holding about 12 litres of water. M. Parmentier proposes pipes holding 20 litres for use in orchard irrigation. At Messina the upper end of the *catuso* projects slightly above the soil, the opening being covered with a brick or tile.

In the summer of 1889, at Portici, near Naples, I experimented on two lemon-trees of the same age and size, watering one in the usual manner and the other by means of a drain-pipe sunk vertically in the earth. During that hot summer, in the sandy, volcanic soil at the foot of Vesuvius, the difference between the effects of the two methods of watering was very apparent. The lemon-tree provided with the vertical drainage-pipe prospered on a ration of water about 50 per cent. less than that necessary for the control tree watered from the surface.

The sunk end of the drainage-pipe is made to rest on loose stones or potsherds, which form air-chambers. Thus clogging of the pipe is prevented, and the water that is poured down gets well absorbed and distributed just where the roots are more vigorously developing and renovating their absorbing organs.

The subsoil air-chamber is as important as the water-pipe. During drought the deep aeration of the soil, when moisture is sufficient, provokes the growth of the roots and the renewing of the root-hairs, increasing their power of absorption and at the same time favouring deep-soil nitrification. The roots are induced to develop chiefly around the reservoir of moist, warm air, where respiration and growth find favourable conditions, the network of young and active rootlets thickening around the spot where the watering is concentrated and nitrates are being actively formed. The loss by evaporation and percolation is minimised. Moreover, the close air under the foliage of the trees, as M. Parmentier remarks, is maintained in a less damp condition than is usual in the deeply shaded citrus orchards, where the development of parasites and pests is much favoured by the moist shade.

M. Parmentier observed that vegetables watered by underground irrigation are more tender and of higher market value than vegetables watered by submersion, or by any other method by which the foliage, stalks, and upper parts of the roots are wetted. Indeed, it may be added that the wetting of the foliage increases transpiration, and consequently the waste of water.

By means of vertical-pipe irrigation dilute liquid manure can be applied far more effectually and economically than by the usual method of night-soil manuring In the case of vegetables and fruit-trees subsoil liquid manuring is also advisable from a sanitary point of view.

In arid climates, and wherever the economy both of water and of liquid nitrogenous manure is of special consequence, the Messina and Parmentier method of underground watering by vertical drainage is much to be recommended.

New Sources of Aluminium.

I WAS much interested in the account given in NATURE of October 23 of the new methods of extraction of aluminium from clays of the kaolin class (formed from the denudation of volcanic rocks) by means of nitric acid and electric furnaces in Norway. When this source of production is generally adopted, as no doubt it will be owing to the diminishing supplies of cryolite and bauxite, it seems probable that the vast quantities of "decomposed porphyry" discovered by the late Prof. Jacob during his geological explorations in the Rocky Mountains (some of which have been mistaken for chalk by prospectors) will then form an inexhaustible source of supply for that valuable metal.

Radiation Temperature: Dew.

THE letter in NATURE of October 23 on radiation temperature from Mr. Spencer Pickering reminds me that the theory of the equilibrium temperature is given by Clerk Maxwell in his little-known article on Diffusion ("Ency. Brit.," ninth edition, p. 218). Maxwell shows that in still-air temperature θ_0 a thermometer will gain heat per sec. $4\pi CK(\theta_0-\theta_1)$, where C is the electrical capacity of the bulb, K the conductivity constant for air; and that it will give up heat per sec. $AR(\theta_1-\theta)$, where A is the area of the bulb, R the radiation constant, and θ the temperature towards which radiation occurs. If the bulb be spherical $C=r$, its radius. Consequently,

$$4\pi rK(\theta_0-\theta_1)=4\pi r^2R(\theta_1-\theta),$$

or

$$K(\theta_0-\theta_1)=rR(\theta_1-\theta).$$

That is, the conductivity effect depends on the radius of the bulb. Mr. Pickering has observed this in the case of small bulbs. He goes on to apply this result to small objects, such as the pistils and stamens of flowers. I would like to point out another effect to which his observations apply, namely, that true dew (arising from radiation) is not found on spiders' webs. If webs are examined when dew is on the ground they are found to be dry. When drops of water are found they arise from the collecting action of the webs on mist or fog, *i.e.* by the collection of drops already formed. I have confirmed this on many occasions. I conclude that whenever drops are found on webs it is the result of fog or mist.

SIDNEY SKINNER.

Surface-Tension.

OWING to surface-tension, a surface of mercury supports easily a sovereign placed flat upon it. Care must, of course, be taken to avoid amalgamation.

I shall be greatly obliged if one of your readers will supply me with a formula for determining the size of the largest sphere of gold that can just be supported by mercury. As the numerical solution of the equation may be troublesome, I venture to ask only for the formula.

C. T. WHITMELL.

Hyde Park, Leeds, November 3.

Exceptional Dryness of October, 1919.

METEOROLOGISTS have directed attention to the exceptional dryness of the past October. It is also interesting to note that the amount of drainage-water percolating through 20 in., 40 in., and 60 in. of soil in the open field for the month of October as recorded by the Rothamsted Experimental Station gauges is *nil*. The three gauges, each measuring 1/1000 acre, were built in 1870, and in no previous year is October shown quite dry, 1897 being the nearest with a reading of 0·001 in. The following are the figures for October:—

	20 in. gauge	40 in. gauge	60 in. gauge	Rainfall
Average of 50 years	1·848	1·798	1·669	3·233
Max. 1891	5·589	5·716	5·479	6·764
Min. 1897	*nil*	0·001	0·001	0·960
1919	*nil*	*nil*	*nil*	1·073

The 50-year records show that October is one of the four months when the ground is wettest.

SOUND RANGING.

SOUND ranging consists in the location of the source of a sound, such as the report of a gun, by means of measurements made on the sound-wave which spreads from the source. When it seemed probable, in the latter part of 1914, that the struggle in France was going to develop into trench warfare, the possibility of locating enemy batteries by this means was recognised, and many experiments were started independently to find a method of sound ranging which could be used in the field.

Suppose that there is a gun at the point S in Fig. 1. The report of the gun spreads as a spherical sound-wave, with a uniform velocity, and is received by stations at A, B, and C. If the time intervals between the arrival of the sound at A, B, and C are measured, a very simple construction gives the position of the gun. For instance, if the sound gets to B a time t_1 after it gets to A, and to C a time t_2 after it gets to A, circles are described around B and C the radii of which are equal to the distances travelled by sound in times t_1 and t_2 respectively. If a circle is found which passes through A, and touches the circles around B and C, the gun position will be at its centre. Therefore, by installing a series of observation stations along the front at surveyed positions, and recording the times at which the report arrives at these stations, it is possible to plot the position of the enemy battery on a map on which the observation stations are marked. This is the essential idea underlying sound ranging. Three stations only are necessary, but more may be employed in order to confirm the location.

There are other ways of plotting the gun position, given the time intervals. For instance, if the time interval between A and B is t_1, the gun must lie on a hyperbola with foci at A and B which is such that the difference in the distances from the foci of any point on the curve is Vt_1, where V is the velocity of sound. Another pair of stations give another hyperbola, and by finding where this intersects the first the gun position is determined. This was the method actually employed on the plotting-boards used by the sound-ranging sections. The hyperbola approximates so closely to its asymptote near the gun position that the asymptote can be used equally well, which makes the method a very simple one in practice.

The French Army started experiments in sound

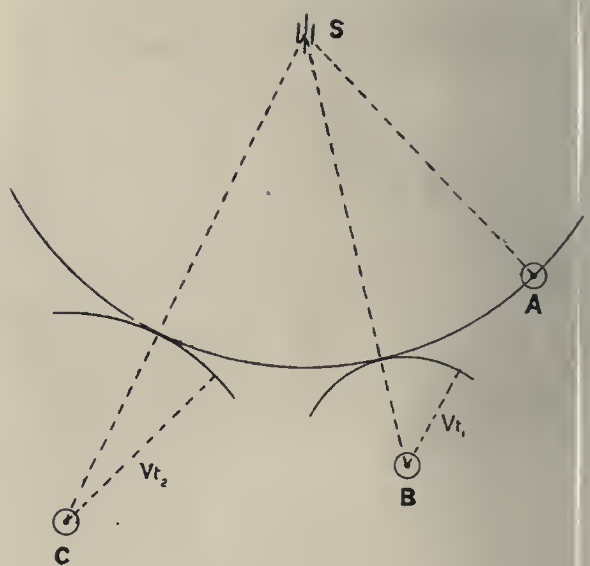

FIG. 1.

ranging in 1914, and obtained results which showed that the method was a promising one. From the very beginning development took place along two lines. Either observers were used, who recorded the time of arrival of the sound by pressing a key, or the sound was registered automatically by some form of microphone. In both cases the stations were connected electrically to a central station, where the signals sent by the observers or microphones were registered on a chronograph of some form. It was soon found that observers were not sufficiently accurate. They made errors amounting to one-tenth of a second, whereas it is necessary to time the arrival of a sound to 0·005 second in order to make a satisfactory location. This accuracy was attained by the system in which the arrival of the sound was registered by a microphone, and both in the French Army and ours a microphone system was finally adopted.

Our attention was directed to the French results in the early part of 1915, and a proposal to form an experimental sound-ranging section was laid before the Experiments Committee at General Headquarters. The committee at first decided against ordering any apparatus, but was persuaded to alter its decision, and an English sound-ranging section was sent to the front in October, 1915. Sound ranging was still in its infancy, and the results obtained were very disappointing. In fact, it was doubtful at one time whether the continuation of the experiments would be authorised. Fortunately, sound ranging just survived these early trials, and during 1916 sufficient sections were formed to cover the whole front.

The apparatus which we adopted was designed by M. Bull, of the Institut Marey, in Paris, and was one of several with which the French Army was experimenting. It is not possible to describe the apparatus fully. The recording apparatus consists of an Einthoven galvanometer with six strings, each string being connected to a microphone at a receiving station. The currents which the microphones send to the recording instrument cause the corresponding strings to vibrate, and their movements are recorded photographically on a moving kinematograph film. At the same time, by interrupting the light which photographs the strings on the film, at intervals of 1/100 second, a series of time markings is ruled on the film, which makes it possible to measure the time interval between the arrival of the sound at two stations. The microphone finally used was of a special type adopted after experiments at the front. Its special feature is that it is very sensitive to sounds of long wave-lengths, such as gun reports or shell bursts (the wave-length of the report of a large gun may be 250 ft.), while comparatively insensitive to ordinary sounds, such as speech, rifle fire, traffic, and so on. The credit of its design is due to Lt. Tucker, an officer serving in the experimental section in 1916.

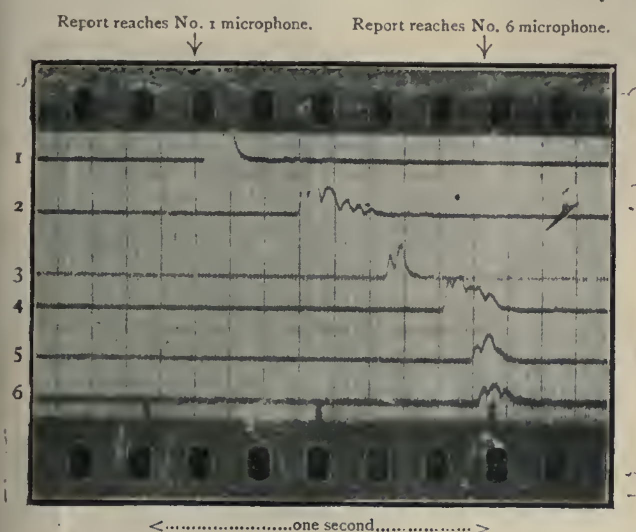

FIG. 2.—The figure is an enlarged print of the record of a 15 cm. howitzer, the report of which has reached No. 1 microphone first and No. 6 microphone last. The film has been moving from right to left while the record was being taken. The time intervals are marked by vertical lines, one hundred to the second, every tenth line being heavier so as to facilitate counting. The horizontal lines represent the shadows of the Einthoven strings, which lie across the slit behind which the film is exposed, and the movements of which are shown on the record.

A record of a German 15-cm. howitzer is illustrated in Fig. 2.

The installation of a section using the Bull apparatus is shown in Fig. 3. There are six microphones, spaced along a "base" about 9000 yards long and 4000 yards behind the front line. These are wired up to a central station which is placed in a cellar or dug-out some 5000–6000 yards from the front line. In front of the base are the "advanced posts." An observer is stationed at each of these. When he hears a hostile gun fired, he presses a key which sets in motion the apparatus at the central recording station. The kinematograph film runs through the camera, the lamp is turned on, and all is ready to record any sounds reaching the microphones. Having allowed time for the sound to reach all the microphones, the forward observer raises his key and the recording apparatus stops. He telephones to the central station a report giving his estimate of the direction from which the firing has come, of the target, and of the calibre of the piece. The film is developed and fixed by a

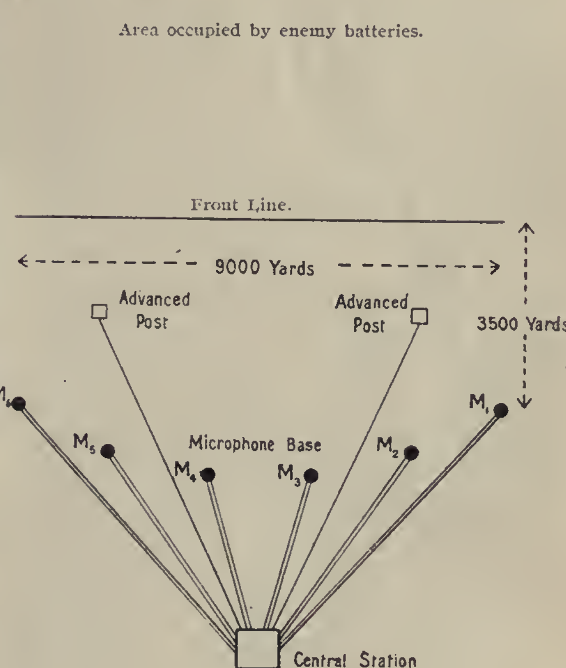

FIG. 3.

photographer; this can be done in ten seconds by using strong solutions. It is handed over to a computer, who reads the time intervals and plots the result, and the location of the battery is telephoned to all interested. The time taken to work out a result is generally from four to ten minutes after the battery fires. The location is first telephoned to the artillery, in order that immediate action may be taken if desired. The neighbouring sections and other units engaged in location are then informed in order that results may be compared. At the end of the day the section sends in a full report of the day's work, and this is used by the compilation staff employed in estimating the positions and strength of the enemy artillery in any particular sector.

In 1917 and 1918 there were about thirty sections on the Western front, each section having four officers and forty men. The average number of locations obtained per day by each section was about five, though on a day when conditions were particularly favourable it was not uncommon for a section to get thirty, forty, or even more locations. Long spells of westerly weather were responsible for keeping the average number so low, because it was found impossible to "sound-range" in a wind blowing from the base towards the enemy guns. The sound is deflected upwards in the well-known manner, and fails to be recorded by the most sensitive microphone.

The accuracy of the results was tested in many ways. After a successful advance it was possible to examine the positions the enemy batteries had occupied and compare them with the locations. When this could not be done, an examination of aeroplane photographs generally revealed the gun pits, when sound ranging or other methods of location had indicated the approximate battery position. The average error of location, at a range of 10,000 yards, was about fifty yards, though naturally the conditions under which the section was working affected the accuracy greatly. Whenever possible, the aeroplane photograph was relied on to give the exact battery position. The sound-ranging results were especially valuable, however, in that they gave not only the approximate location of the battery, but also its calibre and the target at which it was firing. The shell-burst was recorded as well as the gun report, and so the time of flight of the shell could be found. The character of the report was a clue to the calibre of the piece. The area shelled could be examined to find the shell fragments, and there were other clues to the calibre which made it possible for sound ranging to give very full information about any battery recorded, and this greatly enhanced the value of the locations.

The most serious of the difficulties encountered by the sections were: Confusion between the gun report and the shell-wave which precedes it in the case of a high-velocity shell; inaccuracy caused by ignorance as to the effect of wind and temperature on the sound-wave; interruption by the noise of our own artillery and the enemy batteries; cutting of the lines by shell fire and traffic or by enthusiasts of other units collecting cable of a very useful type; the difficulty of survey of the microphone positions in a country where all landmarks were destroyed; and in the final stages of the war the problem of transporting and installing the section quickly when the line moved every few days. Experience solved these difficulties one by one, and towards the end of the war the sections reached a high state of efficiency, though the limit of development had by no means been attained, and it is certain that they might have played an even greater part than they did in the final struggle.

The British system of sound ranging, founded on the Bull recording apparatus, was developed entirely by officers of sound-ranging sections working at the front. The original experimental section was installed on Kemmel Hill, south of Ypres, and its researches were carried out there. Later, when there were sections along the whole front, it was arranged that an officer from each section should attend a conference which was held every two months. At the conference, proposed improvements were gone into, the equipment was discussed, results were compared, and the report of the discussion was submitted to General Headquarters. This informal conference did more than anything else to improve the work of the sections —it stimulated rivalry and ensured that all proposed alterations in the existing methods were subjected to severest criticism by men who had first-hand experience before they were adopted or turned down. The officers were for the greater part university men who had had a scientific training, and it would not be possible to imagine a more keen and enthusiastic body of men. They were sorely tried in the early days of sound ranging, when they worked under great difficulties, and had yet to prove that reliance could be placed on their results; but they were amply repaid when sound ranging came to its own at the end of the war, and was recognised as one of our most valuable means of locating the enemy's batteries.

RESULTS OF THE TOTAL SOLAR ECLIPSE OF MAY 29 AND THE RELATIVITY THEORY.

THE results obtained at the total solar eclipse of May 29 last were reported at a joint meeting of the Royal and the Royal Astronomical Societies, held on November 6. The stations occupied were Sobral, in North Brazil, and Principe Island. Two cameras were employed at Sobral, the 13-in. objective of the Greenwich astrographic equatorial, and a 4-in. lens, of 19-ft. focus, lent, together with an 8-in. cœlostat, by the Royal Irish Academy. It was realised, before the expedition started, that the cœlostat was scarcely suitable for observations of such extreme precision as were required to detect and measure the small shift in the places of the stars that might be produced by the sun's attraction. War conditions, however, made it impossible to construct a suitable equatorial mounting, though it is hoped that this may be done before the eclipse of 1922.

The results, to some extent, but, fortunately, not entirely, justified these apprehensions. The eclipse plates taken with the 13-in. (stopped down to 8 in.) are out of focus. Since the focus was good on photographs taken at night a few hours earlier, and also on the check plates taken before sunrise in July, the explanation appears to be a change of figure of the cœlostat mirror, due to the heat of the sun. These plates were compared with the July check plates by using a duplex micrometer. They show an undoubted gravitational shift, the amount at the sun's limb being 0·93″ or 0·99″, according to two different methods of treatment. The probable error, as estimated by the individual discordances, is about 0·3″, but there is reason to suspect systematic error, owing to the very different character of the star-images on the eclipse and check plates. This instrument supports the Newtonian shift, the amount of which is 0·87″ at the limb. There is one mode of treatment by which the result comes out in better accord with those of the other instruments. Making the assumption that the bad focus did not alter the scale, and deducing this from the July plates, the value of the shift becomes 1·52″.

The results with the 4-in. lens are much more satisfactory. The star-images are well defined, and their character is the same on the eclipse and check plates. As the duplex micrometer would not fit these plates, a key-plate, on which the film was placed away from the lens, was taken in July, and all the plates in turn were placed in contact with this plate and compared with it. The resulting shift at the limb is 1·98″, with a probable error of 0·12″. The values from the separate stars are in good accord, and they support the fact of the shift varying inversely as the distance from the sun's centre; they are thus unfavourable to its being due to refraction, as was suggested by Prof. Newall at the meeting. Moreover, Prof. Lindemann pointed out that the comets of 1880 and 1882 had traversed this region without giving the slightest evidence of having encountered resistance; as their speed was about 300 miles per second, a vivid idea is given of the extreme tenuity of any medium that they encountered.

The Principe expedition was less fortunate in the matter of weather, but a few plates showed five stars. Since no check plates of the eclipse field could be taken there, another field near Arcturus was photographed, and both it and the eclipse plates were compared with plates of the same fields taken at Oxford with the same object-glass. It was, moreover, necessary to assume that the scale of the eclipse plates was the same as that of the check plate. This is justified by the fact that the diurnal variation of temperature in Principe is only some 4° F., and that there had been no bright sunshine on the mirror before totality. The measures indicate a shift at the limb of 1·60″, with a probable error of 0·3″.

It will be seen that the mean of this result and that with the 4-in. at Sobral agrees very closely with Einstein's predicted value 1·75″. It was generally acknowledged at the meeting that this agreement, combined with the explanation of the motion of the perihelion of Mercury, went far to establish his theory as an objective reality. Sir J. J. Thomson, who presided, spoke of the verification as epoch-making; he suggested that it would probably have a bearing on electrical theory, but he regretted the very complicated form in which Einstein expressed his theory, and hoped that it might be possible to put it into a form in which it would be more generally comprehensible and useful.

Dr. Silberstein laid great stress on the failure to confirm Einstein's third prediction, that of the displacement of lines in the sun's spectrum towards the red, to the amount of 1/20 Ångström unit; this had not been verified, in spite of the careful search made by Dr. St. John and Mr. Evershed. As the probable error of their measures was much less than the quantity predicted, he looked on this result as final; some people had suggested that the shift might be veiled by a systematic outward movement of the photosphere, but as Dr. St. John made measures both at the sun's centre and limbs, that suggestion was not tenable. Prof. Eddington admitted that the failure threw doubt on the validity of some of the steps which led Einstein to his gravitational result; but he contended that the two other successes indicated that the result was right, even if reached by a wrong method.

There was some discussion on Prof. Lindemann's method of photographing stars in daylight by the use of red screens. However, the eclipse method seems more trustworthy, and the Astronomer Royal expressed the hope that the eclipse of 1922 might be observed with equatorials. The star-field is not so rich as in the late eclipse, but with longer exposure much fainter stars could be recorded. The eclipse-track crosses the Maldive Islands and Australia, and is therefore fairly accessible.

A. C. D. Crommelin.

THE JUBILEE OF "NATURE": CONGRATULATORY MESSAGES.

It is with a certain amount of diffidence that we give here a number of cordial messages which have reached us upon the attainment of the fiftieth anniversary of the foundation of Nature. We believe, however, that many readers will be interested not only in the friendly greetings expressed in these messages, but also in the references to the work of science, and its expanding field of usefulness. To the official representatives of scientific societies and university institutions, and to the other men of light and leading who have honoured us with their congratulations, we offer our sincerest thanks. Such appreciation of past efforts affords the strongest stimulus to future endeavour.

While Nature has the advantage of the active interest and co-operation of so many distinguished leaders in the world of science, the columns of the journal will continue to represent with authority the position and claims of progressive knowledge. In sending us best wishes for continued fulfilment of this function, Dr. Hilda Brade-Birks and the Rev. S. Graham Brade-Birks, of the South-eastern Agricultural College, Wye, refer us to some striking verses in the seventh chapter of the Wisdom of Solomon in the Apocrypha, and the words are of such interest as expressing the human outlook upon natural knowledge that we are glad to reproduce them:—

God hath granted me to speak as I would, and to conceive as is meet for the things that are given me: because it is He that leadeth unto wisdom, and directeth the wise.

For in His hand are both we and our words; all wisdom also, and knowledge of workmanship.

For He hath given me certain knowledge of the things that are, namely, to know how the world was made, and the operation of the elements:

The beginning, ending, and midst of the times: the alterations of the turning of the sun, and the change of seasons:

The circuits of years, and the positions of stars:

The natures of living creatures, and the furies of wild beasts: the violence of winds, and the reasonings of men: the diversities of plants, and the virtues of roots:

And all such things as are either secret or manifest, them I know.

Scientific and Other Societies.

Royal Society. *President:* Sir Joseph Thomson, O.M.—The council of the Royal Society offer to the Editor and publishers of Nature their congratulations on the fiftieth anniversary of the publication of that journal. They desire to express their appreciation of the services rendered to science by Nature during the past fifty years, both by the promotion of research and especially by providing an efficient and convenient means for workers in one branch of science to keep in touch with the progress made in other departments of scientific activity. They recall with satisfaction the fact that the jubilee of the election into the society of their distinguished fellow, Sir Norman Lockyer, coincides with that of his jubilee as Editor of Nature.

Royal Society of Edinburgh. *President:* Dr. John Horne, F.R.S.—I am glad to have the opportunity of expressing my high appreciation of the invaluable services rendered by Nature in promoting scientific research in Scotland during the last fifty years. In 1862 a distinguished Scottish man of science deplored the progressive decay, during the previous half-century, of the once illustrious Scottish school of geology. Since that time the progress in each department of geological investigation in Scotland has been remarkable through the labours of English and Scottish geologists. The publication of Nature has been a powerful stimulus to geologists and other men of science in North Britain to test all previous work in the light of the most recent research.

Royal Irish Academy. *President:* The Right Hon. and Most Rev. J. H. Bernard, D.D., D.C.L., Provost of Trinity College, Dublin.—The jubilee of Nature marks the completion of fifty years' useful aid to science, and the proprietors are heartily to be congratulated on the fruitfulness of their undertaking. The application of science to the practical needs of mankind is taking a wider range every year, and the president of the Royal Irish Academy wishes all success to the Editor of Nature in his efforts to encourage and give publicity to the aims of scientific research and its importance to the nation.

Royal Dublin Society. *Vice-President:* Prof. J. Joly, F.R.S.—In furthering scientific progress, Nature has played no small part, for it has supplied a vital necessity: early publication of new ideas, new results, and new projects. We who now write know that our earliest efforts found encouragement in its columns. May the early efforts of our successors continue to gather from its columns the same encouragement and the same stimulus! Looking back, we recognise and acknowledge that Nature has played an important part in our lives.

Royal Anthropological Institute. *President:* Sir Everard im Thurn, K.C.M.G.—The council of the Royal Anthropological Institute has commissioned me to convey to the Editor of Nature very hearty congratulations on the jubilee of that journal and on fifty years' successful furtherance of science generally, and not least of anthropology. Our subject may be said to have developed during the same period from a merely interesting to a scientific stage. We anthropologists foresee a very special task lying before us in the immediate future, in the betterment of the almost innumerable races included in our world-wide Empire. We look to Nature for continued and increased help in the furtherance of this work.

Royal English Arboricultural Society. *President:* Major G. L. Courthope.—May I offer my congratulations to Nature upon attaining its jubilee, and upon the excellent work it has done, during its fifty years of life, in the promotion of scientific study? The passing of the Forestry Act opens a fresh vista of useful possibilities to the student of natural science—a vista in which, I am sure, Nature will play its part. In the United Kingdom scientific forestry has been the rare exception rather than the rule, with the result that our 3,000,000 acres of woodlands produce only a fourth of the yield which we might expect from them if scientific principles had been applied to the varying natural conditions of our countrysides. Let us hope that the next fifty years will make up for our shortcomings in the past.

Royal Institute of British Architects. *President:* Mr. John W. Simpson.—Many congratulations will be received on the issue of the jubilee number of Nature, and I shall feel privileged by being allowed to add my own tribute. The journal has achieved a great position in the scientific world by reason of its sane and unprejudiced attitude towards research; and, in common with all highly specialised technical callings, the architectural profession is greatly indebted to it. To the Science Standing Committee of the Royal Institute, and its various committees which are occupied with scientific research into matters connected with heating, lighting, construction, and building materials, Nature is especially valuable. Pray accept my sincere good wishes for a long-continued prosperity.

Royal Astronomical Society. *President:* Prof. A. Fowler, F.R.S.—The field of scientific investigation is ever widening with the advance of knowledge, and those who are engaged in research are fortunate in being always able to look with confidence to Nature to keep them well-informed as to the latest developments in their own and other branches of science. By its timely announcement of approaching phenomena and its record of current work and thought the journal has rendered important services to astronomers, and can scarcely have failed to stimulate an intelligent general interest in the results of their work.

Royal Engineers Institute, Chatham.—The president and council of the Royal Engineers Institute offer their most sincere congratulations to Nature on the attainment of its jubilee. They recognise with a lively sense of appreciation the high standard consistently set in its columns. They offer the Editor their thanks that he has never failed to enforce the great lesson: that the search for knowledge, pursued for its own ends and with no immediate thoughts of material gain, should be one of the most potent driving forces in the life of a nation. Without this impulse no material advance in civilisation is possible. Now at the present time, at the end of a devastating war which finds many exhausted and some despairing of the future, it is more than ever necessary to hold this beacon aloft and to convey a message of encouragement to all workers engaged in the great search for natural knowledge, bidding them remember that, whatever be the temporary distractions of the time, they should never lose sight of the central truth: that with them lies, in no small degree, the future of the world.

Royal Horticultural Society. *Chairman of Council:* Mr. Harry J. Veitch. *Secretary:* Rev. W. Wilks.—Like most ancient arts, the practice of horticulture was rooted in tradition and hedged about by empiricism. Advancing knowledge gradually lets in light upon its many branches, stimulates its dormant buds into growth, and surrounds its roots with the vitalising environment of experiment. It is an art that lays all Nature under contribution; that can flourish best where knowledge of Nature is deepest. In the name of British horticulturists we congratulate Nature, which has done so much to spread knowledge, upon its fifty years of usefulness, and wish it and those whose work it tells of continued diligence and success.

Royal Society of Medicine. *From the* President.—During the fifty years that Nature has provided a weekly summary of science the changes in medicine, particularly as regards diagnosis and treatment, have been without parallel. This is shown by a comparison of the toll of disease, on one hand in the late war, and on the other in the Crimean, North and South, and Franco-Prussian Wars. The changed picture is due to the practical application of science. Pasteur's researches gave us bacteriology and a knowledge of the nature of infection, and rendered possible the modern treatment of wounds, introduced by Lister, and the use of serums and vaccines. The diagnostic and therapeutical use of X-rays, the employment of radium, and many other advances are further gifts from science. But this transformation of medical practice only reveals a multitude of important problems concerned with the prevention, early detection, and effective treatment of disease, and for their solution we must look to scientific research.

Royal College of Surgeons. *President:* Sir George H. Makins, G.C.M.G.—The realm of science may well acclaim the jubilee of Nature, and no less all those concerned in the promotion of the public good. The occasion arrives opportunely, for at no time has the public sense been so forcibly awakened to the influence of the applications of science to such divergent objects as trade, medicine, war, or the feeding of the population. If important changes founded on the progress of science are to be effectively introduced, those who will be affected must be educated and prepared beforehand. In this great work Nature has taken and must take a prominent part, an aim no less wide-reaching than that of bringing students in every branch of science into association and establishing a common bond of sympathy and mutual understanding between them.

Royal United Service Institution. *Chairman of the Council:* Admiral Sir F. C. D. Sturdee, Bart., K.C.B., K.C.M.G., C.V.O.—As chairman of the council of the Royal United Service Institution, I wish to convey the congratulations of the council and myself to the proprietors and Editor of Nature on attaining its jubilee. We all recognise the excellent service that the journal has rendered to science during the last fifty years. Science, while aiming at the development of human progress, was ready to turn its thoughts and genius to helping the Empire in its time of trial. This fact is most thoroughly appreciated by the Navy, Army, and Air Force, and as one of their representatives I wish to express my thanks, and trust that Nature will continue its help to the fighting Services for the defence of the Empire.

Highland and Agricultural Society of Scotland. *Chairman of Directors:* Mr. Charles Douglas, C.B.—It gives me great pleasure to congratulate the Editor of Nature on the attainment by that journal of its jubilee. Writing as a representative of the agricultural industry, I desire to acknowledge the immense benefits which that industry has received from the development of science, and especially in the field of chemistry. It is universally recognised that the future success of the industry depends in large measure on the further application of scientific discovery. Both fundamental and practical research in bacteriology promise to give invaluable results, whether in the near or remote future; and the further development of engineering in its application to agriculture offers great prospects of economy and increased efficiency in production. I offer my most sincere good wishes for the future of Nature.

Society of Public Analysts and Other Analytical Chemists. *President:* DR. SAMUEL RIDEAL.—As president of the Society of Public Analysts, I beg to offer you congratulations on reaching the jubilee of NATURE. The journal has always been the pioneer of scientific progress in this country, and has contributed not a little in its development at the present time. It looks as if the Government and the daily Press are still far from realising what the promotion of science and its value to the national needs means. Members of my society, who are for the most part Government officials under Acts passed so long ago as 1875, a few years after your first number appeared, have recently been, I believe, transferred to a new Government Department, the Ministry of Health, which starts on its new career, like its predecessor, without any adequate representation of pure science on its councils. Your weekly numbers must have a beneficial effect upon the national development, and I hope that your circulation will increase and that the knowledge which you reveal will be assimilated and rendered more and more available for the general good.

Anatomical Society of Great Britain and Ireland. *President:* PROF. ARTHUR KEITH, F.R.S.—NATURE is the link which binds British men of science together. It is essential, and I wish it long life and prosperity.

Institution of Automobile Engineers. *President:* MR. THOMAS CLARKSON.—A lover of science is content to follow devotedly the object of his affection regardless of whether his revenue is likely to be speedily augmented thereby. He should, nevertheless, take a broad view that does not exclude the consideration of probable benefit to the community as a result of his endeavours. In other words, the true man of science is a public servant in the widest sense, and his work is directed to bettering the conditions of life, reducing its toil, evil, and "dis-ease," while increasing its pleasure and charm: for example, by adding to our knowledge and power of controlling the forces and amenities of Nature; by solving the problem of increased production with greater leisure to the worker; by increasing cultivation; by reducing the cost of transport, and thereby facilitating intercourse.

Biochemical Society. DR. ARTHUR HARDEN, F.R.S. —The recognition of biochemistry—linked on one hand with chemistry, and on the other with biology— as a distinct branch of science has gradually come about during the half-century covered by the publication of NATURE. To students of this borderland science NATURE, with its comprehensive and impartial treatment of the physical and biological sciences, has always been of special value, bringing within their reach the opinions and discoveries of other workers, whose results, obtained in fields beyond their own boundaries, are yet of great interest and often of supreme importance to them. It is precisely this universality of scientific interest which constitutes the chief value of NATURE to the investigator, and as long as this is maintained, so long will the journal continue to flourish and earn the gratitude of its scientific readers.

British Academy. *President:* SIR F. G. KENYON, K.C.B.—The jubilee of NATURE is not a matter of interest to students of natural science alone. It is, I hope, generally recognised now that the interests of science and of the humanities are not hostile, and that the welfare of the nation depends on the advance of knowledge in both these spheres, and in a fuller recognition of the necessity of both. NATURE, I am sure, under its present administration, will, without prejudice to the subjects with which it is specially concerned, continue to advocate the cause of knowledge and intellectual culture as a whole; and all friends of the humanities will wish it God-speed.

British Association. *President:* SIR CHARLES A. PARSONS, K.C.B., F.R.S.—The British Association sends its most cordial greetings to NATURE on the completion of its fiftieth anniversary. The influence of NATURE on the advancement of science for half a century has been wide and comprehensive, and a powerful factor in popularising scientific thought and progress. To men of science also it has been of great assistance by chronicling contemporary progress in the advance of the sciences and arts, and has been a medium for the interchange of information, knowledge, and ideas.

Chemical Society. *President:* SIR JAMES DOBBIE, F.R.S.—The advance of chemistry takes place to-day along a front which has been enormously extended since the first number of NATURE was issued. Moreover, it is supported by forces so vastly superior in number, in organisation, and in equipment to those existing in 1869 that scientific workers may go forward in the confident anticipation that the progress of the next fifty years will be even more wonderful than that of the half-century which has witnessed the elucidation of the constitution of the most complex organic compounds and the formulation of the periodic law, and has revealed the structure of the atom. Amongst the agencies to which the improvement of the position of science in this country is due NATURE takes an important place, not only by the opportunities it has afforded scientific men for interchange of views, but also by the force and persistency with which it has advocated the cause of scientific education and brought the claims of science before the attention of the Government.

Institute of Chemistry. *President:* SIR HERBERT JACKSON, K.B.E., F.R.S.—It gives me very great pleasure to offer, on behalf of the Institute of Chemistry, hearty congratulations to NATURE on fifty years of work in the best interests of science. At no part of that period has the importance of applying science to industry been more evident than it is today, and at no time, perhaps, has it been more abundantly clear that sound and broad training in pure science is imperative if real progress is to be made in its applications. May NATURE flourish and continue to spread knowledge of science, to show its necessity in education, and to point out how prolific a source it is of benefits to mankind.

Institution of Electrical Engineers. *President:* MR. ROGER T. SMITH.—NATURE attained its jubilee within a few days of the first full meeting of the International Electrotechnical Commission held since peace was signed. Well-known electrical engineers representing twenty-one foreign countries met in London to standardise, for those nations participating, some of the fundamental constants and relations on which the applications of electrical science to industry depend. NATURE throughout its career has stood in the first place for pure science, and since most of the important applications of science to industry have grown from the discoveries of the worker in pure science, I recognise the high standard of NATURE's work and of its ideals, and hope that both may long continue in the same happy combination.

North-East Coast Institution of Engineers and Shipbuilders. *President:* MR. A. ERNEST DOXFORD.—I have the greatest pleasure in congratulating NATURE upon the attainment of its fiftieth birthday. Throughout the past half-century the journal has maintained its character as the organ of workers in fields where science is studied mainly for its own sake, and has refused to sacrifice accuracy to the demands of what is understood as "popular" science. It is a healthy sign that the periodical should be so prosperous, testifying to the existence of a constant and active desire for British scientific literature of a high standard. I sincerely wish continued prosperity to the good work which NATURE is undoubtedly doing. The development of the journal along its present lines cannot but be beneficial to scientific progress.

Institution of Engineers and Shipbuilders in Scotland. *President:* DR. T. BLACKWOOD MURRAY.—As president of the Institution of Engineers and Shipbuilders in Scotland, allow me to express our congratulations on the occasion of the jubilee of NATURE. While perhaps the journal, dealing as it does largely with questions of pure science, may be said to be at the extreme pole from that occupied by the intensely practical applications of science which form the life-occupation of us engineers, still I think every day it is being more and more realised that it is largely due to the pioneer in pure science that we owe all modern developments in engineering. The worker in pure science may be likened to the explorer making excursions into virgin country, while we follow along after as the builders of towns and founders of industry. The day has passed when the practical engineer was inclined to scoff at science and theory, and was too prone to point to apparent contradictions of practice as against theory. Nowadays no engineer can hope to succeed unless he takes advantage of all that science can teach him. It therefore gives me much pleasure to take this opportunity of wishing NATURE continued prosperity.

Faraday Society. *President:* SIR ROBERT HADFIELD, BART., F.R.S.—It is with much pleasure I learn of the jubilee of NATURE—a publication which has done so much in the past to assist science and scientific development; in fact, its name has been a household word throughout the world. I should like to offer my best wishes for the future success of this valuable aid to those who strive to promote science and scientific interests. There never has been a time in the history of our nation when it was more desirable that the best possible stimulus should be afforded to those who guide the destinies of the British Empire in educational matters, especially matters relating to science and its development, which surely in the near future will have its proper position allotted to it in our Government Departments and establishments. It has been well said that, of developments in such Departments, Science is the "Cinderella." It is therefore to be hoped that steps will be taken to remedy this crying injustice, which is so damaging to the true interests of the nation.

Geological Society. *President:* MR. G. W. LAMPLUGH, F.R.S.—During the past fifty years NATURE has faithfully mirrored for us the advance of science all along the line, and epitomised and discussed the new results, both observational and speculative. It has enabled the individual worker to keep in touch with the main currents of progress in branches other than his own; moreover, it has served him as a general chronicler of happenings in the sphere of science, and has gratified his desire to know something about the personality of the leading investigators, past and present. I congratulate the Editor on the sustained skill with which the complex task has been accomplished, and I look forward with confidence to its successful continuance.

Illuminating Engineering Society. *President:* MR. A. P. TROTTER.—Maxwell, at the British Association meeting in the year after NATURE first appeared, referred to the reciprocal effects of the progress of science. "When the student has become acquainted with several different sciences, he finds that the mathematical processes and trains of reasoning in one science resemble those in another so much that his knowledge of the one science may be made a most useful help in the study of the others." The expansion of all branches of science in these fifty years has compelled most of us to specialise, not in one branch, but in a bough or a twig of the tree of knowledge. The pages of NATURE have enabled this broad acquaintance to be made and this useful help to be rendered, not only between mathematics and physics, but also between all the natural sciences.

Institute of Journalists (Scientific and Technical Circle). *Chairman:* MR. LEON GASTER.—I gladly take this opportunity of congratulating NATURE on the attainment of its jubilee, and expressing my great appreciation of the work it has done, and is doing, for the promotion of science and the encouragement of education. NATURE in many respects occupies a unique position. It speaks with an authority on scientific matters that is unrivalled; it has been fortunate in enlisting the help of experts in every field of science; and its treatment of subjects is invariably up to date. At the same time its outlook is sufficiently broad for it to interest many persons outside strictly scientific circles, and thus to promote that general appreciation of the value of science which is so essential in these times. I am sure that this useful record of work, extending for fifty years, has established the position of NATURE as a permanent and indispensable publication in the interests of the advancement of science.

Linnean Society. *President:* DR. A. SMITH WOODWARD, F.R.S.—The president and council of the Linnean Society desire to associate themselves in the congratulations due to the Editor and publishers of

NATURE on the attainment of the jubilee of the journal. It is a noteworthy achievement of British science to have maintained for fifty years an organ of intercommunication for scientific workers perused and recognised by the men of learning of all nations. In these modern days of high specialisation it is more than ever important that those engaged in research should have the easy access to a summary of all current progress, such as NATURE affords, and naturalists unite with other men of science in expressing their best wishes for the continued success of the weekly publication to which they are already so much indebted.

Manchester Literary and Philosophical Society.—The council of the Manchester Literary and Philosophical Society desires, on the occasion of the completion of fifty years issue of NATURE, to express its high appreciation of the valuable aid which that journal has given to the development of science during that period. The council hopes and believes that the high standard of the reviews, reports, and original articles which has always characterised the journal in the past will be fully maintained in the future, and that with the growing recognition of the vital importance of scientific knowledge the journal will exert a constantly increasing influence for the diffusion of true learning.

London Mathematical Society. *President:* MR. J. E. CAMPBELL, F.R.S.—The London Mathematical Society is just four years older than NATURE; in the early days and later the work of the society was promoted by a brief report of its activities in that journal. The volumes of NATURE with their indexes, especially the earlier ones, have permanent value as one of the most effective sources of reference for the general history of scientific progress in the last half-century. It is much to be desired that this very essential service to the scientific world may be maintained unimpaired.

Institution of Mechanical Engineers. *President:* DR. EDWARD HOPKINSON, M.P.—The jubilee of NATURE is an event of more than passing interest. During the last fifty years NATURE has been a potent factor in the diffusion of scientific knowledge. The realm of science is vast. Its boundaries are being constantly pushed further into the unknown. Of necessity, scientific workers must become more and more specialised in particular lines of research, and they need the help of some organ through which they can watch the progress of science in general. Such a survey NATURE has provided, always up-to-date and always discriminating, and in so doing has helped to raise the status and strengthen the fellowship of scientific men throughout the world. To a much wider circle of men engaged in profession and industry, whose daily work is so exacting as to preclude serious scientific study, NATURE affords the opportunity of keeping in touch with scientific discovery and thought. Lastly, NATURE has done much, though much remains to be done, towards convincing our administrators and politicians that to neglect science and to fail to act upon its precepts is to doom the national life to decay.

Mineralogical Society. *President:* SIR WILLIAM PHIPSON BEALE, BART.—Among the many scientific societies which will be moved to express gratitude and goodwill on the occasion of the jubilee of NATURE the Mineralogical Society of Great Britain and Ireland finds a place. The society was founded in February, 1876, under the presidency of Henry Clifton Sorby; and in December, 1883, under the presidency of Prof. Bonney, it absorbed the Crystallological Society. It is a proud thing to be able to say, in recalling these two names, that the society has seen, and taken some part in, the development of the domain of the mineralogist and crystallographer into the wide fields of molecular physics, the exploration of which has been the most marvellous work of distinguished men of science in recent years. It is equally pleasant to recognise the co-operation of NATURE, associated with the name of Lockyer, in stimulating interest in, and sustaining the work of, such research, cultivating the ground some years before the Mineralogical Society came into existence.

Institution of Mining and Metallurgy. *President:* MR. HUGH K. PICARD.—For fifty years NATURE has provided a link between workers in the fields of pure and applied science. During the war the achievements of chemistry and metallurgy, many of which have been recorded in its pages, were nothing short of astounding; indeed, no branches of scientific learning were more thoroughly tested or gained greater victories over almost insuperable difficulties. Urgency demands that *results* should be secured at any cost; consequently economics had to take second place. In the coming peaceful fight for the world's trade the metallurgist and chemist are faced with a new set of difficulties brought about primarily by the high costs of fuel and labour. They cannot look forward to well-earned rest, but must devote themselves anew to the problem of reducing the cost of production, always having before them the important economic factors which can no longer be put in the background.

Optical Society. *President:* PROF. F. J. CHESHIRE.—There is only one NATURE, as there is only one *Punch*—each supreme in its own sphere.

Institution of Petroleum Technologists. *President:* SIR FREDERICK BLACK, K.C.B.—In earlier days men with scanty knowledge, if any, of science found, and in crude fashion utilised, natural petroleum. To-day large production and economical utilisation demand the services of the geologist, the chemist, and the engineer, all of whom have a common platform in the pages of NATURE. The geologist, by his study of strata, directs effort to the more likely places. The chemist, by research and analysis, ascertains the proportions and properties of the constituent fractions of the crude oil. The applied science of the engineer and the chemist turns laboratory methods and apparatus into those of the commercial refinery. Contrast the early crude methods with those of to-day, and some realisation will result of the work already done by science in guiding the utilisation of a great gift of Nature. The field for similar effort is still great.

Physical Society. *President:* PROF. C. H. LEES, F.R.S.—As president of the Physical Society I desire to offer my congratulations to Nature on attaining its jubilee. There are, unfortunately, few physicists left who read the first number on its appearance, and it is hard for those of us who have grown up to expect Nature as regularly as Friday morning to realise how difficult it was fifty years ago to get trustworthy information on any scientific subject of special interest at the moment without going to original sources and reading at great length. To the specialist who is anxious to keep in touch with the world of science outside his own groove Nature comes as a refresher, and to the general reader who finds his daily paper too untrustworthy on scientific matters it is an invaluable authority.

Physiological Society. Prof. W. D. Halliburton, F.R.S.—The Physiological Society has no president, and has never had one. At a recent meeting of the society I was deputed (as the oldest member present) to convey to the Editor of Nature our hearty congratulations to that journal on having reached its jubilee, and to thank its staff for all they have so successfully done in the promotion of scientific interests during the last fifty years. The position of science to-day is very different from what it was in 1869. There still remains much to be done in the education of the public in reference to the value of science to the nation at large, but we anticipate that in the future, as in the past, Nature will occupy a prominent place in this branch of education. The recent war has during the last five years brought home to the people a keener appreciation of the national value of science than the preceding forty-five years of peace, and in the time of "reconstruction" now entered upon all will hope that both rulers and ruled will realise and act upon the imperative nature of the study of science, both pure and applied, if our efforts to make the world a better place are to be successful. The Physiological Society desires me to allude in conclusion, when sending a message to a literary journal, to the fact that it also has undertaken the publication of a periodical entitled *Physiological Abstracts*, by means of which its own particular part of the gospel may be spread. It was a direct outcome of the powerful stimulus of war, and we trust when the time of its jubilee arrives it may be able to show as good a record as its elder sister Nature.

Röntgen Society. *President:* George B. Batten, M.D.—"Work is worth doing for work's sake." Twenty-four years ago Röntgen, following the work of Crookes and Lenard, discovered X-rays, and a translation of his paper appeared in the columns of Nature (January 23, 1896) within a few days of the announcement of the discovery. In less than a quarter of a century the discovery has been of inestimable benefit to mankind not only in diagnosis and treatment, but also in metallurgy, and has created quite a new and extensive industry. Moreover, the investigation by Rutherford and a host of workers of the properties of X-rays and of the kindred rays of radioactive substances has increased our knowledge to such an extent that our conceptions of the ultimate constitution of matter and of the universe have been enlarged and revolutionised.

Foreign Academies and Scientific Societies.

Belgium.

Académie Royale des Sciences, des Lettres et des Beaux-Arts de Belgique. *Permanent Secretary:* M. Paul Pelseneer.—It is a great satisfaction for the Royal Academy of Sciences of Belgium to greet the first jubilee of Nature. The Academy highly appreciates what Nature has done for the promotion of science, especially in helping the speedy diffusion of the most important discoveries in every department. The Academy wishes the next period of fifty years to be still more fruitful, and that Nature may assist scientific progress in the future as much as in the past. The Academy thinks that the "Entente Cordiale" of the inter-Allied academies and the newly instituted International Council for Scientific Research, in Brussels, will be, by a methodical co-ordination of work, the best and quickest means of promoting scientific knowledge. Lastly, the Academy thinks all scientific workers understand that it is urgent to compensate for five years' interruption by a renewal of activity and production.

France.

Société d'Encouragement pour l'Industrie nationale. *Le Président:* M. L. Lindet.—La Société d'Encouragement pour l'Industrie nationale a suivi avec intérêt les publications scientifiques du journal Nature; elle y a souvent rencontré des articles de science industrielle dont elle a fait son profit, en même temps qu'elle se félicitait de voir Nature faire à son Bulletin des emprunts fort bien sélectionnés. Son ancienneté, qui remonte à 1801, lui donne toute autorité pour souhaiter à Nature, aujourd'hui cinquantenaire, une longue et glorieuse existence.

Société de Géographie, Paris. *Le Président:* Le Prince Bonaparte, de l'Institut de France. *Le Secrétaire Général:* M. G. Grandidier.—La Société de Géographie ne saurait demeurer indifférente à la célébration du cinquantenaire de Nature. En effet, depuis le jour où elle a commencé de paraître, Nature s'est toujours intéressée à la géographie; elle lui a fait sa place parmi les sciences dont elle s'occupait, et, par nombre d'études publiées dans ses différents fascicules, elle a, d'autre part, indirectement contribué à ses progrès. Aujourd'hui, Nature peut encore agir de même, et même plus efficacement que jamais; il n'y a plus à réaliser de grandes découvertes géographiques; mais, par contre, que d'études minutieuses sur le relief, le climat, la flore, la faune, l'homme aussi, s'imposent aux travailleurs! En publiant des travaux originaux, en donnant les conclusions des principaux mémoires parus ailleurs, Nature continuera de bien servir la géographie après 1919, exactement comme elle l'a fait précédemment, durant le demi-siècle écoulé depuis 1869.

Holland.

Dutch Academy of Sciences, Amsterdam. *President:* Prof. H. A. Lorentz.—On the occasion of the jubilee of Nature I have great pleasure in expressing my high appreciation of the important services it has rendered to science during the fifty years of its existence. The wonderful progress that has been made in all directions has been faithfully recorded in the columns of this journal, which has been a most valuable source of information and a great aid in their work to scientific men all over the world. I heartily hope it may remain so for many years to come.

Norway.

Bergens Museum. *President:* DR. JOHAN LOTHE.—During the war natural science amply proved what immense powers it wields and what great ends it can attain. In the work of reconstruction and peaceful development which is before us we shall look with greater expectations to science and to the results of scientific research. A highly trained staff of scientific workers, with well-furnished laboratories at their command, will then be an invaluable asset to any nation. At the same time we may entertain a hope that science, which is of necessity international, will in course of time be able to renew the bonds of international intercourse and co-operation which have been broken by the war, and thus enable mankind to bring the work for peace among nations to a happy end.

Portugal.

Academia das Sciências de Lisboa. *President (Class of Sciences):* JOSÉ JOAQUIM DA SILVA AMADO.—The great advances of science since the second half of the eighteenth century which are enjoyed by us, and the benefits of which are increasing every day, have been the result of three essential conditions, namely:—(1) The progressive triumph of the freedom of thought over the old tyranny of a dull scholasticism and its metaphysics, by which intellectual advancement was retarded for so long; (2) the establishment of the fertile and sound principles of experimental method; and (3) the wide publication, with comments and criticisms through books and periodicals, of the valuable scientific conquests obtained by the genius of man. In the group of periodicals which have contributed so powerfully to bring the extensions of natural knowledge in their diverse manifestations before a wide circle of readers NATURE, the fiftieth year of which is now celebrated, has contributed very greatly. The journal must be considered an active promoter of scientific learning, and of the spirit by which the treasury of human knowledge is enriched. Associating ourselves with its jubilee feast, we send our very hearty compliments to NATURE's Editor and publishers.

Switzerland.

Société de Physique et d'Histoire Naturelle de Genève. *Le Président:* M. J. CARL. *Le Secrétaire:* M. E. JOUKOWSKY.—Les naturalistes genevois ont appris avec plaisir que le périodique NATURE fêtait prochaînement le cinquantenaire de sa fondation. Ils apprécient les immenses services que ce journal a rendu à la diffusion des sciences naturelles par ses comptes rendus judicieux de l'activité des académies, par ses critiques des publications scientifiques et surtout aussi par des articles originaux dûs à la plume des savants anglais et étrangers les plus éminents. Tout en se mettant au service de la science pure, NATURE s'est toujours efforcé de tenir ses lecteurs au courant des progrès réalisés dans la technique et dans l'enseignement des sciences naturelles. Persuadés que votre journal continuera à occuper un des premiers rangs parmi les périodiques scientifiques, nous rendons hommage au travail que vous avez accompli et souhaitons à votre entreprise le meilleur succès dans l'avenir.

Société Helvétique des Sciences Naturelles. *Central President:* PROF. DR. ED. FISCHER.—I beg to offer my hearty congratulations on the fiftieth anniversary of NATURE. The journal has always in a remarkable manner understood how to present an extraordinarily complete survey of the position and development of the various branches of the natural sciences. It has also had the good fortune to number among its contributors the most distinguished naturalists and thinkers of Great Britain. To our congratulations we add the expression of our grateful recognition of the fact that the journal has repeatedly directed the attention of its readers to Swiss research work and the activity of our society. May NATURE ever succeed in awakening and retaining interest in the high importance of the natural sciences in the widest circles.

United States.

The Franklin Institute, Philadelphia. *President:* MR. WALTON CLARK. (By cable.)—The Franklin Institute extends to NATURE heartiest congratulations on the attainment of its jubilee. No journal has contributed more in the past fifty years to stimulate interest in physical and natural science. May you be as successful in the future; for a widespread knowledge of science is to-day imperative if the civilised nations are to continue to exist.

National Academy of Sciences, Washington. *Foreign Secretary:* PROF. G. E. HALE. (By cable.)—The president, Dr. Charles D. Walcott, requests me to offer his congratulations to NATURE on the occasion of its jubilee and on behalf of the Academy to express the deep appreciation felt in the United States for the work accomplished by NATURE in the advancement of research in the world. During a period of specialisation NATURE's extensive survey of the progress of research has stimulated wider vision and larger effort in spite of repeated discouragement. It has urged upon the statesmen of two generations the vital importance of science to the nation. At a time when the branches of science, no longer isolated, are uniting in common channels, and when Governments once unappreciative are recognising the bearing of research on national security and public welfare, we rejoice in NATURE's expanding influence and the higher opportunities for services opening to it in a newly ordered world.

UNIVERSITIES.

Queen's University of Belfast. *Vice-Chancellor:* REV. THOMAS HAMILTON, D.D.—Most heartily do I congratulate the Editor and proprietors of NATURE on its jubilee. The progress of science in the half-century which has passed since November 4, 1869, when the first number of NATURE appeared, has undoubtedly been more illustrious than that of any previous fifty years (or, for that matter, any previous one hundred and fifty years) of the world's history, and there can be no question that, in that progress, Nature has been indeed *pars magna*. All the indications, however, point to the conclusion that, splendid and memorable as has been the advancement of science in that half-century, the next fifty years will see the chariot wheels revolving with a vastly increased velocity. That being probably so, it is equally clear that the services of such a journal as Nature will, in the future, be more needed than ever before. I congratulate, *ex imo pectore*, all concerned in its publication on the conspicuous ability with which it has been conducted, the splendid progress it has made, and the value of the work it has done since the issue of its initial number. But I also congratulate, with equal cordiality, the entire scientific world, at the commencement of another vitally important half-century, on the possession of such a very ably conducted and enlightened organ, and I fervently pray that, when the year 1969 arrives, it will find our beloved Nature still holding on its way and, in its very old age, still bringing forth such fruit as it now yields from week to week with ceaseless regularity, acceptance, and success.

University of Birmingham. *Vice-Principal:* Sir Wm. Ashley.—The influence of Nature on the welfare of modern universities is matter for grateful acknowledgment. It has fostered that local generosity and enlightened opinion which led to their foundation and endowment. Through its columns there has appeared an informed and helpful criticism that has furthered university growth and development, and its records of progress in science have been of value to all graduates, and specially to those scattered in distant centres. The list of universities is not yet complete. A new age of learning has begun. New centres for promoting "humane" and scientific knowledge are arising. Meanwhile, as one of recent growth, the University of Birmingham cordially congratulates Nature on its successful advocacy of higher learning, and sincerely hopes that its influence may continue to help those who are shaping the educational future of the Empire during the fateful years that are coming.

University of Bristol. *Vice-Chancellor:* Sir Isambard Owen, D.C.L., M.D.—I hope I may be permitted to offer my hearty congratulations to Nature upon the attainment of its jubilee. Since its first appearance in 1869 Nature has occupied an essential place in the scientific life of this country, and may pride itself on having attained the rare position of an indispensable publication. I shall but be voicing the feeling of the whole scientific world in wishing it a long career of continued prosperity and usefulness.

University of Cambridge. *Vice-Chancellor:* Dr. P. Giles.—It must be a great satisfaction to all who admire and wish well to British learning to know that at the end of its fifty years of successful career Nature remains as it has so long been: a most valuable medium of opinion and criticism on scientific subjects. To Nature the man who is remote from academic centres looks for the first information on new discoveries and for a sound judgment on the publications of the scientific world. One result of the war has been an advance, rapid beyond past experience, in many fields of knowledge. Of all such advances may Nature continue to be the herald as heretofore!

University of Durham. *Vice-Chancellor:* Mr. J. S. G. Pemberton.—The Vice-Chancellor, on behalf of the University of Durham in general, and the Dean of the Faculty of Science, on behalf of the Science Faculty at Armstrong College in particular, send hearty congratulations to Nature on the celebration of its jubilee. Nature, in the past, has occupied a unique position in forming a connecting link between workers in various branches of science the world over. Many a time discussions on subjects of interest to more than one scientific section have been carried on in its columns. A notable case was when the late Lord Rayleigh in 1892, in a letter to Nature, asked for suggestions from chemists as to the reason for the discrepancy he had found between the densities of "atmospheric" and "chemical" nitrogen. This led eventually to the successful co-operation of Lord Rayleigh and Sir William Ramsay in the discovery of "argon." Such interlinking between the sciences promises to be of even greater importance in the future.

University of Edinburgh. *Principal and Vice-Chancellor:* Sir Alfred Ewing, K.C.B., F.R.S.—My debt to Nature extends back to the 'seventies, when we were both very young. From time to time I have been a contributor; always an interested reader. In the steady advance and diffusion of scientific knowledge during half a century Nature has taken an honourable part, maintaining a standard which has never failed to command the respect and gratitude of serious workers. That its usefulness may long continue is the confident hope of many who in a double sense are students of Nature.

University of Glasgow. *Vice-Chancellor:* Sir Donald MacAlister, K.C.B.—I attended the dinner given to the Editor of Nature five-and-twenty years ago, when Huxley and other contemporary leaders in science bore strong testimony to the great part which the journal had played in furthering the cause of natural knowledge and inquiry in this country. Nature has, in the fateful years since then, maintained and enhanced its influence and usefulness. It has become, indeed, an indispensable factor in the development of British science. It still furnishes "solid ground" to "the mind that builds for aye." It still informs, chastens, and stimulates the scientific worker and the scientific teacher. None interested in modern higher education in particular can afford to overlook a single weekly number, except at the risk of missing a link in the evolution of the subject.

The University, Leeds. *Vice-Chancellor:* Sir Michael Sadler, K.C.S.I.—We bring our tribute of gratitude and honour to those who have made the columns of Nature during its fifty years of public service a source of indispensable help and stimulus to students of science and to those engaged in scientific education. The exacting care with which it has been edited, the impartiality and precision of its judgments, the wide range of its information, the accuracy of its reports, have given NATURE in its own sphere unique distinction and authority. These have been used for the disinterested furtherance of investigation and for the support of the claims of science upon national attention and support.

University of Liverpool. *Vice-Chancellor:* PROF. J. G. ADAMI, F.R.S.—Looking backwards over the last quarter of a century spent overseas in Canada, I cannot but realise the heavy debt owed by me and other university teachers there to NATURE for keeping us in touch with the advances made in the various fields of science. Here, in Britain, the great dailies deal increasingly with the latest scientific developments. It is not so with the daily Press in North America. That is becoming more rather than less local and provincial. The broad survey given in NATURE fills a void in the New World that is in part bridged over in the Old. Perhaps more abundant illustrations and one or two articles each week upon the application of science and the laws of Nature to industry, added to the present contents, would widen the circle of its readers, increase its influence, and reflect the spirit of the age.

University of Manchester. *Vice-Chancellor:* SIR HENRY A. MIERS, F.R.S.—In common with all readers of NATURE, I regard its jubilee as a great event. Life would have been a different thing to us without our weekly NATURE, which has become an old friend because it has preserved its character unchanged. This is a great achievement and a testimony to the wisdom with which it was originally planned. Always a real scientific journal, it has continued to be also a popular journal in the best sense, and a great help in these days of increasing specialisation. A new and complete index to the first 100 volumes would be invaluable to all scientific workers.

University of Oxford. *Vice-Chancellor:* REV. DR. H. E. D. BLAKISTON.—The Vice-Chancellor of the University of Oxford is interested to hear that NATURE attains its jubilee in November, and offers his congratulations to the Editor. He cannot profess to be a constant reader of any scientific periodical; but when he wants clear information on any topic of scientific interest which is attracting public attention, or details of the career of any member of the University or of his own college who has obtained distinction in natural science, his first thought is to obtain the loan of a copy of the current number of NATURE.

University of Sheffield. *Chancellor:* THE MOST HON. THE MARQUESS OF CREWE, K.G.—I am happy to add my name, as Chancellor of Sheffield University and chairman of the Governors of the Imperial College, to the long list of those who are congratulating NATURE on its life of fifty years. As the nation becomes more and more conscious of its need for scientific training and the encouragement of research, it will continue to set an increasing value on NATURE, both as a record of progress and as the trusted vehicle for the expression of scientific opinions.

PERSONAL.

PROF. ISAAC BAYLEY BALFOUR, F.R.S.—NATURE, founded in the period of revolution in scientific thought following Darwin, by presentation of the work and aims and its advocacy of the claims of science, has been a powerful factor during fifty years in securing recognition by the nation of the importance of science which the lessons of the war have enforced. The world of science is proud of it. May its influence in this new period of reconstruction continue to operate forcefully, so that congratulations at its centenary may be as gratefully tendered as are those we offer now.

SIR GEORGE BEILBY, F.R.S.—I gladly record my grateful appreciation of the services rendered by NATURE to the cause of scientific culture in the best sense. The increasing tendency to specialisation by individual workers makes it more and more desirable that their touch with science in its widest aspects should be maintained with the minimum of effort on their part. This, it appears to me, will continue to be—as it has been in the past—one of the most valuable functions of NATURE.

SIR JAMES CRICHTON-BROWNE, F.R.S.—For fifty years NATURE has held the mirror up to Science and faithfully reflected her every movement. Each volume has been a record of the best brain-work of the year, ranging from the simplest observations to the most recondite abstractions. Recent issues have revealed the tremendously destructive forces that science wields, and have suggested that it has been owing to the lack of science in high places, and to the blundering that ignorance and arrogance beget, that these malign forces have been let loose on mankind. But science unperverted is beneficent, and nothing is more urgently needed at this hour than its teaching and popular exposition. Great is Science—"mightiest in the mightiest"—and NATURE is its handmaid. *Floreat Scientia! Floreat "Natura"!*

RIGHT HON. LORD BRYCE, O.M., F.R.S.—The amazing, and indeed unprecedentedly rapid, progress made during the last half-century in practically every branch of physical science, together with the increasing specialisation of most branches, has made it more and more difficult for those non-scientific persons who watch with eager curiosity the steps in that progress to follow its developments. Such persons, and especially those who occupy themselves with the study of the humanistic departments of knowledge, have long valued highly the help they receive from your journal. As one of these, I desire to congratulate the conductors of NATURE on the services it has rendered, and to express cordial wishes for its continued prosperity.

SIR FRANCIS DARWIN, F.R.S.—NATURE has for a number of years seemed to its many readers to be a beneficent natural phenomenon occurring weekly. It is wisely variegated so as to give just the type of information and criticism that we need. I warmly congratulate the Editor on its jubilee.

PROF. WYNDHAM R. DUNSTAN, C.M.G., F.R.S., DIRECTOR, IMPERIAL INSTITUTE.—I gladly take this opportunity, on the occasion of its jubilee, to congratulate NATURE on the important aid it has given to scientific work and interests, and on the position it has achieved as an organ of scientific opinion, not only in this country, but throughout the world.

SIR F. W. DYSON, F.R.S., ASTRONOMER ROYAL.—The advancement of science owes a great deal to NATURE, which keeps men of science in constant touch with one another's work. The outstanding feature of the journal is the combination of thoroughness and trustworthiness with readability and attractiveness of form. Grateful recognition should be accorded to NATURE for its able championship of the necessity of scientific research and the claims of workers in science. It was pointed out to me recently how closely the first number published fifty years ago resembles in form and contents the current numbers. Evidently great care and thought were given to the design and scope of the journal. In offering congratulations to the Editor and publishers, I should like to express the hope that NATURE may be as useful and successful in the next fifty years.

RIGHT HON. H. A. L. FISHER, M.P., PRESIDENT OF THE BOARD OF EDUCATION.—NATURE is one of the authoritative voices of current scientific opinion. It provides the members of the scientific community with the means of publishing newly discovered facts of general interest and importance, and enables them to follow the current work and thought in their own and in other branches of science. To those dwelling on the outskirts of the scientific community, the non-professional men of science, it furnishes a valuable *résumé* of scientific news and progress, while in its columns the general public can never fail to find intelligible references to facts of interest and importance. For fifty years NATURE has most successfully performed this important function. Victory in the war could not have been achieved without the aid of science; and the vigorous pursuit of science, both pure and applied, is essential to the welfare of the nation in peace. And now we find that a general interest in science has been reawakened by its successes in the war, while our universities and colleges are crowded with students whose keenness has never been equalled, and from whom science will recruit the workers lost during the war. I trust that a new era of progress and prosperity has opened for British science, and I hope that in this era NATURE will continue to play its important part and to add to its success of the past.

M. CAMILLE FLAMMARION.—La collection de NATURE brille aux meilleurs rayons de la bibliothèque de mon observatoire. C'est une opulente et précieuse mine scientifique, admirablement composée. Dès la première page, du 4 novembre 1869, nous avons sous les yeux son vaste programme, dans un éloquent commentaire de Huxley sur les aphorismes de Goethe : "Nature ! We are surrounded and embraced by her : powerless to separate ourselves from her, powerless to penetrate beyond her." Oui, la Nature nous enveloppe de ses merveilles ; la Science a pour mission de l'interpréter. "Un demi-siècle passera," ajoutait Huxley, "et nous jugerons notre œuvre." Ce demi-siècle est passé. La Rédaction de cette revue peut être fière de son œuvre. J'ajouterai que NATURE est souvent en avance de plus d'un demi-siècle. Ainsi, dans ce premier volume, de 1869, on peut voir, p. 304, une carte du "railway tunnel under the Channel," p. 407, une dissertation sur la 4e dimension, et p. 14, une étude de Norman Lockyer sur la couronne solaire, le tout en avence sur nos réalisations actuelles ! Félicitations et vœux pour un nouveau demi-siècle.

RIGHT HON. SIR AUCKLAND GEDDES, K.C.B., G.B.E., M.P., PRESIDENT OF THE BOARD OF TRADE.—I should like to congratulate NATURE on its long life now extending to half a century, and to wish it an even more vigorous and fruitful existence in the future. Any influence which at the present time directs the English mind to the facts of science is of service to the State. Industry, which we must now develop both in scientific economy and in volume to a level undreamed of in the days of our national pre-war wealth, needs every inspiration which science can give. NATURE is one of the possible vehicles of that inspiration, and therein lies its immediate practical importance. Of its importance to science it is unnecessary for me to speak.

DR. J. W. L. GLAISHER, F.R.S.—I was an undergraduate in my third year of residence when I saw the first number of NATURE in a shop-window, and I remember well its purchase and my interest in reading it, and how a little group of undergraduates criticised its name and discussed its contents and future. I now contemplate with admiration the hundred and three volumes and their services to science, and I am impressed by their perfect uniformity and absolute consistency of purpose. The "Notes" date from the first number, and have supplied scientific information, English and foreign, such as did not exist before, and is still unique. From the first, astronomy occupied a prominent place, and the "Astronomical Column" has been a most valuable feature from the early 'seventies. The reviews and accounts of the British Association meetings have always seemed to me especially important. The study and teaching of natural science in the University of Cambridge were in 1869 just making a feeble beginning. I read in the first number of NATURE that Mr. Bonney, of St. John's (still among us), would lecture on natural science, and that Mr. Trotter (Coutts Trotter of the "Coutts Trotter Studentship," who died in 1887) would lecture on electricity, magnetism, and botany, and the Editor added the remark that he congratulated the University on the increased desire for instruction in these subjects, but asked whether the number of men in the University competent to teach them was so small that it was found necessary to entrust electricity and botany to the same lecturer. Well, so it was. Trotter, a fellow of Trinity, had just returned from a course of study in Germany, and had induced the college to let him give these lectures. Though a mathematical man, I (perhaps induced by the paragraph in NATURE) was one of the three persons who attended Trotter's lectures on physiological botany, then an absolutely new subject in the University. The other two students soon ceased to attend, and I was the sole lecturee until Trotter considered that he had carried the subject far enough. This illustrates the vast change that fifty years have made in the University. Not many persons are now living who can remember

—and those of a later generation must find it difficult to credit—the almost complete lack of interest in natural science that existed in the University when NATURE was founded; and even in mathematics (though included in the arts) there was no encouragement—quite the reverse—to research of any kind. The progress that has been made from the stagnation of the 'sixties is enormous, and to this great expansion of thought, study, and learning NATURE has largely and worthily contributed.

SIR R. T. GLAZEBROOK, F.R.S., LATELY DIRECTOR OF THE NATIONAL PHYSICAL LABORATORY.—Those of us who have read the pages of NATURE weekly for nearly the full period of its life can realise very keenly its value and appreciate the influence it has had on the progress of natural science. It fills, and that in a most admirable manner, an important place in scientific literature; it has served as the means whereby many of the most marked advances of science have been made known to the world, and in its pages will be found the account of discoveries of the highest value to mankind. It is a privilege to send to its veteran founder the heartiest congratulations on its jubilee.

SIR DANIEL HALL, K.C.B., F.R.S., PERMANENT SECRETARY, BOARD OF AGRICULTURE.—Looking back even so far as one's earliest student days, I see NATURE as a continuous and essential part of my scientific life. It has been especially so to me, because most of my time has been spent in the country, remote from the ordinary scientific meeting grounds, and with few opportunities of learning by conversation what was going on in the scientific world. Thus one became dependent upon NATURE for information as to the changing currents of scientific opinion and for the necessary knowledge of what work was being done in other fields of science than one's own. During the period in which I have known it, the notable features of NATURE have been its catholicity, its fairness, and its dignity. It has worthily stated the case of science to the English-speaking world.

MR. W. B. HARDY, SEC. R.S.—I congratulate NATURE on its fifty years' record. Since the journal was founded science has advanced to an extent which will be realised only by the historian of the future. The advance has been made possible by intense specialisation, and the greatest service which NATURE has rendered (and indeed, in my opinion, can render) is that it has kept its readers in touch with the general progress in natural knowledge. Every movement of importance has found an expression in its pages.

PROF. W. A. HERDMAN, F.R.S., PRESIDENT-ELECT OF THE BRITISH ASSOCIATION.—NATURE is now a firmly established institution in the world of science, bringing us week by week welcome additions to knowledge, news of work in progress, helpful discussions of new views, and sound critical judgments on affairs scientific and educational. Throughout the past fifty years this journal has consistently and authoritatively upheld the freedom, dignity, and practical importance of science, and has established a splendid record of scientific progress and a fine tradition of disinterested service to the advance and diffusion of natural knowledge.

SIR ALFRED KEOGH, G.C.V.O., G.C.B., RECTOR, IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY.—The attainment by NATURE of its jubilee is a notable event. Fifty years of labour in the furtherance of those principles by which, in many departments of work, unsubstantial axioms were to yield pride of place to scientific truth is no mean achievement. We may well think that the burden of the future, if different from that of the past, is no less difficult. The stimulation of inquiry, the spreading of knowledge, and the demonstration of the necessity of not merely thinking, but of thinking scientifically, are amongst the most important achievements which NATURE has successfully attempted. The interests of science are the interests of the State, and in the vista which is now opening we can all perceive a future in which the well-being of humanity is entirely dependent upon the progress of knowledge and discovery. To aid, encourage, and stimulate progress and to record advancing knowledge is henceforward, as in the past, the task of NATURE. As we look back with pride, so we may look forward with an expectant hope.

SIR JOSEPH LARMOR, M.P., F.R.S.—The early volumes of NATURE especially formed an admirable, indeed still indispensable, record of the progress of scientific discovery in our times. They were interesting without ceasing to be exact, and thereby potent to mitigate the specialisation that is inevitable for the secure and fruitful advancement of knowledge. The journalistic and discursive tendencies of the present time render such an authoritative organ, of type purely scientific, more than ever desirable.

PROF. A. LIVERSIDGE, F.R.S.—Having been a subscriber to NATURE from its first appearance, and having read every number, I wish to offer my congratulations upon its jubilee, as well as my best wishes for its continued usefulness and success.

SIR OLIVER LODGE, F.R.S.—I well remember the appearance of the first number of NATURE, when I was eighteen years old and an enthusiastic amateur student of science. The comprehensive character of the new journal was typified by an eloquent introduction by Huxley at the request of Sir Norman Lockyer. And many a man of science must have been grateful to one of the few periodicals which at a high level keeps its readers in touch with practically all branches of scientific knowledge. Over-specialisation is a real danger, and most publications necessarily cater for a limited group only, thus preventing free and easy interchange of thought across the boundary, and excluding the ordinarily educated public from participation in the current progress of science. Comprehensiveness has been the note of NATURE, and consequently it has been able to render conspicuous service. Even our rulers and literary men may occasionally find time to glance at a periodical such as this, and thereby the disastrous divorce between science and letters and public affairs is mitigated. Long may NATURE flourish, and continue to be read in all civilised countries.

PROF. W. C. MCINTOSH, F.R.S.—NATURE, with which I have been familiar from its first number onward to date, has filled an important place in the scientific literature of our country, and in a manner which has won the confidence and elicited the help of every department of science. Moreover, its reputation is as solid abroad as at home. Its long series of volumes is indispensable in every university library and in every scientific institution or laboratory. The attainment of its jubilee, therefore, is an occasion for cordially congratulating the Editor and publishers on their long and successful labours, and for wishing them a future as fertile as the past.

SIR PHILIP MAGNUS, M.P.—As one of the early contributors to NATURE, I welcome the celebration of its jubilee as indicating its value to an ever-increasing number of readers, and the permanent place it has made for itself in the scientific world. During the past half-century the progress of science has been even more rapid than the most sanguine of its devotees could have anticipated. Towards that progress the publication of NATURE has largely contributed. It has stood in close touch with the results of the most recent scientific investigations, and one may truly say that no journal has been more ably conducted; none has been more successful in realising and satisfying the requirements of those who are actively engaged in scientific work. To the Editor of NATURE and his staff I venture to offer my sincere congratulations.

RIGHT HON. SIR HERBERT MAXWELL, BART., F.R.S.—As one of what must be but a small remnant of those who remember the birth of NATURE, let me offer humble, but cordial, tribute to the great service it has rendered to science throughout half a century. Born in a period of fierce controversy, it has proved faithful to the purpose of its sponsors, shedding a clear and steady light on the pathway of research, maintaining a lucid record of modern discovery, and stimulating the appetite for knowledge in many minds. The hand of its veteran Editor, Sir Norman Lockyer, has indeed been steady on the helm. May NATURE long retain its pre-eminence among English scientific journals!

RIGHT HON. SIR ALFRED MOND, M.P., FIRST COMMISSIONER OF WORKS.—I heartily congratulate the Editor of NATURE on the fact that his periodical, which has done so much to awaken and foster interest in science, should now be celebrating its jubilee. It has always presented the progress of scientific activities in a readable, popular, and accurately scientific manner. The readers of NATURE have been enabled to keep abreast of scientific progress, and always knew that they could rely upon the soundness of the information to be found in its pages. I hope that the general recognition of the importance of science to the progress of humanity which is now manifesting itself will extend still further in the future the valuable work and influence of this excellent journal.

PROF. JOHN PERRY, F.R.S.—I congratulate NATURE on its jubilee. I have read with interest the greater part of almost every copy issued in the fifty years, and this interest has not been confined to my own subjects, for NATURE is constantly enticing me across the borders into biology. I cannot recollect a single copy which has been much below the standard which the paper has established for itself, and I can recollect many which exceeded even that very high standard. If England were idealistic, it would bestow a decoration much higher than O.M. upon NATURE.

SIR WILLIAM J. POPE, K.B.E., F.R.S.—During the last fifty years the great truth that all human progress is dependent upon scientific knowledge has gained much more general recognition than it previously enjoyed. The life-work and the writings of our foremost men of science of the last half-century—Huxley, Tyndall, Kelvin, Roscoe, Meldola, and a host of others—have been largely instrumental in clarifying popular opinion as to the value and significance of scientific research. Throughout this period NATURE has devoted itself persistently to the task of presenting the case for science, both by systematically recording the conclusions of scientific men and by editorial elucidation and comment. Although much has been achieved, far more remains yet to be done. We look to NATURE in the future, as in the past, to impress public opinion with the necessity for giving scientific methods and results a prominent place among the activities and in the councils of the nation.

SIR DAVID PRAIN, C.M.G., C.I.E., F.R.S.—Among the services rendered by NATURE to science during the half-century which has passed since its foundation, one of the greatest will appear to the thoughtful to have been the adoption of the attitude consistently maintained in its pages towards the application of natural knowledge to everyday affairs. Launched at a dismal time when the philistinism of the nineteenth-century attitude of men of affairs towards science was only equalled by that of men of science towards affairs, NATURE had the courage to revert and adhere to that more humane perception of the seventeenth century: that the first duty of Science herself is to improve her new knowledge for use. The wider acceptance of this old doctrine which we welcome to-day NATURE may fairly claim as an abiding reward.

SIR HARRY R. REICHEL.—Hearty greetings to NATURE on its fiftieth anniversary! Science is now becoming the guiding principle of material progress, and its pursuit is justified and recommended to the public by the promise of material returns. Among those who still regard science as a branch of philosophy and worthy for its own sake, NATURE will always hold its own peculiar and honourable place. In its pages the worker whose horizon is not restricted by exclusive devotion to his own subject can follow the lines of advance along other paths of inquiry. A journal which can serve such a wide range of interests without falling into "popular" science must always occupy a unique place in the intellectual life of the nation.

PROF. J. EMERSON REYNOLDS, F.R.S.—I beg to offer my hearty congratulations to the Editor of NATURE on the jubilee of that valuable journal. NATURE has long filled so important a position in British scientific journalism, and reflected scientific progress so fully in the past, that I doubt not it will continue to do so in the future with even greater success.

PROF. W. RIPPER.—I desire to add my tribute of congratulation and thanks to the many which you will doubtless receive on the occasion of the attainment of Nature's first jubilee. The whole scientific community of this country is indebted to you for the great service you have rendered to science in recording with wise discrimination the progress of science and the growth of natural knowledge. Your journal is welcomed week by week as a very real friend, and we trust it may long continue to serve the great cause of science with the same distinction and ability as in the past.

Sir Ronald Ross, K.C.B., K.C.M.G., F.R.S.—I write as editor of *Science Progress* to congratulate Nature on attaining its jubilee. It is with warm feelings that I do so, because Nature has been the medium of publication for almost all scientific men, whether as regards their scientific work or their personal difficulties, or even questions of organisation, emolument, and so on, for fifty years. It is preeminent as a scientific organ, and the editorship of it is universally recognised as being extraordinarily efficient. I myself know the difficulties, and appreciate, therefore, the way in which they are completely overcome.

Prof. Arthur Schuster, Sec. R.S.—I desire to convey to the Editor of Nature my sincere congratulations on the completion of the first fifty years of life of the periodical which under his guidance has attained a unique position in the scientific world. By a well-balanced combination of scientific articles, reviews, discussion by correspondence, personal notes, and general information, it soon established and continued to maintain a distinguished reputation wherever science is pursued. If continued in the same spirit of liberal thought and impartial criticism, Nature may look forward to an equally prosperous future.

Dr. D. H. Scott, F.R.S.—The fifty years of Nature's brilliant career have seen great developments in botany, as in every other science. It is true that the previous half-century, which witnessed the birth of the cell theory and the acceptance of evolution, was a greater era; it was then that scientific botany, as part of biology, was created; the succeeding period has been one of vigorous and manifold growth. When Nature started Darwinism had already won its first triumphs; it maintained and strengthened its position down to the end of the century, and then came a change. The rediscovery of Mendel's work in plant-breeding established the new science of genetics and transformed current ideas of evolution. Another new science, cytology, the intimate study of the cell, and especially of the nucleus, arose, to work hand-in-hand with genetics, revealing the nature of fertilisation and, in a certain degree, the mechanism of segregation. These are matters of fundamental significance, common to both the biological sciences. In the same field, but within the stricter limits of botany, we have the discovery of the spermatozoids of the maidenhair-tree and the Cycads, linking these primitive seed-plants with the Cryptogams, and through them with the animal kingdom, and of the strange phenomenon of double fertilisation in the higher flowering plants. Other new developments are the growth of a comparative anatomy of plants, now extended to the oldest fossil remains, and the advent of ecology, or physiology in the field. Of all this and much more a record will be found in the long series of the volumes of Nature.

Sir Aubrey Strahan, K.B.E., F.R.S., Director of the Geological Survey of Great Britain.—I am glad to avail myself of the opportunity of sending my congratulations on the attainment by Nature of its jubilee. The high standard aimed at in the earliest issue has been well maintained, and Nature has now for half a century been our leading weekly journal on pure science. As regards geological literature, apart from the valuable original articles which appear in its columns, its reviews especially supply a want which is not provided for elsewhere. I venture to express the hope, which I believe will be shared by all scientific men, that Nature may continue to fulfil its high functions for many years to come.

Sir J. J. H. Teall, F.R.S., lately Director of the Geological Survey of Great Britain.—That Nature has rendered great services to science in general and to all its branches is universally admitted. I have followed its development from the time of its first appearance until now with interest, sympathy, and admiration; and it is with a profound feeling of gratitude that I offer my hearty congratulations on the celebration of the jubilee of the great journal which has been edited with so much tact and ability for fifty years.

Prof. H. H. Turner, F.R.S.—The benefits of such work as yours are absorbed into the scientific system so naturally that, for the most part, they excite no attention. All the more is it, therefore, appropriate that at certain epochs notice should be expressly directed towards them and an attempt made to integrate what we have been quietly receiving for so many years in order that we may be truly thankful. It gives me great pleasure to be one of those invited to put our thanks into words.

Dr. Henry de Varigny, Scientific Editor of the "Journal des Débats."—As an old and very faithful reader who has never failed throughout forty years to read Nature, I beg to send my thanks to the Editor, contributors, and publishers for the pleasure and information they have given me. Nature has been, and remains, *the* organ of British scientific thought and progress. All the work of Britain's magnificent team of naturalists, astronomers, physicists, chemists, biologists, etc., has been made known to the world by Nature. Sincere thanks are due for the good work done in the interest of scientific progress, and cordial congratulations to the Editor on this anniversary. May both he and Nature live long to pursue their task, one which becomes more useful and essential than ever before to culture, *haud teutonico sed humano sensu*; and may we all, on both sides of the Channel, maintain that cordial understanding so firmly maintained through the ordeal of blood and fire for the freedom of civilisation.

Sir H. Trueman Wood.—I have been a regular reader of Nature since 1870—for forty-nine out of its fifty years of existence. There cannot be very many now left who can say as much, so I hope I may be allowed to add my voice to the chorus of congratulation which I am sure will greet the completion of its first half-century. Others may be better qualified to testify to the value of its services to various branches of science, but nobody can be more appreciative of the help it has given to the progress of science generally, especially in this country, which is fortunate in possessing what is admittedly the leading scientific newspaper in the world. The thanks of all associated with scientific matters are due alike to its eminent founder, still happily amongst us, and to the publishers who co-operated with him in what at the time can scarcely have been regarded as a very promising speculation.

Dr. Henry Woodward, F.R.S.—Having been present at a dinner at the Garrick Club in 1869 to inaugurate the birth of Nature, now in its fiftieth year, I feel proud to be permitted to offer by hearty congratulations to the Editor and the publishers upon this memorable occasion of its jubilee. It is no small undertaking to have produced more than 2600 weekly numbers of a journal embracing every branch of natural knowledge during half a century. Long may Nature flourish, and long may the founder be spared to see its prosperity and, with the eminent firm of Macmillan, enjoy its cosmopolitan honours and high scientific reputation.

NOTES.

The King has been pleased to approve of the following awards this year by the president and council of the Royal Society:—Royal medal to Prof. J. B. Farmer for his notable work on plant and animal cytology, and Royal medal to Mr. J. H. Jeans for his researches in applied mathematics. The following awards have also been made by the president and council:—Copley medal to Prof. W. M. Bayliss for his contributions to general physiology and to biophysics; Davy medal to Prof. P. F. Frankland for his distinguished work in chemistry, especially that on optical activity and on fermentation; Sylvester medal to Major P. A. MacMahon for his researches in pure mathematics, especially in connection with the partition of numbers and analysis; and Hughes medal to Dr. C. Chree for his researches on terrestrial magnetism. The following is a list of those recommended by the president and council of the Royal Society for election to the council at the anniversary meeting on December 1:—*President:* Sir J. J. Thomson, O.M. *Treasurer:* Sir David Prain, C.M.G. *Secretaries:* Mr. W. B. Hardy and Mr. J. H. Jeans. *Foreign Secretary:* Prof. W. A. Herdman. *Other Members of the Council:* Mr. J. Barcroft, Mr. C. V. Boys, Sir J. J. Dobbie, Sir F. Dyson, Prof. J. B. Farmer, Sir W. M. Fletcher, K.B.E., Prof. F. W. Gamble, Sir R. T. Glazebrook, Prof. J. W. Gregory, Dr. A. C. Haddon, Sir R. A. Hadfield, Bart., Sir A. B. Kempe, Sir W. J. Pope, K.B.E., Dr. S. H. C. Martin, Prof. A. Schuster, and Prof. W. P. Wynne.

The President of the French Republic, accompanied by Mme. Poincaré, received a cordial welcome upon his arrival in London on Monday, on a visit to the King and Queen. British men of science would wish to convey to President Poincaré the expression of their high regard for the influence France has always exerted in the cause of science and civilisation in Europe, and of fraternal greetings to the eminent leaders in intellectual activity who are preserving this great heritage. A banquet in honour of President and Mme. Poincaré was given by the King and Queen at Buckingham Palace on Monday evening. On Tuesday the President, accompanied by Mme. Poincaré, visited the City and were presented with an address by the Lord Mayor. To-day the President is to be installed as Lord Rector of Glasgow University, and, with Mme. Poincaré, will be entertained at luncheon at the University, after which he is to be presented with the freedom of the city.

A correspondent informs us that the Village Club at Wimbledon, wherein, as Sir Norman Lockyer explained in our jubilee number, the idea of Nature was born, was founded by Dr. Joseph Toynbee (father of Arnold Toynbee), and one of his intentions was to have a local museum in the building. Such a museum is now there, brought together by the more recently established John Evelyn Club for Wimbledon. The Village Club premises were occupied by the military during the war, but the collections have now been replaced and are again open to the public. They include prints, pictures, maps, and a photographic survey, as well as many antiquities, bygones, and natural history specimens, all connected with the locality. It is hoped that the portrait of Sir Norman Lockyer will soon adorn the walls of the museum.

Sir E. Ray Lankester has just completed fifty years' editorship of the *Quarterly Journal of Microscopical Science,* and the current issue of that well-known periodical (vol. lxiv., part 1) contains a brief summary by Prof. G. C. Bourne of the contents of the journal for the last half-century, demonstrating very clearly the important part that it has played in the development of modern biological science. We offer our hearty congratulations to Sir Ray Lankester on this notable occasion, and hope that many more volumes may appear under his distinguished editorship.

In reply to a question by Sir Philip Magnus, Mr. Bonar Law has announced that the Commissioners to be appointed under the Forestry Acts are as follows:—Lord Lovat (chairman), Director of Forestry, B.E.F., France, and member of Forestry Reconstruction Sub-Committee and of the Interim Forest Authority; Mr. F. D. Acland, M.P., chairman of the Home-grown Timber Committee, chairman of the Forestry Reconstruction Sub-Committee, and chairman of the Interim Forest Authority; Lord Clinton, formerly president of the Royal English Arboricultural Society and member of the Interim Forest Authority; Mr. L. Forestier-Walker, M.P.; Sir John Stirling-Maxwell (hon. secretary), formerly president of the Royal Scottish Arboricultural Society and member of the Forestry Reconstruction Sub-Committee; Mr. T. B. Ponsonby, member of the Interim Forest Authority; Mr. R. L. Robinson, member of the Interim Forest Authority, secretary of the Forestry Reconstruction Sub-Committee, and formerly head of the Joint Forestry Branches of the Board of Agriculture and Office of Woods; and Col. W. T. Steuart-Fotheringham, member of the Interim Forest Authority.

After a successful military campaign the House of Commons has frequently voted large sums of money from public funds to the commanders under whose guidance the conquest was won. National recognition of a like kind was given to Jenner by a grant of 10,000*l.* made by the House in 1802, and by a further grant of 20,000*l.* five years later, the intervening period having strengthened the opinion as to the efficacy of vaccination and its great benefits to the nation at large. Sir Ronald Ross has long urged that this principle should be commonly followed in connection with great discoveries by which numerous human lives are saved, as it is as the result of military conquests. In the case of a medical man devotion to research means the sacrifice of private practice, and when the result of his work is to the great advantage of the human race at large, or the nation in particular, much can be said in favour of just compensation to him. To further this reasonable claim for awards for medical discovery, a joint committee of the British Medical Association and the British Science Guild has just been formed. Sir Ronald Ross entertained the members of the committee to luncheon on November 4, and among those present were Prof. W. M. Bayliss, Sir Alfred Keogh, G.C.B., Dr. R. T. Leiper, Prof. B. Moore, Col. Nathan Raw, M.P., and Dr. W. Somerville. At a meeting held on the same day it was decided that each of the members of the committee should collect information regarding medical research work and discovery already carried out which he considers worthy of recompense by the Government or other bodies, and Sir Ronald Ross undertook to collate and edit the information in a report to the committee for further action.

IN June, 1917, the Fuel Research Board was asked by the Board of Trade and other Government Departments concerned to advise as to the most suitable composition and quality of gas. In January last the Board made its report, and this has since been the basis of negotiations between representatives of the Board of Trade, gas companies, and local authorities. An agreement has now been reached, and from a recent statement by Sir A. Geddes, in reply to a question in the House of Commons, a Bill will shortly be introduced to give effect to the recommendations of the Fuel Research Board as modified by the agreement now arrived at. The gas consumer will be charged for the potential thermal units supplied to him, the unit to be 100,000 British thermal units. The gas companies are to declare the calorific value of the gas they propose to supply, no fixed standard being laid down by Parliament. The British thermal units supplied are to be calculated by multiplying the number of cubic feet registered by the consumer's meter by the *declared* gross calorific value of the gas per cubic foot. (The original proposal of the Fuel Research Board is modified by the introduction of the word "declared.") The calorific value of the gas is to be continuously measured and recorded. As regards the proportions of inert constituents allowable, the Board's original proposal was a maximum of 12 per cent., the gas companies claiming to be freed from any restrictions in this direction. The compromise now agreed upon states that the amount of inert constituents shall not exceed 20 per cent. for two years, 18 per cent. for the next two years, and 15 per cent. afterwards. The gas undertaking is to adjust, and if need be to replace gratis, the burners in consumers' appliances so that the gas delivered can be burned in these appliances with safety and efficiency. It will no doubt require some time for the consumer to become accustomed to these changes and to be educated up to grasp the meaning of the new unit, but, owing to the time required to make the new instruments and to adjust the consumer's appliances, it will probably be three or four years after the passing of the new Bill before gas is supplied over the whole country under the new conditions.

PROF. A. FOWLER, professor of astrophysics, Royal College of Science, South Kensington, has been awarded a gold medal by the National Academy of Sciences, Washington, in recognition of his eminent contributions to astronomical science.

PROF. A. W. CROSSLEY, professor of chemistry in the University of London (King's College), has been appointed director of research to the British Cotton Industry Research Association.

NOTICE is given that applications for grants from the Chemical Society Research Fund, made upon forms obtainable from the assistant secretary of the society, must be received on or before Monday, December 1 next.

THE Geological Survey of Great Britain and Museum of Practical Geology, Jermyn Street, S.W.1, have been transferred for administrative purposes from the Board of Education to the Department of Scientific and Industrial Research as from November 1. Correspondence with reference to the work of the Survey should be addressed as heretofore to the Director of the Survey and Museum, Jermyn Street, S.W.1.

AT a general meeting of the members of the Royal Institution, held on November 3, the special thanks of the members were returned to Mr. Richard Pearce for his donation of 100*l.* to the fund for the promotion of experimental research at low temperatures; to Mr. Robert Mond for his gift of laboratory material; and to Sir Humphry Davy Rolleston for his gift of a drawing of Sir Humphry Davy's birthplace and a water-colour of his statue in the Market Place, Penzance.

AT University College, London, on Tuesday, tablets in memory of Lord Lister were unveiled before a large and distinguished assembly. The Duke of Bedford, who opened the proceedings, said that every civilised community realised the debt of gratitude it owed to Lord Lister. Sir George Makins, president of the Royal College of Surgeons, unveiled the tablet to be erected in University College Hospital, and Sir Joseph Thomson, president of the Royal Society, that to be erected in University College.

AT the anniversary meeting of the Mineralogical Society, held on November 4, the following officers and members of council were elected:—*President*: Sir William P. Beale, Bart. *Vice-Presidents*: Prof. H. L. Bowman and Mr. A. Hutchinson. *Treasurer*: Dr. J. W. Evans. *General Secretary*: Dr. G. T. Prior. *Foreign Secretary*: Prof. W. W. Watts. *Editor of the Journal*: Mr. L. J. Spencer. *Ordinary Members of Council*: Mr. H. F. Collins, Mr. J. P. De Castro, Prof. H. Hilton, Mr. Arthur Russell, Dr. A. Holmes, Miss M. W. Porter, Mr. R. H. Rastall, Sir J. J. H. Teall, Mr. A. F. Hallimond, Dr. F. H. Hatch, Mr. J. A. Howe, and Mr. W. Campbell Smith.

THE meeting of the Physical Society of London on November 28 (at 5 p.m. in the Imperial College of Science, South Kensington) is to be devoted to a discussion of the subject of lubrication. The physical qualities of a good lubricant have for long eluded capture, and it is expected that the discussion will at least furnish a step towards the solution of the problem, and at the same time create a wider interest in the subject. Amongst those who will take part are the following:—L. Archbutt, R. Mountford Deeley, W. B. Hardy, secretary R.S., F. W. Lanchester, H. M. Martin, Principal Skinner, and Dr. T. E. Stanton. The meeting is an open one, and all who are interested in the subject are invited to attend.

DR. JOHN BROWNLEE has investigated statistically the periodicity of influenza epidemics. Considering specially the years 1889–96, he finds that the interval between the epidemics is thirty-three weeks, there being a missed epidemic when an epidemic is due in the autumn (*Lancet*, November 8, p. 856). With regard to the recent epidemics, from July 13, 1918, to March 1, 1919, the maximum points are separated by thirty-three weeks; from March 1 to October 1, 1919, is also thirty-three weeks. An epidemic is therefore due, but falls at an unsuitable season, and should therefore be small, and so far this is the case. On the same sequence the next epidemic should occur in January or February of the new year.

LORD MILNER, Secretary of State for the Colonies, has appointed a Committee to consider the position of the medical services of the various Colonies and Dependencies, with the view of maintaining and increasing the supply of candidates and of securing contentment within the service; and to consider whether the principle of assimilating the medical service of neighbouring Colonies may usefully be extended, and, if so, how far and by what means. The members of the Committee are:—Sir Walter Egerton, K.C.M.G. (chairman), Lt.-Col. Sir Harry Verney, Bart., Sir Humphry D. Rolleston, K.C.B., Sir W. B. Leishman, K.C.M.G., Lt.-Col. Sir James Kingston Fowler, K.C.V.O., Mr. T. Hood, Mr. A. Fiddian, and Mr. J. E. W. Flood (secretary).

AMONG the old mathematical worthies who are buried in the churches of the City of London is Nathaniel Torporley, who was interred in the church of St. Alphage, London Wall, now being demolished. Torporley, of whom there is a sketch in the Dictionary of National Biography, was born in 1564, the same year as Shakespeare. From the Shrewsbury Grammar School he passed to Oxford, graduating in 1584 from Christ Church and taking Holy Orders. It is said that for some years he resided in France and was amanuensis to François Vietá. After his return to England he became one of the pensioners of Henry Percy, the ninth Earl of Northumberland, and, like his contemporaries Harriott, Dee, Warner, and Allen, spent a part of his life at Sion College. Among his writings was one containing a rule for solving spherical triangles. Torporley died at Sion College, and was buried on April 17, 1632. The Church of St. Alphage was, we understand, destroyed in the Fire of London, 1666, but was afterwards rebuilt.

THE activities of the Royal Photographic Society naturally divide themselves into two sections, namely, the pictorial and generally illustrative and the scientific and technical. We are very pleased to see that a few of the more energetic members are taking the latter division in hand in order to develop it by extending its scope and encouraging scientific work. The "Scientific and Technical Group" consists already of 137 members of the society, and it is hoped that this number will soon be largely augmented. The members of the group pay a small additional subscription, the disposal of this fund being exclusively under the control of the administrative committee of the group. It is hoped to be able to distribute among the members abstracts or translations of scientific communications made to other societies or publications, as well as to arrange for scientific and technical lectures and papers. The Royal Photographic Society has always been the most important photographic centre in this country, and it is to be hoped that this new arrangement will be energetically pursued, and that it will lead to a greatly increased interest being taken in the science of photography.

THE annual council meeting of the National Union of Scientific Workers was held on Saturday, November 8, at the Imperial College Union, South Kensington, and was attended by delegates from nine branches. The chair was taken by the retiring president, Dr. O. L. Brady, and the chief business was the adoption of the annual report and of the rules, and the election of officers and executive committee for the ensuing year. Dr. J. W. Evans was elected president, Dr. Norman Campbell treasurer, and Mr. Eric Sinkinson secretary. At the dinner which followed, Dr. Evans, who presided, expressed the hope that the union, in company with such other bodies as the British Association and the British Science Guild, would do great things for science. Sir Ronald Ross, replying to the toast of "The Guests," thought there were three points for which the union might press:—(1) Better payment for newly qualified men, including the modification of the present system of research assistantships; (2) pensions on a transferable basis for staffs of universities and other institutions; and (3) payment for advice given to Government and municipal bodies, which frequently did not even give travelling allowances. The union should also press for public recognition and awards for inventions.

IN an able and very valuable summary of the mammals in the Melbourne Zoological Park, Dr. W. H. D. Le Souef, the director, contrives to give a lively description of all the more important indigenous mammals of Australia. As might have been expected, he adds some very interesting facts to what is known of the life-histories of these animals. Throughout he is constantly insisting on the need for legislation to stay the work of tho exterminator. Over vast tracts of country some species have become absolutely wiped out. It is not a little disconcerting indeed to learn that the skins of wallabies and kangaroos are exported by the hundred thousand, for this means that vested interests are sure to beget strenuous opposition to the proposal which has been made to frame protective measures to secure the survival of at least a remnant of this remarkable fauna. But we trust this legislation will be speedily effected, or it will come too late. An additional toll upon this fauna is levied by the dogs, foxes, and cats which have been introduced by settlers, and in many cases have become feral. This memoir, which is illustrated by a number of very beautiful photographs, is issued by the New York Zoological Society.

THE *Journal of Indian Botany*, the first number of which appeared in September, has been started under the editorship of Mr. P. F. Fyson, of the Presidency College, Madras, to provide a means of publishing botanical work done in India which would not naturally find a home in the existing botanical journals of that country. In addition to original papers it is proposed to publish abstracts and reviews of papers which appear in other journals. The editor appeals for help to Indian botanists to make the journal, which will appear monthly, a success. The present issue contains a short paper by L. A. Kenoyer on the dimorphic female flower of *Acalypha indica*, a common tropical weed belonging to the family Euphorbiaceæ, which grows over most of India as a weed on waste ground. The lateral female flowers resemble those of Ricinus (Castor Oil) and the Euphorbiaceæ generally, but the terminal flower of the spike has one in place of three carpels, and develops one seed, which also differs slightly in size and structure from the normal seed. S. L. Ghose gives a systematic account of the Myxophyceæ, or blue-green algæ of Lahore, which occur throughout the year in drains and watercourses, artificial tanks, ditches, and on moist ground and tree-trunks. The study of this group has hitherto been neglected in

India. The author describes about twenty species which occur commonly, and others are occasionally met with. L. J. Sedgwick discusses the distinguishing features of some closely allied species of the genus Alysicarpus (Leguminosæ); and P. F. Fyson and M. Balasubrahmanyam describe the growth and root-structure of the strand-grass, *Spinifex squarrosus*, as a factor in the marine strand vegetation of Madras.

THE recent work of the French in Morocco under the direction of Gen. Lyautey is described in detail by M. A. de Tarde in a well-illustrated article in the *Geographical Review* for July (vol. viii., No. 1). Gen. Lyautey has not stayed his hand during the war, but has continued a policy of reconstruction on a bold scale, building roads, railways, and harbours, improving agriculture, and multiplying schools, hospitals, and administrative buildings. The growth of European population in the larger town is not to be allowed to crush the native town, nor is the European quarter to form part of the old town. All European towns are to be separated from native towns by a strip of ground, on which no building is allowed. The task of planning the European towns has been entrusted to competent architects and engineers under the direction of M. Prost, who recently drew up plans for the extension of Antwerp. The plans for Casablanca, the chief port, Rabat, Fez, Marrakesh, and Meknes are now complete.

AT the first meeting of the new session of the Institution of Petroleum Technologists, held on October 21, a paper was read by Mr. A. Philip on "Some Laboratory Tests on Mineral Oils." The author referred at length to the imminent need for the standardisation of tests and methods in petroleum analysis, and considered that it would not be feasible to prepare and circulate standard material of known composition. He therefore urged the very detailed description of procedure, so that it would be possible for a reasonably accurate repetition of results to be obtained from chemists working in different laboratories. The sampling of oils was described minutely as practised at Portsmouth, and great emphasis was laid on this all-important preliminary operation. The author then dealt with the distillation of crude oils, and described a novel experimental still of very considerable merit and ingenuity, designed to minimise the time occupied in the determination of the light oils and water-content of a given material. Tabular matter illustrated the application of the method, and results were given of the analysis of the Hardstoft oil. Methods of determining the vapour pressure of petrol, calorific value, moisture, and flash-point were criticised, and the procedure adopted in the lecturer's laboratory was detailed. It was shown that the flash-point of a fuel oil was liable to an experimental error of nearly 5 per cent., whilst if the oil was wet the discrepancies were very much more serious. In consequence a considerable tolerance should be allowed in specifications. A discussion followed, in which Sir Thomas Holland, Prof. Brame, and Dr. Ormandy made reference to the subject of standardisation, whilst Dr. Dunstan, Mr. Mitchell, and Mr. Lomax brought forward criticisms of the various methods detailed in the paper.

THE *Engineer* for October 24 contains a description of the recently completed undertaking for the supply of water to Greater Winnipeg. The quantity rendered available amounts to 85,000,000 gallons per day, which should suffice for the needs of the city for some time to come, as the present number of inhabitants is only some quarter of a million, and the consumption 44 gallons per head per day. The water is obtained from Shoal Lake, with an area of 107 square miles, and a catchment basin of 360 square miles, which is connected with the larger expanse of 1400 square miles known as the Lake of the Woods. It is described as soft and excellent in quality; the chlorine content is three parts per million. The distance conveyed is 96½ miles. Of this 77⅓ miles is cut-and-cover work, with culverts varying from 10 ft. 9 in. by 9 ft. to 6 ft. 5 in. by 5 ft. 5 in. There are 7 miles of river siphons and 9½ miles of reinforced concrete pressure pipe. The distributing mains in the city of Winnipeg consist of 2⅝ miles of 48-in. concrete pipe. The work was commenced in 1913, and estimated to cost just above 2,600,000*l*.

MR. F. W. CLIFFORD, librarian to the Chemical Society, contributes to the *Library Association Record* for August an article on "The Library of the Chemical Society: A Record of a Recent Attempt at Co-operation." The Chemical Society has always aimed at including in its library every book and periodical that might help its fellows in their work. During the war this library has been of the greatest assistance to the nation, since it was found to contain most of the important works of foreign origin which Government Departments and manufacturers wished to consult. This increased use of the books impressed upon the library committee the importance of further extension in the technical direction. The council therefore invited a number of kindred societies to co-operate with it in extending the technical equipment of the library by appointing representatives on the library committee and by giving financial assistance for the purchase of books. The members of the societies thus co-operating are able to use the library on the same terms as fellows. The invitation has been accepted by the Association of British Chemical Manufacturers, the Biochemical Society, the Faraday Society, the Institute of Chemistry, the Society of Chemical Industry, the Society of Dyers and Colourists, and the Society of Public Analysts. This form of co-operation might perhaps be adopted with advantage by other libraries devoted to special branches of knowledge.

Messrs. George Bell and Sons, Ltd., announce:—"The Physiology of Vision: With Special Reference to Colour-blindness," Dr. F. W. Edridge-Green; "Practical Biological Chemistry," Bertrand and Thomas, translated by Capt. H. A. Colwell; "An Introduction to the Study of Vector Analysis," Prof. C. E. Weatherburn; "Nomography," Dr. S. Brodetsky; "Differential Equations and their Applications," Dr. H. Pioggio; and "Intermediate Chemistry," Prof. A. Smith. The same publishers have in preparation "Recent Investigations in Fluorescence and Related Phenomena," Prof. R. W. Wood; "A Text-book of Zoology," Prof. C. H. O'Donoghue; and "Physics: An Intermediate Course," Dr. A. O. Rankine. *Messrs. J. M. Dent and Sons, Ltd.*, are about to publish a portfolio of twenty-four coloured "Nature Studies" by E. J. Detmold. The issue will be limited to 500 sets, each of which will be numbered and accompanied by a certificate signed by the artist. *Messrs. Longmans and Co.* have in the press for appearance next year vol. i. of the treatise on "Higher Inorganic and Theoretical Chemistry," in six volumes, upon which Dr. J. W. Mellor has been working for the past twelve years. They also announce "A Manual of Practical Anatomy," 3 vols. (vol. i., The Extremities; vol. ii., The Head and Neck; and vol. iii., The Thorax and Abdomen), Prof. T. Walmsley; "Structural Steelwork," E. G. Beck; "A First-Year Physics for Junior Technical Schools," G. W. Farmer; and "Life in Early Britain: A Survey of the Social and Economic Development of the People of England from Earliest Times to the Norman Conquest," N. Ault. The new list of *Messrs. George Routledge and Sons, Ltd., and Kegan Paul and Co., Ltd.*, includes:—"The Social Maladies: Tuberculosis, Syphilis, Alcoholism, Sterility," Dr. J. Héricourt, translated, with a final chapter, by B. Miall; "Agriculture and the Farming Business," O. H. Benson and G. H. Betts; "Wonders of Insect Life," J. H. Crabtree; "Germination," A. E. Baines; and "Bakery Machinery," A. W. Mathys; "The Clay-working Industries," A. B. Searle; "Direct-current Dynamos and Motors," Prof. W. B. Griffith; "Electric Cooking and Heating," W. A. Gillott; "Engineering Instruments and Meters," E. A. Griffiths; "Manufacture and Installation of Electric Cables," C. J. Beaver; "Reproduction and Utilisation of Sound," H. O. Merriman; "The Turbo-Alternator," Dr. S. F. Barclay; and "The Utilisation of Natural Powers," E. L. Burne (in Routledge's Industrial Supremacy Books).

Arrangements have been completed for the amalgamation of the business carried on by Mr. Robt. W. Paul at New Southgate, London, with the Cambridge Scientific Instrument Co., Ltd. Mr. Paul will join the board of directors, and the manufacture of instruments will be continued both at Cambridge and at New Southgate. On January 1, 1920, the name of the company will be altered to the Cambridge and Paul Instrument Co., Ltd., and as soon as possible the head office and showrooms will be transferred to London.

The South-Eastern Union of Scientific Societies was established in 1896, and includes more than seventy affiliated societies. A correspondent writes to point out that the union was omitted from the list given last week. The list was not intended, however, to include unions or federations of societies, but rather individual societies which meet periodically throughout the year.

OUR ASTRONOMICAL COLUMN.

The Leonid Meteors.—Though no special display of these objects is to be expected this year, the sky should be vigilantly watched on the nights from November 13 to 16, and particularly during the hours following midnight. The moon will be at the last quarter on November 14, being visible in the morning hours, but her light will be feeble and cannot materially interfere with the aspect of the shower. The radiant point in Leo does not rise until about 10.20 p.m. If any of the usual bright, streaking meteors are observed from this system, their apparent paths amongst the stars should be carefully recorded. There is no doubt, from the observations obtained in past years, that the stream of November Leonids is continuous in all sections of the orbit, and that there are considerable differences in the apparent strength of the shower witnessed from year to year. The maximum may be expected on the morning of November 15 or 16.

The shower of meteors connected with Biela's comet is due to return a few nights later than the Leonids, and, as the moon will then have waned to the crescent shape, observations may be favourably made should the atmosphere be suitable and free from the clouds and fogs so common to our climate at this season of the year.

The Group of Helium Stars in Orion.—There has for long been a natural curiosity to find the distance of the great nebula in Orion. The problem became more hopeful when it was found that the group of helium stars was probably connected with the nebula, as appeared both by their configuration and by identity of radial motion (about +22 km./sec.). Dr. Bergstrand, of Upsala, has published (Nova Acta Reg. Soc. Scient. Upsal., ser. iv., vol. v., No. 2) an attempt to find this distance. First, he made a careful re-examination of proper motions in order to find the rate of closing in on δ Orionis, owing to increasing distance from us; he found for the parallax 0·0044″, with probable error 0·0049″. The second method was based on the assumption that the scattering of individual proper motions is comparable with that of the radial velocities; he thus obtained 0·0076″, with probable error less than 0·002″. It will be seen that the two determinations are of the same order of magnitude, and are also comparable with some other values; thus Dr. Charlier, in his memoir on the B stars, gave figures for the Orion group of which the mean is 0·0118″, and Prof. Kapteyn by another method found 0·0058″. Also four of the stars are binaries, and the mean of their hypothetical parallaxes, as given by Messrs. Hertzsprung and Stebbins, is 0·0078″.

From the large area that the group covers in the sky there is reason to expect a corresponding range in the individual distances. Hence we may look on the various determinations as satisfactorily accordant, and conclude that in putting the distance of the nebula as 400 light-years we are not very far from the truth.

The Secular Acceleration of the Moon.—In a recent paper Mr. Nevill claimed to have shown that the observations of the last three centuries prove that the acceleration does not differ from its theoretical value. Prof. E. W. Brown, in the Proceedings of the Royal Society (Series A, vol. xcvi.), shows that, by making suitable changes in initial longitude and mean motion, a change as great as 5·4″ in the acceleration will make changes in the longitude that are less than 1·6″ for the whole interval between 1620 and 1950. Quantities so small as this cannot be evaluated from the observations, so long as the large inequality with period of the order of three centuries remains unexplained by theory. Hence, apparently, the ancient eclipses, unsatisfactory as the records of them are, supply the only material available for determination of the acceleration.

THE GLASS RESEARCH ASSOCIATION.

It is now widely known that among the industries which have been profoundly influenced by the war the glass and glassware industry of the United Kingdom occupies a foremost place. Not only have the pre-war products of this industry, as they existed in this country before the war, been found essential for a wide range of national purposes during wartime, but the necessity has also been forcibly realised of creating certain special sections of this industry, previously non-existent in the country, to supply glass and glassware, glass instruments, and glass apparatus directly necessary for the prosecution of the war, as well as similar articles equally vital as being indispensable for the efficient operation of other industries. The importance of the glass industry to the economic life of the nation is to be measured largely by its effect upon, and indispensability to, other industries. This has been fully recognised by the Government in the inclusion of scientific glassware and illuminating glassware, as well as optical glass, in the schedule of unstable "key" industries.

But the revolutionising effect of the war upon the glass industry is not alone manifest in the creation of these "key" sections which previously were monopolised by Germany and Austria, whose glass manufacturers had attained great strength and reputation, and certainly dominated the markets of the world, or even in the resuscitation of other sections (*e.g.* the so-called "flint" glass sections) of the industry, which, though long established in this country, were rapidly declining as the result of unfair foreign competition. The feature even more significant than either of these, and the ground of the future hope that a stable and prosperous British glass industry will be firmly established, is the shedding of the old spirit of isolation and exclusiveness which possessed the manufacturers of this country. Invariably in each works there existed a policy of secrecy, together with an unwarranted satisfaction with old-fashioned rule-of-thumb manufacturing ideas and an absence of scientific method. This inevitably resulted in inability to organise for production upon progressive modern lines. During the war there has been a wonderful awakening to the new possibilities of glass production in this country, and there is now happily evidenced among the manufacturers a new spirit of co-operation combined with an enthusiasm for investigation and research, and a desire to adopt new methods and equipment involving the scientific control of manufacturing operations.

The establishment of the Glass Research Association, which after nearly twelve months' spade-work by an earnest provisional committee was launched on its career on October 14 at the first general meeting held at the Institute of Chemistry, when the first council of the association was elected, well illustrates the changed aspect which the industry has assumed. This association has been formed on the lines approved by the Department of Scientific and Industrial Research for the encouragement of research. During the next five years the association will expend at least 100,000*l.* upon investigations into the many problems of glass and glassware manufacture.

There is a vast and difficult field to cover, as will appear from the consideration of the following groups of main problems to be attacked:—Chemical and physical properties of glasses; fuels, refractories, furnaces, treatment of glass-making materials, glass-founding, temperature measurement and control; glassware-forming operations (hand and mechanical), glassware-making machinery; annealing, lamp-blown work, and other finishing operations; design, lay-out, and equipment of glass factories; and scientific methods of storing, packing, and transit. These are but the general problems. When they are considered in relation to the enormous varieties of types of glass articles, from common bottles, food and beverage containers, chemical and medical bottles, on one hand, to the elaborate products of the lamp-blown glassware bench-worker (*e.g.* condensers, gas-analysis apparatus, thermometers, artificial eyes, X-ray tubes, syringes, etc.) on the other; from window-glass and plate-glass to beakers, flasks, and accurately calibrated and graduated glassware; from tumblers and the numerous domestic and fancy articles of glassware in common use to electric lamps, miners'-lamp glasses, and a host of articles essential for illuminating purposes; and, in addition, the varieties of special glasses required for scientific instruments, for decorative purposes, for machinery, and for building, it is easy to realise that the problems are not lacking in number, variety, or fascination.

To consider only one problem for a moment: the manufacture of glass tubing. All scientific workers understand the essential importance of being able to obtain varieties of glass tubing having definite chemical and physical properties, and at the same time satisfying stipulated degrees of dimensional accuracy within narrow limits. Few realise the enormous difficulties involved in the production of such tubing, the wastage caused by the careful selection necessary to obtain satisfactory quality, and how much depends upon the high degree of individual skill in the worker engaged in glass tube-drawing. The Glass Research Association will not rest satisfied until, by securing the concentration of engineering genius upon this problem, glass tubing can be turned out with dimensional accuracy comparable with that secured in producing tubing of brass or other metals, and at the same time possessing such specific chemical and physical properties as are necessary for workability in the blow-lamp. This problem affects vitally a whole section of the industry—the lamp-blown scientific glassware section—for glass tubing is the raw material of this section, and the problems involved in making many precise and important instruments (*e.g.* butyrometers, clinical and other thermometers, hydrometers, etc.) are nearly all solved when the proper tubing can be accurately and consistently produced.

There are at the present time approximately four hundred firms engaged in glass and glassware manufacture in the United Kingdom, employing about 50,000 workers. It is anticipated that the research work of the association will commence in earnest at the beginning of next year. Before that date the council of the association hopes that every one of these four hundred firms will have applied for membership.

The report of the provisional committee to the general meeting on October 14 showed that a membership of 107 had already been reached; that a promise had been secured from the Committee of the Privy Council for Scientific and Industrial Research to pay to the association a total grant not exceeding 75,000*l.* within a period of five years on condition that during this period members of the association contribute an aggregate sum of not less than 5000*l.* per annum in subscriptions. The financial statement also revealed that towards this sum of 5000*l.* per annum promises from the 107 members had reached 4654*l.* 10*s.* (subscriptions from members are on a voluntary basis from 10*l.* to 100*l.* per annum, according to ability to pay), and, in addition to this, the association had received a handsome donation of 1000*l.* from a well-known firm of glass manufacturers.

In addressing this first general meeting of the Glass Research Association, Sir Frank Heath, Secretary of the Department of Scientific and Industrial Research, who with his colleagues has rendered invaluable assistance to the promoters of the association, congratulated the members upon having brought together in this scheme of co-operative research such diverse sections of a complex industry, and also upon the particularly high financial contribution secured from the Government, due to the inclusion of unstable "key" industry sections of the glass industry, and the recognition that, in spite of the great things already accomplished in the production of these special types of glassware, an enormous amount of research and experimental work is still necessary to place these sections on a firm foundation.

Referring to various phases of the future activities of the Glass Research Association, Sir Frank Heath suggested that existing facilities such as those available at the National Physical Laboratory and the Sheffield University Department of Glass Technology should be used to the utmost, at any rate in the initial stages; that a bureau of information should be established; and that very careful efforts should be made to obtain the right director of research. The importance of his being able to win the best from his research workers by "team-work" was mentioned. In this connection the council of the association wishes it to be widely known amongst scientific workers that it is anxious to secure that the best available scientific brains and ability shall be devoted to the problems of this industry. There can be no doubt as to the value of the opportunity offered for research, the attractiveness of the subjects for investigation, and the huge difficulties to be surmounted. The ideal director for this association is not an individual research worker whose glory is to work in splendid isolation, but is he who will bring expert knowledge of the methods of scientific research to bear upon these complex problems, who possesses such personality as to attract promising young research workers to his side, and who is also an administrator qualified to secure the carrying on of a large volume of research work along a broad front touching the various sectional interests concerned, and to co-ordinate the efforts being made through the various laboratories, institutions, and works to which specific research and experimental work will be allotted.

In an advertisement which has appeared for a director of research a lower limit to the salary has been mentioned, but it may here be stated that the council intends to pay a salary commensurate with the qualifications of the candidate selected to fill the office, and it will be very considerably higher than the figure mentioned if the council can obtain its ideal director.

There are brilliant opportunities in this field of scientific investigation for the chemist, the physicist, and the engineer. Glass engineering in particular is in its infancy in this country, and the modern problems of glass manufacture are rapidly resolving themselves into those to be solved mainly by the highly trained engineer who specialises in the study of glass-making processes.

The Glass Research Association is an earnest effort to carry out co-operative research on an extensive scale for an industry of prime national importance, and it has been launched with great promise. Everything now depends upon the support of the whole industry and upon the calibre of the scientific workers who will undertake the investigations.

It is not too much to hope that the present membership will soon be doubled, and that scientific ability and genius of the highest order will be found to energise this great undertaking and ensure its success.

EDWARD MEIGH.

THE TOBACCO BEETLE.

BULLETIN No. 737 of the United States Department of Agriculture, published last March, has for its subject "The Tobacco Beetle: An Important Pest in Tobacco Products," and on reading what its writer, Mr. G. H. Runner, has to say about the pest, one is almost tempted to believe that the "precious herbe" is fitted for nothing so much as the breeding of maggots. At any rate, Mr. Runner makes it quite clear that tobacco at every stage of its manufacture, from the dried leaf up to the finished product, is a most attractive diet for the grub or larva, and that the conditions under which the leaf is usually manufactured and stored are almost ideal for the development and reproduction of the beetle. What a pity King James did not know all this when he wrote his "Counterblaste," and was led in irony to exclaim, "O omnipotent power of tobacco!" But the tobacco beetle, *Lasioderma serricorne*, was probably altogether unknown in his days, and even now is not at all common in England. It cannot withstand exposure to extreme cold for any great length of time, and thrives best, sometimes reproducing at the unusual rate of three or more generations each year, where a warm, equable temperature, a moist atmosphere, and suitable food for the grub occur together. That is why it is so much better known in America, especially in the States bordering on the Gulf of Mexico, than it is in this country. It is well known also in India and the islands of the Far East.

Here in England the tobacco beetle is an imported species, only occasionally met with, though sometimes in very large numbers, as was the case not many years ago when it swarmed in the warehouses around one of the London docks, whither it had come in a cargo of turmeric from India. Its larvæ feed, like those of the common "biscuit weevil" or "drug-store beetle," *Sitodrepa panicea*, which belongs to the same family, on almost every kind of dried product of vegetable origin. Hence the beetle is almost as much at home with the druggist and the grocer as it is with the tobacconist. Tobacco, however, except in the green or growing state, which it does not touch, appears to be its principal food, and, according to Mr. Runner, it selects the higher grades of leaf, cigar, and cigarette in preference to those of inferior quality.

Methods to be taken for the destruction or control of the little pest, and various experiments and trials made with that object in view, are described at some length in the bulletin, which contains as well a full account of the whole life-history of the insect illustrated by figures, some of which are particularly well done, and there is also a list of special memoirs and other papers relating to the subject. The bulletin, therefore, although apparently prepared more especially for the benefit of the tobacco manufacturer and dealer, will be of considerable value to the practical entomologist, and ought, indeed, to have some interest also for every true lover of the weed.

THE BRITISH ASSOCIATION AT BOURNEMOUTH.

SECTION H.

ANTHROPOLOGY.

OPENING ADDRESS BY PROF. ARTHUR KEITH, M.D., LL.D., F.R.S., PRESIDENT OF THE SECTION.

The Differentiation of Mankind into Racial Types.

FOR a brief half-hour I am to try to engage your attention on a matter which has excited the interest of thoughtful minds from ancient times—the problem of how mankind has been demarcated into types so diverse as the Negro, the Mongol, and the Caucasian or European. For many a day the Mosaic explanation—the tower of Babel theory—was regarded as a sufficient solution of this difficult problem. In these times most of us have adopted an explanation which differs in many respects from that put forward in the book of Genesis; Noah disappears from our theory and is replaced in the dim distance of time by a "common ancestral stock." Our story now commences, not at the close of an historical flood, but at the end of a geological epoch so distant from us that we cannot compute its date with any degree of accuracy. Shem, Ham, and Japheth, the reputed ancestors of the three great racial stocks of modern times—the white, black, and yellow distinctive types of mankind—have also disappeared from our speculations; we no longer look out on the world and believe that the patterns which stud the variegated carpet of humanity were all woven at the same time; some of the patterns, we believe, are of ancient date and have retained many of the features which marked the "common ancestral" design; others are of more recent date, having the ancient pattern altered in many of its details. We have called in, as Darwin has taught us, the whole machinery of evolution—struggle for existence, survival of the fittest, spontaneous origin of structural variations, the inheritance of such variations—as the loom by which Nature fashions her biological patterns. We have replaced the creative finger by the evolutionary machine, but no one is more conscious of the limitations of that machine than the student of human races. We are all familiar with the features of that racial human type which clusters round the heart of Africa; we recognise the Negro at a glance by his black, shining, hairless skin, his crisp hair, his flattened nose, his widely opened dark eyes, his heavily moulded lips, his gleaming teeth and strong jaws. He has a carriage and proportion of body of his own; he has his peculiar quality of voice and action of brain. He is, even to the unpractised eye, clearly different from the Mongolian native of North-Eastern Asia; the skin, the hair, the eyes, the quality of brain and voice, the carriage of body and proportion of limb to body pick out the Mongol as a sharply differentiated human type. Different from either of these is the native of Central Europe—the Aryan or Caucasian type of man; we know him by the paleness of his skin and by his facial features—particularly his narrow, prominent nose and thin lips. We are so accustomed to the prominence of the Caucasian nose that only a Mongol or Negro can appreciate its singularity in our Aryanised world. When we ask how these three types—the European, Chinaman, and Negro—came by their distinctive features, we find that our evolutionary machine is defective; the processes of natural and of sexual selection will preserve and exaggerate traits of body and of mind, but they cannot produce that complex of features which marks off one racial type from another. Nature has at her command some secret mechanism by which she works out her new patterns in the bodies of man and beast—a mechanism of which we were almost ignorant in Darwin's day, but which we are now beginning to perceive and dimly understand. It is the bearing of this creative or morphogenetic mechanism on the evolution of the modern races of mankind which I propose to make the subject of my address.

Hid away in various parts of the human frame is a series of more or less obscure bodies or glands, five in number, which, in recent times, we have come to recognise as parts of the machinery which regulate the growth of the body. They form merely a fraction of the body—not more than 1/180th part of it: a man might pack the entire series in his watch-pocket. The modern medical student is familiar with each one of them—the pituitary body, about the size of a ripe cherry, attached to the base of the brain and cradled in the floor of the skull; the pineal gland, also situated in the brain, and in point of size but little larger than a wheat-grain; the thyroid in the neck, set astride the windpipe, forms a more bulky mass; the two suprarenal bodies situated in the belly, capping the kidneys, and the interstitial glands embedded within the substance of the testicle and ovary, complete the list. The modern physician is also familiar with the fact that the growth of the body may be retarded, accelerated, or completely altered if one or more of these glands become the seat of injury or of a functional disorder. It is thirty-three years now since first one woman and then another came to Dr. Pierre Marie in Paris seeking relief from a persistent headache, and mentioning incidentally that their faces, bodies, hands, and feet had altered so much in recent years that their best-known friends failed to recognise them. That incident marked the commencement of our knowledge of the pituitary gland as an intrinsic part of the machinery which regulates the shaping of our bodies and features. Dr. Marie named the condition acromegaly. Since then hundreds of men and women showing symptoms similar to those of Dr. Marie's patients have been seen and diagnosed, and in every instance where the acromegalic changes were typical and marked there has been found a definite enlargement or tumour of the pituitary body. The practised eye recognises the full-blown condition of acromegaly at a glance, so characteristic are the features of the sufferers. Nay, as we walk along the streets we can note slight degrees of it—degrees which fall far short of the borderline of disease; we note that it may give characteristic traits to a whole family—a family marked by what may be named an acromegalic taint. The pituitary gland is also concerned in another disturbance of growth—giantism. In every case where a young lad has shot up, during his late "teens," into a lanky man of seven feet or more—has become a giant—it has been found that his pituitary gland was the site of a disordered enlargement. The pituitary is part of the mechanism which regulates our stature, and stature is a racial characteristic. The giant is usually acromegalic as well as tall, but the two conditions need not be combined; a young lad may undergo the bodily changes which characterise acromegaly and yet not become abnormally tall, or he may become—although this is rarely the case—a giant in stature and yet may not assume acromegalic features. There is a third condition of disordered growth in which the pituitary is concerned—one in which the length of the limbs is disproportionately increased—in which the sexual system and all the secondary sexual characters of body and mind either fail to develop or disappear—where fat tends to be deposited on the body, particularly over the buttocks and thighs—where, in brief, a eunuchoid condition of body develops. In all these three conditions we seem to be dealing with a disordered and exaggerated action of the pituitary gland; there must be conditions of an opposite kind where the functions of the pituitary are disordered and reduced. A number of cases of dwarfism have been recorded where boys or girls retained their boyhood or girlhood throughout life, apparently because their pituitary gland had been invaded and partly destroyed by tumours. We shall see that dwarfism may result also from a failure of the thyroid gland. On the evidence at our disposal, evidence which is being rapidly augmented, we are justified in regarding the pituitary gland as one of the principal pinions in the machinery which regulates the growth of the human body and is directly concerned in determining stature, cast of features, texture of skin, and character of hair—all of them marks of race. When we compare the three chief racial types of humanity—the Negro, the Mongol, and the Caucasian or European—we can recognise in the last-named a greater predominance of the pituitary than in the other two. The sharp and pronounced nasalisation of the face, the tendency to strong eyebrow ridges, the prominent chin, the tendency to bulk of body and height of stature in the majority of Europeans, is best explained, so far as the present state of our knowledge goes, in terms of pituitary function.

There is no question that our interest in the mechanism of growth has been quickened in recent years by observations and discoveries made by physicians on men and women who suffered from pituitary disorders, but that a small part of the body could influence and regulate the growth and characterisation of the whole was known in ancient times. For many centuries it has been common knowledge that the removal of the genital glands alters the external form and internal nature of man and beast. The sooner the operation is performed after birth, the more certain are its effects. Were a naturalist from a unisexual world to visit this earth of ours it would be difficult to convince him that a brother and a sister were of the same species, or that the wrinkled, sallow-visaged eunuch with his beardless face, his long, tapering limbs, his hesitating carriage, his carping outlook, and corpulent body was brother to the thick-set, robust, pugilistic man with the bearded face. The discovery that the testicle and ovary contain, scattered throughout their substance, a small glandular element which has nothing to do with their main function—the production of genital cells—was made seventy years ago, but the evidence which leads us to believe that this scattered element—the interstitial gland—is directly concerned in the mechanism of growth is of quite recent date. All those changes which we may observe in the girl or boy at puberty—the phase of growth which brings into full prominence their racial characteristics—depend on the action of the interstitial glands. If they are removed or remain in abeyance the maturation of the body is both prolonged and altered. In seeking for the mechanism which shapes mankind into races we must take the interstitial gland into our reckoning. I am of opinion that the sexual differentiation—the robust manifestations of the male characters—is more emphatic in the Caucasian than in either the Mongol or Negro racial types. In both Mongol and Negro, in their most representative form, we find a beardless face and almost hairless body, and in certain Negro types, especially in Nilotic tribes, with their long, stork-like legs, we seem to have a manifestation of abeyance in the action of the interstitial glands. At the close of sexual life we often see the features of a woman assume a coarser and more masculine appearance.

Associated with the interstitial glands, at least in point of development, are the suprarenal bodies or glands. Our knowledge that these two comparatively small structures, no larger than the segments into which a moderately sized orange can be separated, are connected with pigmentation of the skin dates back to 1894, when Dr. Thomas Addison, a physician to Guy's Hospital London, observed that gradual destruction of these bodies by disease led to a darkening or pigmentation of the patient's skin, besides giving rise to other more severe changes and symptoms. Now it is 150 years since John Hunter came to the conclusion, on the evidence then at his disposal, that the original colour of man's skin was black, and all the knowledge that we have gathered since his time supports the inference he drew. From the fact that pigment begins to collect in and thus darken the skin when the suprarenal bodies become the seat of a destructive disease we infer that they have to do with the clearing away of pigment, and that we Europeans owe the fairness of our skins to some particular virtue resident in the suprarenal bodies. That their function is complex and multiple the researches of Sir E. A. Sharpey Schafer, of T. R. Elliott, and of W. B. Cannon have made very evident. Fifteen years ago Bulloch and Sequeira established the fact that when a suprarenal body becomes the site of a peculiar form of malignant overgrowth in childhood, the body of the boy or girl undergoes certain extraordinary growth changes. The sexual organs become rapidly mature, and through the framework of childhood burst all the features of sexual maturity—the full chest, muscularity of limbs, bass voice, bearded face, and hairy body—a miniature Hercules—a miracle of transformation in body and brain. Corresponding changes occur in young girls—almost infants in years—with a tendency to assume features which characterise the male. Prof. Glynn (*Quart. Journ. of Med.*, vol. v., p. 157, 1912) has recently collected such cases and systematised our knowledge of these strange derangements of growth. There can be no doubt that the suprarenal bodies constitute an important part of the mechanism which regulates the development and growth of the human body and helps in determining the racial characters of mankind. We know that certain races come more quickly to sexual maturity than others, and that races vary in development of hair and of pigment, and it is therefore reasonable to expect a satisfactory explanation of these characters when we have come by a more complete knowledge of the suprarenal mechanism.

During the last few years the totally unexpected discovery has been sprung upon us that disease of the minute pineal gland of the brain may give rise to a train of symptoms very similar to those which follow tumour formation of the cortex of the suprarenal bodies. In some instances the sudden sexual prematurity which occurs in childhood is apparently the immediate result of a tumour-like affection of the pineal gland. We have hitherto regarded the pineal gland, little bigger than a wheat-grain and buried deeply in the brain, as a mere useless vestige of a median or parietal eye, derived from some distant human ancestor in whom that eye was functional, but on the clinical and experimental evidence now rapidly accumulating we must assign to it a place in the machinery which controls the growth of the body.

We come now to deal with the thyroid gland, which, from an anthropological point of view, must be regarded as the most important of all the organs or glands of internal secretion. Here, too, in connection with the thyroid gland, which is situated in the front of the neck, where it is so apt to become enlarged and prominent in women, I must direct attention to a generalisation which I slurred over when speaking of the pituitary and suprarenal glands. Each of these glands throws into the circulating blood two sets of substances—one set to act immediately in tuning the parts of the body which are not under the influence of the will to the work they have to do when the body is at rest and when it is making an effort; another set of substances—which Prof. Gley has named morphogenetic—has not an immediate but a remote effect; they regulate the development and co-ordinate the growth of the various parts of the body. Now, so far as the immediate function of the thyroid is concerned, our present knowledge points to the gland as the manufactory of a substance which, when circulating in the body, regulates the rate of combustion of the tissues; when we make a muscular effort, or when our bodies are exposed to cold, or when we become the subjects of infection, the thyroid is called upon to assist in mobilising all available tissue-fuel. If we consider only its immediate function it is clear that the thyroid is connected with the selection and survival of human races. When, however, we consider its remote or morphogenetic effects on growth, its importance as a factor in shaping the characteristics of human races becomes even more evident. In districts where the thyroid is liable to that form of disease known as goitre it has been known for many a year that children who were affected became cretins—dwarf idiots with a very characteristic appearance of face and body.[1] Disease of the thyroid stunts and alters the growth of the body so that the subjects of this disorder might well be classed as a separate species of humanity. If the thyroid becomes diseased and defective after growth of the body is completed, then certain changes, first observed by Sir William Gull in 1873, are set up and give rise to the disordered state of the body known as myxœdema. "In this state," says Sir Malcolm

[1] The story of the discovery of the action of the thyroid gland is told by Prof. G. M. Murray, *Brit. Med. Journ.*, ii., p. 163, 1913.

Morris (*Brit. Med. Journ.*, i., p. 1038, 1913), "the skin is cold, dry, and rough, seldom or never perspires, and may take on a *yellowish* tint; there is a bright red flush in the malar region. The skin as a whole looks transparent; the hair of the scalp becomes scanty; the pubic and axillary hair, with the eyelashes and eyebrows, often falls out; in many cases the teeth are brittle and carious. All these appearances disappear under the administration of thyroid extract." We have here conclusive evidence that the thyroid acts directly on the skin and hair, just the structures we employ in the classification of human races. The influence of the thyroid on the development of the other systems of the body, particularly on the growth of the skull and skeleton, is equally profound. This is particularly the case as regards the base of the skull and the nose. The arrest of growth falls mainly on the basal part of the skull, with the result that the root of the nose appears to be flattened and drawn backwards between the eyes, the upper forehead appears projecting or bulging, the face appears flattened, and the bony scaffolding of the nose, particularly when compared with the prominence of the jaws, is greatly reduced. Now these facial features which I have enumerated give the Mongolian face its characteristic aspect, and, to a lesser degree, they are also to be traced in the features of the Negro. Indeed, in one aberrant branch of the Negro race—the Bushman of South Africa—the thyroid facies is even more emphatically brought out than in the most typical Mongol. You will observe that, in my opinion, the thyroid—or a reduction or alteration in the activity of the thyroid—has been a factor in determining some of the racial characteristics of the Mongol and the Negro races. I know of a telling piece of evidence which supports this thesis. Some years ago there died in the East End of London a Chinese giant—the subject, we must suppose, of an excessive action of the pituitary gland—the gland which I regard as playing a predominant part in shaping the face and bodily form of the European. The skeleton of this giant was prepared and placed in the Museum of the London Hospital Medical College by Col. T. H. Openshaw, and anyone inspecting that skeleton can see that, although certain Chinese features are still recognisable, the nasal region and the supra-orbital ridges of the face have assumed the more prominent European type.

There are two peculiar and very definite forms of dwarfism with which most people are familiar, both of which must be regarded as due to a defect in the growth-regulating mechanism of the thyroid. Now, one of these forms of dwarfism is known to medical men as achondroplasia, because the growth of cartilage is particularly affected, but in familiar language we may speak of the sufferers from this disorder of growth as being of the "bulldog breed" or of the "dachshund breed." In the dachshund the limbs are greatly shortened and gnarled, but the nose or snout suffers no reduction, while in the bulldog the nose and nasal part of the face are greatly reduced and withdrawn, showing an exaggerated degree of Mongolism. Among achondroplastic human dwarfs both breeds occur, but the "bulldog" form is much more common than the "dachshund" type. The shortening of limbs with retraction of the nasal region of the face—pug-face or prosopia we may call the condition—has a very direct interest for anthropologists, seeing that short limbs and a long trunk are well-recognised racial characteristics of the Mongol. In the second kind of dwarfism, which we have reason to regard as due to a functional defect of the thyroid, the Mongolian traits are so apparent that the sufferers from this disorder are known to medical men as "Mongolian idiots"—for not only is their growth stunted, but their brains also act in a peculiar and aberrant manner. Dr. Langdon Down, who gave the subjects of this peculiar disorder the name "Mongolian idiots" fifty-five years ago, knew nothing of the modern doctrine of internal secretions, but that doctrine has been applied in recent years by Dr. F. G. Crookshank ("The Universal Medical Record," vol. iii., p. 12, 1913) to explain the features and condition of Mongoloid imbecile children. Some years ago (*Journ. of Anat. and Physiol.*, 1913) I brought forward evidence to show that we could best explain the various forms of anthropoid apes by applying the modern doctrine of a growth-controlling glandular mechanism. In the gorilla we see the effects of a predominance of the pituitary elements; in the orang, of the thyroid. The late Prof. Klaatsch tried to account for the superficial resemblances between the Malay and the orang by postulating a genetic relationship between them; for a similar reason he derived the Negro type from a gorilline ancestry. Occasionally we see a man or woman of supposedly pure European ancestry displaying definite Mongoloid traits in their features. We have been in the habit of accounting for such manifestations by the theory, at one time very popular, that a Mongoloid race had at one time spread over Europe, and that Mongoloid traits were atavistic recurrences. An examination of the human remains of ancient Europe yields no evidence in support of a Turanian or Mongol invasion of Europe

All these manifestations to which I have been directing your attention—the sporadic manifestation of Mongoloid characters in diseased children and in healthy adult Europeans, the generic characters which separate one kind of ape from another, the bodily and mental features which mark the various races of mankind—are best explained by the theory I am supporting, namely, that the conformation of man and ape and of every vertebrate animal is determined by a common growth-controlling mechanism which is resident in a system of small but complex glandular organs. We must now look somewhat more closely into the manner in which this growth-regulating mechanism actually works. That we can do best by taking a glimpse of a research carried out by Bayliss and Starling in the opening years of the present century. They were seeking to explain why it was that the pancreas poured out its digestive juice as soon as the contents of the stomach commenced to pass into the first part of the duodenum. It was then known that if acid was applied to the lining epithelial membrane of the duodenum, the pancreas commenced to work; it was known also that the message which set the pancreas into operation was not conveyed from the duodenum to the pancreas by nerves, for when they were cut the mechanism was still effective. Bayliss and Starling solved the puzzle by making an emulsion from the acid-soaked lining epithelium of the duodenum and injecting the extract of that emulsion into the circulating blood. The result was that the pancreas was immediately thrown into activity. The particular substance which was thus set circulating in the blood and acted on the pancreas, and on the pancreas alone, and thus served as a messenger or hormone, they named secretin. They not only cleared up the mechanism of pancreatic secretion, but at the same time made a discovery of much greater importance. They had discovered a new method whereby one part of the human body could communicate with and control another. Up to that time we had been like an outlandish visitor to a strange city, who believed that the visible telegraph or telephone wires were the only means of communication between its inhabitants. We believed that it was only by nerve-fibres that intercommunication was established in the animal body. Bayliss and Starling showed that there was a postal system. Missives posted in the general circulation were duly delivered at their destinations. The manner in which they reached the right address is of particular importance for us; we must suppose that the missive or hormone circulating in the blood and the recipient for which they are intended have a special attraction or affinity for each other—one due to their physical constitution—and hence they, and only they, come together as the blood circulates round the body. Secretin is a hormone which effects its errand rapidly and immediately, whereas the growth or morphogenetic hormones, thrown into the circulation by the pituitary, pineal, thyroid, suprarenal, and genital glands, act slowly and remotely. But both are alike in this: the result depends not only on the nature of the hormone or missive, but also on the state of the local recipient. The local recipient may be specially greedy, as it were, and seize more than a fair share of the manna in circulation, or it may have "sticky fingers" and seize what is not really intended for local consumption. We can see that local growth—the development of a particular trait or feature—is dependent not only on the hormones supplied to that part, but also on the condition of the receptive mechanism of the part. Hence we can understand a local derangement of growth—an acromegaly or giantism confined to a finger or to the eyebrow ridges, to the nose, to one side of the face, and such local manifestations are not uncommon. It is by a variation in the sensitiveness of the local recipient that we have an explanation of the endless variety to be found in the relative development of racial and individual features.

Some ten years after Starling had formulated the theory of hormones, Prof. W. B. Cannon, of Harvard University, piercing together the results of researches by Dr. T. R. Elliott and by himself on the action of the suprarenal glands, brought to light a very wonderful hormone mechanism—one which helps us in interpreting the action of growth-regulating hormones. When we are about to make a severe bodily effort it is necessary to flood our muscles with blood, so that they may have at their disposal the materials necessary for work—oxygen and blood-sugar, the fuel of muscular engines. At the beginning of a muscular effort the suprarenal glands are set going by messages passing to them from the central nervous system; they throw a hormone—adrenalin—into the circulating blood, which has a double effect; adrenalin acts on the flood-gates of the circulation, so that the major supply of blood passes to the muscles. At the same time it so acts on the liver that the blood circulating through that great organ becomes laden with blood-sugar. We here obtain a glimpse of the neat and effective manner in which hormones are utilised in the economy of the living body. From that glimpse we seem to obtain a clue to that remarkable disorder of growth in the human body known as acromegaly. It is a pathological manifestation of an adaptational mechanism with which we are all familiar. Nothing is better known to us than that our bodies respond to the burden they are made to bear. Our muscles increase in size and strength the more we use them; increase in the size of our muscles would be useless unless our bones also were strengthened to a corresponding degree. A greater blood supply is required to feed them, and hence the power of the heart has to be augmented; more oxygen is needed for their consumption, and hence the lung capacity has to be increased; more fuel is required—hence the whole digestive and assimilative systems have to undergo a hypertrophy, including the apparatus of mastication. Such a power of co-ordinated response on the part of all the organs of the body to meet the needs of athletic training presupposes a co-ordinating mechanism. We have always regarded such a power of response as an inherent property of the living body, but in the light of our growing knowledge it is clear that we are here dealing with an hormonic mechanism, one in which the pituitary gland is primarily concerned. When we study the structural changes which take place in the first phase of acromegaly (see Keith, *Lancet*, ii., p. 993, 1911; i., p. 305, 1913), we find that not only are the bones enlarged and overgrown in a peculiar way, but also the muscles, the heart, the lungs, the organs of digestion, particularly the jaws; hence the marked changes in the face, for the form of the face is determined by the development of the upper and lower jaws. The rational interpretation of acromegaly is that it is a pathological disorder of the mechanism of adaptational response; in the healthy body the pituitary is throwing into the circulation just a sufficiency of a growth-regulating substance to sensitise muscles, bones, and other structures to give a normal response to the burden thrown on the body. But in acromegaly the body is so flooded with this substance that its tissues become hypersensitive and respond by overgrowth to efforts and movements of the slightest degree. It is not too much to expect, when we see how the body and features become transformed at the onset of acromegaly, that a fuller knowledge of these growth-mechanisms will give us a clue to the principles of race differentiation.

There must be many other mechanisms regulated by hormones with which we are as yet totally unacquainted. I will cite only one instance—that concerned in regulating the temperature of the body. We know that the thyroid and also the suprarenal glands are concerned in this mechanism; they have also to do with the deposition and absorption of pigment in the skin, which must be part of the heat-regulating mechanism. It is along such a path of inquiry that we expect to discover a clue to the question of race colour.

This is not the first occasion on which the doctrine of hormones has been applied to biological problems at the British Association. In his presidential address to the Zoological Section at Sheffield in 1910 Prof. G. C. Bourne applied the theory to the problems of evolution; its bearing was examined in more detail in an address to the same section by Prof. Arthur Dendy during the meeting at Portsmouth in 1911. At the meeting of the association at Newcastle in 1916 Prof. MacBride devoted part of his address to the morphogenetic bearings of hormones. Very soon after Starling formulated the hormone theory, Dr. J. T. Cunningham applied it to explain the phenomena of heredity (Proc. Zool. Soc. London, p. 434, 1908). Nay, rightly conceived, Darwin's theory of pan-genesis is very much of the same character as the modern theory of hormones.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Prof. G. H. F. Nuttall, Quick professor of biology, has received from Mr. P. A. Molteno, of Trinity College, a letter dated October 23 desiring to present to the University a sum of 20,000*l.* to provide suitable buildings and fittings for an institute for research in parasitology, and a further sum of 10,000*l.* to provide an income for the upkeep and maintenance of the institute. Plans have been drawn up by Mr. Harry Redfern for the erection of this institute on the Downing site.

The special lectures by Sir J. J. Thomson on positive rays, and by Prof. Eddington on the theory of relativity and gravitation, have been postponed until the Lent term.

The recommendations of the General Board of Studies on (*a*) a proposed readership in geography, (*b*) a proposed readership in agricultural physiology, and (*c*) a proposed readership in estate management have been passed by the Senate.

The University is full to overflowing, and the difficulty of obtaining accommodation has been met only partially by extending the limits to a 2½-mile radius from Great St. Mary's Church. Practically all the colleges are strictly limiting their numbers. One of the most striking characteristics of the post-war population is the enormous increase in the numbers of men pursuing the study of natural, economic, and mechanical sciences. For example, the engineering school has now between 600 and 700 students; in the chemistry school between 1100 and 1200 names have been entered for lectures and nearly 1000 for practical work; while, instead of the 100 expected, some 240 students attended the elementary class in physiology. The difficulties of accommodation are severe now, but next year and the year after, when these students have passed the elementary stage and require more elaborate equipment and teaching, the situation will be almost impossible unless steps are taken to increase the laboratory accommodation and teaching resources. The difficulty in doing so is partly that of building—though, fortunately, the building strike has just been settled—and partly that of providing the funds required for construction, equipment, and *personnel*. Some help in this direction may be expected from the State, but the State will not be able to replace the private benefactor in assisting the University in its present exceptional opportunity of promoting the teaching of and research in science.

OXFORD.—The question of admitting women to matriculation and degrees has entered upon a new phase. It had been intended to seek Parliamentary sanction for the framing by the University of provisions for the removal of the academic disabilities of women. It now appears that, by the unsolicited action of the House of Commons itself, the way will be opened for the admission of women to matriculation and degrees without any special appeal to Parliament for the purpose. Legislation with this object will probably be undertaken in the near future.

Col. Thomas E. Lawrence, a leading authority on the topography, ethnology, and languages of Arabia and Mesopotamia, distinguished also for his political and military services in the late Arabian anti-Turkish campaign, has been elected to a research fellowship at All Souls College.

In Congregation on November 11, the statute making Greek optional in Responsions, which was thrown out by Convocation in June last, was reintroduced with a fresh preamble, under which it will be possible for amendments to be moved limiting the exemption from compulsory Greek to candidates for honours in science or mathematics, and to candidates for a pass degree. The preamble, after speeches by Mr. Barker, of New College, and Prof. Gilbert Murray, passed without a division.

DR. J. H. GRINDLEY, of Cork, has been appointed principal of the Dudley Technical College.

DR. ALEX HILL is resigning the principalship of University College, Southampton, in order to devote his full activities to the Universities Bureau, of which he is secretary.

MISS M. E. LAING has been appointed research assistant in physical chemistry in connection with the Leverhulme chair of physical chemistry at the University of Bristol.

A READER in estate management is shortly to be appointed by the General Board of Studies of the University of Cambridge at an annual stipend of 500*l*. Applications for the post must be sent to the Vice-Chancellor on or before November 30.

APPLICATIONS are invited by the Senate of the University of London for the Keddey Fletcher-Warr studentships for the promotion of post-graduate research. The studentships are open to men and women, tenable for three years, and of the annual value of not less than 200*l*. Applications must be received by the Academic Registrar of the University of London, South Kensington, S.W.7, not later than December 31 next.

A SERIES of free public lectures has been arranged for delivery in the botanical lecture-room of the University of Glasgow during the winter session, 1919–20, at 8.30 p.m., on the second Monday of each month from November to March inclusive. The list of lectures, including that by Prof. C. H. Desch, on November 10, on "The Growth of Crystals," is as follows:—On December 8, "Scotland and France," Prof. R. S. Rait; on January 12, "The Language of the Poilus"; on February 9, "The Beginnings of Geography," Prof. J. W. Gregory; and on March 8, "Finance and Reconstruction," Prof. W. R. Scott.

PROF. JOHN COX will resume on Monday next, at 6.30 p.m., the course of lectures on modern scientific discoveries and their practical application to life and industry at Gresham College, Basinghall Street, E.C.2, by a lecture on "Oerstedt and the Telegraph." These lectures are given mainly with the view of enforcing the need that applied science is necessary, not only for the commercial prosperity of any modern community, but also for its very existence. Other lectures in the course deal with long-distance telephony, the motor and dynamo, the nature of light, streamlines and aeroplanes, sound-ranging, directional wireless, listening under water, radio-activity, etc.

THE annual general meeting of the Science Masters' Association will be held at the London Day Training College, Southampton Row, W.C.1, on Tuesday and Wednesday, January 6 and 7, 1920, under the presidency of Mr. W. W. Vaughan, master of Wellington College. Among the subjects to be discussed are:—The Teaching of Organic Chemistry; Biology in the School Science Syllabus; Laboratory Management—(*a*) Training of Assistants and (*b*) Cost of Apparatus; Science Teaching in the Early Stages—(*a*) Science in the Preparatory School and in Common Entrance and Entrance Scholarship Examinations for Public Schools, and (*b*) Teaching Junior Forms; and The Divorce of Laboratory and Class-room Courses.

A CONFERENCE of representative men and women which met at the Bedford College for Women (University of London) on November 5 unanimously decided on carrying out an extension which will involve an appeal to the public for funds. In order to organise the appeal, an executive committee has been appointed, of which Col. Sir Hildred Carlile, Bart., M.P., is chairman and Viscountess Elveden hon. treasurer. The college, built to accommodate 400 students, now has 550. The proportion of science students has greatly increased, and is now one-third of the total number. In the chemistry department the students number 130, and the working places are only forty-six. In the matter of residence the same difficulties occur; despite the addition of three new hostels, there remains this term a long waiting list of students wishing to come into residence. It is hoped that the appeal will enable the college to make provision for the increased demands made upon it by the attention now given to higher education for women.

SOCIETIES AND ACADEMIES.

London.

Zoological Society, October 21.—Prof. E. W. MacBride, vice-president, in the chair.—E. G. **Boulenger**: Report on the research experiments on methods of rat destruction carried out at the society's gardens.—Dr. A. Smith **Woodward**: The zoological position and affinities of Tarsius.

Paris.

Academy of Sciences, October 13.—M. Léon Guignard in the chair.—C. **Moureu** and C. **Dufraisse**: The stabilisation of acrolein. The methods of spontaneous alteration of acrolein. The spontaneous transformation into disacryl, the soluble resin, appears to be a modification undergone by pure acrolein. Acrolein purified with the greatest care always underwent this spontaneous condensation on standing. The speed of transformation can be modified by light, high temperature, and the presence of impurities.—R. **Bourgeois**: A collection of paintings of clouds.—M. **Leblanc**: Very rapid rotations.—P. **Boutroux**: A family of multiform functions, integrals of a differential equation of the first order.—J. **Andrade**: The weighing of a friction during the relative sliding of two solids in contact.—E. **Belot**: The movement of translation of a gaseous vortex ring in a resisting medium.—H. **Vanderlinden**. The ephemeris of the Borrelly comet, 1919*c*.—G. **Sagnac**: The absolute mechanics of waves and the Newtonian relativity of energy.—Q. **Majorana**: Gravitation.—G. **Claude**: The industrial employment of extremely high pressures. In compressing gases to pressures of 1000 atmospheres, no difficulties may be expected to arise in the pumps of the compressors or in the receivers, which can easily be made of sufficient strength to give security. The real difficulty will arise in the connections, which must be absolutely tight if serious losses are to be avoided. The author has constructed apparatus which, after charging with gas compressed to 1000 atmospheres and immersing in water, allowed no bubbles of gas to escape.—A. **Bolland**: Microchemical reactions of thiosulphuric acid.—V. **Cremieu** and A. **Lepape**: The separation by solidification of pure carbon dioxide from a gaseous mixture. Starting with a mixture containing 95 per cent. of carbon dioxide, cooling to −80° C., and compressing slightly, the solid carbon dioxide precipitated is chemically pure.—J. **Guyot** and L. J. **Simon**: The action of concentrated sulphuric acid on methyl alcohol.—J. **Révil** and P. **Combaz**: The age and the conditions of formation of the lignites of Voglans in the Chambéry region. A discussion and criticism of the views recently put forward by M. Corceix.—I. **Barthoux**: Succession of old eruptive rocks in the Arabian Desert.—J. **Pellegrin**: New contribution to the ichthyological fauna of Lake Tchad.—F. **Ladreyt**: The complex symbiotic cell.—J. **Amar**: Respiration in confined air.—F. **Bordas**: The preparation and conservation of sera and vaccines by drying in an absolute vacuum. The vaccines are dried in a high vacuum and the water-vapour evolved is removed by freezing. After drying, the tube is sealed and the vaccine thus removed from the action of both water and oxygen. The activity of such preparations can be preserved for several years.

October 20.—M. Léon Guignard in the chair.—M. **Henneguy**: An account of the work of the late Gustav Retzius.—G. **Bigourdan**: A project of uranographic classification, completing other classifications in present use.—A. **Blondel**: The characteristics of oscillation of lamps with three electrodes, utilised as generators of sustained oscillations.—M. **de Chardonnet**: Remark on a communication of Gen. Bourgeois. The use of autochrome plates instead of hand-paintings for clouds is suggested as being more practical. As regards the question of the stability of the images, some coloured photographs of the sky taken ten years ago, now presented to the Academy, are still in a good state of preservation.—M. **Petrovitch**: Definite integrals, of which the decimal part is expressed with the aid of prime numbers.—G. **Kolossoff**: The movement of a solid in an indefinite liquid.—A. **Foch**: The resonance of water-mains provided with an air-chamber.—A. **Bichet**: A system of aiming at objects in the air. Suggestions for a new means of mounting telescopes, searchlights, and guns for improving the aim at moving objects in the air.—G. **Chavanne**, L. P. **Clerc**, and L. J. **Simon**: Analyses of German aviation petrols. The results given were obtained by a combination of careful fractional distillation with the measurement of the critical solution temperature of the fractions in aniline, details of which have been given in earlier communications. Twenty specimens were examined, the composition of which averaged 10 per cent. aromatic hydrocarbons, 40 per cent. saturated cyclic hydrocarbons, and 50 per cent. paraffins. The deviations of the separate specimens from the average were very small.—P. **Robin**: The peroxide of benzaldoxime. A study of the decomposition by prolonged boiling in benzene solution, and of the prolonged oxidation with iodine and sodium carbonate.—J. **Barthoux**: Cretacean volcanic rocks of Egypt and Sinai.—G. B. M. **Flamand**: The discovery of a lens of coal at Port-Gueydon. Two analyses are given, together with reasons for supposing that this deposit really belongs to the Coal Measures.—M. **Bezagu**: Variations of the respiration of leaf-cells with age.—A. **Sartory**: A new fungus of the genus Scopulariopsis isolated from a case of onychomycosis.

DIARY OF SOCIETIES.

THURSDAY, NOVEMBER 13.

ROYAL SOCIETY, at 4.30.—Lt.-Col. R. McCarrison: The Genesis of Œdema in Beriberi.—W. Robinson: The Microscopical Features of Mechanical Strains in Timber and the Bearing of these on the Structure of the Cell-wall in Plants.—W. B. Bottomley: The Effect of Nitrogen-fixing Organisms and Nucleic Acid Derivatives on Plant Growth.—Agnes Arber: The Vegetative Morphology of *Pistia* and the Lemnaceæ.—W. J. Young, A. Breinl, J. J. Harris, and W. A. Osborne: Effects of Exercise and Humid Heat upon Pulse Rate, Blood Pressure, Body Temperature, and Blood Concentration.

ROYAL COLLEGE OF PHYSICIANS, at 5.—Dr. E. G. Browne: The Origins and Development of Arabian Medicine: II. Four Great Medical Writers of Persia (IX.-XI. Cent.). (FitzPatrick Lecture.)

ROYAL SOCIETY OF MEDICINE (Clinical Section), at 5.—H. Curtis: Three Cases of Malignant Disease of the Face illustrating Modern Methods of Radical Operation.

INSTITUTION OF ELECTRICAL ENGINEERS (at Institution of Civil Engineers), at 6.—Roger T. Smith: Presidential Inaugural Address.

OPTICAL SOCIETY, at 7.30.—Miss L. M. Gillman: The Chromatic Variation of Spherical Aberration in Cemented Doublets.—Instructor-Commander T. Y. Baker: The Correction of First Order Astigmatism of a Single Lens used with a Stop.

ROYAL SOCIETY OF MEDICINE (Neurology Section), at 8.30.—P. Sargent: Lessons of the War applied to Spinal Surgery.

FRIDAY, NOVEMBER 14.

ROYAL ASTRONOMICAL SOCIETY, at 5.—W. S. Franks: Micrometrical Measures of Double Stars, List VII.—F. Strömgren: A New Class of Periodic Solutions in the General Problem of Three Bodies.—J. Evershed: (1) Is Venus Cloud-covered? (2) The Solar Prominence of 1919, May 29.—J. Halm: Statistical Investigation of the Distribution of the Stars and their Magnitudes.—H. H. Turner and Mary A. Blagg: The Long-period Variable W Cygni.—N. Liapin: A Method of Determining the Mean Accidental Variation in Daily Rate of a Number of Chronometers.—H. Bell: A Proposal to Construct New Tables for Finding Position-lines at Sea.—The following Paper is promised:—Royal Observatory, Greenwich: Corona and Prominences at the Eclipse of 1919 May 29.

PHYSICAL SOCIETY, at 5.—S. Butterworth: The Self-Inductance of Single Layer Flat Coils.—Dr. N. W. McLachlan: An Experimental Method of Determining the Primary Current at Break in a Magneto.—F. W. Newman: Note on a Modified Form of Wehnelt's Interrupter. (With Demonstration.)

MALACOLOGICAL SOCIETY OF LONDON (at the Linnean Society), at 6.—G. C. Robson: Studies in British Hydrobiidæ, Part I.—H. C. Fulton: Description of a New Sub-species of *Papuina tayloriana*, Ad. & Rve.—J. E. Cooper: Additions to a List of Recent Middlesex Mollusca.

SATURDAY, NOVEMBER 15.

PHYSIOLOGICAL SOCIETY (at London School of Medicine for Women), at 4.30.

INSTITUTION OF ELECTRICAL ENGINEERS (Informal Meeting) (at Chartered Institute of Patent Agents), at 7.—W. E. Warrilow and others: Discussion on Engineering Advertising.

SURVEYORS' INSTITUTION (Junior Meeting), at 7.

MONDAY, NOVEMBER 17.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.—W. R. Davidge: The Problems of London Housing.

ROYAL GEOGRAPHICAL SOCIETY (at the Æolian Hall), at 8.30.—Sir Alfred Sharpe: A Recent Journey in Liberia.

TUESDAY, NOVEMBER 18.

ROYAL HORTICULTURAL SOCIETY (at Vincent Square, S.W. 1), at 3.—C. H. Senn: Potato Possibilities.

ROYAL SOCIETY OF MEDICINE, General Meeting of Fellows, at 5.

ROYAL STATISTICAL SOCIETY, at 5.15.—E. H. Godfrey: Fifty Years of Canadian Progress, 1867–1917.

INSTITUTION OF CIVIL ENGINEERS, at 5.30.—M. F. Wilson: Admiralty Harbour, Dover

INSTITUTION OF PETROLEUM TECHNOLOGISTS (at Royal Society of Arts), at 5.30.—Rear-Admiral (Retd.) P. Dumas: The Conservation of Oil.

ZOOLOGICAL SOCIETY OF LONDON, at 5.30.—Sir Edmund Giles Loder, Bt.: Exhibition of the Skull of a Beaver.—Major J. S. Hamilton: Field-Notes on some Mammals in the Bahr el Gebel, Southern Sudan.—Dr. J. F. Gemmill: (1) The Development of the Mesenteries in *Urticina crassicornis* (Actinozoa). (2) The Leptomedusan *Melicertidium octocostatum*.—M. Turner: The Nematode Parasites of a Chapman's Zebra.—Rev. A. H. Cooke: The Radula of the Mitridæ.—Lt.-Col. S. Monckton Copeman: Experiments on Sex Determination.—Dr. C. F. Sonntag: The Variations in the Digastric Muscle of the Rhesus Macaque and the Common Macaque.—E. S. Russell: Note on the Righting Reaction in *Asterina gibbosa*, Penn.

WEDNESDAY, NOVEMBER 19.

ROYAL UNITED SERVICE INSTITUTION, at 3.—D. Ogg: German Naval Propaganda.

ROYAL SOCIETY OF ARTS, at 4.30.—Sir H. Trueman Wood: Science and Industry.

ROYAL METEOROLOGICAL SOCIETY, at 5.—Lieut. C. W. B. Normand: Effect of High Temperature, Humidity, and Wind on the Human Body.—Capt. A. J. Bamford: Some Observations of the Upper Air over Palestine.—E. G. Bilham: Barometric Pressure and Underground Water Level.

GEOLOGICAL SOCIETY OF LONDON, at 5.30.—Prof. J. E. Marr: The Pleistocene Deposits in the Neighbourhood of Cambridge.

INSTITUTION OF ELECTRICAL ENGINEERS (Wireless Sectional Meeting) (at Institution of Civil Engineers), at 6.—Prof. C. L. Fortescue: The Design of Multiple Stage Amplifiers using Three Electrode Thermionic Valves.

ROYAL MICROSCOPICAL SOCIETY, at 8.—H. M. Carleton: Note on Cajal's Formalin-silver Nitrate Impregnation Method for the Golgi Apparatus.—F. I. G. Rawlins: Report on the Collection of Metallurgical Specimens recently presented to the Society by Sir Robert Hadfield, Bart., F.R.S.

THURSDAY, NOVEMBER 20.

ROYAL SOCIETY, at 4.30.—*Probable Papers:* W. J. Johnston: A Linear Associative Algebra suitable for Electro-magnetic Relations and the Theory of Relativity.—Sir Joseph Larmor: Note on Mr. W. J. Johnston's Calculus for Generalised Relativity.—G. E. Bairstow: The Variation with Frequency of the Conductivity and Dielectric Constant of Dielectrics for High Frequency Oscillations.—F. J. W Whipple: Equal Parallel Cylindrical Conductors in Electrical Problems.—G. A. Schott: The Scattering of X- and Y-Rays by Rings of Electrons. A Crucial Test of the Electron Ring Theory of Atoms.

LINNEAN SOCIETY, at 5.—T. K. Patten: Plants collected in Mesopotamia and in Southern India.—C. C. Lacaita: *Orchis maculata* from Monte Gargano.—Dr. G. C. Druce: Two New British Plants.—Miss Trower: Paintings of British *Rubi*.—Prof. R. C. McLean: Sex and Soma.

INSTITUTION OF MINING AND METALLURGY (at Geological Society), at 5.30.—H. L. Sulman: A Contribution to the Study of Flotation.

CHEMICAL SOCIETY (and Informal Meeting), at 8.

FRIDAY, NOVEMBER 21.

INSTITUTION OF MECHANICAL ENGINEERS, at 6.—C. G. Conradi: The Present Position of Mechanical Road Traction.

INSTITUTION OF ELECTRICAL ENGINEERS (Students' Meeting) (at the City and Guilds (Engineering) College), at 7.—A. P. Trotter: Opening Address.

VERTEBRATE EMBRYOLOGY.

Text-book of Embryology. Vol. xi. *Vertebrata with the Exception of Mammalia.* By Prof. J. Graham Kerr. Pp. xii+591. (London: Macmillan and Co., Ltd., 1919.) Price 31*s.* 6*d.* net.

THE second volume of this important text-book of embryology deals with all the vertebrate groups with the exception of the mammalia. It is unnecessary to say that a more highly qualified authority than Prof. Graham Kerr to expound the many intricate problems of the subject could not be found, but what does impress the reader is the clear insight into the depths of these problems that the author has gained by his own detailed and important original investigations.

It is not surprising to find that, in this comprehensive treatise, the archaic but unfortunately inaccessible mud-fish—Lepidosiren—plays a predominant *rôle*, and that our old friends of the embryological laboratory—the chick and the tadpole—are relegated to minor parts; but Prof. Kerr convinces us that this is as it should be.

The highly specialised vertebrates that we can get in abundance for our class work are not the best types in which to search for the clues to the solution of the many problems of vertebrate embryology. It is rather in the more archaic forms with larger histological elements and a primitive anatomical structure—such as the Dipnoi, the Ganoidei, and the Urodela—that the embryologist has found by experience that he obtains his most satisfactory results.

The need for a text-book of this description which deals fully with the fundamental problems of embryology, as distinct from a text-book that deals only with the development of a few selected types, has long been felt, and a brief reference to one or two of these problems may be given to indicate the manner in which the author expounds them in the light of modern embryological research.

There has been no more highly controversial problem in embryology than the question of the origin of the nerves from the central nervous system. Prof. Kerr describes in some detail the result of his own researches on the development of the motor nerves of Lepidosiren, and gives a critical summary of the theories of His, Balfour, and Hensen. His own opinion is finally expressed and may be very briefly indicated by the following sentence (p. 111): "It is suggested that the development of the actual nerve fibril is simply the gradual coming into view of a pathway produced by the repeated passage of nerve impulses over a given route."

The origin of the paired appendages of vertebrata is another of these debated problems on which distinguished morphologists have held very divergent views. Here, again, the author sets before the student the "branchial theory" associated with the name of Gegenbaur, and the continuous "lateral fin" theory which was supported by Balfour, before expounding his own views in what he calls the "external gill hypothesis." This hypothesis is based on the supposition that the external gills extended further back than they do in any living vertebrate, and that, being potential organs of support, and also potential organs of movement, as indicated by their flicking movements in some existent larvæ, they became transformed into purely locomotive and supporting paired appendages. The limb girdle on this hypothesis is a modified branchial arch skeleton, shifted backwards as in the theory of Gegenbaur.

With the lateral fin theory already so well established in this country, it is not likely that Prof. Kerr will find his views in this matter generally accepted, but there is so much that is interesting and ingenious in the way in which his hypothesis is expounded that the student must benefit by its careful consideration. There are many other problems of absorbing interest, to which space does not permit us to refer, discussed in the spirit of just consideration of the views of previous writers, and a clear expression of the author's own opinion. This is the feature which commends the volume most strongly to the student who is capable of appreciating something more than a plain statement of the facts that have been discovered.

But a word of high praise must also be given for those parts of the work that are purely descriptive. It is always a difficult matter to condense into the allotted space the main results of exhaustive researches, but Prof. Kerr has accomplished this part of the task with great skill and judgment. In some cases, perhaps, a little more expansion would have been advisable. For example, in the chapter on the development of the brain a fuller explanation, with a figure, of what is meant by the term "Archipallium" would be most useful, or, again, in the description of the development of the vertebral column of Sphenodon, in which the student, puzzled by the myotomes being opposite to the protovertebræ in Fig. 152 C, but alternate with them in Fig. 152 B, will find no key to the puzzle in the text. But minor criticisms such as these seem out of place in reviewing a book which has so many merits.

We are glad to find that in writing this text-book Prof. Kerr has not withheld from us the fruits of his ripe experience as a teacher and investigator, for we find in chap. x. a most excellent general account of the development of the chick, illustrated by many good figures, and accompanied by practical instruction in laboratory methods. This chapter will prove to be of great value to the beginner and to his teachers. Moreover, in the last two chapters we are given most interesting and useful comments on the practical study of the embryology of the lower vertebrata and on the guiding principles of embryological research. Prof. Kerr has rendered a great service to scientific students by the publication of this volume, a volume which undoubtedly will take a high rank among modern text-books of zoological science. It is something better than a mere text-book of embryology, as it deals very fully with many of the most important principles of biological philosophy, and will prove very useful as a guide for practical research work in other branches of zoological science. S. J. H.

THE RARER ELEMENTS.

(1) *The Analysis of Minerals and Ores of the Rarer Elements for Analytical Chemists, Metallurgists, and Advanced Students.* By Dr. W. R. Schoeller and A. R. Powell. (Griffin's Scientific Text-books.) Pp. x+239. (London: Charles Griffin and Co., Ltd., 1919.) Price 16s. net.

(2) *The Metals of the Rare Earths.* By Dr. James Frederick Spencer. (Monographs on Inorganic and Physical Chemistry.) Pp. x+279. (London: Longmans, Green, and Co., 1919.) Price 12*s.* 6*d.* net.

THE two volumes before us, taken together, form a very complete treatise on the rarer elements, their occurrence, properties, and the methods for their separation. Although they overlap in some measure, each contains much information of the highest importance at the present day.

The practical value of many of the rarer elements has recently been brought into prominence, and it is becoming increasingly plain that, locked up in these little-known minerals widely distributed over the earth's surface, there are elements possessing properties of hitherto unrealised value and importance.

Radium has shaken the old conceptions in chemistry and physics to their very foundations. Uranium, tungsten, tantalum, molybdenum have given us steels which have profoundly influenced the engineering trades and the production of artillery. Thorium and cerium have preserved the gas industry as a means of illumination. Cerium and the rare earth metals rendered us almost independent of the lucifer match. These are but a few indications of the potential value of the rarer elements.

(1) This volume, which naturally comes first, deals exhaustively with the minerals from which the rarer elements are derived, and gives very clear and practical instructions for their recognition, and the properties, chemical reactions, and method for separating the elements. The design of the work is distinctly original, and the authors have included as much trustworthy information about each element as is available at the present time, together with descriptions of the spectroscopic, magnetic, electroscopic, and other apparatus used in research. It is abundantly clear that they have a very practical acquaintance with their subject; novel chemical and physical reactions are given that are apparently taken direct from the laboratory note-books.

The elements are taken in the order of their groups in the periodic system, and the text is arranged under two headings—"General Information," which includes spectroscopic and other physical reactions; and "Mineral Analysis," including qualitative and quantitative estimations and chemical reactions.

There is no general index, but in its place two lists are produced, one giving the names of nearly two hundred minerals containing rare elements, and the other the various methods for separating them from the bodies most frequently accompanying them.

A table of atomic weights and gravimetric factors is included.

(2) The title of this volume strikes one as a little inappropriate, for the metallic properties of the rare earth elements are those about which least is known, but the author is to be congratulated upon having collected together the essential details of all that is known in the domain of the "Rare Earths."

This field has a fascination of its own, quite apart from any utilitarian considerations; that is only realised by those who have worked in it; so great is that fascination that it has claimed the best energy of some of the most honoured men of science. Berzelius, Nilson, Clevé, Lecoq de Boisbaudran, Delafountain, Moissan, Crookes, Urbain are only a few that have fallen under the spell of the "Rare Earths." The work, hitherto exceedingly difficult on account of the rarity of the minerals needed, has been greatly facilitated by the development of the "mantle" industry, because in the extraction of the very large quantities of thorium and cerium needed for that purpose, all the members of the rare earth group are thrown out as by-products, and can be procured with comparative ease.

The substantial monograph under notice is an advance upon any of the excellent works that have recently appeared on the subject. The most remarkable feature in the volume is the great number of references to authorities that are given; these number as many as 1029, and will be found of very great value to the student, enabling him easily to consult the original memoir.

The author's remarks, though good, are sometimes liable to be misleading; in this connection we notice that, in reviewing the work of the late Sir William Crookes on the rare earths, and the suggestion there put out as to the possible existence of "meta-elements," the author states on page 7 that Crookes, by fractional precipitation, obtained seven fractions of different basicity which had different absorption spectra, which he called meta-elements. This may be a clerical error by the use of the term "absorption" instead of "phosphorescence," for the matter is quite correctly stated on page 66.

In point of fact, Crookes's contention was that the purest yttria obtainable gave under the cathodic discharge, *in vacuo*, a discontinuous spectrum consisting in numerous more or less nebulous coloured bands, and that by fractionating this material it was possible to separate these bands forming bodies from each other, and it was to these bodies, all components of pure yttria, that he gave the name of meta-elements. This question of the cause of the discontinuous phosphorescent spectra is by no means settled, and offers a field of most interesting research.

The history and analysis of each of the chief rare earth minerals is given, and this is followed by a good description of the various methods of fractionation used for separating the closely associated members of the rare earth groups. The methods of spectroscopic analysis are given, as is also the use of the magnetometer, an instrument only recently applied to these researches.

The cerium and yttrium groups of the rare earths are each separately described, and the latest determination of the atomic weights are given, together with the methods by which they were obtained.

In the discussion of the position of the rare earths in the periodic system the author includes the elements scandium and thorium, which for various reasons are not generally considered members of the rare earth group at all. It is not difficult to find places for these, especially the former, which is undoubtedly the "ekaboron" of Mendeléeff, but the placing of the closely allied bodies of the cerium and yttrium groups remains as big a puzzle as ever.

The final chapter deals with the uses of the rare earth elements; with the exception of cerium, which is absolutely essential to the production of an efficient "mantle," these are not numerous and are comparatively recent. But enough has been said to show the importance and value of the study of the rare earths, and the author's very complete work, taken in connection with that of Messrs. Schoeller and Powell, will aid very greatly in the study of these little-known bodies from which we can confidently expect great results.

J. H. GARDINER.

RACE AND NATIONALITY.

Race and Nationality: An Inquiry into the Origin and Growth of Patriotism. By Dr. John Oakesmith. Pp. xix+300. (London: William Heinemann, 1919.) Price 10*s.* 6*d.* net.

THE thesis which Dr. John Oakesmith maintains in this work is one which concerns anthropologists as well as politicians and historians. His doctrine that the national frontiers of Europe have no racial significance is a truth so apparent that no proof needs to be adduced. Yet it is perhaps well that the fact should again be insisted on at the present time because the public mind is still influenced by the vigorous anthropological teaching of last century, wherein it was maintained that the Saxon and Celtic elements in the population of these islands were of diverse racial stocks. We agree with Dr. Oakesmith that there is no single character or set of characters in body or mind by which an anthropologist can tell an Irishman from an Englishman. The claim for Irish separation does certainly not depend on a difference of race, for both English and Irish are members of the same racial stock, and of the two the Irish are the more representative of the Nordic or North Atlantic race.

The independence of nationality and race, however, is but a minor issue in Dr. Oakesmith's main thesis. This concerns itself chiefly with an inquiry into the nature of nationality. He defines and redefines it in many passages, but the following may be taken as representing his final conclusion (p. 75): "Nationality is a conviction based upon practical realities, upon the facts of historical development, and upon the demands of human experience." This represents rather what he hopes nationality may come to mean in the future, for in the present he recognises that mixed with its rational or utilitarian qualities there are both passions and emotions. Rightly enough, he maintains that if these passions and emotions could be eliminated and only the intellectual conception of nationality left, then wars would cease, and the world would come by the peace it longs for. Such is the main thesis of this book.

Does race, then, play no part in separating and keeping apart the masses of humanity? Dr. Oakesmith seriously maintains that "to envisage race as an operating objective factor in evolution of societies is both unscientific and unphilosophical" (p. 74). He cites the case of the Jewish people in England to prove that "race is a metaphysical conception having no foundation in practical life." "With proper adjustments of education," Dr. Oakesmith solemnly asserts, "you can turn an Oriental Jew into an Occidental Englishman." In other words, were we to substitute a Jewish for a native baby in every cradle of England for a generation, English nationality would remain just what it has been since the Anglo-Saxon invasion. Or, to alter the parallel, if we were to substitute babies from China, Central Africa, or Greenland, England would stand just where she did if Dr. Oakesmith is right. It is unnecessary, in the light of experience to be gathered from every part of the world, where diverse races come in close contact, to do more than say that race, unfortunately, is much more than Dr. Oakesmith supposes it to be—a "metaphysical conception."

A. KEITH.

OUR BOOKSHELF.

Sanitation Practically Applied. By Dr. Harold Bacon Wood. Pp. vi+473. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1917.) Price 13*s.* 6*d.*

THE author of this volume is assistant commissioner to the West Virginia State Department of Health, and he prepared it as a "corollary to the numerous excellent treatises on the theory of hygiene and the laboratory manuals" for the use primarily of the health officer and for the student of public health topics. In the main it is intended for and will best meet the needs of the American worker and student.

Judged from the book alone, it is perfectly clear that Dr. Wood is well qualified to write upon the subject he has taken up. Although some of the subjects are dealt with sketchily enough, he gives the impression that he has had experience; that he has worked in the field; that he has kept his eyes open and knows generally what should be done and how to do it. The American health officer and student of public health topics may very safely take him as a guide. The English health worker even may find something of value in what he has to say, though he has no reference to English works and workers, and his viewpoint is purely American, and his methods, most of them, not such as are or could be applied in this country.

The book is not a large one, but Dr. Wood covers the greater part of the field of health work, dealing with such subjects as statistics; control of communicable diseases; child welfare; school hygiene; pure foods, etc.

The treatment throughout is practical, and the writing is good and attractive. The same may be said of the illustrations, of which there is a fair number. As already hinted, it is unlikely that Dr. Wood's book will have more than a limited appeal in this country, but it will probably receive a good welcome from and be found useful by health workers in the United States.

The Study of the Weather. By E. H. Chapman. (The Cambridge Nature Study Series.) Pp. xii+131. (Cambridge: At the University Press, 1919.) Price 3s. 6d. net.

THIS little book on elementary meteorology will be welcomed by the school-teacher, to whom it makes its primary appeal. Though the serious student of the science may at first feel that it has no place on his shelves, yet, should he at some time be called upon to lecture to a non-scientific audience, he will find a perusal of its pages of no small value. The matter dealt with is mainly confined to features of the weather which can readily be observed by young people without special apparatus, and it is presumably for this reason that any reference to pressure and temperature conditions in the upper air is omitted. With the foregoing rather notable exception the groundwork of meteorology is well covered. One of the chief features of the book is the series of exercises, of which more than 250 are given. These vary from some very simple questions to others which the teacher would be well advised to think out carefully before putting to his class if he wishes to avoid finding himself in an awkward position. Many of these questions are calculated to arouse a most healthy interest in the minds of the pupils. One example must suffice. "What kind of weather is it that causes the inside walls of a building to stream with moisture?"

The Cambridge University Press is to be congratulated on the clearness of the printing and the excellence of the get-up of the book. The frontispiece is particularly pleasing. Numerous illustrations and charts are included in the text.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Percussion Figures in Isotropic Solids.

IN the issue of NATURE for October 9, Prof. C. V. Raman, of Calcutta, illustrated the conical fracture produced by the impact of a steel ball on a plate glass surface.

The following observations, which may be regarded as supplementary, were made by the writer some time ago with the object of finding what really happens when a glass surface is being ground, or, as it is technically termed, smoothed by an abrasive such as carborundum. Individual grains of a good abrasive have a nodular form, and the abrasion of glass appears to arise from the impact or pressure of the grains.

Two polished surfaces of glass were placed face to face with a few grains of carborundum between them, and the specimen was compared with a similar one in which steel balls of 1 mm. diameter were substituted for the carborundum. Pressure was applied uniformly over the whole surface, and while the pressure was being applied, the plates could be translated one over the other, thus producing the actual machine conditions. The observations were made by means of a polariscope. As the appearances were identical, steel balls were used throughout the later experiments, thus enabling the conditions to be better controlled.

It will be assumed that the polished appearance of glass is due to an amorphous surface layer. When the surface particles are acted upon by mechanical forces, the molecules, or possibly groups of molecules, rearrange themselves, the result being akin to the surface of a liquid. This conception was first advanced by Lord Rayleigh, and there is now a large mass of supporting evidence. When a piece of glass is worked mechanically, the surface molecules are so profoundly agitated that they are able to rearrange themselves under the action of intermolecular forces.

Fire glazing similarly consists in thermally agitating the molecules. Very small forces are sufficient to weaken the molecular cohesion by the required amount. Chemical action may produce a similar result. An optical surface may be reduced quite uniformly by the action of HF, provided the fluorides as formed are not allowed to crystallise and the bath is kept in continuous movement. When a piece of glass is fractured comparatively slowly, the forces at the edge of propagation of the fine crack must be very great, and, as before, the molecules are able to flow or rearrange themselves to form a polished surface layer. But when the fracture takes place suddenly, and almost explosively, as, for example, in the cooling of a pot of optical glass, portions of the surface may have a matt appearance to the unaided eye. This type of matt surface has been discussed very fully by M. Charles de Freminville, of Paris, who regards it as a type of multiple fracture. This explanation is more probable than the alternative one that the time of fracture is too small to permit of viscous flow.

When a steel ball is pressed lightly on the polished surface of a glass block, the appearance, when viewed between crossed Nicols, is as in the diagram (Fig. 1). The central black cone has an angle of about 20°, which remains practically independent of the pressure of the ball. The cone of strain *b, b* has an angle of about 90°. Some surface light is visible at d and d. At low pressures the dark cones c and a merge softly into b. As the pressure is increased, the interfaces become more intense and clearly defined, but the angles do not appreciably alter. The central cone proceeds from the surface first as a rod or filament of a remarkably black intensity.

Further gentle increase of pressure causes the surface layer to rupture as indicated in Fig. 2, which is

FIG. 1. FIG. 3. FIG. 4. FIG. 5. FIG. 6.

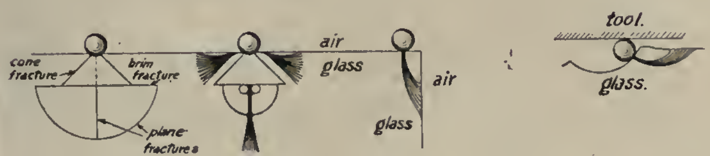

FIG. 7. FIG. 8. FIG. 9. FIG. 10.

a photograph of a surface repeatedly ruptured by gentle impact. If the Nicols are paralleled, black rays will be seen proceeding from the edge of the crack as in Fig. 3, their direction indicating that the crack is normal to the surface and merely superficial. The Fig. 1 appearance remains unaltered.

A new phenomenon makes its appearance when the pressure is again increased. Immediately under the ball there appears, as in Fig. 4, a sphere pierced by the filament of the cone a, and having a black outline tinged with red on the outside. The interior is filled with green-blue light, otherwise the general appearance of Fig. 1 remains unaltered. If now the Nicols are paralleled, the conical fracture (Fig. 5) previously illustrated by Prof. Raman will be seen, and by examination at intermediate positions of the Nicols, it will be evident that the cone fracture which takes place along the surface of b is tangential to the sphere which it encloses. The fracture can be extended up to a limit which it is difficult to exceed, even by a great increase of the rate of application of the pressure.

If the pressure is increased again, the crushing point is soon reached. The glass under the ball collapses almost explosively, a faint click being audible, and the ball sinks deeply through the surface. The cavity thus produced is lined with a snow-white layer of powdered glass.

On the polariscope at the moment of fracture several interesting developments may be observed. First, as the result probably of the greater area of pressure contact, the cone of light b broadens out laterally; secondly, the cone fracture may extend horizontally like the brim of a hat, thus definitely terminating the depth below the surface; and thirdly, the space within the cone becomes cleft by two fracture planes apparently normal to one another, and having their line of intersection on the axis of the dark cone a.

If only one diametral plane appears, the other may be developed by an increase of pressure. Sometimes the second plane is terminated at the axis, but it can always be extended across the first plane. The appearance of the fractures is now as indicated in Fig. 6. If the diametral plane fractures terminate at the base of the cone, they may be extended by pressure to the end of the rim, as in Fig. 7.

Under crossed Nicols two new coloured spheres identical with the original one may make their appearance just under the base of the cone fracture, as in Fig. 8, indicating the existence of subsidiary fractures.

But if a polished transverse section of a glass plate smoothed with carborundum is observed microscopically, it will be seen immediately that surface conchoidal fractures predominate, and that, if cone fractures do exist, they are very shallow.

In the workshop process of smoothing preparatory to polishing, the smoothing tool moves over the glass surface, but movement of the experimental plates did not alter the general characteristics outlined above, nor did the presence of water afford an explanation of the results obtained in practice.

Evidently mere pounding of a glass plate cannot result in a smoothed surface of a technical order.

As in all the previous experiments the pressure was applied at the centre of the block, where the horizontal forces were balanced, a new series was carried out near the margin of the plate. The new appearance, corresponding with the stage illustrated in Fig. 1, is indicated in Fig. 9, from which it will be seen that the central cone is now deviated towards the side, its axis following the characteristic conchoidal section. In other respects the sequence of phenomena was as before. Thus, after the cone fracture which was of a shallower order took place, and the crushing point was reached, the diametral plane fracture followed the axis of the deviated central cone, and the cavity from which the splinter was removed had the characteristic conchoidal appearance.

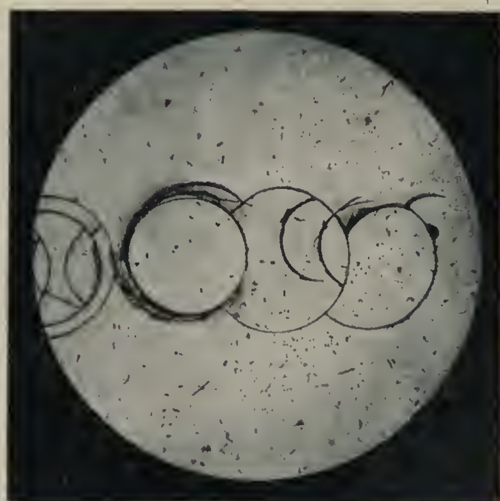

FIG. 2.—Surface percussion cracks on glass. Magnification 42×.

It is presumably the impact of the carborundum grains on the edges of cavities on the glass to be ground that produces the conchoidal splinters as indicated in Fig. 10. It would appear, therefore, that it is the diametral plane fracture that is of primary importance, and that, in the processes of smoothing, the horizontal movement is required to force the abrasive grains against the sides of the cavities. From actual tests it is found that the rate of abrasion is directly proportional to the pressure and to the relative speed of translation.

JAMES WEIR FRENCH.

Anniesland, Glasgow, October 13.

The Breeding of the King Penguin.

THE Zoological Park at Edinburgh has had the good fortune to possess, almost from its inception, a small group of king penguins. Three of the birds were received in January, 1914, from South Georgia, a second consignment, of which three survived, arriving in the spring of 1917. A hope was excited that they might breed when two of them were observed to be mating in the autumn of 1915, but nothing further occurred at that time. In the late summer of 1917 one of the birds became broody, and sat in the posture of incubation for about a month, but no egg was apparently laid, nor was this bird one of the two which had been observed to be paired. It was not until 1918 that the paired birds really settled down in earnest, and much interest was aroused when, on July 8 of that year, one of them was found to have an egg.

The king penguin, like its near relative the emperor penguin, makes no nest, but carries the single egg on its feet, where it is held in place and covered for warmth and protection by a fold of the skin and feathers of the abdomen, which, being furnished with a constricting muscle, grips the egg tightly. The brooding penguin can not only travel about with the egg in position, but even scratch its head with one foot while still holding the egg securely. Both sexes share in the work of incubation, the transfer of the egg having been observed on the second day. The parental instinct is very strong in the king penguin, not only in mated, but in the unattached birds as well. The group at this time contained three other birds, and their presence, or perhaps nothing but the very obvious conflict of desire for simultaneous possession of the egg between the husband and wife, may have been the cause of the misfortune which followed; at any rate, it was disappointing to find, after about two weeks, that the egg had been broken and that its custodian was believed to be relieving the tedium of duty by occasionally sipping its contents.

The floor of the enclosure consists of shelving rock, and to reduce the risk of breakage if an egg were produced this year, a large bed of sand was laid down. The next incident was again disappointing, for in July an egg was laid, but within an hour or so it had disappeared. As none of the birds showed any disposition to incubate it, I formed the opinion that it had been laid by one of the unmated birds, and this seemed to be confirmed when, on September 1, the female of the pair was found to have an egg. The other three birds were at once removed from the enclosure so that they should not interfere, and for two days all went well, the male bird taking the egg at night and the hen during the day. On the third day, however, the calling of one of the other birds—the third of the three originally imported—seemed to disturb the male, and he left his wife, refused to have anything more to do with the egg, and spent the day (and probably the night) in calling to the third bird and trying to get to it. After some days, as the female seemed to be suffering from the unrelieved care of the egg, and neither bird would feed, it was decided to put the third bird back. When this was done they all settled down together, and the male resumed his share in the labour, the third bird usually standing near.

The time during which each bird had the egg varied from a day to a week or more. The female when she had the egg always remained in the same place, where she made a slight hollow in the sand, but when the male had it he occasionally went for a walk round the enclosure, shuffling along with the egg on his feet. He even descended from one ledge of rock to another by turning round and working himself down backwards—a performance which led to several narrow escapes for the egg.

As the period of incubation elapsed the result was awaited with some anxiety, and it was in no small degree gratifying to find, on October 22, that the egg was chipped and the chick inside alive. It was not, however, until two days later that the chick was clear of the shell, the period of incubation thus being seven weeks and four days. The chick when hatched was comparatively small, and the skin was bare, but in a few days it increased considerably in size. The young bird, like the egg, is kept between the feet of the parent and covered by the fold of skin; it is fed at frequent intervals with semi-digested fish disgorged by the parent. As in the case of other birds which feed their young by this method, the chick places its head in the parent's mouth and takes the food from the gullet.

Apart from accident, there seems every likelihood that the young bird will be reared. It may be claimed which feed their young by this method, the chick king penguin has bred outside those islands of the Antarctic seas on which it has its home, and the record is a unique one.

T. H. GILLESPIE.

Zoological Society of Scotland, Edinburgh, October 29.

A Helium Series in the Extreme Ultra-Violet.

IT has been shown that the helium series first discovered in a terrestrial source by Fowler can be represented by the formula

$$V = 109750\left(\frac{1}{\left(\frac{n_1}{2}\right)^2} - \frac{1}{\left(\frac{n_2}{2}\right)^2}\right),$$

where n_1 has the value 3 or 4 (Evans, *Phil. Mag.*, vol. xxix., p. 284, 1915).

If n_1 be given the value 2, and n_2 the successive value 3, 4, and 5, lines result at wave-length 1640·1, 1214·9, and 1084·7. My previous investigations of the helium spectrum did not afford much evidence as to the existence of these lines (*Astrophys. Journ.*, vol. xliii., p. 92, 1916); a recent search, however, has been more successful. With a powerful disruptive discharge in helium, a sharp, fairly strong line appears at 1640·2; no trace of it is found in hydrogen under the same electrical conditions, and it does not occur in helium when the discharge circuit is free from capacity. Under the same violently disruptive condition the line at 1216, always present in helium and hydrogen, develops a satellite on its more refrangible side; this satellite is not well resolved, but its wave-length appears to be about 1215·1. The region that should be occupied by 1084·7 is obscured by a strong pair at 1085, probably due to an impurity.

Owing to the difficulties of vacuum spectroscopy, it is perhaps unwise to claim that the evidence in this case is conclusive. I regard it as very probable, however, that two members of this series in helium have been found in the extreme ultra-violet.

THEODORE LYMAN.

Harvard University, October 25.

Variations of Refractive Index.

EXPERIMENTS conducted in the research laboratory of the firm of Adam Hilger, Ltd., by Mr. G. M. Fleming show that, in certain circumstances, distinct differences of refractive index may occur in certain liquids at the separating surface between the liquid and a polished glass surface. In a few exceptional cases the differences are very great; in the case of ether, for instance, they may amount to as much as 0·02 in the refractive index.

These results appeared to me of considerable importance, and it was intended that the investigations should be continued here.

As a first hypothesis, I proposed to assume that the effect was due to variations of pressure in the neighbourhood of the interface, such variations of pressure being due to cohesion, and occurring according to the intimacy of contact between liquid and glass. Very attractive lines of thought suggest themselves when the phenomenon is contemplated from this point of view.

Unfortunately, more urgent preoccupations intervened, and the results have therefore been communicated to the director of the British Scientific Instrument Research Association, in the hope that he may find a place in the programme of work for further study in this direction. Meanwhile, I should be grateful if any of your readers could refer me to any prior observations of the kind. F. TWYMAN.

Research Department, Adam Hilger, Ltd., 75A Camden Road, N.W.1, November 7.

The Audibility of Thunder.

FROM reading a recent letter in NATURE (October 16) discussing the distance that thunder can be heard, I am induced to send you the following observation:—On the evening of February 26, 1912, when camped on North Chincha Island (off the west coast of South America), a brilliant display of lightning in the distant high interior to the east attracted our attention. The cloud-stratum from which the storm evidently issued lay far behind the clear coastal zone and the lower foothills, but hid from my camp the upper regions of the Cordillera. Both I and a Peruvian friend heard quite clearly the low distant peals of thunder. As I had been told that thunder was an almost, if not a quite, unknown phenomenon on the coast—this was the first thunderstorm, indeed, that my companion, a man of more than forty years of age, had experienced—I purposely made a record, during the best part of an hour, of the intervals elapsing between the flashes and the peals, and from my journal I find the average to have been 320 seconds. HENRY O. FORBES.

Beaconsfield, Bucks, November 7.

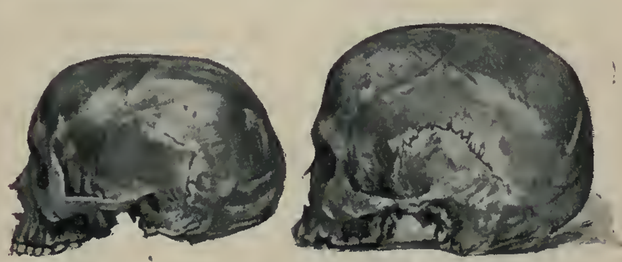
Linkage in the Silkworm: A Correction.

IN referring to Tanaka's work on silkworms I made (NATURE, November 6, p. 216) a mistake which should be corrected. His discovery was not that two characters linked in the male were not linked in the female, but that in a case of linkage common to both males and females it is only in the males that crossing-over occurs. Since, on the analogy of Abraxas, the female is presumably in the silkworm the heterozygous sex, this observation is complementary to and consistent with Morgan's evidence that in Drosophila there is no crossing-over in the male, which in that animal is heterozygous in the sex-character. The paper is in Journ. Coll. Agr., Tohoku Imp. Univ., vii., 1916, pt. 3. Also the forms found by Patterson associated with males and females should have been called "asexual," not "inter-sexes." W. BATESON.

November 14.

THE PREHISTORY OF SOUTH AFRICA.[1]

THE bulk of Dr. McCall Theal's book is as valuable now as it was when first issued, twenty years ago. But though "illustrated and enlarged," it is not "improved" so much as one would have expected. Dr. Theal does not make much use—though he alludes to its publication in 1911—of Dr. Péringuey's important study of the Stone age in South Africa, though the theories of Péringuey and Shrubsall would have materially helped him in his attempts to picture the first peopling of South Africa by Man. Also, in the scanty evidence he has gathered together of the origin and wanderings of the Bushman race he—as do most other historians of Africa—overlooks the statement of the Italian traveller, Ludovico di Varthema, who in his 1508 voyage across the Indian Ocean stopped at Mozambique, and, journeying a short distance inland to some table-topped mountain, described a short-statured savage people living on the mountain-top whose language consisted largely of "clicks," "like the sounds used by Sicilian mule-drivers." I have myself gathered up and recorded legends in South Nyasaland of a yellow-skinned, Bushman-like tribe that lived down to a few hundred years ago on the inaccessible upper parts of Mts. Mlanje and Chiperone.



(a) (b)

FIG. 1.—Drawings of the skulls of two Strandlooper types: (a) the oldest and most like to the Hamite or the Cro-Magnon of Europe; (b) a Strandlooper skull that is very Bushman-like. The originals are approximately the same size.

So far as we can trace the race movements in Africa south of the Zambezi prior to the definite entry of South Africa into recorded history, we find them to be something like this: At a comparatively remote period—say, thirty to twenty thousand years ago—there was living in southernmost Africa a human type now named or nicknamed the Strandloopers ("shore-runners"), whose skulls show a slight resemblance to the Bushman type, but whose brain capacity was much higher (1600–1500 c.c. in the male, compared with an average of 1200 c.c. in the Cape Bushman, and an average of 1480 c.c. in the Bantu-speaking Negroes). The higher type of Strandlooper skull (*a* in Fig. 1) in fact reminds one of the Hamitic skulls of North-east Africa or of the Cro-Magnon type of Europe thirty thousand

[1] "Ethnography and Condition of South Africa before A.D. 1505." By Dr. George McCall Theal. Second Edition in the Present Form (Illustrated), Enlarged and Improved. Pp. xx+466. (London: George Allen and Unwin, Ltd., 1919.) Price 8*s*. 6*d*. net.

years or so ago. These scarcely Negroid Strandloopers, according to Péringuey, were the earliest humans in South Africa, so far as our very slight evidence can be applied to the making of theories. But apparently, though they brought with them the European arts of their time, and especially

FIG. 2.—A photograph of the Nile Delta pygmy type of (?) 8000 years ago from a pre-dynastic "slate palate."

their gift of drawing, they imparted some of these to the Bushman mind and then died out.

Another question hinted at, but not adequately discussed, in Dr. McCall Theal's book is that of the different physical types of Bushmen. There is a Bushman language and culture common to all these (degraded or primitive) peoples, but the

FIG. 3.—A photograph of a very old Cape Bushman.

shape of the head differs considerably. Some—Dr. Theal gives a photograph of a woman—exhibit a greater degree of prognathism than any other known human race. I could supplement Dr. Theal's example by several others, not, unfortunately, at my disposal for reproduction at this moment. The North Kalahari Bushmen have sometimes projecting brows; the Cape Bushmen, on the other hand, are usually neither prognathous nor prominent-browed. Some Bushmen have fairly long skulls; others have head-forms markedly round and brachicephalic. Possibly these varieties in the shape of the skull may indicate a fusion of Negroid types, some of which stood low in the scale of humanity, especially in language. There are apparently two features (besides steatopygy) characteristic of the Bush race which all these varying types hold in common: one is the configuration of the ear, and the other is peculiarities in both the male and female external genitalia. I do not know whether the "Bushman ear" has been definitely noted in other Negro or Negroid races, but the peculiarities of the genitalia can be noted here and there up the eastern side of Africa until the eastern Mediterranean is reached.

The Bushmen, indeed, seem to have entered

FIG. 4.—Head of a North Kalahari Bushman.

Africa—no doubt very anciently—from the direction of Arabia or Syria, and to have wandered down the eastern side of the continent until they settled in South-east and South-west Africa.

The Hottentots came very much later—the forest Negroes and the Nilotics may have preceded them in East and South-west Africa. They arose probably from a blending somewhere in eastern equatorial Africa between the Bushman type, the Hamitic or Nilotic Negroids, and the forest Negroes. Their push southwards seems to have been diagonal, first from the regions south of the Victoria Nyanza to the Nyasa-Tanganyika plateau, and thence to South-west Africa. Finally, they advanced along the coast of South-west Africa to the lands south of the Orange River. Like the Bushmen, they formed tribes that differed much in facial appearance. Those that the Portuguese and Dutch found established in Cape Colony were lighter in colour and far less ugly than the Hottentots farther to the north-west or inland, and their culture was higher, as though they had preserved more of the Nilotic or Hamitic intermixture.

The pygmies of the Nile Delta, of prehistoric Egypt, seem certainly to have been Negroid, but more like the Asiatic Negroes, and presenting few resemblances to the Bushmen. The steatopygy of Bushmen and Hottentots developed into a local exaggeration (chiefly in the women), but occasionally appears in the Congo pygmies, the East African Bantu, the Nilotic Negroes, and even the Whiteman races of the Mediterranean.

I cannot quite share Dr. Theal's theories concerning the origin of the Bantu languages, but as I have already exceeded the space allotted to me, I must deal with my points of difference elsewhere.

Fig. 5.—Portrait of a Cape Bushman of the orthognathic type.

On the other hand, I am obstinately in agreement with his views on the subject of the earlier stone buildings of South-east Africa, of the Zimbabwe type; they were never (the earlier and more elaborate) built by Negroes, Bantu or Hottentot; they were—so far as we can be certain on any subject that has not at present conclusive proof—built by a non-Negro people, possibly the Phœnicians coming from some base in southern Arabia. The secondary and much later work was very likely done by Arab gold-seekers prior to the Islamic period. All that the more intelligent Bantu peoples, such as the Karaña or their allies, did on the verge of their entry into the history of South Africa was to carry on very clumsily surface gold-mining and the use of stone for building rough, low walls and circular huts.

The accompanying reproductions illustrate my own as well as Dr. Theal's theories. The first is copied from Péringuey and Shrubsall's "Stone Age in South Africa"; the second was given me by Prof. Flinders Petrie; the third by Mr. Leo Weinthal; the fourth is from a photo by Dr. Leonhard Schultz; and the fifth is from the collection of the Royal Anthropological Institute.

H. H. Johnston.

LT.-COL. B. F. E. KEELING.

By the death of Lt.-Col. Keeling Surveyor-General of Egypt, that country has lost one of its ablest officials. Lt.-Col. Keeling was born in 1880, and educated at Bradford Grammar School and at Trinity College, Cambridge, where he took firsts in the Natural Sciences and Mechanical Science (Engineering) Triposes. On leaving Cambridge he went to the Royal Arsenal, Woolwich, and then to the National Physical Laboratory, where he worked especially on metrology.

In 1904 Keeling joined the Egyptian Survey Department, where he took charge of the major triangulation, and in the next year of the Helwan Observatory also. Here he designed and built the comparator houses for the comparison of the standards of the Survey, and organised the geodetic survey of Egypt, in connection with which a gravity survey of the Nile Valley and neighbouring regions was undertaken. He also started precise levelling in Egypt, and under his direction a network of bench-marks has been formed in the Delta of the greatest value to irrigation. An investigation into the subsoil water-level of the Nile Valley, and its effect on the cotton crop, came also under his direction, while his work on standards of length led to the formation of the Weights and Measures Office under his direction.

In meteorology Keeling introduced research on the upper air at Helwan Observatory, where kites and pilot balloons were regularly used, and in 1908 he made a journey to the Upper Nile for the study of the upper-air currents during the rainy season. In 1913 the more scientific branches of the work carried out in the Survey Department were amalgamated to form the Physical Service, with Keeling as director, and in 1915 this service was transferred to the Ministry of Public Works as a separate Department.

In December, 1914, Keeling left Egypt in order to take up military duties, and received a commission in the Royal Engineers. He was at first attached to the Ordnance Survey, and placed in charge of the map publication department; but it was his keen desire to serve at the front, and in February, 1916, he joined a Field Survey company in France. He was wounded in the autumn of 1916, and did not return to France until 1917, when he commanded first the Depôt Field Survey Company, and then the 3rd Field Survey Battalion; he was promoted to the rank of lieutenant-colonel. The Survey battalions were now organising new methods of ranging by sound and observation, and by his force of character Keeling was particularly successful in gaining the confidence of the artillery in these methods, and it would be difficult to over-estimate the effect on many operations which he thus exercised. He was present at the Somme battle, the attack on Cambrai, the great German attack in 1918, and the subsequent British advance.

Keeling returned to Egypt in April, 1919, as head of the Survey of Egypt, having also been appointed chairman of the newly formed Board of Cotton Research, and with his accustomed zeal had already started to develop geodetic and other lines of work in the Department. He was a man of unbounded energy, who combined foresight and skill in administration with a sound scientific training, and his loss is a serious one to Egypt. He had only recently been married, and the sympathies of all are with his widow.

H. G. LYONS.

NOTES.

A CONFERENCE of delegates representing the Mediterranean nations is about to meet at Madrid to organise an international scheme of fishery investigations and to set up a central office for the co-ordination of the results and their publication in French, Spanish, Italian, and English. Four exploring ships are to be at the disposal of the office—the *Hirondelle II.* belonging to the Prince of Monaco, a specially built Italian ship, and two other vessels provided by France and Spain. In the meantime, while the full scheme is being elaborated, the Italian Government is beginning investigations in the Dardanelles. In the main, the object of the researches will be the development of the sea-fishing industries, and the results primarily sought will relate to the life-histories of edible fishes. Hydrographic work will also be carried out. Several big expeditions have made investigations of this nature in the past, but there is still much to be discovered, and sustained research is, of course, imperative in the study of variability of the productivity of the fisheries.

WE note with great regret that Mr. S. D. Chalmers died on Friday, November 7. Born at Wallsend, near Newcastle, New South Wales, Mr. Chalmers had a brilliant career at the University of Sydney, whence a travelling fellowship took him to Cambridge. There he graduated as thirteenth Wrangler in a very strong year. After holding lecturerships in mathematics at Owens College, Manchester, and at the Royal Naval College, Greenwich, he became the first head of the newly organised department of technical optics at the Northampton Polytechnic Institute at Clerkenwell, a post which he held until his premature death at the age of forty-two. Since 1903 Mr. Chalmers's work had been entirely devoted to optics, and his activities were largely identified with the Optical Society of London, of which he was for a time honorary secretary, and in 1909–10 president; and also with the two Optical Conventions of 1905 and 1912. His published work, his teaching, and his personal advice and example have done much for the optical industry of this country, and it is greatly to be regretted that one of the ablest workers in this field has been lost to us at a time when that industry needs all its strength. During the war Mr. Chalmers not only assisted the industry by personal advice and help, and by a large amount of responsible testing work, but he also organised and supervised a special training workshop in which girls were trained to become skilled grinders and polishers of lenses. There can be no doubt that his untimely death is to be ascribed to the excessive strain of these activities, followed by the further strain arising from a combination of a pressure of many students and an inadequacy of staff.

ALL those interested in the afforestation question in this country, and cognisant of the vital economic and social problems bound up with it, will have been relieved at the answer given by Mr. Bonar Law, in reply to Sir Philip Magnus, on the subject of the Commissioners to be appointed under the Forestry Act. It will be remembered that the Forestry Bill was passed by the House of Commons in August last, having been previously accepted by the House of Lords. The Act provided for the appointment of a Central Forestry Commission, consisting of eight Commissioners who should be responsible for the forest policy in Great Britain and Ireland, and anxiety as to the non-appointment of the Commissioners was being felt. The names of the eight Commissioners were announced in last week's NATURE. The member of the Commission who has had a technical and scientific forestry training is Mr. R. L. Robinson, the Cabinet having accepted the principle that at least one Commissioner should possess a scientific training in forestry. We should like to have seen a representative of the purely scientific side of forestry upon the Commission, and also a second expert member possessing a practical and wide knowledge of forestry conditions throughout the British Empire and other parts of the world outside western continental Europe. The advice such a member could tender on many points of vital importance in connection with the afforesting of the great waste areas in this country would prove invaluable. This is a weak spot in the Commission, a disability which, it may be hoped, will be quickly realised by such a broad-minded, energetic, and capable administrator as the chairman, Lord Lovat, has already proved himself to be. In other respects the selection of the Commissioners gives every promise of assuring the fulfilment of the desired results.

WE much regret to record the death, on November 14, at eighty years of age, of Dr. John Aitken, F.R.S., a frequent contributor to our correspondence columns, and distinguished for his lifelong researches on the nuclei of cloudy condensation and related subjects of meteorological physics.

THE ninety-fourth course of juvenile lectures founded by Faraday at the Royal Institution will be delivered this Christmas by Prof. W. H. Bragg on "The World of Sound."

ANNOUNCEMENT is made in the *Times* that Prof. M. Planck, Berlin University, and Prof. H. Stark, Griefswald University, have been respectively awarded the 1918 and 1919 Nobel prizes for physics, and Prof. F. Haber, Berlin University, the 1918 Nobel prize for chemistry.

PROF. WM. BERRYMAN SCOTT, president of the American Philosophical Society, sends us the following congratulatory message from Princeton:—"I am very glad to congratulate you, officially, upon the completion of the first half-century of NATURE's career, to express the cordial wish and hope that that career may long continue in ever-increasing honour and usefulness, and to give some appreciation of the very great services which the journal has rendered to scientific men throughout the world, especially to those of the English-speaking lands."

THE second annual general meeting of the British Association of Chemists was held on November 15 in Manchester, Prof. J. W. Hinchley, the president, presiding. The council is giving much thought to the important question of the representation of chemists and technical workers generally on the joint industrial councils formed under the Whitley scheme, and was able to report that, as a result of the labours of its special sub-committee, a federation of scientific and technical organisations has been formed for the purpose of advancing the claims of brain-workers to representation alongside capital and labour.

APPLICATIONS are invited by St. Bartholomew's Hospital Medical School for election to the Rose research fellowship, which is of the yearly value of 600*l.*, exclusive of laboratory expenses. The subject of the research is "The Pathology and Treatment of Lymphadenoma." The person appointed must devote the whole of his time to the fellowship. Applications, with not more than three testimonials, the names of three referees, and particulars of the lines upon which the applicant's proposed research is to be carried out, must reach the Dean of the school not later than December 15 next.

THE retirement of Mr. George A. Macmillan from the honorary secretaryship of the Society for the Promotion of Hellenic Studies should not be allowed to pass without notice in these columns. It was on Mr. Macmillan's initiative, due to the enthusiasm for Greek art and archæology kindled by a visit as a young man to Greece, that the society was founded forty years ago, and during those forty years he has acted as its secretary and been the mainspring of its activities. He has worked in close partnership with all the leading Greek archæologists of this generation, encouraged numberless young men, and afforded generous financial assistance to many enterprises. He is a shining example of one who, having put his hand to a task, does not weary in well-doing, but carries it on through the working years of a lifetime. Even now Mr. Macmillan is not wholly withdrawing from the work of the society, for in vacating the secretaryship he has accepted the honorary treasurership, and his counsel will still be available for the cause for which he has done so much.

BARON ROLAND VON EÖTVÖS, Hungary's greatest man of science, died on April 8 last in Budapest. The son of the Hungarian writer and politician, Baron Josef von Eötvös, he was born at Buda on July 27, 1848. He began his university career at the University of Budapest, and continued his studies under Kirchhoff, Helmholtz, and Bunsen at the University of Heidelberg. He also spent a short time at Königsberg under Franz Neumann. Having obtained the degree of doctor of philosophy at Heidelberg, von Eötvös became a *Dozent* in physics at Budapest University, and in 1872 he was elected to the chair of theoretical physics at that university. Some years later he was also elected to the chair in experimental physics, and for a short period was Minister of Education in Hungary. Von Eötvös occupied the position of president of the Hungarian Academy of Science for many years, and in 1891 he founded the Hungarian Mathematical and Physical Society, the presidency of which he held until his death. He was also the Hungarian representative of the International Commission for earth measurement.

THE Hunterian Society celebrated its centenary on November 12 by a dinner at the Trocadero Restaurant. Dr. Langdon Brown, the president, was in the chair, and Sir Norman Moore (the president of the Royal College of Physicians), Dr. Addison, Sir George Newman, Sir Archibald Garrod, and Sir Frank Dyson (the Astronomer Royal) were among the guests. The society's annual silver medal was presented to Mr. John Adams for his work in connection with the Corporation of London's Thavies Inn clinic for the treatment of expectant mothers and their infants affected by syphilis. The Hunterian Society was founded in 1819 by Sir Thomas Blizard, an admirer of the Hunters, and especially of John Hunter, and has numbered among its presidents Dr. Bright (from whom Bright's disease derives its name), John Hilton (the surgeon), Hughlings Jackson, and Sir Thomas Crosby (a former Lord Mayor). In earlier days consultants resided mostly within the City boundaries, and the society has always kept in touch with the City of London, and resolved to make to Mr. Adams a special centenary award of its medal.

THE British Cotton Industry Research Association was formed some months ago to promote scientific research in connection with the cotton industry, in co-operation with the scheme of the Government Department of Scientific and Industrial Research. The first problem before the association after its incorporation was to secure the services of a man of the highest attainments, who would be able not only to undertake the direction of the association's researches, but also in the difficult initial stages to construct sound foundations for the building up of the institute of the future. As mentioned last week, the council has made this appointment, and by securing the services of Dr. A. W. Crossley, C.M.G., F.R.S., Daniel professor of chemistry at King's College, London, as director of research, the association is making a very fortunate and promising start. In his new post Dr. Crossley will be responsible to the council for the direction of all the research and for the whole internal management of the institution. It will probably not be possible for him to devote his whole time to the work before Easter, but he will no doubt be able to give the association preliminary assistance before then.

THE President of the Board of Agriculture and Fisheries (Lord Lee of Fareham) has now approved of the reorganisation of the Board and the regrouping of its functions into five main Departments, each under an executive head responsible, in the case of the three Agricultural Departments, to the President direct, and in the case of the Fisheries and Welsh Departments to the President through the Parliamentary Secretary (Sir A. Griffith-Boscawen, M.P.). Sir A. Griffith-Boscawen, in addition to his duties as Parliamentary Secretary, has been appointed Deputy-Minister of Fisheries. The following appointments have also been made:—Sir A. Daniel Hall, Chief Scientific Adviser to the Board and Director-General of the Intelligence Department; Mr. Lawrence Weaver, Chief Commercial Adviser to the Board and Director-General of the Land and Supplies Department; Mr. F. L. C. Floud, General Secretary to the Board and Director-General of the Finance and Economics Department; Mr. H. G. Maurice, Fisheries Secretary and Principal Assistant Secretary to the Board; and Mr. C. Bryner Jones, Welsh Secretary, in special charge of the Welsh Office. Mr. R. J. Thompson and Mr. H. L. French have been appointed Assistant Secretaries to the Board to fill the vacancies created by the promotions of Mr. F. L. C. Floud and Mr. H. G. Maurice.

IN continuation of the excellent work left unfinished by the late Major Bendire on the life-histories of North American birds, there has recently been issued by the United States National Museum (Bulletin 107, Washington: Government Printing Office) an instalment devoted to the Nearctic diving birds of the order Pygopodes, prepared by Mr. Arthur Cleveland Bent with the co-operation of numerous well-known ornithologists. This volume affords much valuable and up-to-date information relating to the courtship, nesting, eggs, period of incubation, young, plumages, food, behaviour, breeding range, winter range, migrations, egg-dates, etc., of thirty-six species, one-third of which are members of the British avifauna. Among the mass of important and interesting information afforded only a few items can be referred to. It may be mentioned that the comparatively little known large-billed puffin, the haunts of which are confined to a limited portion of the Arctic Ocean, has recently greatly increased in numbers on the north-west coast of Greenland, which is regarded as being the westerly limit of its range. Welcome particulars are given relating to the life-history of the yellow-billed loon or Adam's diver, the eggs and nest of which are figured. There is also an excellent summarised history of the extinct great auk, and a figure of the egg, now in America, which was formerly in the collection of the late Sir William Milner, Bart. The author is to be congratulated on the able manner in which he has presented the results of his studies of the extensive and valuable material at his disposal, and also on the interesting series of pictures of bird-life, about eighty in number, from photographs taken direct from Nature. The volume is further enriched by thirteen coloured plates of eggs.

MESSRS. MACMILLAN AND CO., LTD., have in preparation a "Dictionary of Applied Physics," to be issued probably in four volumes, under the editorship of Sir Richard Glazebrook, who will have the assistance of a number of distinguished contributors. The work is intended to include the range of physical science in its application to engineering and manufacture; it will cover, therefore, a wide ground, and needs the co-operation of many writers. It should appeal to many workers, for the fact that scientific investigation and inquiry form the foundations of new methods of manufacture and are required before any marked advance is possible is now very fully realised. It is hoped, in the various sections of the Dictionary, not only to supply up-to-date information as to what has been done in the past, but also to give some indication of pioneering directions for further progress. The present is a suitable time for such a work; new industries are springing up, old industries are being reconstructed, and there are few which do not involve some process or processes based on the discoveries of physics. Pure science, as the president of the Royal Society stated some little time back, may cause a revolution in an industry. It will be the object of the Dictionary to indicate in a concise form the application of the most recent advances of physics to trade and manufacture.

WE have received a catalogue of X-ray and electro-medical apparatus from Messrs. Watson and Sons, Ltd., comprising 369 pages, well illustrated. The whole range of appliances, radiological and electrical, now in use for therapeutic and diagnostic purposes is covered, together with numerous parts of apparatus suitable for research purposes. Prominent among the latter are high-tension transformers which the modern investigations in radio-metallurgy have demanded. Useful information is also to be found in these pages as to the careful use and appropriate technique of many of the appliances, as witness the remarks upon intensifying screens and the management of the various types of Coolidge tubes now available. A considerable section is devoted to stereoscopy; fluoroscopic examinations embodying stereoscopic vision are now possible with comparatively little addition to the installations generally found in a hospital department.

MR. ROGER T. SMITH gave his presidential address to the Institution of Electrical Engineers on November 13. As the railways of this country are shortly to be subjected to fresh legislation, the choice of a railway electrical engineer as president was a happy one. Mr. Smith considered the question of superseding the steam locomotive by the electric locomotive both for passenger and goods services. The coal necessary to produce a given hauling effect on the railway by means of an electric locomotive is at the most 40 per cent. of the coal burnt in the furnace of a steam locomotive to produce the same result. This would mean a saving of between 7,000,000 and 8,000,000 tons of coal each year. It has been estimated that to electrify all the railways in Great Britain would cost 300,000,000*l.* If coal ever rose to 45*s.* per ton, the saving of fuel would itself pay 5 per cent. on the investment. The average cost of running a locomotive in 1913 was 1240*l.*, the cost of coal and water being about 37 per cent. of the total cost. The average capital cost of a steam locomotive this year is 7000*l.*, but the average cost of an electric locomotive, including electric equipment of line, but exclusive of power-house and high-tension lines, would be about 35,000*l.* Mr. Smith calculated that to enable the electric train to earn the present revenue per train-mile, the passenger electric train would have to weigh more than half as much again as the steam train, and the electric goods train would have to be at least 1000 tons in weight, which is much heavier than the average steam train for goods. He considered only main-line electrification, and he admitted that some of his data are controversial. He emphasised the importance of standardisation in main-line electrification, and, judging from our present knowledge, he suggested that the direct-current system, working at 1500, or possibly 3000, volts, would be the most economical for use over the whole country. The problem is of the greatest national importance. In the future the demand for scientifically trained traction engineers will be very great.

THE annual report of Lloyd's Register of Shipping for the year ending June 30 last is discussed in the *Engineer* for October 31. During the year 1251 vessels of 3,801,221 tons gross were classified by the committee, including 294 vessels for Government service. The United States headed the list with 470 vessels of 1,883,759 tons. Included in the total were 156 vessels of 943,487 tons built upon the Isherwood system of longitudinal framing, of which 35 were intended for carrying oil-fuel in bulk. It is of interest to note that, owing to the difficulty of obtaining a sufficient number of cylindrical boilers, the greater portion of the vessels built in America and all the wood vessels built in Canada during the war were fitted with water-tube boilers. Also a large proportion of the vessels built in America were fitted with geared turbines, most of them being of the double-reduction type. Besides their ordinary work, the surveyors rendered great assistance to the Admiralty in the design, construction, and production of special types of vessels, and also to the French Government in the inspection of shell steel, of which 1,401,114 tons were passed by the society's surveyors. More than 200 German vessels taken over under the peace terms have been surveyed by the committee's surveyors. The collective capacity of new cold stores and extensions carried out under Lloyd's survey amounts to 7,500,000 cub. ft. The committee has also undertaken research work at its own expense, one of the subjects at present engaging the attention of the special sub-committee on research being the effect of a fluid cargo in the form of oil in bulk on the behaviour of a ship in a seaway, and the manner in which energy passes between the ship and the fluid in the holds. The report is voluminous, and it is only possible to touch upon a few of the leading items of interest.

THE new monthly *Conquest*, of which the first number has just been issued, will fill a want long felt by the British public for a magazine giving, in popular language, an account of the scientific and technical achievements of the day. Readers having a technical bent were obliged to glean what information they could from the technical journals proper, or, if they read French sufficiently well, to subscribe to a well-known French periodical which fulfils the same function. The first number contains well-written and illustrated articles on the running of the London tubes, the technique of film-making, the internal structure of metals (by Dr. Walter Rosenhain), and other interesting contributions.

The Cambridge University Press hopes to have vol. iii. of the "Cambridge British Flora" ready for publication before the end of the year. Other announcements of the same publishers are a new edition of Prof. A. H. Keane's "Man, Past and Present," completely revised and largely rewritten by Mrs. Quiggin, with the assistance of Dr. A. C. Haddon; "Pleasure—Unpleasure," an experimental investigation on the feeling-elements, Dr. A. Wohlgemuth; "Chemistry for Textile Students," Prof. B. North and N. Bland; "Machine Drawing for Electrical Engineers," E. Blythe; "Food Poisoning and Food Infections," Dr. W. G. Savage; "Practical Exercises on the Weather and Climate of the British Isles," W. F. Stacey; "The Physiology of Farm Animals, Part i. (General)," Dr. F. H. A. Marshall; "General Psychology," W. S. Hunter; "Practical Geometry," C. Godfrey and A. W. Siddons; and "The Elements of Analytical Conics," Dr. C. Davison. *The Library Press, Ltd.*, has nearly ready for inclusion in its Manufacturing Problem Series "The Management Problem," E. T. Elbourne, and in preparation "The Reorganisation Problem," J. E. Powell, and "The Workers' Problem," W. Wilkinson. *The S.P.C.K.* will publish "Woodcraft Scouting in Town and Suburb," the Rev. W. Bren ("Silver Wolf").

A CATALOGUE (No. 78) interesting not only by reason of its contents, but also from the fact that many of the volumes offered for sale are from the libraries of the late Prof. T. McKenny Hughes and Mr. W. E. Balston, and that the geological portion of the library of Dr. Henry Woodward is included, has just been circulated by Messrs. Dulau and Co., Ltd., 34-36 Margaret Street, W.1. The 1018 works listed range over the subjects of zoology, botany and horticulture, geology and palæontology, astronomy, physics, etc., geography and travel. Many scarce books are on sale, but the majority of the volumes offered are obtainable for reasonable prices.

READERS of NATURE on the look-out for bargains in books for personal use or for presents would do well to see the Catalogue (No. 183) just issued by Messrs. W. Heffer and Sons, Ltd., Cambridge. All the works listed are new copies, and the reductions in price from those at which they were originally published are in many cases remarkable. Most branches of literature are represented, and many well-known books of science of comparatively recent publication are included.

MR. F. EDWARDS, 83 High Street, Marylebone, W.1, has just published an illustrated Catalogue (No. 395) of valuable early English and foreign books. The sections most likely to appeal to readers of NATURE are those referring to works dealing with Africa, America, Medicine, Herbals, Husbandry, and Natural History.

THE Society of Glass Technology should have been included in the list of scientific societies founded in the last fifty years given in the jubilee issue of NATURE. The society was founded in November, 1916, and has 550 members. Its work has frequently received favourable notice in our columns.

OUR ASTRONOMICAL COLUMN.

LARGE FIREBALL.—On November 2, at 7.6 p.m., a fireball of considerable brilliancy was seen by Mr. C. P. Adamson, of Wimborne, Dorset. Its observed flight was from $40°+7°$ to $51°+4°$, and it had an extremely slow motion, its visible duration being carefully estimated as five seconds. The nucleus left a short train behind it.

The same object was observed by Dr. Cowper at Shanklin, Isle of Wight. The meteor was comparable with a football in regard to apparent size and shape. It fell in due east in a nearly vertical direction.

From these details it is not possible to deduce exact values for the height, etc., and further observations are required. Probably the radiant was at $312°+14°$; and the height, 56 to 29 miles; path, 39 miles; and velocity, 10 miles. The object was over France in the region 45 miles east of Boulogne.

COMETS.—Mr. Sassaki, of Kyoto, Japan, discovered a comet on October 25 in R.A. 20h. 17m. 20s., south declination 27° 11′, the G.M.T. being October 24d. 23h. It was reobserved on November 9 by M. Schaumasse at the Nice Observatory, and was then found to be identical with Finlay's periodic comet, for which the Nice Observatory had already published a search ephemeris. As the comet's period is close to 6½ years, it is well placed every thirteen years, and usually escapes observation at the intervening return. On November 11 it approached the earth within some 15,000,000 miles, its apparent magnitude being 9·0. The following is an ephemeris for Greenwich midnight:—

	R.A. h. m. s.	N. Decl. ° ′	Log r	Log Δ
Nov. 21 ...	0 35 0	5 15	0·0606	9·3149
25 ...	1 4 20	9 24	0·0713	9·3657
29 ...	1 28 4	12 38	0·0818	9·4166
Dec. 3 ...	1 48 4	15 7	0·0920	9·4658
7 ...	2 6 12	17 1	0·1020	9·5140

The following is a continuation of the ephemeris of Schaumasse's periodic comet 1911 VII. for Greenwich midnight. The magnitude is about 12·5:—

	R.A. h. m. s.	N. Decl. ° ′	Log r	Log Δ
Nov. 19 ...	13 15 41	2 32	0·1081	0·2671
23 ...	13 28 47	1 28		
27 ...	13 41 30	0 26	0·1198	0·2710
		S. Decl.		
Dec. 1 ...	13 53 51	0 34		
5 ...	14 5 49	1 32	0·1329	0·2745

The above ephemerides do not claim great accuracy, and some sweeping may be necessary to find the comets.

Later.—The Finlay ephemeris needs corrections of -24m. R.A., $-3°$ decl.

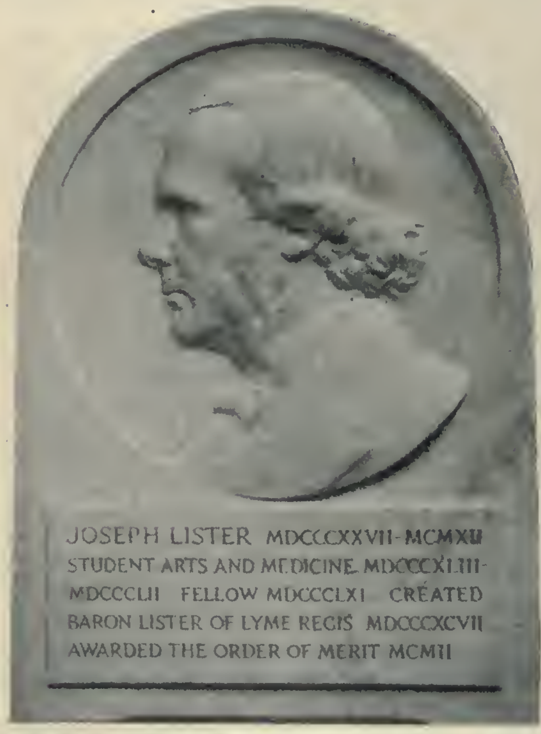
M. Ebell gives the following orbit of Kopff's comet 1919*a*, from observations 1919 July 31, August 20, September 16 (*Ast. Nach.*, 5016):—

T = 1919 June 28·210 G.M.T.	$\phi = 30° \ 56' \ 40{\cdot}6''$
$\omega = 19° \ 43' \ 51{\cdot}0''$ } 1919·0	$\mu = 538{\cdot}904''$
☊ $= 263° \ 48' \ 51{\cdot}4''$ } 1919·0	$\log a = 0{\cdot}545664$
$i = 8° \ 41' \ 30{\cdot}1''$ } 1919·0	Period = 6·5841 years

The mean observed period between 1906 and 1919 is 6·5766 years.

UNVEILING OF LISTER MEMORIAL TABLETS.

BRIEF mention was made last week of the unveiling at University College, London, of two bas-relief tablets in memory of Lord Lister, one of the most distinguished *alumni* of the college. There were present the Duke of Bedford (president of the Lister Memorial Committee), the president of the Royal Society, the president of the Royal College of Surgeons, Sir William Lister, the Misses Lister, and Miss Godlee (relatives of the late Lord Lister), the



Lister Memorial Tablet at University College, London. A similar tablet has been secured for University College Hospital, where Lister was student and house surgeon in 1843–52.

Vice-Chancellor of the University, the Provost of University College and Lady Foster, Sir John Bradford, Sir George Thane, Sir Thomas Barlow, Sir John Tweedy, Sir Ernest Hatch, and many others. The proceedings were opened by the Duke of Bedford, who referred to Lister's connection with University College, and commented upon the great value of Lister's presence in the House of Lords. Before unveiling the tablet destined to be erected at University College Hospital, where Lister was once house surgeon, Sir George Makins outlined the main events of Lister's life, the success of which was due to his thorough training as a student. Sir Joseph Thomson unveiled the tablet for University College. He said that Lister, one of the glories of British science, began his connection with the Royal Society at the early age of thirty-three, when he was elected a fellow. During Lister's five years' tenure of the presidency of the society much excellent administrative work was carried out, and this epoch saw the inception of several famous biological investigations organised by the society. The Provost (Sir Gregory Foster) then invited Sir Edwin Cooper Perry (the Vice-Chancellor), Sir George Thane, Sir Ernest Hatch, and Mr. Raymond Johnson to accept the tablets on behalf of the bodies they represented. Sir George Thane, in reply, mentioned that University College had that day been presented with one of Lister's prizes received whilst a student, and he expressed the hope that owners of Lister mementoes might present them to the college. On behalf of the memorial committee Sir John Tweedy conveyed the thanks of the subscribers to the sculptor, Prof. Havard Thomas.

THE BRITISH ASSOCIATION AT BOURNEMOUTH.

SECTION I.

PHYSIOLOGY.

OPENING ADDRESS (ABSTRACTED) BY PROF. D. NOËL PATON, M.D., F.R.S., PRESIDENT OF THE SECTION.

IN the advance of every science certain difficulties and dangers which must be encountered tend to make the progress of knowledge somewhat devious, somewhat zigzag in character.

(1) The study of the metabolism of proteins in the animal body, especially when they are considered as a source of energy, illustrates this in a striking manner. Liebig's teaching insisted on their prime importance. The investigations of Voit and of Fick and Wislicenus—unsatisfactory as the latter were—caused a swing to the other extreme, to the view that carbohydrates, not proteins, are the main source of energy. The work of Pflüger and of his school brought about a temporary swing back to Liebig's teaching. Only when it became possible to study the respiratory exchanges along with the excretion of nitrogen was a true knowledge gained of the relative importance of proteins and of the other two proximate principles.

(2) As regards the use of proteins in the building and repair of the tissues, progress has been more direct, and has ultimately led to the recognition of the importance of the constituent amino-acids as the "building stones" of the proteins. In this connection the importance of the diamino-acids lysin, histidin, and arginin must be recognised. Their presence has been shown to be necessary for growth. The presence of guanidin in the arginin molecule requires more attention than it has yet received.

(3) An aspect of protein metabolism which has been more recently elucidated is the physiological activity of the constituent amino-acids in explaining the stimulating action—the specific dynamic action—of proteins upon the general metabolism and upon heat production.

The evidence of whether guanidin may be a product manifesting a physiological action in the body is worthy of study. The investigations of Kossel and Dakin and the earlier work of Thompson do not negative the probability of the liberation of guanidin from arginin in muscle, while the more recent work of Inouye and of Thompson indicate that guanidin may be split off from arginin. The formation of guanidin, either free or combined, from non-protein sources was demonstrated by Burns to occur in the hen's egg during the first twelve days of incubation up to the time of the appearance of creatin. That the cholin of the lecithin of the yolk is the precursor is rendered probable by the evidence adduced by Reisser and by Baumann Hines and Marker that creatin is formed from cholin.

That free methyl-guanidin is a normal constituent of muscle has been shown by the work of various investigators, and these results have been confirmed recently by Henderson. It is a normal constituent of the urine, even of such animals as the horse, which lives upon a creatin-free diet.

Guanidin and methyl-guanidin have marked physiological actions. They stimulate the efferent neurons of the spinal cord, causing tremors, jerkings, and extensor tonus. In large doses applied to the spinal cord, they paralyse. On the nerve-endings in muscle they have first a stimulating effect, so that the electrical excitability is increased, but later and in large doses they have a curare-like action. The symptoms are similar to those following ablation of the parathyreoids and to those of idiopathic tetany in children. In the blood and in the urine of parathyreoid ectomised dogs and in the urine of children with tetany, Burns and Sharpe demonstrated an enormous increase in the amount of guanidin present, an increase to which Koch had previously directed attention.

The conclusion seems to be that, under normal conditions, free methyl-guanidin maintains a tonic action on the efferent neurons and so on the muscles, and that the amount of guanidin is controlled by the parathyreoids.

The few observations so far made point to the excretion unchanged of only a part of injected guanidin. A possible explanation of this seems to be that part is linked with acetic acid and so converted to creatin and then rendered inert.

Previous work on the formation of creatin from glycocyamin, guanidin acetic acid, renders this probable. Recently in my laboratory Wishart has found a distinct increase in the creatin content of the muscles after the injection of guanidin sulphate, thus proving the conversion.

The nature of the combination of creatin in muscle is not yet known. Folin maintains that creatin is an integral part of the muscle substance, and that it is liberated as muscle dies and disintegrates. Evidence of this is lacking, and some recent experiments by Wishart show that in muscle frozen during life and extracted near the freezing-point the creatin content is the same as in muscle treated in the usual way. Folin's own work on the concentration of creatin in muscle does not seem to support his theory.

In the light of these results and of this view of the mode of formation of creatin from guanidin, what is the significance of the creatin which appears in the urine? This problem may best be investigated in animals in which the question of the relationship of creatin to creatinin need not be considered. Meissner in 1868 maintained that this is the case in birds, and his conclusion I verified in 1910. It has since been further substantiated by the work of Thompson. In birds during fasting the excretion of creatin is increased, just as in mammals the excretion of the combined creatin and creatinin is generally increased. Myers and Fine claim that the creatin excreted is derived from the creatin present in muscle at the beginning of the fast, while Stanley Benedict and Osterberg maintain that there is a constant fresh formation of creatin. The experimental basis of the latter conclusion seems to be unsubstantial, since they administered protein containing arginin and therefore guanidin, from which the creatin might have been formed.

In 1910 I maintained that, from the amount of creatin excreted by the bird during a fast, the amount of muscle disintegrated might be calculated. Whether the liberated creatin is simply excreted, or whether its resynthesis into muscles is prevented, the amount in the urine indicates the breakdown and non-regeneration of muscle, *i.e.* the *actual* disintegration. Hence a study of the relationship of the creatin nitrogen to the total nitrogen excreted enables a conclusion to be drawn as to whether the loss is falling chiefly upon muscle or upon other organs of the body. A study of the metabolism of the bird in fasting shows that such conclusions may be drawn, and, accepting Folin's most recent view of the significance of urinary creatin and creatinin, the excretion of the nitrogen in these substances, taken along with the total excretion of nitrogen, affords a means of elucidating further the progress of protein metabolism in fasting.

The work of Cathcart and others seems to show that creatin, in the presence of carbohydrates, may be resynthesised into the muscle substance. This in no way invalidates the view that it is formed to detoxicate guanidin. Lecithin, which is undoubtedly used in the construction of the tissues, plays a like part in detoxicating cholin.

As regards the relationship of creatin to creatinin, in spite of the very considerable literature which has appeared upon the subject, our knowledge has advanced little since the time of Meissner. The mass of evidence seems to favour the view that the creatinin daily excreted is derived from the creatin of muscle, but that the power of conversion is very limited, and that it varies in different individuals and in different species of animal.

The considerations here adduced seem to point to the conclusions:—(1) That creatin is formed from excess guanidin or methyl-guanidin in order to limit the toxic action of these; (2) that it is to a limited extent stored in muscle, any excess being excreted in the urine, either unchanged as in the bird, or in the form of creatinin in the mammal; (3) that during fasting and in the absence of carbohydrates it is liberated as the muscle disintegrates; and (4) that it may be recombined into the muscle molecule if the supply of carbohydrates is adequate.

RADIOTELEGRAPHY DURING THE SOLAR ECLIPSE OF MAY 29.[1]

In connection with the solar eclipse of May 29 the committee arranged for the carrying out of experiments on the effect of the eclipse on signals transmitted across the central line. The British Admiralty stations at Ascension and the Azores transmitted continuously during the transit of the umbra across the Atlantic Ocean. Observing stations north of the equator were for the most part asked to listen to Ascension for at least an hour round about the time when the umbra passed between themselves and Ascension; observers south of the equator were asked for the most part to listen to the Azores. Certain selected stations north of the equator were also asked to listen to the Azores, so as to afford check observations upon the variations which might be observed in signals passing across the central line of the eclipse, and, similarly, selected stations south of the central line were asked to listen to Ascension. The American station at Sayville also transmitted a programme during a portion of the period of the eclipse, and arrangements were made for special experiments between Darien and the Falklands, and between an Egyptian station and a South African station.

[1] Report of a Committee of the British Association presented to Section A at the Bournemouth meeting, September 1919.

The main portion of the experiment hinged upon Ascension. The umbral cone passed from west to east, and was expected to affect in succession the strength in which signals were received at such stations as Demerara, Jamaica, the stations on the coast of the United States and Canada, stations in Ireland, England, France, Italy, the Mediterranean, and Egypt.

The shadow of the moon struck the earth first at dawn on the coast of South America and swept across the continent in the course of half an hour, at first with enormous velocity, but losing speed as the Atlantic Ocean was approached. About the middle of the Atlantic Ocean and near the equator the speed of the shadow was about one-third of a mile per second. On crossing the African continent from the Gulf of Guinea to the Mozambique Channel the speed gradually increased, and the eclipse finished at sunset near Madagascar. The effects of the moving shadow were investigated under three heads:—

(1) Strays.

(2) Signals not crossing the denser parts of the shadow.

(3) Signals crossing through or near the umbra.

Strays.

These were bad on the day of the eclipse and on the preceding day in Europe, North America, and temperate latitudes on the Atlantic Ocean. They were very few in Central and South America and in the central equatorial Atlantic. In Central America the conditions were exceptional meteorologically, the day having less rain than nearly every day of the preceding three weeks. The preliminary survey of the results recorded throughout the part of the globe reaching from Constantinople to Rio de Janeiro suggests that there was no outstanding occurrence in regard to frequency or intensity of strays that could be directly ascribed to the passage of the shadow.

Signals not Traversing the Dense Shadow.

Many observations were made in northern Europe and America on the signals from the Azores, which were arc-signals of 4700 metres wave-length. The observing points extended from Berlin through Holland, France, Italy, Spain, and Great Britain to stations near the Atlantic coast of the United States. There were no unusual variations in the strength of the signals from the Azores.

Another class of experiment comes under this heading. It was suggested by the effect sometimes observed at sunset or sunrise, in which the twilight band when on one side of a transmitting station appears to strengthen as if by reflection the waves received at a station on the other side of the transmitting station. In order to test whether such reflections occurred during an eclipse certain stations on the south of the central line of the eclipse were asked to listen to Ascension, which was also south of the central line. The stations at Durban and Port Nolloth (South-West Africa) found no trace of the effect, and, in fact, the former concluded that the signals from Ascension were rather worse after the eclipse began. An analogous experiment on the northern side was carried out by one of the Malta stations and also at Rosyth, listening to Cairo, with similar conclusions.

Effect of Signals Passing across the Central Line.

Arrangements were made for the transmission of signals from the Darien station of the Panama Canal zone, and several stations in South America attempted to receive the signals. The report from the Falkland Islands has not yet come to hand, and the other stations in South America did not succeed in picking up the signals. The only observation made on the earlier stages of the eclipse are those of Demerara listening to Ascension. Fluctuations in signal strength are reported, but no steady increase or decrease in strength. Ships at sea within the penumbra report a strengthening of all signals during the eclipse. The most striking results were obtained at some of the stations in France, Malta, and Teneriffe. At Meudon and at Rousillon the signals from Ascension were received practically only while the eclipse was in progress. Both Malta and Teneriffe found that the eclipse produced a great improvement in the strength of signals. On the other hand, Durban was unable to pick up Cairo, though this is usually possible, but Aden was picked up with greater intensity than normal. On the whole, the records show that the improvement in signal strength reached its highest value long before the umbra intervened between the stations, and this value persisted after the umbra had passed; that is to say, if ionising processes are the cause of the change in the strength of signals, the results indicate that the processes are practically fully accomplished in a given region of the air before the arrival of the umbra at that place, so that there appears to be nothing left for the umbra to do in the few minutes of complete shadow it brings.

The thanks of the committee are due especially to the Admiralty for arranging that their stations at Ascension and the Azores should transmit the necessary signals, and also to the American Government for making similar arrangements regarding Savville and Darien. Thanks are due also to the American, French, and Italian Governments, the Admiralty, the War Office, the Air Ministry, and Marconi's Wireless Telegraph Co., Ltd., for undertaking observations and recording the variations in signal strength.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The council of the Senate reports that, after consultation with Sir W. J. Pope, it is considered desirable to establish a professorship of physical chemistry, the stipend of 1000*l.* per annum to be furnished out of the benefaction of the British Oil Companies.

The General Board of Studies has recommended the appointment of Mr. A. Amos, of Downing College, as University lecturer in agriculture. This appointment is proposed in view of the new scheme of study in agriculture, extending over three years, and the large increase of students in the department of agriculture.

GLASGOW.—President Poincaré was installed as Rector of the University on November 14, and delivered his rectorial address in English to an assembly of four thousand students and other members and friends of the University in St. Andrews Hall. The proceedings were conducted in admirable order, the students recognising that M. Poincaré was not only their Rector, but also the honoured chief of an Allied State, visiting this country as his Majesty's guest. The Vice-Chancellor, Sir Donald MacAlister, K.C.B., conferred on him the degree of LL.D. *honoris causa* before the installation. The Vice-Chancellor wore the Cross of Commander of the Legion of Honour, with which the President had privately invested him before the public ceremony.

At a meeting of the University Court held afterwards, the Rector in the chair, a number of important gifts to the University were announced. Among them were contributions amounting to about 20,000*l.* for the erection of a memorial chapel in commemoration of graduates and students who had fallen in the war; and 2000*l.* from Mr. Bonar Law and other heirs of the late Mr. J. R. K. Law, of Glasgow, for the foundation of a post-graduate studentship in applied science, to be held by bachelors of science pursuing advanced study or research at universities or scientific institutions in Canada, the United States, or France. The Rector was also asked to accept, on behalf of the French Government, a collection of about 500 volumes, chiefly Scottish, illustrative of the ancient Franco-Scottish alliance. These had been contributed by members of the University as a fraternal gift to the University of Nancy, in M. Poincaré's native province of Lorraine, the library of which had been completely destroyed by a German incendiary bomb in October, 1918, a few days before the armistice. The Rector accepted the gift, and presented to the University of Glasgow a fine Sèvres vase for the Hunterian Museum as a souvenir of his visit. In the afternoon President Poincaré was made an honorary freeman of the City of Glasgow.

Mr. John T. Cargill has offered the University a gift of 20,000*l.* to found a chair of applied physics.

DR. R. H. PICKARD, F.R.S., principal of the Municipal Technical School, Blackburn, has been appointed principal of the Battersea Polytechnic.

MRS. MARIA LOUISA MEDLEY has bequeathed 20,000*l.* to the University of Oxford to be applied for a George Webb Medley scholarship for the promotion of the study of political economy.

LORD MILNER, Secretary of State for the Colonies, has appointed a Committee to consider whether the staff of the Agricultural Departments in the Colonial Services is adequate, and, if necessary, to recommend increases of staff; to consider whether the rates of salary offered to the agricultural staff are adequate, and, if necessary, to suggest improvements; and to make recommendations for improving the arrangements for recruiting agricultural staffs for the Colonies. The members of the Committee are:—Sir Herbert Read, Assistant Under-Secretary, Colonial Office (chairman); Lt.-Col. Sir David Prain, director of the Royal Botanic Gardens, Kew; Sir Henry Birchenough, chairman of the Empire Cotton-growing Committee; Prof. J. B. Farmer, professor of botany, Imperial College of Science; Sir Francis Watts, Imperial Commissioner of Agriculture for the West Indies; Major R. D. Furse, Assistant Private Secretary (Appointments), Colonial Office; and Mr. F. L. Sidebotham, of the Colonial Office (secretary).

THE KING has approved the appointment of Royal Commissioners to consider the applications which have been made by the Universities of Oxford and Cambridge for financial assistance from the State, and for this purpose to inquire into the financial resources of the Universities and of the colleges and halls therein, into the administration and application of these resources, into the government of the Universities, and into the relations of the colleges and halls to the Universities and to each other, and to make recommendations. The Commissioners constitute one body, but are authorised to sit for purposes of inquiry in three separate committees. They consist of the following:—*Chairman of Commission:* Mr. H. H. Asquith. *Oxford Committee:* Mr. H. H. Asquith (chairman), Lord Chalmers, Sir John A. Simon, the Very Rev. T. B. Strong (Dean of Christ Church, Oxford), Sir H. A. Miers (Vice-Chancellor of Manchester University), Prof. W. H. Bragg (Quain professor of physics in London University), Prof. W. G. S. Adams (Gladstone professor of political theory and institutions, Oxford), Miss Emily Penrose (Principal of Somerville College, Oxford), and Mr. Albert Mansbridge. *Cambridge Committee:* Mr. G. W. Balfour (chairman), Mr. Arthur Henderson, Sir W. Morley Fletcher (fellow of Trinity College, Cambridge), Sir Horace Darwin, Mr. G. M. Trevelyan, Dr. H. K. Anderson (Master of Gonville and Caius College, Cambridge), Miss B. A. Clough (Vice-Principal of Newnham College, Cambridge), Dr. Montagu R. James (Provost of Eton College), and Prof. A. Schuster (secretary of the Royal Society). *Committee on Estates Management:* Lord Ernle (chairman), the Hon. Edward Strutt, Sir Howard Frank, Sir J. H. Oakley (past-president of the Surveyors' Institution), and Mr. H. M. Cobb (fellow and member of the council of the Surveyors' Institution). The secretary of the Commission is Mr. C. L. Stocks. There are three assistant secretaries, namely:—For the Oxford Committee, Mr. Marcus N. Tod, fellow and tutor of Oriel College, Oxford; for the Cambridge Committee, Mr. Edward Bullough, fellow of Gonville and Caius College, Cambridge; and for the Estates Committee, Mr. C. B. Marshall. The offices of the Commission are at 2 Queen Anne's Gate Buildings, Queen Anne's Gate, S.W.1.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, October 24.—Prof. C. H. Lees, president, in the chair.—Dr. N. W. **McLachlan**: The effect of pressure and temperature on a meter for measuring the rate of flow of a gas. The theory of an instrument for measuring the rate of flow of a gas is outlined, the effects of variation in the temperature and pressure of the gas being taken into consideration. This theory is tested experimentally for pressures varying from 1250 to 250 mm. Hg, and for temperatures from 10° C. to 100° C. It is found to be fairly accurate. The results are applied to the measurement of the rate of flow of gas on an aeroplane in the upper atmosphere, where a reduction in temperature and pressure is encountered. It is shown that the instrument reading for a certain N.T.P. volume of gas depends on the altitude, but that this volume can be obtained by using a correction factor.—Capt. J. H. **Shaxby**: A cheap and simple microbalance. The instrument, devised for bacteriological use, had to be cheap and moderately robust. It consists of a long horizontal fibre joining the lower ends of two vertical beams, each pivoted very little above its centre of mass. A small weight acting at the middle of the fibre thus causes a considerable depression. This is read off by arranging a slider on a vertical millimetre scale about 2 ft. in front, so that the middle of the fibre and a second short fibre placed just behind it are in line with a "peephole" on the slider. Adjustment is provided for quickly and largely altering the sensitiveness. The deflections are converted to masses by the use of calibrating weights. The apparatus is built up from a "Meccano" set.—J. W. T. **Walsh**: The resolution of a curve into a number of exponential components. The paper gives a method for the resolution of a curve of the compound exponential form $B = \sum_{1}^{n} a_1 e^{-\lambda_1 t}$ into its components, the values of a and λ for the n different exponential terms being found from $2n$ values of B equidistant along the axis of t. A method is also given for finding the most probable values of these constants from any number ($>2n$) of observed values of B taken at irregular intervals of t.

Aristotelian Society, November 3.—Prof. James Ward, president, in the chair.—The **President**: Inaugural address: In the beginning . . . The problem that the universe sets us is an inverse problem. But the two most distinguished philosophers amongst us, starting from the Absolute as their criterion, declare the whole world as we know it, including ourselves, as infected with contradictions, which are only resolved in the Absolute. Precisely how resolved we do not know, and never can know. But at least everything is blended and transformed into one perfect experience in which no finite centres of experience as such are respected or retained. Is the Absolute, then, making sport of us, it is asked, since the untransformed, discrepant "appearances," it would seem, must ever remain to perplex us? No, it is replied; for these appearances are the Absolute's revelation to us. Moreover, in the unification of our originally disjointed experiences which underlies all human development, and again in the ever-increasing mutual "transparency" of formally distinct individuals—who are thereby ever more and more enabled to think and feel and act as one—we can see the beginning of the process that in the Absolute is eternally accomplished. But, it was rejoined, the progress of knowledge shows no sign of reducing the categories of thought to the mere "adjective" with which, perhaps, it began. Nor does our advance to a higher unity show any tendency to replace stability and originality of character by mere "connections of content." In conclusion, it was urged that it is hopeless to attempt to begin from the point of view which only a *completed* philosophy could occupy. To advance continuously and be coherent—that should be our golden rule. The whole procedure would be tentative—that must always be the case with inverse problems. Crises, too, there would be again, as in the past; but such crises, after all, would only be cases of "sloughing an outgrown skin," not of radical disease. Philosophy on the whole had progressed; and so long as it followed the method which Nature herself observes—to make no leaps—why should it not progress still?

Mineralogical Society, November 4 (Anniversary Meeting).—Sir William P. Beale, Bart., president, in the chair. —Dr. W. R. **Schoeller** and A. R. **Powell**: Villamaninite, a new mineral. The new mineral, which occurs, disseminated in black grains and plates, with a distinct cleavage, and in small nodules with a radially fibrous structure, in a crystalline dolomite near Villamanin, Cármenes district, León province, Spain, has probably a composition corresponding with $(Cu,Ni,Co,Fe)(S,Se)_2$. Its streak is sooty-black, hardness 4½, and specific gravity 4·4–4·5; it is opaque.—A. **Russell**: The occurrence of phenakite and scheelite at Wheal Cock, St. Just, Cornwall. The author found good specimens of these minerals in 1914 at Wheal Cock, which is the locality whence came the crystal (undoubtedly phenakite) described by Sowerby in 1804 as argilla electrica or white tourmaline. Phenakite was not known until 1833 as a distinct species.—L. J. **Spencer**: New crystal-forms on pyrites, calcite, and epidote. On pyrites the dyakis-dodecahedron (641) occurs as large, well-developed faces on five specimens, one of them from Traversella, Piedmont, and the others from coal-shales of unknown locality. On 424 crystallised specimens of pyrites in the British Museum collection, 35 crystal-forms were noted. Faces of the cube are present on 76·6 per cent. of the specimens, the octahedron on 62·7 per cent., the pentagonal-dodecahedron (210) on 54·7 per cent., and the dyakis-dodecahedron (321) on 36·1 per cent. As simple forms, not in combination with other forms, they are represented by 12, 2, 2½, and ½ per cent. respectively. The decomposition of specimens of pyrites in collections was discussed. Calcite, a clear scalenohedral crystal, probably from Iceland, consists of a combination of the two scalenohedra (201) and (12.0.7), both largely developed, and with an angle of only 4½° between corresponding faces. Epidote, a crystal, probably from Ala, Piedmont, closely resembling in appearance the yellow prismatic crystals of anatase, carries a minute face (134) (Dana's orientation) in addition to twenty other crystal-forms.—Dr. G. F. Herbert **Smith**: A curious crystal from the Binnental. The crystal, which was found with a few loose sartorite crystals in the Trechmann collection, is twinned and tabular in habit, and shows signs of corrosion. The symmetry is peculiar, since, although a face occurs at right angles to the prism edge, it is neither a plane nor a pole of symmetry, and the crystal appears to represent a new species of sulpharsenite.

MANCHESTER.

Literary and Philosophical Society, October 7.—Mr. Francis Jones, vice-president, in the chair.—Sir Henry A. **Miers**: The future of the Manchester Literary and Philosophical Society. Attention was especially directed to the urgent need in societies for informal discussions, a work performed by such societies in their pioneer days. With the increase of scientific knowledge the tendency has been for scientific people to segregate into special groups. As a result of this, the papers read at modern specialist societies are calculated to appeal only to experts. A reaction is indicated by recent attempts at co-operation between the humanities and sciences. Great work could be done by making the most recent advances in science understood by those who were not experts, and by promoting meetings at which new ideas can be expressed in language intelligible to all. There is danger of a scientific hierarchy, and of a cleavage between specialists and amateurs. Investigators might be encouraged to give popular expositions of their own discoveries to a general audience, in addition to the more severely scientific paper intended for publication.

PARIS.

Academy of Sciences, October 27.—M. Léon Guignard in the chair.—C. **Moureu** and A. **Lepape**: The stabilisation of acrolein. An empirical method of stabilisation. The crude aldehyde is shaken with 10 per cent. of its weight of dry sodium bicarbonate. The acidity is reduced to 5 per cent. of its original value, and the acrolein so produced is practically stable.—A. **Chatelet**: Hypercomplex numbers with associative and commutative multiplication.—E. T. **Bell**: Particular representations by some quadratic forms of Liouville.—P. **Chevenard**: The viscosity of steels at high temperatures. A chrome-nickel steel wire was maintained at a constant temperature in an atmosphere of nitrogen, and the elongation under a fixed load measured photographically as a function of the time.—H. **Vanderlinden**: Observations of Borrelly's comet 1919*c*. Measurements were made at the Royal Belgian Observatory at Uccle on October 18, 22, and 23. On October 22 the comet appeared as a nebulosity of 1′ diameter. The nucleus was clear, and of magnitude about 9.—J. **Volmat**: The application of aerial photography to hydrographic surveys. Photographs from an aeroplane of the sea-floor in the neighbourhood of Brest proved the great possibilities of this method of marine surveying. Several points of rock which had escaped previous careful surveys were discovered with ease.—L. **Majorana**: Experiments on gravitation.—E. **Perucca**: Plane waves laterally indefinite, with pendular vibrations, which reflection and refraction associate with one or two given analogous systems of incident waves.—H. **Muraour**: The comparison of explosion temperatures calculated starting from the specific heats with those calculated starting with the explosive pressures.—M. **Chelle**: The transformation of hydrocyanic acid into thiocyanic acid in the course of cadaveric putrefactions; experiments made *in vitro*. In putrefactive phenomena hydrocyanic acid is in part transformed into thiocyanate. In some experiments *in vitro* with known quantities of cyanide added to normal blood, after ten days the hydrocyanic acid had apparently disappeared, but could be almost wholly recovered by oxidising the thiocyanate formed.—L. **Joleaud**: The tectonic of the neighbourhood of Tilouanet (Oran).—C. E. **Brazier**: The relations of the wind with gradient in the lower layers of the atmosphere.—J. **Ubach**: Observations made at Buenos Aires during the annular eclipse of the sun of December 3, 1918. Details of variations of the magnetic declination observed during the eclipse.—E. **Sollaud**: The influence of the conditions of the medium on the larvæ of *Palaemonetes varians microgenitor*.—J. **Nageotte**: Osteogenesis in grafts of dead cartilage.—A. **Paillot**: Karyokinetosis; new facts and general considerations.—A. **Marie**, C. **Levaditi**, and G. **Banu**: New attempts to transmit the treponeme of general paralysis to the rabbit.

DIARY OF SOCIETIES.

THURSDAY, NOVEMBER 20.

ROYAL SOCIETY, at 4.30.—W. J. Johnston: A Linear Associative Algebra suitable for Electro-magnetic Relations and the Theory of Relativity.—Sir Joseph Larmor: Note on Mr. W. J. Johnston's Calculus for Generalised Relativity.—G. E. Bairsto: On the Variation with Frequency of the Conductivity and Dielectric Constant of Dielectrics for High Frequency Oscillations.—F. J. W. Whipple: Equal Parallel Cylindrical Conductors in Electrical Problems.—G. A. Schott: The Scattering of X- and γ-Rays by Rings of Electrons. A Crucial Test of the Electron Ring Theory of Atoms.

ROYAL SOCIETY OF MEDICINE (Dermatology Section), at 4.30.—*Cases*: Dr. Bunch: Case of Linear Morphœa.—Dr. MacLeod: (1) Melanotic Lesion on Sole of Foot; (2) Case for Diagnosis.—Dr. Barber: (1) Case for Diagnosis-Blastomycosis (?); (2) Erythrodermie Congenitale Ichtyosiforme.

LINNEAN SOCIETY, at 5.—K. Patten: Plants collected in Mesopotamia and in Southern India.—C. C. Lacaita: *Orchis maculata* from Monte Gargans, Italy.—Dr. G. C. Druce: Two New British Plants.—Miss Trower: Paintings of British *Rubi*.—Prof. R. C. McLean: Sex and Soma.

INSTITUTION OF MINING AND METALLURGY (at Geological Society), at 5.30.—H. L. Sulman: A Contribution to the Study of Flotation.

CHILD STUDY SOCIETY (at Royal Sanitary Institute), at 6.—Dr. D. Forsyth: The Pre-School Girl.

CHEMICAL SOCIETY (and Informal Meeting), at 8.

FRIDAY, NOVEMBER 21.

ROYAL SOCIETY OF MEDICINE (Otology Section), at 5.—H. Tilley: Presidential Address—A Plea for the Better Education of the Medical Student in Oto-Rhino-Laryngology.

INSTITUTION OF MECHANICAL ENGINEERS, at 6.—C. G. Conradi: The Present Position of Mechanical Road Traction.

INSTITUTION OF ELECTRICAL ENGINEERS (Students' Meeting) (at the City and Guilds (Engineering) College), at 7.—A. P. Trotter: Opening Address.

JUNIOR INSTITUTION OF ENGINEERS (at Royal Society of Arts), at 7.

ROYAL SOCIETY OF MEDICINE (Electro-Therapeutics Section), at 8.30.—Dr. G. B. Batten: Apparatus for Obtaining Morton Wave Current and Static Modalities from a Coil.—Major G. Cooper: The Artificial Stimulation of Muscle, with Demonstration of a New Form of Faradic Coil.

MONDAY, NOVEMBER 24.

INSTITUTE OF ACTUARIES, at 5.—Dr. C. E. Howell: The Reversionary (or Prospective) and Collective Methods of Valuing Widows' Funds, with some Notes on the Valuation of the Church of Ireland Widows' and Orphans' Fund.

TUESDAY, NOVEMBER 25.

ILLUMINATING ENGINEERING SOCIETY (at Royal Society of Arts), at 5.30.—L. Gaster: The Works of Lambert.—The Hon. Secretary: Report on Progress.

INSTITUTION OF CIVIL ENGINEERS (Extra Meeting), at 5.30.—H. H. Gordon: Metropolitan Road and Rail Traffic.

ROYAL ANTHROPOLOGICAL INSTITUTION, at 8.15.—Dr. W. Strong: Some Personal Experiences in British New Guinea.

WEDNESDAY, NOVEMBER 26.

ROYAL UNITED SERVICE INSTITUTION, at 3.—Maj.-Gen. Sir George Aston: Combined Operations.

ROYAL SOCIETY OF ARTS, at 4.30.—Dr. H. B. Morse: British Trade in China.

WIRELESS SOCIETY OF LONDON (at Institution of Civil Engineers), at 6.—J. Scott-Taggart: A System for the Reception of Continuous Waves.

ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 8.—G. Brewer: Some Kite-Balloon Experiments.

THURSDAY, NOVEMBER 27.

ROYAL COLLEGE OF SURGEONS, at 3.—Annual Meeting of Fellows and Members.

INSTITUTION OF ELECTRICAL ENGINEERS (at Institution of Civil Engineers), at 6.—C. C. Paterson, J. W. T. Walsh, A. K. Taylor, and W. Barnett: Carbon Arcs for Searchlights.

FRIDAY, NOVEMBER 28.

PHYSICAL SOCIETY, at 5.—Discussion on Lubrication. To be opened by Dr. T. E. Stanton. Speakers include Principal Skinner, W. B. Hardy, F. W. Lanchester, and H. M. Martin. Visitors are invited to this Meeting.

THURSDAY, NOVEMBER 27, 1919.

THE ROYAL COMMISSION ON THE UNIVERSITIES OF OXFORD AND CAMBRIDGE.

SEVERAL months ago, Mr. H. A. L. Fisher, President of the Board of Education, made the important announcement that the Government had decided to appoint Commissions to inquire into the position of the Universities of Oxford and Cambridge. At both Universities the existing resources have proved inadequate to meet the increased cost of maintenance of the various departments, and the authorities of each independently applied to the Government for financial aid. It was understood that in due course comprehensive inquiries into the whole resources of the Universities and their colleges, and the use made of them, would be instituted; and preliminary grants of 30,000*l.* to each University were accepted on this condition. With reconstruction in the air and Government inquiries in the fashion, it is not surprising, therefore, that a Royal Commission (under the chairmanship of Mr. Asquith), with separate Committees for Oxford and Cambridge, and a further Committee dealing with estate management, has now been appointed to inquire into the financial resources of the two Universities and of the colleges, into the administration and application of these resources, into the government of the Universities, and into the relation of the colleges to the Universities and to each other.

It is more than forty years since the last Royal Commission on the Universities of Oxford and Cambridge was appointed, and the advisability of a new Commission has frequently been suggested in recent years. The question was debated in the House of Lords in 1907, but it was believed at the time that it would be better for the Universities to institute reforms from within; and at Oxford the Chancellor, Lord Curzon, made an extensive inquiry into the possibility of such reforms, following it up by an open "letter" addressed to the University, containing a number of valuable suggestions. Some of these have since been acted upon, but others, such as the abolition of compulsory Greek in the entrance examination, have temporarily succumbed to the conservatism of certain members of the University, more especially the non-resident members of Convocation. Still other questions, such as that relating to degrees for women, have been postponed owing to the war, but they are likely to come up for consideration in a very short time. Hence there would not have been any very cogent grounds for the immediate appointment of a fresh Commission, had it not been for finance. At Oxford, whilst the income of the University has fallen, its expenses have greatly increased. Science in particular, owing to the increase in the number of its students and to the range of their studies, has been forced to make special demands for further laboratory accommodation and for increased grants for teaching purposes.

Considering the special needs of science, the composition of the Oxford Committee is not altogether satisfactory. Of the nine members of the Committee, only two are men of science, whilst in the Cambridge Committee science has been assigned twice as great a representation. However, there can be no question of the suitability of the scientific representatives themselves. One of them, Sir Henry Miers, when professor of mineralogy at Oxford, was of invaluable assistance, by his moderation and persuasiveness, in bringing the just claims of science before the resident members of the University. Prof. W. H. Bragg will bring to the inquiry the freshness and width of outlook of one who has had experience of research and professorial teaching in two hemispheres. Miss Penrose, the principal of Somerville College, is a worthy exponent of the claims of women, while Labour is presumably represented by Mr. A. Mansbridge.

The Cambridge Committee is one to which, at any rate as individuals, and from the point of view of the University itself, little exception can be taken. It contains one woman (Miss Clough), one representative of Labour (Mr. Arthur Henderson), six (or, including Miss Clough, seven) members of the University, and four distinguished fellows of the Royal Society, namely, Sir W. Morley Fletcher, Sir Horace Darwin, Dr. H. K. Anderson, and Prof. A. Schuster. It is, however, a pity that the younger generation should be so inadequately represented. The Committee has an average age of about sixty years, and although there are many really distinguished members of the University between the ages of twenty-eight and forty-three, and it is these men who will have mainly to bear the brunt of the next twenty years, there is nobody on the Committee to emphasise their point of view. The absence also of an expert in finance, industry, or economics is noteworthy, and—one would imagine—will make the task of the Committee more difficult.

Apart from these objections, however, it is clear that Cambridge has nothing to fear, and may have much to gain, from its Committee's activities. The four scientific members are known as men of sound judgment, wide knowledge, and an enthusiasm for scientific progress, while they have been as much concerned with the importance of science to the well-being and prosperity of the community as with its value in education and in the improvement of human knowledge. All of them are men who personally have done valuable original research, and shown the capacity for affairs and the sound judgment necessary in these days of organised scientific work.

The terms of reference of the Commission relate, not only to questions of finance, but also to the government of the Universities and the relations of the colleges to the Universities and to each other; hence the inquiry is likely to be an extensive one. In the course of the inquiries to be made, many anomalies will doubtless be revealed. Our educational structure is curiously unbalanced. It has grown up cathedral-like, and bears witness to the loving, if sometimes misguided, benefactions of many generations. We trust that the Commissioners, while retaining all that is good—and there is much that is worthy of preservation—will ensure a more economical and equitable distribution of the fruits of past benefactions for the encouragement of religion, learning, education, and research.

In particular, we would direct attention to the need for greater facilities for research, not only in pure science, but also in modern philosophy. It is almost incredible that Oxford, the home of classical learning, cannot boast of a single exponent of modern philosophy who might be expected to explore the regions of thought revealed by recent scientific research on space and time. The discontinuities of modern physics should surely not appeal in vain to the heirs of the wisdom of the Greek philosophers.

Further, the hard-worked science tutor should be afforded time and facilities for research. A critical study by the Commissioners of the distribution of tutors in the various subjects and of the relative number of pupils allotted to each tutor would form an instructive lesson on our educational methods. Some relief could be given to science tutors if it were made compulsory for candidates for degrees in science to obtain exemption from preliminary physics and chemistry before admission to the University. This would also relieve the already overburdened laboratories.

Other questions relating to natural science with which the Commission must deal are: (*a*) The urgent need for further buildings and equipment, and for increased staff, if the present rush of students is to be met, and if research is to be maintained; (*b*) the sufficient remuneration of the teaching and research staffs, and the recognition of the fact that the research worker is no less entitled to payment for his labours than the business man, the teacher, or the labourer; (*c*) the better support of natural science by the colleges (in proportion to its importance, natural science is inadequately assisted by many colleges in the matter of scholarships, fellowships, and lectureships); (*d*) the provision of pensions for professors and other officials, and the introduction of a definite age for retirement. This last matter is particularly important in natural science, where the professors have administrative and organising duties, as well as those of lecturing and directing research, and there is no reason why a university should be an exception to the general rule in any large undertaking, national or private, that an executive appointment should be subject to an age limit.

The Committee on Estate Management will have to consider the more efficient administration of college property, and may recommend the adoption universally of the system already agreed to by three important colleges at Cambridge of employing a common estate office connected with the School of Agriculture. The present system of awarding scholarships, the subject of women's degrees, the finances of the women's colleges, and the cost of living of the average undergraduate are among the more controversial matters to be decided. Whatever may be the course of their deliberations, however, it is clear that Cambridge will not be encouraged, as it might have been under another type of Commission, to cease its national function as a home of "religion, learning, and research," and to become a place merely of technical instruction. Whatever faults the Commission may have will lie, not in a lack of sympathy for education and research in the best sense, but in a rather conservative outlook and an inability to understand the urgency of really radical changes, in an insufficient appreciation of the needs and demands of the great labouring classes of the country, and in lack of understanding of the point of view of the younger generation.

PRINCIPLES OF RADIO-COMMUNICATION.

The Principles underlying Radio-communication. Radio Pamphlet No. 40. December 10, 1918. Signal Corps, U.S. Army. Pp. 355. (Washington: Government Printing Office, 1919.) Price 55 cents.

THIS book has been prepared by the Bureau of Standards, Washington, under the direction of the Chief Signal Officer of the Training

Section of the United States Army. It gives an accurate survey of the theory of electromagnetism with special stress on its application to practical radio-communication. Very little mathematical knowledge is assumed on the part of the reader, and the familiar analogies given will be a great help to beginners.

The first and second chapters give a clear *résumé* of elementary electricity and the working of dynamos. In the third chapter radio-circuits are described, stress being laid on coupled circuits, oscillations, damping and effective resistance. The fourth chapter describes electromagnetic waves, and the academic theorist will be surprised at the simplicity and accuracy of the transmission formulæ used in practice. Descriptions of the best types of antennæ and of open and closed coil aerials are also given. In chap. v. the apparatus used in transmission and reception is described, and it is carefully stated which is suitable for damped and which for undamped waves. Chap. vi., the final chapter in the book, will be very helpful to many, as it gives an excellent account of the various types of vacuum tubes now in use. By means of the characteristic curves the working of the three-electrode tube is simply explained. Its use as an amplifier, modulator, and generator of oscillations is fully described. The method of connecting vacuum tubes in cascade is also given.

Many fail to recognise how easy it is to detect radio-waves, and how simple is the necessary apparatus. For damped waves, all that is required is a telephone receiver, a rectifier (crystal "detector," or, better, a vacuum tube), and a tuning coil. It seems to us to be foolish for the Post Office to keep up the comedy of pretending to regulate the use of such sets. Now that the licences to technical colleges have been formally withdrawn it would be politic to issue new ones without any further delay.

The latest developments of radio-communication make the subject of absorbing interest to the engineer and the man of science. For instance, the power involved in the sound-waves generated in ordinary speech is of the order of the hundred-millionth of a watt, and yet in radio-telephony this controls several thousands of watts, the alternating currents being at radio frequency. In the pre-war days the use of crystal rectifiers introduced an element of uncertainty into everyday working. This was overcome by the Fleming valve, which is now replaced by the three-electrode vacuum tube. For measurement purposes the vacuum tube is far superior to the "buzzer" as a source of oscillations. If several tubes are used in the same circuit, and each tube has its own battery, then the amplitude and frequency of the current-waves can be made practically constant.

There are very many interesting and novel facts given which will be of great value to the radio engineer. The book can be heartily recommended to every man of science who wishes to know the latest practical developments. A. R.

ROUND THE WREKIN.

Shropshire: The Geography of the County. By Prof. W. W. Watts. Pp. x+254. (Shrewsbury: Wilding and Son, Ltd., 1919.) Price 2*s*. 6*d*. net.

SHROPSHIRE, in its combination of mountain and plain, in the varied flow and scenery of its river, for which the whole county serves as catchment basin, in the extent of its stratified rocks from pre-Cambrian to Lias, in their yield of coal, building-stones, metals, and workable clays, lends itself admirably to treatment by a geographer who is also a geologist, and it is needless to say that Prof. Watts, whose geological studies of the county alone or in conjunction with Prof. Lapworth have been a guide to so many, avails himself thoroughly of the opportunity. The rich and beautiful forests, the meres, and the rocky uplands support a multiform assemblage of birds. The more important among these and other animals are noted, but it might have been mentioned that a complete series of the vertebrate fauna has been collected and placed on exhibition by Mr. H. E. Forrest in the Shrewsbury Museum. The diversified agriculture and the numerous industries down to the making of "churchwardens" are briefly correlated with rocks and soil.

But Prof. Watts recognises that the great interest of Shropshire lies in its human inhabitants and their history. Though Palæolithic man has left no trace in the county, his Neolithic successors are known, not merely from their weapons, stone circles, and barrows, but from their many descendants in the present population. The Brythons, who became the Cymry to themselves, the Welsh to their enemies, are now represented by about one-tenth of the inhabitants. Their coracle is still used by Severn fishermen. It was the struggle between them and the English compound of Angles and Normans that so long made Shrewsbury a city of prime importance. All this eventful history and its relation to the physical features is clearly summarised by Prof. Watts.

The beautiful half-timbered houses of the fifteenth, sixteenth, and seventeenth centuries are famous, but such stone mansions as those of Benthall and Condover, such castles as Stokesay, Ludlow, and Shrewsbury, and the fine ecclesiastical architecture of Buildwas, Wenlock, Ludlow, and Shrewsbury, receive description and illustration so far as space admits. A chapter on the place-names is of peculiar interest, and the sections on communications and the origins of the chief towns are excellent lessons in political geography. Coloured physical and geological maps form the end-papers of the book.

There is an index, but it has not helped a reviewer fresh from his home-county to find the explanation of "Meole," the meaning of the "Weeping Cross," the origin of Bomer and similar "pools," or any reference to the "Burries" or Burgs of Bayston Hill. Farquhar's "Recruiting Sergeant" might be worth a line. A Salopian also may suggest that the hills once studied by Prof. Watts should be called "the Breidden," not "the Breiddens." But these remarks are not criticisms. The book will prove a charming and trustworthy companion to any observant traveller in the beautiful native county of Charles Darwin.

OUR BOOKSHELF.

Tri-lingual Artillery Dictionary. By E. S. Hodgson. With introduction by Col. J. H. Mansell. In three volumes. Vol. i., *English-French-Italian.* Pp. viii+92. (London: Charles Griffin and Co., Ltd., 1918.) Price 5s. net.

WITH the progress of every department of engineering, new technical terms are being continually introduced into the languages of various nations. In the case of artillery, the difficulty of intercommunication which thus arises is considerably increased owing to the conditions under which international relations become necessary in the progress of military operations. Any reader who thinks himself to be a good French or Italian scholar will receive a rude awakening if he opens any page of this book. Even among the most commonplace technical terms he will find the French and Italian equivalents to be quite different from anything that would naturally have been imagined. It is quite evident that much of the work of preparing such a book falls within the definition of original research.

It might be possible for officers of various nations to make each other understand their meaning by pointing to a gun or a model or a drawing, but the use of the telephone renders this method inadequate. By making this dictionary of the size of a quarter-plate photograph, Mr. Hodgson has given officers a book which they can easily carry about and use in communicating with their French and Italian colleagues. The latter ought, of course, to have corresponding books also. It is, moreover, quite certain that a companion volume for German will be urgently needed under any conditions which the future may have in store.

Apropos of dictionaries, the following suggestion is not without a certain significant aspect, namely, that a dictionary is wanted between the language of the Tripos type of mathematical examination paper and the language of the engineering factory. The difference of language certainly does harm. G. H. BRYAN.

The Mycetozoa: A Short History of their Study in Britain; an Account of their Habitats Generally; and a List of Species Recorded from Essex. By Gulielma Lister. (Essex Field Club Special Memoirs, vol. vi.) Pp. 54. (Stratford, Essex: The Essex Field Club; London: Simpkin, Marshall, and Co., Ltd., 1918.) Price 3s. net.

THE Essex Field Club has done well to reprint as a whole the subject-matter of Miss Lister's two presidential addresses, and in this way to render them available to a larger public than the readers of the *Essex Naturalist.*

The list of species recorded from Essex is mainly of county interest, but it is the county to which Miss Lister and a number of friends who have been inspired by her work and that of her father have devoted special attention, and therefore serves as an object-lesson to naturalists in other counties. The tabulated lists at the end of the book of the species recorded from similar areas in the Home Counties, the West of England, and the North of Scotland respectively, indicate what may be done by a few enthusiasts in the study of this interesting little group at the base of organised life.

But the greater part of the volume is of wider interest. The first section, on the study of Mycetozoa in Britain, is an historical *résumé* of their study in this country, from the time of John Ray, who refers to one of our commoner species in his "Synopsis of British Plants" in 1696, and of Dillenius, who figures several species in an enlarged edition of the "Synopsis" in 1724, to the classic "Descriptive Catalogue of the Mycetozoa," by Mr. Arthur Lister, in 1894. This monograph, in the preparation of which Miss Lister shared, and the handy little "Guide to the British Species" have done much to extend the study of the group, both in Great Britain and abroad, as is indicated by the rapidly increasing number of species in successive editions of the "Guide," the fourth of which is now being issued by the Trustees of the British Museum.

The second section, on the habitats of the Mycetozoa, will be of great service to workers in indicating where to look for these organisms, and what species are likely to be found in special environments. The habitat varies remarkably, including woodlands, alpine pastures, moorland, rocks, bare earth, sawdust- and straw-heaps, manure, and even bone. A useful list gives a selection of the habitats with the associated species.

Guide to the Study of the Ionic Valve: Showing its Development and Application to Wireless Telegraphy and Telephony. By W. D. Owen. Pp. vii+59. (London: Sir Isaac Pitman and Sons, Ltd., n.d.) Price 2s. 6d. net.

THIS little book is divided into fifteen chapters, each chapter consisting of three or four paragraphs of large print describing the historical development of the ionic valve, the principles on which it works, and the various types of valve that are now used in wireless telegraphy. The diagrams are clear, of large size, and not overcrowded with details. References are given to the original papers describing the various forms of valves and their developments. The book can be recommended to all who intend to take up the serious study of radio-telegraphy, as it will impress the main facts about the ionic valve on their minds.

LETTERS TO THE EDITOR.

Holland and International Rivers.

IN NATURE of October 16 is published an address on "The International Rivers of Europe," read at the British Association by Prof. L. W. Lyde. A large part of the address is concerned with the proposition that Holland is the only European country which has so far failed to accept the salutary principle that a great navigable river cannot be monopolised by a single political unit against riparians—a proposition which Prof. Lyde tries to prove, amongst other things, by an analysis of the case of the Ghent-Terneuzen Canal.

In order not to occupy too much of your space I shall deal only with that question (although some extraordinary remarks of Prof. Lyde's on the Maas and the Rhine invite comment), and only with the most important aspect of it, which is that of the dimensions of the canal in Dutch territory. Prof. Lyde denies the truth of the Dutch assertion that Belgium has enjoyed freedom of navigation on the ground that the dimensions of the Terneuzen-Ghent Canal are too small in Dutch territory. He then gives an outline of the history of the enlargements, which, if his statement about freedom of navigation means anything, should prove that Holland is responsible for those dimensions. Now not only does Prof. Lyde not prove this, but it is contrary to well-established fact. Holland has never put any difficulties in the way of Belgian desires for the enlargement of a waterway which, as a commercial communication, serves mainly, if not exclusively, the interests of the port of Ghent. Prof. Lyde calls italics to his aid to emphasise that eight years were wasted in the 'seventies before the Convention of 1879 was concluded, which arranged for the first enlargement. Wasted by whom? If one reads up the story in Guillaume, "L'Escaut," vol. ii., p. 439 (the authoritative work on this matter, published in 1902 by the then Belgian Minister at The Hague), one sees that in 1874 already the Dutch and Belgian Governments had reached an understanding, but that the Belgian Parliament, moved by an agitation which had its origin in Antwerp (where Ghent was feared as a possible competitor), threw over the Belgian Government.

The Convention of 1895 was concluded, as Guillaume puts it, "aisément" ("easily")—that is to say, the Dutch acceded at once to the requests put forward by the Belgians. In the same way, when, in 1902, while the enlargement was still being executed, the Belgian experts decided that a further enlargement was desirable, the two Governments agreed almost at once on a new convention in which the dimensions were laid down which the canal has at the present moment. If those dimensions are smaller in Dutch than in Belgian territory, it is because the works of 1895 were in 1902 in a more advanced state in the Dutch than in the Belgian part of the canal, so that in the latter they admitted more easily of readjustment. But the dimensions in the Dutch part are those which the Belgians asked for, and no other, nor have they since then asked for any further enlargement which Holland has refused. On the contrary, if, as a result of the negotiations now proceeding in Paris, new works of enlargement are undertaken, it will be found that the Dutch Government has already acquired ground at Terneuzen in order to facilitate the enlargement of the locks.

Where, in this history, is the justification for complaints about obstacles in the free navigation of Ghent? Prof. Lyde says that under international control improvements would be adopted on their merits—so they have under the existing *régime*; and that under international control the successive enlargements would have been completed much sooner—this is an assertion quite unsupported by any evidence. Prof. Lyde says also that under international control the cost of the enlargements should have been met out of the profits on the traffic. Under the existing *régime* navigation is quite free, and there are no such profits. But I believe that Prof. Lyde advocates the establishing of tolls under an international authority. I doubt whether this extraordinary idea would recommend itself to international commerce or to Ghent!

Far from being unique in denying a neighbour's right of free access to the sea, Holland has in modern times consistently respected it. There has been nothing "stupid" or "selfish" about her attitude. It is perfectly true that she might have acted very selfishly and still remained within the bounds of legality; if that shows that the existing legal *régime* should be amended, it is all the more unfair to blame Holland, who never took advantage of it to harm her neighbour's interests.

P. GEYL.

London, October 25.

I AM obliged for your courtesy in sending me Dr. Geyl's letter. Most of it is concerned with the dimensions of the Terneuzen Canal, which Dr. Geyl calls "the most important aspect of the question." I considered it so unimportant that my only comment on it was: "As the *accidental* difference in dimensions is a real handicap to Belgium, Holland should have been scrupulous to compensate by all possible courtesy and other facilities."

Dr. Geyl goes on to say that my denial that Belgium has had freedom of navigation is based "*on the ground* that the dimensions in Dutch territory are too small"! A glance at the address in your issue of October 16 will prove the inaccuracy of this attempt to divert attention from the actual facts on which I based my assertion that Belgium had not freedom of navigation.

To anyone who would care to know exactly how Holland has acted on these international waterways, I venture to say that Kaeckenbeeck's purely legal "International Rivers" (published by the *Grotius* Society) is more illuminating than Guillaume's account of what is, after all, his own success as Belgian Minister at The Hague.

"Where, in this history," Dr. Geyl asks, "is the justification for complaints about obstacles in the free navigation . . .?" In Dr. Geyl's history, nowhere. Mine was more discursive and gave precise instances, with dates and references, of facilities being denied and delayed by the Dutch; and I notice on p. 319 of the current R.G.S. Journal, in a legal review of Kaeckenbeeck's book, the words: "Germany [on the Rhine] joins hands with the Dutch in setting up restrictive regulations against foreigners." One relatively trivial case illustrates both the denial and the delay. In January, 1906, the Belgian Government formally asked the Dutch Ministry of Finance to forgo customs formalities—with all their delay and inconvenience—on boats moving only and directly between Ghent and Antwerp. The Dutch Ministry replied in January, 1907, and refused.

The profits on the canal trade are so great that Terneuzen has relatively heavier tonnage than any other Dutch port, even including Rotterdam; and the "extraordinary idea" of putting a toll on boat and cargo for the upkeep and improvement of the waterway is as old as the Roman Empire, and was the actual *régime* on the Rhine in the most prosperous days of its commerce—under the French.

I entirely agree with what Dr. Geyl says about the canal dimensions and their origin, but it does not touch my really serious and deliberate assertion that Belgium has suffered, and is suffering, from gross "international servitude." L. W. LYDE.

University College, London.

The Colours of Racehorses.

IN my "Origin and Influence of the Thoroughbred Horse" (1905, pp. 441 *ff.*) I supported my other arguments to prove that the "blood" horse originated in Libya (North-West Africa), and that his primal colour was bay, by giving in one table the results of my examination of the colours of the winners of the Derby, the Oaks, and the St. Leger, and in another table the colours of the first three horses in each of these races in the three decades from 1870–99. Grey does not appear in them at all, and black only twice, whilst chestnut—which (like brown, black, and grey) I maintain is not an original colour, but due to crossing the bay Libyan horses and the ancient dun horses of the Upper European-Asiatic area—shows a steady decrease.

In view of the discussion aroused by the winning of the Derby by a grey (Tagalie) in 1912, and by a black (Grand Parade) in the present year, it may interest some of your readers if I give my tables brought up to date for the last fifty years:—

TABLE I.—*Winners.*

	b.	b. or br.	br.	ch.	br. or bl.	bl.	gr.
1870–79 ...	15	0	2	12	1	1	0
1880–89 ...	16	0	5	8	0	1	0
1890–99 ...	17	0	7	6	0	0	0
1900–09 ...	15	4	6	5	0	0	0
1910–19 ...	18	0	5	5	0	1	1

TABLE II.—*First Three Horses.*

	b.	b. or br.	br.	ch.	br. or bl.	bl.	gr.
1870–79 ...	36	1	13	34	4	2	0
1880–89 ...	42	1	16	28	0	2	0
1890–99 ...	54	2	17	16	1	0	0
1900–09 ...	47	5	17	19	0	2	0
1910–19 ...	51	2	18	16	0	2	1

It will be seen that in the first three decades chestnut gave way steadily to bay and brown; that in the fourth decade chestnut dropped 1 in the winners, but regained a little in the lower horses (19 against 16); that in the present decade, whilst it retains the same number of winners as in the last, it has lost the slight gain made in the lower horses; and that in the fourth decade bay dropped in the winners from 17 to 15, and in the total from 54 to 47, but the loss in the winners is more apparent than real, since four bay-or-browns were amongst the winners. In the present decade, in spite of the reappearance of black and grey amongst the winners, bay has more winners (18) than ever before, though in the total number of horses it has not quite regained its old position (54).

Thus, in defiance of the sporadic reappearance of black and grey, bay seems steadily bent on superseding all other colours. WILLIAM RIDGEWAY.

Gravitation and Light.

IT may or may not have been noticed that the refractivity $(\mu-1)$ at any point, required to produce the Einstein deflection, is the squared ratio of the velocity of free fall from infinity to the velocity of light. OLIVER LODGE.

Mariemont, Edgbaston, November 24.

Variation of Refractive Indices.

MR. TWYMAN (NATURE, November 20, p. 315) will find in Trans. Chemical Society (1906, vol. lxxxix., p. 417) an account of some observations by Miss Florence Isaac and myself which indicate that the refractive index of a solution of sodium nitrate at the surface of contact with glass is slightly greater than that of the same solution in contact with calcite.

It was our intention to continue and extend these observations, but we have never been able to do so. HENRY A. MIERS.

The University, Manchester, November 22.

Neon.

IN response to inquiries, may I use your columns to make two announcements in reference to the above?

First, by making use of a new and more powerful method of positive-ray analysis (the description of which is now in the press), I have succeeded in obtaining measurements of mass and other evidence of sufficient accuracy to prove beyond all dispute that atmospheric neon (atomic weight 20·200, O=16) is a mixture of two isotopes of atomic weights 20·00 and 22·00 correct to about 1/10th per cent.

Secondly, permission to publish being now granted, a full account of recent experiments on "Neon Lamps for Stroboscopic Work" will shortly appear in the Proceedings of the Cambridge Philosophical Society. F. W. ASTON.

Cavendish Laboratory, Cambridge,
November 19.

Bird Migration.

THE captain of the Portuguese steamer *Bolama*, recently touching here on her voyage from Cape Verde Islands to Lisbon, reports that near the Canary Island, Las Palmas, his ship was visited by an immense cloud of swallows settling in thousands upon every part of the vessel and resting until early dawn, when almost every bird departed. Nothing is known as to the direction in which the birds were travelling or why they should be found far away over the open sea in such a southerly latitude. Two swifts are perennially present and nest at Madeira, but the chimney-swallow is only known as a rare straggler; and in the last fifty-five years I have not known of the passing of any migrating flock, though our latitude is five hundred miles north of the locality indicated in the *Bolama* occurrence. So strange an incident might be taken from the pages of Pliny or Ambroise Paré, and cannot fail to interest those of your readers who are working on the subject of migration. MICHAEL C. GRABHAM.

Madeira, October 27.

Luminous Worms.

FROM the communications which reach me I learn that this subject is creating a great deal of interest. At the same time all the information is vague and unsatisfactory, and I am unable to obtain specimens of the creatures themselves. The vagueness of the information is due in great measure to the lack of knowledge which still prevails respecting the Oligochæte fauna of this country. A few local names are in use, such as dew-worm, brandling, lob-worm, and cockspur, but these are as valueless for scientific purposes as cuckoo-flower or bachelor's buttons would be to a botanist.

It will be some time before my volume on British earthworms is published by the Ray Society. In the meantime, will not some publisher undertake to issue a small popular handbook of British worms, with illustrations, at a shilling? We have about fifty earthworms in this country, but only a dozen or so are by any means common, and it would be very easy for our working naturalists to get a grip of the subject, and thereby render immense service to a branch of science which is of the utmost practical value. Though I have written a large number of articles on our Annelids during the past thirty years, there is nothing on the subject which is available in a popular and handy form for would-be students, and in this matter such a handbook is sadly overdue.

May I venture once more to appeal to readers of Nature for specimens of luminous worms or other creatures, as well as for rare, unusual, or abnormal forms, that would merit attention in my Ray Society monograph? Hilderic Friend.

Cathay, Solihull, November 6.

The Doubly Refracting Structure of Silica Glass.

In an interesting letter on the above subject in Nature of October 23 Lord Rayleigh mentions that, when used with accurately crossed Nicols, "a circular disc of optical quality silica showed a spiral structure." Upon reading this letter I was reminded of a very interesting colour effect I saw several years ago in fused quartz which had been acted on by the rays from radium. As is well known, crystalline quartz assumes a uniform yellowish-brown or brownish-red colour when "rayed" by the rays of radio-active substances; the formation of coloured streaks and of patches similar to the markings of marble has also been observed. On the other hand, fused quartz generally assumes a uniform brownish-violet colour when exposed to radium rays.

In his work preparatory to the determination of the atomic weight of radium, Hönigschmid (*Wien. Ber.*, cxx., 1617, 1911) used fused quartz evaporating basins for recrystallising large quantities of radium chloride, and these afterwards showed a remarkable spiral coloration. Radiating from the centre of each basin was a series of spiral-shaped streaks of a dark violet colour, which continued in many cases almost to the top of the basin. Their upper extremity would undoubtedly be limited by the height to which the radium chloride solution had occupied the vessel. The space between the streaks showed little or no coloration. As is usual in such cases, the coloration disappeared on heating the dishes in a Bunsen flame, a brilliant bluish-violet luminescence being produced.

It has generally been assumed that the conditions in the quartz which give rise to these "streaks" are connected with the mode of manufacture of such vessels, and I believe the above colouring effects may be of interest in view of Lord Rayleigh's interesting observation of the "optical heterogeneity" of silica glass. Robert W. Lawson.

October 31.

The Antiquity of Man.

In the altogether excellent jubilee number of Nature (No. 2610, vol. civ.) there is, I notice, a short paper entitled "The Antiquity of Man" contributed by Dr. A. Smith Woodward. We are told in this paper (p. 212) that "as discoveries progress it becomes increasingly clear that true man, of the family Hominidæ, *cannot* [the italics are mine] be earlier than Late Pliocene or the dawn of the Pleistocene." We learn also that "so long ago as 1880" Sir William Boyd Dawkins, "for other reasons," came to the same conclusion.

As your readers are doubtless aware, the question as to when man first appeared upon this planet has always been of what may be termed the "vexed" order, and generally regarded as unsettled.

But though it may be the opinion of Dr. Smith Woodward and of Sir William Boyd Dawkins that "true man" cannot be of a greater antiquity than "Late Pliocene or the dawn of the Pleistocene," it does not necessarily follow that such an opinion is correct. The chief evidence upon which the idea of the great antiquity of the human race is based—evidence not mentioned in Dr. Smith Woodward's article—is that afforded by the various implements of flint and other rocks which have been found embedded in certain Pliocene and Pleistocene strata. These humanly fashioned stones are comparatively numerous, and afford evidence of a more complete type than is provided by the "few fragments of apes and man" which have hitherto been recovered from ancient deposits.

In view also of certain discoveries made in Suffolk since 1909 (described by Sir Ray Lankester and by myself), and the results of the excavations carried out during the last twelve months in the Red Crag at Foxhall, near Ipswich, I would venture to regard it as highly probable that a type of man capable of flaking flints in a clearly dexterous manner was present in that part of the country not later than Middle Pliocene times, and possibly even earlier. Further, these discoveries have demonstrated that, as would be expected, these Mid-Pliocene individuals were preceded by an earlier race or races of people who fashioned their flints in a less skilful manner. But whether these ancient flint-flakers were "true" men or not I am quite unable to say. I should imagine, however, that, judging from the kind of implements found, they had attained to a status far above that of any known ape.

It is clear, then, that Dr. Smith Woodward's views, as expressed in the jubilee number of Nature, upon the antiquity of man do not coincide with those of many of us who have made a study of early flint implements. Moreover, the fact that such widely divergent views upon this question are possible shows the urgent need for further research, especially as the present palæontological evidence, upon which Dr. Smith Woodward's opinions are founded, is, from its very nature, largely negative in character.

J. Reid Moir.

I think our present knowledge of the facts and principles of palæontology justifies the statement I made. I intentionally omitted all reference to chipped flints because I regard them as inconclusive evidence.

A. Smith Woodward.

WESTERN TURKESTAN.

Western Turkestan has been, for all practical purposes, a closed land ever since the final subjugation of the Turkomans by Skobeleff in 1880. Political conditions made it difficult for Europeans, and particularly for British, to travel in the province. It was reserved for the expedition organised in 1905 by an American, Mr. Pumpelly,[1] to make the first scientific exploration of the region between the Pamir and the Caspian. Since then little or no exploration has been carried out.

During 1918 and 1919 opportunities occurred of visiting Turkestan, unhindered by the old restrictions, and much valuable experience was gained by the members of the British forces which at one time and another penetrated the province. A voyage across the Caspian in March, 1919, took me to Turkestan to a point within eighty miles of the Oxus, near Charjui, and the unusual facilities of the journey enabled me to see much that would not have been very accessible under prewar conditions.

Once the Caspian is crossed and the Caucasus left behind, one is in a region where the subjection of the routine of life to physical limitations is very marked. Krasnovodsk, the port of Western Turkestan, a cluster of drab houses on the foot of arid and treeless hills, lives solely on what the ships and the railways bring to it. The route to inland Turkestan passes south-east from the town, skirting the long arm of Balkhan Bay, and passing between a gap in the hills—a gap which, it is generally agreed by geologists, was more than once in historical times the passage through which the Aral and the Caspian were joined; the northern junction of these waters is believed by Kropotkin and others to have been round the north end of the Ust Urt Plateau into the bay of Mortvy Kulduk.

Once through this gap, the route runs nearly due east, and the plain of Kara Kum opens out to the north with the long *sierra* ridge of Kopet Dagh screening off Persia on the south. From Kizil Arvat to Askhabad, a distance of about 130 miles, the railway and caravan route to the east runs between the desert and the foothills. Numerous prehistoric mounds, mostly of the flat-topped variety, are found along the foothills and bear testimony to the antiquity of the route.

Except for occasional oases, the Kara Kum plain is a vast and continuous desert, almost entirely flat, and with camel-thorn as its only vegetation. But though now it is for the most part desert, the fertility of the oases, round which cotton- and corn-fields are abundant, suggests infinite possibilities, as the desert, at least between Kizil Arvat and New Merv, is of rich clay, and not of sand. Here and there a simple system of converging trenches leading down from the foothills has provided the irrigation the general absence of which is the chief obstacle to agriculture.

Russian rule, prior to the revolution, by encouraging and subsidising the growth on a large scale of cotton and cereals, had largely contributed to transforming the Tekke Turkomans into a sedentary and agricultural race. In place of the temporary camps of forty years ago, one now sees large villages, which comprise groups of two or more *Kibitkas*, enclosed in a mud wall. Sometimes even the *Kibitkas* are replaced by permanent single-storied flat-roofed houses of the Caucasian type—the whole resembling the type of walled farm common in Macedonia. Recent upheavals, however, have revived the nomadic spirit. The Tekke Turkomans, largely at the instigation of the Yomut Turkomans, who are in a less fertile area, have shown signs of a movement *en masse* to less troubled areas in the south.

Askhabad, situated well out on the plain, is in the most fertile region of all Western Turkestan. It serves as the chief internal commercial centre of the province, while Kizil Arvat is rather the clearing-house for exports and imports. Dried fruits, carpets, fish from the Caspian, and furs are always to be found in its large and prosperous market. Afghans from the south, Sarts from Bokhara, Persians from over Kopet Dagh, and even Greeks from Baku and Batum, make up, with the Tekkes and Yomuts, the cosmopolitan crowd typical of a market-place of the Middle East. Whether the produce of the little-known but prosperous seal fisheries of the North Caspian penetrate these regions I was unable to find out, but the museum at Askhabad contains a collection of interesting photographs and implements illustrating this industry.

The main trade connections of New Merv are with the East and South, and carpets and silks form the staple produce of the town. The town itself is on the banks of the Murghab river, which is here no inconsiderable stream, being on an average about 50 ft. in width and well protected with dykes.

Old Merv, the ancient Antiocheia, the mediæval "Queen of the Earth," is situated some twenty miles east of New Merv. It is a sombre and impressive ruin, covering about thirty square miles. The ancient walls of the citadel still stand, hardly damaged by the passage of time, close by the woods and fields of the model estate of the late Tsar at Bairam Ali. The prosperous nature of this estate is proof of what the soil of Turkestan is capable when dealt with scientifically.

Between Old Merv and the Oxus are only rolling sand-dunes, unproductive and desolate. The process of desiccation is still continuing in Western Turkestan, and the geological causes that have affected in so many and various fashions the course of history in these regions are still operative. The Oxus, which originally flowed due north to Aral, later changed its direction, running a south-westerly course into Lake Sarykamish and the Uzboi Channel of the old Aralo-Caspian Sea. Later it reverted to its original northern flow. The Aral has been alternately marsh and sea. The causes of these changes are still the ruling factors in a land where the human element is not active. The province, left to itself, is passing through another cycle in which a shrinkage of water supply is the most marked feature. In 1842 the Abougir Gulf of Lake Aral comprised 3500 square kilometres of water surface; to-day it is practically dry. The province is essentially

[1] See Pumpelly, "Explorations in Turkestan." (Published by the Carnegie Institution of Washington in 1905 and 1908.)

an inland region dependent on adjacent mountains and lakes for its water. Methodical irrigation might yet reclaim much that in the near future will be absorbed into desert. S. CASSON.

THE BRITISH ASSOCIATION AND SCIENTIFIC RESEARCH.

THE valuable work done for science by the research committees of the British Association is well known in the scientific world, but few people outside are familiar with its nature, extent, or influence. It is not commonly understood that all members of such committees render their services without fee of any kind, or even receive travelling expenses to attend meetings; indeed, as a general rule, a member not only gives his time and knowledge freely, but also adds somewhat to his personal expenditure. The association makes grants of a few pounds annually to some of the research committees, but others are without grants; and in many cases the chairmen and secretaries meet the necessary expenses out of their own pockets.

The committees thus represent at its highest and best united work for the promotion of natural knowledge, and their constitution could not well be improved. The subjects and members are put forward by the various sections of the association, and any grants desired have to pass the scrutiny of the Committee of Recommendations, which is made up of representatives of all the sections. The organisation is, in fact, one in which men of science themselves decide upon subjects of research, and allocate the slender funds at their disposal to aid selected inquiries and reports. Obviously, this system is both efficient and economical, and its general adoption would be in the best interests of progressive knowledge.

The amount of money which the association can allocate as grants in aid is, however, only about 1000*l.* per annum, and this has to be shared between thirty or more research committees. As other funds are now available for scientific research, it has been suggested that the association should limit its aid to committees to the payment of secretarial and like expenses, instead of attempting to provide for actual investigations by the small grants it is able to afford.

The work of the research committees has, however, been of such high value throughout the existence of the association that no one would wish to make any change which would diminish its importance; and there is not the slightest doubt that whatever funds the association has available for research will be usefully applied. The present position is clearly stated in the subjoined communication from Prof. John Perry, treasurer of the association, being mainly remarks made by him before an evening discourse on September 11 at the recent Bournemouth meeting of the association. No general appeal is made for funds, but it is to be hoped that wealthy benefactors will follow the example of Sir James Caird and others interested in the promotion of scientific knowledge, for no more effective machinery for attaining this end could be devised than that provided by the British Association committees.

"You are aware that, after paying printing and office expenses, the funds of the British Association are devoted to scientific research. For more than eighty years we have spent more than 1000*l.* a year on research, long before ordinary people had heard of research.

"Every year we form many research committees; each of them is formed of the foremost men of science of Great Britain, who receive none of the money themselves, and their accounts for mere out-of-pocket expenses are carefully audited. These researches in the past have created some entirely new sciences, have led directly and indirectly to the creation of many new industries, and they have largely produced the world's present natural knowledge. And now to my point. Yesterday a very prominent member of the association asked me about our finances. I had to admit that even before the war we were meeting with difficulties due to the increased cost of printing and other things, that since the war we have been behindhand to the extent of more than 1000*l.* every year, and that we have never yet asked for the help of moneyed men. The only gift we have ever received from a moneyed man was a voluntary gift from Sir James Caird, who handed me 11,000*l.* at the Dundee meeting. My questioner said we ought to ask for help, and that he was willing to start a fund with a sum of 1000*l.* At this moment he does not wish to have his name mentioned.

"I need not dwell on the importance of our research work, as I feel sure that every person here who has himself done original work shares my opinion that when we limit our expenditure on research, and especially on pure scientific research, we shall begin to be a bankrupt association—bankrupt, that is, morally from the point of view of science, if not actually in the financial sense.

"The moneyed men of Great Britain are most willing to help any good object when they get proof that it really is a good object. We cannot complain of want of their help, for they did not know the facts. At the same time, the treasurer of an association with such a record as ours does not feel happy at the prospect of begging for help."

In the two days of the meeting following that on which I made this statement, the fund was raised to a total of 1475*l.* I intend to publish in due course a list of names of donors and donations.

To illustrate by many instances (as I might) our claims as to the importance of our researches would unduly prolong this letter, and any selection of a few examples would be unrepresentative. I will cite a single illustration:—The National Physical Laboratory, the scene of researches of which the importance to the nation during the war and earlier cannot be overestimated, had its origin (if its antecedents be traced backward) in the Kew Observatory, which was maintained by the British Association from 1842 to 1872, in which period the association spent some 12,000*l.* on its upkeep.

DR. JOHN AITKEN, F.R.S.

DR. JOHN AITKEN, widely known for his unique researches in meteorology, died at Ardenlea, Falkirk, on Friday, November 14, at the ripe age of eighty years. Although he served his apprenticeship as a marine engineer, Dr. Aitken's intellectual interests drew him into the fields of physical research, for which he received a stimulus as a student under Sir William Thomson (Lord Kelvin) in Glasgow University. He lived a retired life in Falkirk in a house which was largely fitted up as a laboratory, whence he would emerge from time to time to communicate some novel experiment or observation to the Royal Society of Edinburgh. Dr. Aitken frequently visited the Continent, partly for his health's sake, and never failed to utilise his opportunities in studying at first hand the varied meteorological conditions of our globe. He published scientific papers in the *Philosophical Magazine* and through the publications of the Royal Societies of London and Edinburgh, but it was mainly through the latter society that his important investigations were laid before the scientific world.

In his classical memoir on dust, fog, and clouds (1880) Dr. Aitken broke entirely new ground, and by his later paper on dew (1885) he consolidated his reputation as a natural philosopher of the first rank. Those who were privileged to see his demonstrations before the Royal Society of Edinburgh in 1880 can never forget the effective simplicity of his apparatus and the clearness of the argument by which he established the great truth that invisible dust particles are the nuclei on which water vapour condenses to form mist, fog, and cloud in all their infinite variety. By successive slight exhaustions of saturated air in a glass receiver, and by infiltration through cotton-wool of ordinary air from the outside, he gradually cleared it of dust particles; and when this purification had been effected, expansion with cooling of the enclosed air was, in general, unaccompanied by the formation of cloudy condensation. He noted, however, in these early experiments, that after the air had been thus purified of dust particles, a more rapid and somewhat greater expansion was sometimes accompanied by cloudy condensation. The explanation of this was afterwards given by Mr. C. T. R. Wilson, who showed that in dustless saturated air suddenly expanded electric ions acted as nuclei on which drops of water were deposited. This ionic condensation requires a distinctly greater diminution of pressure than is needed to effect the cloudy condensation in ordinary unfiltered air, and in his last paper on the subject of cloudy condensation (Proceedings R.S.E., 1917) Dr. Aitken gave many experimental illustrations of his belief that under ordinary atmospheric conditions the nuclei on which fog, mists, and clouds form are fundamentally the dust particles, although the effect may be occasionally intensified by the presence of ions.

Dr. Aitken followed up his main investigations in many ingenious ways, inventing, for example, an instrument for counting the number of particles in a given specimen of air, and applying it to the study of the conditions under which the number of dust particles varied according to locality, wind, barometric pressure, or time of day. In all these discussions he displayed unusual powers of accurate observation, great skill in devising crucial experiments, and singular gifts in interpreting natural phenomena. His researches led him into questions of colour in cloud, sky, and sea, and into the dynamical laws of cyclones and anticyclones. In this last branch of meteorology he found himself at variance with other leading meteorologists. Dr. Aitken was elected a fellow of the Royal Society of Edinburgh in 1875, and of the Royal Society of London in 1889. By the former he was awarded the Keith medal and prize (1886), and the Gunning jubilee prize (1895), and by the latter a Royal medal in 1917. In 1899 he received the degree of Doctor of Laws from Glasgow University. He was a lovable personality and of great modesty of disposition. Much though his many friends desired it, he would never allow himself to be nominated for high office in the Royal Society of Edinburgh. This, he maintained, was not his *forte*. He was a humble student of natural phenomena, and his one desire was to elucidate the workings of Nature in her everyday moods.

C. G. K.

NOTES.

THE Electricity (Supply) Bill, which passed the report stage in the House of Commons on Tuesday, is a laudable attempt by the Government at constructive economy. In almost every business, combination and standardisation lead to great economies, and this applies in a very special manner to the supply of electricity. An attempt was made on Monday to prove that the Bill in its present form was a breach of the agreement made in the Act of 1888 whereby a term of forty-two years was granted to the companies to carry on their supply without Government interference. This is perhaps technically right, but the companies have no real grievance. The Bill leaves their distributing business undisturbed, and guarantees to supply them with electricity as cheaply as they could generate it for themselves. Lord Moulton and others have laid great stress on the economy, from the point of view of the conservation of coal, of using gas for heating instead of electricity. Many electrical engineers will agree with this view. But although electrical supply companies will provide energy for heating—generally at prohibitive rates—when they are specially asked, they regard the heating load as of minor importance. Electrical heating forms only one of the manifold uses of electricity. Every engineer knows that cheap power is essential to many of our most important industries. Our supremacy as a commercial nation depends on a plentiful supply being available. A cheap and abundant supply would soon effect an industrial revolution, and be a special boon to the manual workers. Another objection that has been urged against the Bill is the danger of strikes. If a national system of supply were adopted, and if the electric workers went on strike, the work of the nation could be held up at any moment and the nation forced to grant the demands of the workers, however unreasonable they were. The experience gained by the workers, however, during the recent railway strike ought to discourage similar action against the community in the future.

UNDER a Bill introduced by the Government last week, power is given to the Board of Trade to safeguard "key" industries in this country by prohibiting the importation of certain articles. Of chief scientific interest among these are analytical reagents, photographic and various other "fine" chemicals, optical glass, laboratory porcelain, scientific and optical instruments, synthetic drugs and perfumes, coal-tar dyes, and dyestuff intermediate products. The method of prohibition is by means of an Order of the Board, but such Orders are to be subject to the approval of a Trade Regulation Committee, consisting of four political heads of Departments, three permanent officials, and ten Members of Parliament. Licences for the importation of any of the prohibited articles may be granted, either generally or in respect of specific quantities or shipments. The proposals appear to be carefully and fairly devised to meet what is admittedly a difficult situation. They have been referred to as measures injurious to scientific teaching and research, but if the industries producing the articles in question are not to be strangled out of existence in this country they must for a time be protected against "dumping"; while the power to allow importation when this appears necessary should act as a check upon excessive prices and prevent scarcity of particular products. The measure in question is eminently one in which very much will depend upon judicious administration.

AMONGST the younger generation of naturalists in this country there would seem to be a great dearth of men well qualified by training and experience to study entomology, not merely as a pastime or for the pleasure and delight they may find in it, but as one of those sciences of life which are of the greatest present value to the State and to humanity at large, and full of potentialities for the future. There was a time when, to one seeking a profession or other means of livelihood, the prospect presented by entomology looked very black indeed, but, according to a letter from Sir Alfred Keogh which appeared in the *Times* of November 20, a number of reasonably well-paid posts are now open to trained young entomologists. The difficulty in finding men properly qualified to fill them need not be a cause of surprise when it is considered that until recently there was scarcely a professional post of the kind in this country outside the British Museum, and that the few in the museum were by no means well-paid. They appear to be no better paid now. Another correspondent, whose letter signed "F.R.S." was published by our contemporary on Saturday last, points out that the pay of an assistant in the museum begins at little more than one-third of the pay of a lieutenant in the R.A.M.C., and never, while he remains an assistant, does it reach a higher level than the pay at which that lieutenant begins. He might have added that an assistant in the Natural History Museum very rarely has a chance to get beyond that stage, since the higher appointments are so extremely few in both number and proportion compared with those in other branches of the Civil Service. There is one only in entomology, which is the second largest department, and the other departments in the same branch of the British Museum are scarcely better off in that respect. It is astonishing that, at a time when the value of science is becoming daily more and more appreciated even by the general public, this state of affairs should continue to exist in one of our leading scientific institutions.

AT the invitation of Lord Glenconner, a very distinguished company assembled at his house in Queen Anne's Gate on Monday last to hear an exposition of the subject of relativity by Sir Oliver Lodge. To give a non-mathematical explanation of the principle and show how it leads to the prediction of changes in the perihelion of Mercury's orbit, which are unexplained by Newtonian theory, the deflection of a ray of light from a star passing near the sun, and the displacement of lines of solar and stellar spectra towards the red, was obviously impossible, and Sir Oliver did not attempt it. He limited himself to a statement of the close agreement between the predicted and measured deflections of star places derived from the photographs of the total solar eclipse of May 29 last, and to an explanation of the effect on dynamical principles. If gravitation is assumed to affect the refractive index of the æther, so that at every point $\mu - 1 = v^2/c^2$, where μ is the refractivity, v the velocity of free fall from infinity, and c the velocity of light, this condition would give the Einstein deflection. Gravitation cannot increase the velocity of light, but Sir Oliver thought that there might be a kind of gyrostatic effect upon a beam coming from infinity the result of which would be a deflection such as has been observed. He preferred to endeavour to explain the observations on dynamical principles before bringing in a new theory. Prof. Schuster, however, at the close of the address, urged that the best way to deal with a theory was to accept it as a working hypothesis and put all its consequences to the test. The announcement of the eclipse results has brought the relativity principle into prominence in the general Press, and many people have consequently become interested in it. For several years scarcely a volume of NATURE has been without contributions on the principle, and we would direct particular attention to two articles in our columns of June 11 and 18, 1914, by Mr. E. Cunningham, a Royal Institution discourse by Prof. A. S. Eddington in the issues of March 7 and 14, 1918, and one by Sir Oliver Lodge in those of September 4 and 25 last.

As was to be expected, the results of the Eclipse Expedition confirming Einstein's theory of gravitation have called forth discussion, support, and opposition from those who find their own particular point of view, physical or metaphysical, in agreement with or in opposition to Einstein's. On the physical side further contributions to the question of the displacements predicted in the solar spectrum are eagerly looked for, and we are glad to note that Sir Joseph Larmor had something of value to communicate to the Royal Society on this point last week. On the metaphysical side the columns of the *Times* have been opened to Mr. Frederic Harrison, reminding us of the views of Comte on the relativity of space and his opposition to the conception of an æther filling all space. At the same time Mr. Thomas Case stoutly defends the view that Newton's definitions and comments on absolute space and time are sound philosophy and firm foundations of his fame; while Prof. Wildon Carr points out that all the modern relativist arguments can be found in Descartes' "Principles." At a meeting of the Cambridge Philosophical Society on November 24 Prof. Eddington gave an exposition of Einstein's theory to a crowded and eager audience of students. In the discussion following, Prof. Hobson remarked that the abstractness of a theory of the physical universe is in no sense an objection to its validity, any theory or hypothesis being in its essence an abstract scheme built up by the mind to fit those phenomena which have been examined up to date.

THE chairman of council of the Royal Society of Arts, Sir Henry Trueman Wood, in an interesting and thoughtful address at the annual meeting on November 19, reviewed the progress which has been made in the development of our natural resources and in the application of science to industry since the foundation of the society more than a hundred and sixty years ago. He pointed to one outstanding fact, that "all our progress was accomplished by individual action, not by State organisation or control."

Latterly, of course, owing to the increase of scientific knowledge, there had been considerable modification of procedure, the introduction of new methods, and the rise of new industries. Now, partly as a result of witnessing the advantages of organisation and of State aid in relation to German industries, there is an increasing demand in this country for similar organisation and help. The State in its attitude towards invention has been, until quite recent times, merely obstructive to progress. Now there seems some risk of running to the opposite extreme. However, as remarked by Sir Henry, it appears to be "the nature of man to swing from one extreme to another like a pendulum," and we have "to remember that if the pendulum swings to and fro, making no advance, still, all the same, the clock goes steadily on." He directed attention to the work of the Department of Scientific and Industrial Research (already described in NATURE), and spoke hopefully of the work carried out under its auspices by the industrial research associations which have been established in connection with various trades. One of the most important, which seems at last to be about to start effective operations, is the Association for Cotton Research, the headquarters of which will be in Manchester.

THE council of the Royal Meteorological Society has awarded the Symons memorial gold medal for 1920 to Prof. H. H. Hildebrandsson for distinguished work in connection with meteorological science.

SIR HENRY A. MIERS, Vice-Chancellor of the Victoria University of Manchester, has been elected president of the Manchester Literary and Philosophical Society.

DR. J. E. STEAD has been nominated by the council of the Iron and Steel Institute as president for next year in succession to Mr. Eugene Schneider. The date of the annual meeting of the institute has been fixed for Thursday and Friday, May 6 and 7, 1920.

PROF. J. C. MCLENNAN, professor of physics and director of the physical laboratory in the University of Toronto, has since 1917 been lent to the Admiralty by the University, and since January last has been acting as Scientific Adviser to the Board of Admiralty. It is now announced that the Lords Commissioners of the Admiralty have received with much regret Prof. McLennan's resignation of this post.

SIR NATHANIEL DUNLOP, whose death in his ninetieth year is recorded in the *Engineer* for November 21, entered early the service of the Allan Line Co., and rose to be deputy chairman. He was also chairman of the Clyde Trust from 1905 to 1907, and received his knighthood shortly after the opening of the Rothesay Dock. Amongst his other activities he was the first chairman of the British Corporation for the Registry of Shipping, and was its honorary president until the last. He served on a number of Royal Commissions appointed to inquire into shipping questions, and was frequently a witness before other Commissions.

CAPT. P. R. LOWE has recently been appointed by the Principal Trustees of the British Museum to be assistant in charge of the bird-room at the Natural History Museum in succession to Mr. W. R. Ogilvie-Grant. Capt. Lowe has for many years devoted himself to ornithological research at the Natural History Museum, the Royal College of Surgeons, and Cambridge University, and has made extensive collections of, and observations on, birds in Madeira, the Canaries, the Azores, the Cape de Verde Islands, the West Indies, Mexico, Florida, the Mediterranean islands and coasts, South Africa, and the British Islands. He has published numerous papers on ornithology, and is the author of "Our Common Sea-Birds," "A Naturalist on Desert Islands," and of the forthcoming works "In the Track of Columbus" and "The Waders." During the war Capt. Lowe served in the R.A.M.C., and was for two and a half years in command of Princess Christian's hospital train.

WITH the object of promoting the technical and practical development of commercial aeronautics, an Institute of Aeronautical Engineers has been founded. It will be developed largely in the interests of aeroplane mechanics and pilots. Like certain existing institutes of a similar character in other branches of engineering and in chemistry, admission to the various grades of membership is to be by examination, in which piloting experience will be a qualification as well as laboratory work and knowledge of mechanical science. The work of the institute is to commence with next year, when an opening address will be delivered by Prof. Bryan, the president-elect for 1920. The secretary is Capt. Douglas Shaw, and the offices are at 32 Charing Cross, Whitehall, London.

ACCORDING to a Bulletin issued by the National Research Council of the United States, and reproduced in *Science* for October 24, the Council has decided, with the co-operation of the American Physical and Chemical Societies, to compile and issue an American Compendium of Physical and Chemical Constants. It is to be both critical and up-to-date, and to this end the universities and research laboratories of America are to be asked to supply the constants at present known. The business and industrial concerns are then to be asked what other constants are required in their work, and the joint committee charged with the issue of the Compendium will see that they are determined and included in the work. The cost is estimated at 20,000*l.*, and this will, it is expected, be obtained from private sources. We need not emphasise here the great value such a Compendium would have for scientific and industrial research in this country. Tables of constants from which untrustworthy values were excluded have been much needed in the past half-dozen years.

THE Secretary of State for the Colonies has, with the approval of the Cabinet, appointed a Committee to prepare a complete scheme of Imperial wireless communications in the light of modern wireless science and Imperial needs. The Committee will (1) consider what high-power wireless stations it is desirable on commercial or strategic grounds that the Empire should ultimately possess; (2) prepare estimates of the capital and annual costs of each station—the life of the plant and buildings, as taken for the calculation of depreciation, to include an adequate allowance for obsolescence; (3) examine the probable amount of traffic and revenue which may be expected from each station; and (4) place the stations recommended in their order of urgency. The Committee is composed as follows:—The Right Hon. Sir Henry Norman, Bart. (chairman), Mr. F. J. Brown, Rear-Admiral F. L. Field, Sir John Snell, Prof. J. E. Petavel, Dr. W. H. Eccles, Mr. J. Swinburne, and Mr. L. B. Turner. The secretary is Brig.-Gen. S. H. Wilson, and the assistant secretary Lt.-Col. C. G. Crawley. All communications in connection with the Committee should be addressed to the Secretary, 2 Whitehall Gardens, S.W.1.

THE work of the National Union of Scientific Workers is described in the first annual report of the executive for the year ending September 30, 1919. The union consists at present of 603 members distributed among a large number of local branches, and shows evidence of great activity in various directions. Among the more interesting are those concerned with the steps taken whereby the union may be registered as a trade union and secure representation on the Whitley councils set up by the Government for its own employees. The status and payment of a living economic wage to research workers have been the subject of consideration, and the union may in this direction prove a much-needed corrective to the growing exploitation of junior workers and their diminishing power to protect themselves. As a healthy revolt against a situation that has become intolerable, and in which the official spokesmen of science have taken only desultory interest, the formation and work of this union are among the most characteristic signs of the times, and its further career will be watched with keen interest. Experience from the early history of other trade and professional unions shows that it is the first step that counts, and the report seems to indicate that the initial difficulties are in course of being surmounted.

IN a recent Smithsonian publication (Smithsonian Miscellaneous Collections, vol. lxix., No. 11) Dr. Aleš Hrdlička, curator of physical anthropology in the U.S. National Museum, Washington, sums up the results of a study of historical and anthropological data relating to the population of Russia. From the point of view of an anthropologist Dr. Hrdlička concludes that, although the "Russian giant may have his Delilahs internally as well as externally," nothing can prevent the population of Russia from coming by its potential powers. He bases his forecast on the fact that there are more than 100,000,000 Russian Slavs, and that every year their birth-rate adds 1,700,000 to their total numbers. "Such a rate of increase of this strong and able portion of the white stock means a biological momentum which in the end must prevail over all opposition." Dr. Hrdlička also notes the fact that there is neither anthropological nor linguistic reasons for the separation of the Ukrainians from the other Slavs of Russia. This is only another example of the fact that claims for national recognition need have no basis in racial differentiation.

A CORRESPONDENT of the *Morning Post* (November 12–13) describes the results of a series of excavations in Mesopotamia conducted by officers of the British Museum. At the beginning of the war the work was in charge of Capt. Campbell Thompson, and it was intended that on his departure on leave he should be replaced by Prof. King, but on the lamented death of that scholar the veteran explorer, Mr. H. R. Hall, took his place. The result is that thirty-two huge cases of antiquities have safely reached England, and throw new and welcome light on Sumerian culture. The most remarkable discoveries were made at Tell Obeid, close to the Biblical Ur of the Chaldees, and include a basalt statue of a king or viceroy who lived five hundred years before Gudea, about 3000 B.C., and a wonderful copper plaque representing a lion-headed eagle, the symbol of the city of Lachish. At Maqayya or Ur a royal palace built about 2400 B.C. has been excavated, and Capt. Campbell Thompson has unearthed a remarkable series of bricks and other artefacts at Abu Shahrein, the city of the Sumerian deity En-ki, god of earth and water. With this material available English archæologists have no longer to depend on the discoveries made by American and French explorers. It may be hoped that strong pressure will be put on the Office of Works to vacate the museum galleries and permit a public exhibition of these valuable antiquities.

IN the *Kew Bulletin* (No. 8, 1919) M. N. Owen gives an account of one of the minor diseases of potato-tubers, which has never been thoroughly investigated. It is known as skin-spot, the tubers becoming dotted with small dark spots during storage. It is found to be due to a minute species of mould-fungus hitherto undescribed (*Oospora pustulans*). The author describes in detail the structure and development of the fungus as determined from artificial cultures. The disease is confined to the surface layers of the tubers, and, besides disfigurement, may cause serious injury by weakening or destruction of the eyes.

OF economic importance is a report on the paper-making qualities of Hawaiian bagasse, or sugar-cane refuse, by A. D. Little (Report of the American Station of the Hawaiian Sugar Planters' Association, Bulletin No. 40). The author discusses various previous attempts to use the waste fibre of the cane as paper-making material, the technique involved, and the commercial aspect of the question. As a result of the investigation it is his opinion that, technically, there are no difficulties which could not fairly easily be overcome, and from an economic point of view the use of bagasse might present under normal conditions an attractive commercial venture.

THE unfailing energy of Prof. Pearson's department at University College, London, has now resulted in the production of a series of tracts published by the Cambridge University Press. The objects of this new series are not only to publish new tables (as well as to republish old and inaccessible tables), but also in due course to issue works on interpolation, mechanical quadratures, calculating machines, and other matters of importance to the practical computer. The first of the series is before us, and is entitled "Tables of the Digamma and Trigamma Functions," by Eleanor Pairman. The work contains tables of the logarithmic derivate of the Gaussian Π-function and of its derivate, in addition to some useful miscellaneous information concerning these two functions. The functions are tabulated to eight places of decimals at intervals of 0·02 from 0 to 16, with tables of second differences. There seems no doubt that this series will be of extreme value to computers, and we must feel deep gratitude to Prof. Pearson for using the resources at his disposal in producing it. Finally, it should be said that the appearance of the first of the series is up to the standard which we have grown accustomed to expect from the Cambridge University Press.

IN making sulphuric acid by the "contact" process, sulphur dioxide is converted into the trioxide by catalytic oxidation and the product absorbed in water to form the acid. A short account of the very effective "Grillo" plant, erected for the purpose in this country by the Ministry of Munitions, is given by Mr. Raymond Curtis in the Journal of the Society of Chemical Industry for October 15. The catalyst employed is platinum, deposited on granules of calcined magnesium sulphate in the proportion of 0·3 per cent. The purified gases from the sulphur burners, heated to about 350° C., are passed through two converters in parallel, each containing 10,000 lb. of the platinised mass distributed on four trays. For absorbing the trioxide produced, towers packed with quartz are used, and practically perfect absorption can be obtained. The purification of the gases, which is important in preventing deterioration of the catalyst, is effected by passing the cooled vapours through coke columns and sulphuric acid drying-towers; arsenic is thus eliminated, and less than 0·02 per cent. of other impurity (water and inert dust) retained. Details of efficiency and production costs are given.

ALTHOUGH salvarsan (dihydroxydiaminoarsenobenzene dihydrochloride) has proved to be an effective remedy for syphilis, its use in medicine is open to the objection that its administration involves the use of a somewhat elaborate technique. Various attempts have been made to overcome this difficulty, the most successful of which is probably the substitution of the sodium *N*-methylenesulphinate (neo-salvarsan) for the parent compound. Medical opinion on the whole is, however, in favour of the view that salvarsan is more powerful and more certain in its action than neo-salvarsan, though the latter is not without its advocates. In continuation of work begun in 1907 by Prof. F. L. Pyman and his collaborators, Messrs. Baxter and Fargher, of the Wellcome Chemical Research Laboratories, described at the last meeting of the Chemical Society a number of arsenic compounds prepared in the hope that they would be suitable for direct intravenous injection in simple aqueous solution. These compounds are arsenobenzenes of a new type obtained by the reduction of benzodiazolearsinic acids, which in turn are produced by the action of acetic or formic acid on diaminophenylarsinic acid and its homologues. The new arsenobenzenes form dihydrochlorides which are soluble in water, but, though they exhibit a reduced acidity as compared with salvarsan, they still prove to be too acid for direct intravenous injection. These experiments are, however, of considerable interest, forming as they do the nucleus of further work on the replacement of amino-groups by heterocyclic nuclei in arsenobenzenes.

ONE of the latest of the many developments of the Mallet type of locomotive on American railways is a simple or non-compound engine for goods and banking service, built at the works of the Pennsylvania Railroad. From an article in the *Engineer* for November 7 we extract some particulars of this locomotive, which weighs 287 tons, or just above 400 tons with the tender. There are four cylinders, 30·5 in. by 32 in.; the driving-wheels are 62 in. in diameter; the boiler-pressure is 205 lb. per sq. in.; and with a maximum cut-off of 50 per cent. the maximum tractive effort is about 135,000 lb. The size of the boiler is notable; its overall length is 54 ft., including a 14·5-ft. fire-box, 11·5-ft. combustion chamber, 20-ft. barrel, and 8-ft. smoke-box. The barrel diameter is from 8·25 ft. to 9 ft. Expansion movements in the great length of the firebox and combustion chamber are provided for by a folded connection plate forming a **U**-shaped pocket. A mechanical stoker is used, and the fire-box has a shaking grate operated by power. The grate area is 112 sq. ft., the heating surface 6656 sq. ft., and the area of the superheater surface 3136 sq. ft. The short cut-off employed in the Mallet engine as a substitute for compounding has been criticised by writers, who consider that the system does not possess the advantages which it may realise when applied to the usual type of simple locomotive.

Messrs. Blackie and Son, Ltd., announce "Triumphs of Invention," C. Hall. *The Cambridge University Press* will shortly publish "The Foundations of Music," Dr. H. J. Watt. *Messrs. Hodder and Stoughton* are to publish "Aerial Transport," H. Thomas, and "Applied Aeronautics," G. P. Thomson. *Messrs. Longmans and Co.* announce a new edition of Prof. W. Watson's "A Text-book of Physics," revised by H. Moss. *Sir Isaac Pitman and Sons, Ltd.*, have nearly ready "Electric Lighting in the Home," L. Gaster and J. S. Dow, and "Compressed-Air Power," A. W. and Z. W. Daw. *The University of London Press, Ltd.*, promise "Africa and Europe" (being Book iii. of the New Regional Geographies Series). It will include the British Isles and the new boundaries resulting from the Peace Treaty. The section relating to the British Isles will also be issued separately.

IN the official announcement of the reorganisation of the Board of Agriculture and Fisheries which was published in last week's NATURE, it should have been stated that Sir A. Griffith-Boscawen has been appointed deputy chairman, and Sir A. Daniel Hall vice-chairman, of the President's Administrative Council.

OUR ASTRONOMICAL COLUMN.

THE LEONID METEORIC SHOWER.—Observations at the middle of the present month proved that a few of the meteors were visible, and that the display was prolonged beyond its usual duration. On the night of November 15, in $2\frac{3}{4}$ hours, Mr. C. P. Adamson, watching from Wimborne, Dorset, recorded eleven Leonids radiating from $151^\circ+22^\circ$. On November 19 he saw five Leonids near their radiant at $149^\circ+23^\circ$. The latter result corroborates an observation in 1876 November 19–22 at Bristol by Mr. Denning, who saw five Leonids from $149^\circ+22^\circ$. These figures would appear to prove that there is no decided motion of the radiant similar to that affecting the centre of the great Perseid stream. A brilliant meteor was seen by Mr. Adamson on November 19 last at 11h. 5m. It gave a series of flashes near the termination of its course, which was from $120^\circ+21^\circ$ to $140^\circ+16^\circ$, traversed in two seconds.

TWO STARS WITH LARGE PARALLAXES.—Prof. F. Schlesinger gives particulars in *Astr. Journ.* (No. 758) of two stars within 14′ of each other that both have large parallaxes and proper motions, and yet are apparently quite independent of each other. The brighter star is B.D.+4·123°, which was found thirty years ago to have an annual P.M. of 1·4″. The following determinations of parallax have been made:—

Name	Parallax ″	Prob. error ″
Schlesinger ...	... 0·15	0·008
Chase ...	... 0·16	0·048
Flint ...	... 0·18	0·040

The other star is of the twelfth magnitude, and was independently found by van Maanen and Wolf to have an annual P.M. of 3·0″. Its place for 1900 is R.A. 0h. 43m. 53s., N. decl. 4° 54·4′.

The following determinations of parallax have been made:—

Name	Parallax ″	Prob. error ″
Schlesinger ...	... 0·27	0·012
van Maanen	... 0·244	0·008

There would seem to be a fair presumption that the faint star is considerably nearer than the bright one, and hence that their close juxtaposition in the sky is accidental.

The second star is one of the twenty stars nearest to the solar system, and is evidently (like the Barnard and Innes stars) in the extreme dwarf stage. It would be of interest to determine its visual magnitude, which is likely to be brighter than the photographic one.

APHELIA OF PLANETS AND COMETS.—Mr. C. D. Perrine examines the grouping of these aphelia in Proc. Nat. Acad. Sci., U.S.A., September, 1919. The grouping of aphelia of the minor planets about a strongly marked maximum in longitude 195° has been pointed out before. It is shown that the aphelia of the forty-five short-period comets are grouped in the same manner. It is further remarked as a coincidence (it can scarcely be more) that the aphelia of the eight major planets are all situated in the same half of the ecliptic, their centre of mean position being in the longitude of the apex of solar motion. The aphelia of the long-period comets appear to be grouped about two maxima, the most strongly marked being near longitude 90°, the other near longitude 270°. Mr. Perrine notes that these are respectively the longitudes of the antapex and apex, and deduces a theory that the comets are captured from interstellar space. The obvious difficulty presents itself that the great majority of such objects would enter the sun's domain with independent velocities of the order of several miles per second, and their orbits would, in consequence, be strongly hyperbolic. Mr. Perrine escapes from this difficulty by suggesting that practically all these hyperbolic comets would pass too far from the sun for us to see them; we should only see those the independent velocity of which was practically zero. These last would, however, be only a very small fraction (perhaps one in ten thousand) of the comets entering the sun's domain, so the number of these would have to be immensely large to supply the number of parabolic comets that we see. The latter number is two or three a year, so the former number would need to be reckoned by millions every century.

THE BRITISH SCIENCE EXHIBITION, GLASGOW.

AN exhibition on similar lines to those of the British Science Guild's Exhibition of last summer is now being held by the Corporation of Glasgow, with the assistance of a scientific advisory committee. The Kelvin Hall, in which the exhibition is held, was erected for the purpose of holding a series of industrial exhibitions, and the Corporation has a special department for their organisation. The exhibits are housed in a single building and on one level, so that there is ample space for their display, and power is available for setting machinery in motion and allowing demonstrations of high-temperature operations. The exhibits are, therefore, seen under very favourable conditions, and the response to the invitation to exhibit has been very gratifying. Owing to an unfortunate combination of circumstances, several firms which were represented in London have been unable to appear, and the absence of some of the leading instrument firms is noticeable; but many of the London exhibits reappear, in some cases in an enlarged form, whilst there have been many additions, especially in regard to engineering and shipbuilding.

A very large area is covered, and an inspection of the exhibition convinces a visitor that the objects shown were well worth bringing together. The enormous progress made during the war and since the armistice in the manufacture of products for which we were entirely dependent on importation is evident, as is the ingenuity displayed in the design of new instruments and machines, both for warlike and for peaceful use. The relaxation of restrictions in regard to secrecy has made it possible to show many improvements which had been kept secret for military reasons, so that there is a most interesting series of instruments illustrating recent developments in wireless telegraphy and telephony, and a very extensive display of modern improvements in aircraft, as shown by the work of firms in the Clyde area.

Steam turbines and oil engines are well represented, as well as such interesting inventions in marine engineering as variable-speed gearing and hydraulic transmitters. Many systems of high-temperature welding, especially with the electric arc, are shown in operation, and examples of varied uses of this process are shown, including the junction of the vertical framing and the roof principals in a steel-frame building. The coal industry is represented by a full-sized model of a coal seam with electric coal-cutters at work, and there are also exhibits illustrating the utilisation of the iron ores and oil-fuel supplies of this country.

The chemical exhibits are, in the main, the same as those which were shown in London, whilst the metallurgical industries naturally receive special attention. The Health Department of the city shows a large and instructive collection of preparations illustrating the relation between micro-organisms and disease, as well as diagrams relating to the smoke nuisance. Several Government Departments and universities are represented by stands, at some of which demonstrations are carried on. A kinematograph hall is used for showing films of scientific interest in connection with engineering, shipbuilding, and metallurgy, as well as with bacteriology. The educational value of the exhibition is very great, and a most remarkable picture is presented of the capacity of British manufacturers to accomplish good work when advantage of scientific guidance is taken.

The opening ceremony was performed on Monday, November 17, by Sir Charles Parsons, the Lord Provost of Glasgow presiding, and testimony was then given as to the importance of science to industrial progress. The exhibition has the advantage of following closely on a most successful housing exhibition, also held by the Corporation, and visited by enormous numbers of people, so that there is every reason to expect results which will be beneficial to science and to industry alike by bringing the two into closer contact, and in educating the public as to the necessity for a close co-operation between them. The exhibition remains open until December 6.

A NEW ASTRONOMICAL MODEL.

THE illustrious scholar Gerbert (A.D. 940–1003), afterwards Pope under the name of Sylvester II., was apparently the first of the schoolmen who illustrated his theoretical lessons on astronomy by the use of globes, which he constructed with his own hands. About the year A.D. 1700 George Graham invented a machine to show the movements of the earth and planets about the sun, a copy of which was made for Charles Boyle, the Earl of Orrery. Hence the name of an apparatus very useful for illustrating lessons in astronomy, although Sir John Herschel did call orreries "very childish toys." But surely the difficulty in teaching astronomy is to make the young pupil think in three dimensions. What are we going to do when the relativists would have us imagine phenomena in four dimensions?

Some forty years ago the prospectuses of schools generally advertised among the subjects taught "the use of the globes and deportment." Presumably the orderly arrangement of the solar system was to be reflected in the conduct of the pupils. The "use of the globes" seems to have disappeared from the apparatus of pedagogy, although the teaching of geography and the elementary notions of astronomy are very much facilitated by their employment. But astronomy as a class subject of general education has unfortunately suffered a lamentable eclipse. Globes have been ousted by calorimeters. Hence the ignorance of even otherwise cultured people of the very elements of the science. Lately there have been welcome signs of a recognition of its educational value, both in the elementary and in the secondary schools. In the Middle Ages astronomy was one of the seven subjects in the curriculum of a liberal education. Those who were privileged to listen to the charming discourse of Prof. Nunn to the Association of Mathematical Masters last January were able to understand how much can be done with cardboard, cylinders, cubes, and other simple appliances to illustrate the chief motions of the heavenly bodies, the observations being made and recorded by the pupils themselves.

Very heartily then do we welcome, for both its scientific and its educational capabilities, the excellent model lately constructed by Dr. William Wilson, and exhibited to the Royal and Royal Astronomical Societies, the British Association, and most of the leading educational and astronomical societies. Everyone who has seen the model has given it unstinted praise. The mechanism is very good. Gearing is done away with, its place being ingeniously supplied by cords and pulleys, with tension regulators and adjustable driving-wheels. There is nothing much to get out of order in the machine. If it does, it can easily be repaired.

But the great value of the model is in the orderly sequence of the astronomical phenomena which can be illustrated by its aid. The pupil is made to advance gradually from the simple to the more complex movements of sun, earth, and moon, illustrating such topics as the year, month, seasons, phases of the moon, motions of the earth, and eclipses, until finally he reaches such phenomena as the retrograde motion of the moon's nodes, the forward motion of the line of apsides of the moon's orbit, and the nature, number, and character of the eclipses possible in any year. It would be a mistake to set up the whole model at once. The curiosity of the pupil should be aroused and his interest sustained by adding the parts gradually and in due order, beginning with the simpler parts, and then advancing to the more complex movements.

Dr. Wilson is to be heartily congratulated on having produced such a valuable, workable astronomical model. So many science masters—excellent omen!—have desired to acquire it that he has felt justified in putting it upon the market and getting it made in quantities. The price is 22*l.* net, carriage paid to any part of the United Kingdom. All communications regarding the model should be addressed to Dr. Wilson himself at 43 Fellows Road, London, N.W.3.

A. L. CORTIE.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

GLASGOW.—At a graduation ceremony held on November 18, honorary degrees were conferred on the American Ambassador, Lord Weir, Sir Joseph Maclay, the Duchess of Atholl, Dame Helen Gwynne-Vaughan, and others, in recognition of war service.

LEEDS.—The following honorary degrees have been conferred:—*D.Sc.:* Admiral Sir Henry Jackson, First Sea Lord, 1915–16; Surg.-Gen. Sir Alfred Keogh; Sir Almroth Wright; Prof. W. H. Bragg; and Mr. J. G. Baker.

LONDON.—The Senate has appointed Sir Cooper Perry to the post of principal officer, which has been in abeyance since Sir Henry Miers's resignation in the summer of 1915. Sir Cooper Perry has represented the faculty of medicine on the Senate from 1900 to 1905, and again from 1915 to the present time, and has been Vice-Chancellor of the University since June, 1917. He will take up his new duties on February 1 next.

The Senate has adopted a resolution expressing appreciation of the generosity of the Worshipful Company of Goldsmiths in presenting to the London Hospital Medical College 15,000*l.* National War Bonds for the endowment of a University chair of bacteriology bearing the name of the company and tenable at that college. The thanks of the Senate have also been accorded to Lord Cowdray for a donation of 10,000*l.* towards the fund for the reconstruction and re-equipment of the engineering buildings at University College, and for a promise of an additional donation of the same amount to be given when the total sum collected in response to the appeal for this purpose reaches 70,000*l.*

A bequest of approximately 3000*l.* is made in the will of the late Mr. T. S. Hughes for the encouragement by scholarships or otherwise of original medical research at the University.

In recognition of the munificent gift of 34,500*l.* by Sir Ralph Forster, Bart., to the fund for the chemistry building and equipment at University College, it has been resolved that the organic department of the chemical laboratories should be known by his name.

The degree of D.Sc. (Economics) has been conferred upon Mr. R. C. Rawlley, an internal student, of the London School of Economics, for a thesis entitled "Economics of the Silk Industry."

The Graham Legacy Committee has, under the regulations for the administration of the Charles Graham Medical Research Fund, made the first award of the gold medal to Dr. Charles Bolton in recognition of the original work in experimental pathology which he has conducted in the medical school of University College Hospital.

OXFORD.—The twenty-first Boyle lecture was delivered by Prof. A. Keith on November 19. Taking for his subject "Race and Nationality from an Anthropological Point of View," the lecturer pointed out that racial problems properly so called came into view only at the beginning of the nineteenth century. The prehistoric record might be divided into a long period of natural subsistence, marked by little change of condition, and a shorter period of conquest of Nature, which was rapid and fateful. The outfit for the first period, both bodily and mental, being in some respects unsuitable for the second, the racial problem resolved itself in effect into a conflict between inherited instinct and present conditions. Illustrations of both racial and national feeling consequent on the contact of different peoples were given from the negroes of North America, the French-Canadians in their relation to the surrounding white population, the Europeans and Maoris in New Zealand. The mingling of blood in South America appeared to have been socially less successful than the maintenance of racial frontiers in the north. Racial feeling, concluded the lecturer, is implanted by Nature for her own purposes of evolution.

DR. J. PROUDMAN has been appointed professor of applied mathematics in the University of Liverpool.

THE Toronto correspondent of the *Times* announced on November 24 that the buildings of the Laval University at Montreal have been destroyed by fire, and the damage is estimated at 400,000*l.* The chief damage was done in the medical department of the University.

SEVERAL representatives of British universities are now in Belgium as guests of the Belgian Government, in order to examine, among other matters, an arrangement for the exchange of teachers and students between British and Belgian universities.

THE under-mentioned staff appointments have been made at the Bradford Technical College:—*Head of Department of Chemistry:* Prof. R. B. Abell. *Lecturer in Chemistry:* Mr. H. P. Starck. *Head of Department of Biology:* Mr. A. Malins Smith. *Head of Department of Dyeing:* Dr. L. L. Lloyd.

ON November 22 President Poincaré inaugurated the French University of Strasbourg. Every endeavour is to be made to attract to the University English and Scottish students who before the war found their way to Bonn, Heidelberg, and Göttingen. The Paris correspondent of the *Times* says that the Germans have left behind them credits amounting to nearly 30,000,000 francs (1,200,000*l.*), which are available for the improvement of the scientific equipment of the University.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 13.—Sir J. J. Thomson, president, in the chair.—Lt.-Col. R. **McCarrison**: The genesis of œdema in beri-beri. Conclusions previously reached by physiological methods of adrenalin estimation are confirmed by chemical methods. Deficiency of certain accessory food factors gives rise to a greatly increased production of adrenalin. Whatever the function of adrenal medulla may be, excessive production of adrenalin, under conditions of "vitaminic" deficiency, is concerned with causation of œdema.—W. **Robinson**: The microscopical features of mechanical strains in timber and the bearing of these on the structure of the cell-wall in plants. The gross and microscopic characteristics of failure in compression are described for spruce, ash, and pitch pine. It is shown that failure is initiated by the development of microscopic planes of slipping in the cell-walls of the wood. The appearance of the slip planes in the cell-walls is accompanied by profound changes in the behaviour of the latter towards many stains and reagents. These changes are discussed in relation to their possible bearing on the process of lignification of cell-walls. In addition to compression, the failures in longitudinal tension and longitudinal shearing are described.—W. B. **Bottomley**: The effect of nitrogen-fixing organisms and nucleic acid derivatives on plant-growth. The products of the nitrogen-fixing organism, *Azotobacter chroococcum*, are shown to have a marked effect in increasing the rate of growth of plants of *Lemna minor* in water culture; and the derivatives of nucleic acid, which the author has found can be extracted from raw peat, are also able to act as accessory food substances. The addition of these two separate materials to the culture solution increased the number of plants from 1817 in mineral solutions only to 96,921 and 80,179 respectively in the liquids containing these substances. Not only was the rate of multiplication increased by these organic materials, but the plants supplied with them also maintained their normal size and health. The nitrogen-fixing organism, *Bacillus radicicola*, is found to have a similar effect to that of *Azotobacter chroococcum*. A similar series of experiments was carried out with the ash of the crude nucleic acid derivatives and of the Azotobacter growth, and neither of these materials had the slightest effect on the rate of multiplication or the health of the Lemna plants. It is therefore the *organic* material which is so essential for the complete metabolism of these plants, and they cannot maintain their normal growth and vigour for any length of time without the presence of small quantities of organic substances.—Agnes **Arber**: The vegetative morphology of Pistia and the Lemnaceæ. Anatomical examination of the "limb" of the leaf of *Pistia stratiotes*, L., the river lettuce, shows that, in addition to normally orientated vascular bundles, there is a series of inverted bundles towards the upper surface. This fact is regarded as indicating that the leaf is of the nature of a petiolar phyllode. This interpretation is extended to the distal part of the frond of the Lemnaceæ (duckweeds).—W. J. **Young**, A. **Breinl**, J. J. **Harris**, and W. A. **Osborne**: Effects of exercise and humid heat upon the pulse rate, blood pressure, body temperature, and blood concentration. The results point to the fact that both exercise and humid heat play a part in producing a rise in blood pressure, pulse rate, and rectal temperature. The degree of rise, however, is controlled by atmospheric conditions, which influence the rate of cooling of the body.

Zoological Society, November 4.—Dr. A. Smith Woodward, vice-president, in the chair.—F. Martin **Duncan**: Photographs showing the actinic quality of the light from a living Pyrophorus beetle. In describing the method employed to obtain the records, the author stated that photospectroscopically the greatest intensity of light action appeared to be in the yellow-green region.—E. **Heron-Allen**: Skiagraphs of the foraminiferan genus Verneuilina from examples grown in a hypertonic tank.—Miss Joan B. **Proctor**: The variation in the number of dorsal scale-rows in our British snakes.—Dr. G. A. **Boulenger**: Some new fishes from near the west coast of Lake Tanganyika.—Dr. G. **Marshall**: The species of the Balaninus occurring in Borneo (Coleoptera, Curculionidæ).—The Hon. P. **Methuen**: Description of a new snake from the Transvaal, together with a new diagnosis and key of the genus Xenocalamus, and of some Batrachia from Madagascar.—Prof. J. P. **Hill**: The placentation of Tarsius.—R. I. **Pocock**: The external characters of Tarsius.

Geological Society, November 5.—Mr. G. W. Lamplugh, president, in the chair.—H. H. **Thomas**: Some features in the topography and geological history of Palestine. A perfectly new method of illustrating and investigating some branches of physical geology is afforded by aeroplane photography. It seems, first, to illustrate in a very striking and convincing form many geological phenomena, such as the structure of a volcano or the land-forms resulting from erosion, and may be of value in the teaching of the science. In the second place it may, in certain circumstances, become a valuable means of research, especially in connection with river development or denudation in a region which is somewhat inaccessible, or where the surface of the ground is very complicated and the main features are obscured by a mass of less important detail. The lecture dealt principally with the illustration of the physical features of Palestine, and owes its origin to the systematic photo survey made over Central Palestine during the war. The lacustrine deposits of the Jordan Valley and their weathering were shown, and also the form of the drainage channels running down into the main valley. The depression of the Dead Sea with reference to the surrounding country has resulted in cañon formation in many places. Some evidences of faulting at different periods can be distinguished. The Jordan at present forms an interesting study in river development, and many of its main features were demonstrated. The relation of the Jordan to the Orontes has been considered, and an aeroplane photographic survey of the country between the two rivers indicates that the Jordan probably originated in northern Syria in earlier times. The Syrian portion of the stream has been captured by the younger Orontes, and this has had a very important effect on the whole topography of the Jordan Valley.

Linnean Society, November 6.—Dr. A. Smith Woodward, president, in the chair.—Col. H. E. **Rawson**: Plant-sports produced at will. The author had observed near Cape Town that shrubs of Kei-apple (*Aberia caffra*) died when they were deprived of the full sun up to a certain altitude in the early morning. This led to experiments in screening plants about this hour for various periods. "Selective screening" resulted in various sports in form and modifications of colour in *Tropaeolum majus*. A special form of *Papaver rhoeas* was obtained and fixed, and other experiments were detailed. The author sums up thus:—The intensity of the light regulates and modifies the coloured bands upon all parts of the plant which have been excited by interference. In Nature selective screening prevails universally, and these experiments suggest that it is deserving of study to bring out its latent potentialities.—L. **Hogben**: Nuclear phenomena in the oocytes of Neuroterus, a gall-fly. The atypical separation of polar bodies in the Hymenoptera parasitica is a consequence of the interruption of the first polar metaphase which appears precociously before the egg is laid. There is no evidence for "amitosis" in the germ-cells of Hymenoptera.—L. V. **Lester-Garland**: A revision of the genus Baphia, Afzel. The author had studied the rich material in the herbaria of the British Museum and at Kew, the number of known species having increased from six (Bentham and Hooker fil. in 1865) to sixty in the present enumeration. The genus is practically confined to tropical Africa, one outlier reaching as far south as Natal, and another as far east as Borneo.

Royal Meteorological Society, November 7.—Sir Napier Shaw, president, in the chair.—Prof. Vilhelm **Bjerknes**: The structure of the atmosphere when rain is falling. Though a comprehensive mathematical analysis of atmospheric movements might be slow in yielding a general solution of the problem of weather forecasting, yet results of practical value were likely to be obtained during the course of the analysis. Such results had been applied to the forecasting of rain in Norway with a fair measure of success. The basis of the method consisted in drawing "lines of flow" of the air and noting where these showed regions of convergence or divergence. Such lines of flow indicated two lines of convergence in a typical depression: (1) where a warm south-westerly wind blows almost normally against the flank of a relatively cold south-easterly current (the warm air rising over the cold here leads to steady rain over a belt some hundreds of kilometres in breadth); and (2) where the cold south-easterly current, curving round the north side of the centre of depression, cuts under the warm south-westerly wind. This causes a region of squally and showery weather along a second narrower belt. Another important application of the lines of flow lies in the forecasting of thunderstorms. Experience showed that in quiet weather in Norway under the system of diurnal breezes certain points regularly become centres of convergence, and it was at these points that thunderstorms first developed, spreading later to surrounding regions.

Royal Anthropological Institute, November 11.—Sir Everard im Thurn, president, in the chair.—S. H. **Warren**: A stone-axe factory at Graig-lwyd, Penmaenmawr. Stone axes of Neolithic types were extensively manufactured out of the fine-grained (andesitic) margin of the Penmaenmawr intrusion of igneous rock. Blocks of scree, many of them of large size, which fell from the crags were gradually flaked down in successive stages until a satisfactory stone-axe blade, ready for polishing, was obtained. There are examples showing every stage of the process, arrested unfinished through accidental breakage, or because the shape being produced was unsatisfactory. Under the last heading it was excessive thickness of the blade which was the greatest source of trouble. Many of the unfinished "wasters" are broken in half, producing the segmental form to variations of which the unfortunate names of "tea-cosy" and "toe-cap" have been applied. Among the waste of the axe-making industry, which is found in great profusion on the mountain-side, the resemblances to Mousterian flake industries are very striking. Equally instructive parallels are to be observed among the "wasters" with characteristic examples of the earlier Palæolithic industries, notably with the earliest of all, or the pre-Chelles. Axes made of the Graig-lwyd rock are being identified from other localities, and further research along these lines is expected to give interesting results.

MANCHESTER.

Literary and Philosophical Society (Chemical Section), October 24.—Sir Henry A. Miers in the chair.—Sir William J. **Pope**: The photography of coloured objects. Previous to the war all the various methods of colour photography—the first of which was devised by Prof. Joly, of Dublin—the modern processes of photographic colour-printing, and the present-day panchromatic photographic methods for obtaining a correct rendering in monochrome of parti-coloured objects, were based upon the success which has been attained in imparting sensitiveness throughout the visual spectrum to the ordinary blue-sensitive photographic plate. By staining the plate with erythrosine it becomes sensitive to green and orange; plates so treated are termed orthochromatic. A number of dyestuffs belonging to the class of cyanine dyes discovered by Greville Williams in 1856 are capable, however, of sensitising a photographic plate throughout the whole range of the visible spectrum. Experimental investigation of sensitising dyestuffs was instituted in the chemical laboratories of the University of Cambridge by Dr. W. H. Mills and Sir William J. Pope at the end of 1914. Methods for producing the ordinary sensitising dyestuffs on a technical scale were devised, and all the sensitisers used by the Allies have been prepared in the Cambridge laboratories since the German importation ceased. The best panchromatic plate made in pre-war days possessed about one-third the sensitiveness to red as to blue light. At the present time a very rapid panchromatic plate is on the market which is much faster to red than to blue light; the rapidity of the plate to red light has been thus increased about fourfold.

DUBLIN.

Royal Irish Academy, November 11.—Prof. G. H. Carpenter in the chair.—Mrs. Lilian **Porter**: Floral development in *Tricuspidaria lanceolata*. Both pentamerous and hexamerous flowers occur. The calyx is quincuncial or irregularly imbricated; the corolla is usually induplicate-valvate, but shows a tendency to contortion; the stamens arise on an enlargement of the receptacle in groups of three alternating with the petals; one stamen is terminal and two are lateral, as in early stages of Tilia, thus emphasising the relationship between Elæocarpaceæ and Tiliaceæ.

PARIS.

Academy of Sciences, November 3.—M. Léon Guignard in the chair.—H. **Deslandres**: Remarks on the constitution of the atom and the properties of band spectra. The concluding paper of four communications on the same subject. A model atom is proposed, the vibrations of which would fall in with the observed regularities in band spectra.—P. **Termier** and G. **Friedel**: The structure of the coal basin of Gard.—P. **Sabatier** and A. **Mailhe**: The catalytic reduction of the halogen acetic esters. At 300° C. ethyl chloroacetate can be reduced by hydrogen in presence of nickel to ethyl acetate, some aldehyde and ethylene being formed by secondary reactions. Under similar conditions ethyl dichloroacetate can be reduced to the monochloroacetate, and ultimately to ethyl acetate. The reaction can also be applied to ethyl trichloroacetate and ethyl bromoacetate.—G. **Bouligand**: Limited and harmonic functions in an infinite domain, zero on the frontier.—S. **Stoïlow**: A classification of ensembles of zero measure.—E. **Kogbetliantz**: The unicity of ultra-spherical developments.—N. E. **Nörlund**: The calculus of finite differences.—T. **Carleman**: Integral equations.—C. **Frémont**: A new method for testing the fragility of metallic tubes. Two new methods of testing notched tubes by shock are detailed.—M. **Amans**: Thrust and power of rotating blades unequally bent.—G. **Fayet** and A. **Schaumasse**: Return of the periodic comet 1911 VII. (Schaumasse). This comet came under the influence of Jupiter, and its elements were, in consequence, considerably modified, and, although the perturbations have been calculated, the exact position of the comet was a matter of uncertainty. After some months' searching a feeble comet (magnitude 12·5) was discovered on October 29, which is very probably the 1911 VII. comet advanced eighteen days. The positions on October 29 and 30 are given, together with the positions of the comparison stars.—G. **Sagnac**: Comparison of experiment with the mechanical theory of the undulatory æther.—G. **Bruhat**: Separators of radiations: application to spectro-polarimetry.—MM. **Ledoux-Lebard** and **Dauvillier**: The fundamental constants of the spectrometry of the X-rays. Different values for the reticular distance d_p for calcite vary between 3·0279 and 3·04 (in 10^{-8} cm.). The results of Bragg, Webster, Compton, Uhler, and Cooksey and Siegbahn are reviewed and in part recalculated, and give $3{\cdot}0346{,}10^{-8}$ cm. as the most probable figure.—P. **Loisel**: The radio-activity of the water from the large spring at Bagnoles-de-l'Orne and its variations. The amount of radium present in this water varies between 22 and $109{,}10^{-12}$ g. per litre, with a mean of 68. The cause of the variation is unknown.—J. A. **Muller**: Remarks on chemical decompositions, simultaneous or successive, provoked by physical agents.—J. **Guyot** and J. J. **Simon**: The action of sulphuric anhydride and of oleum on methyl alcohol. The preparation of dimethyl sulphate. The action of 60 per cent. fuming sulphuric acid upon pure methyl alcohol in the proportions indicated in the paper gives a yield of more than 90 per cent. of methyl sulphate.—E. **Léger**: δ-cinchonine and its isomers: its relations with niquine.—M. **Stuart-Menteath**: Some points on the geology of the Pyrenees.—J. **de Lapparent**: Devonian rocks containing radiolaria in the valley of Bruche (Alsatian Vosges).—P. **Mazé**, M. **Vila**, and M. **Lemoigne**: The action of cyanamide and dicyanodiamide on the development of maize. Cyanamide (0·162 gram per litre), with or without nitrate, kills the seedling. Dicyanodiamide at the same concentration does not kill the plant, and in presence of nitrate is not toxic. Neither acts as a plant-food.—M. **Ringelmann**: Researches on the resistance to wear of parts of agricultural machines.—J. **Pellegrin**: The fresh-water fishes of Morocco.—J. **Legendre**: The food of *Eleotris Legendrei*. This fish is strictly carnivorous, and during the winter eats its own species.—V. **Galippe**: Micro-organisms living in paper: their resistance to the action of heat and of time. Living organisms were obtained from filter-paper which had been sterilised in an autoclave at 120° C. Living organisms were also obtained from paper of various ages, the oldest being a papyrus dating from about 200 B.C.—F. **d'Hérelle**: An epidemic of bird-typhus.

MELBOURNE.

Royal Society of Victoria, October 9.—Mr. J. A. Kershaw, president, in the chair.—F. **Chapman**: Notes on a collection of Tertiary fossils from the Ooldea Soak, South Australia. The author identifies two sets of fossils, the older series being Miocene (Janjukian), and the younger a raised beach deposit of older Pleistocene age. The most remarkable of the Miocene fossils is *Orbicella* (*Heliastraea*) *tasmaniensis*, which hitherto has been confined to the Miocene of Tasmania. This appears to indicate the former existence of land across the Great Bight connecting a lost remnant of the former southerly extension of the Australian continent. The later, Pleistocene, deposits at Ooldea contain the foraminifer Orbitolites, now extinct in these latitudes. The Miocene determinations in this area confirm Prof. J. W. Gregory's and Mr. J. T. Jutson's views of the age of similar limestones in Western Australia.—A. J. **Ewart** and J. R. **Tovey**: Contributions to the flora of Australia, No. 28. Two new species are described, *Casuarina Helmsi* and *Plagianthus monoica*, and the appearance of a number of new naturalised aliens, of which one, *Lolium subulatum*, has proved a useful grass in dry districts. An observation is recorded on a Moreton Bay fig, a large tree of which was ringed at the outbreak of the great war, but did not die until the declaration of peace. The death of the tree was due to the starvation of the roots, and as the young wood was removed the older wood retained the power of conducting water indefinitely. Data are also given in regard to the growth-expansion of an elm which appear to throw doubt upon Trowbridge and Weil's conclusion that frost cracks are formed, not by the expansion of frozen water, but by the contraction of the wood of the tree.

SYDNEY.

Royal Society of New South Wales, October 1.—Prof. C. E. Fawsitt, president, in the chair.—G. J. **Burrows**: The hydrolysis of urea hydrochloride.—Prof. O. U. **Vonwiller**: Notes on the elastic properties of selenium. Selenium in the vitreous form shows viscosity effects like those of pitch. When distorting forces are applied, in addition to the immediate elastic strain, disappearing with removal of the forces, there is a continuous yielding, the distortion increasing so long as the forces are applied. The rate of movement is much greater when the substance is illuminated than when it is in darkness. This effect of light has not hitherto been recorded. Selenium in the crystalline form shows the viscosity effect, but it is very much less than with the vitreous modification.

THE NURTURE OF KEY INDUSTRIES.

THE Bill "to constitute a Trade Regulation Committee, to regulate the importation of goods with a view to prevent dumping, safeguarding key industries and industries affected by the depreciation of a foreign currency," which Sir Auckland Geddes introduced in the House of Commons on November 19, will no doubt meet with strenuous opposition. It is, of course, anathema to the out-and-out Free Trader, and will be viewed with some doubt and suspicion even by those who, while not hide-bound by fiscal shibboleths, are yet distrustful of the bureaucratic control which the Bill would seem to entail. The terms of the amendment for its rejection on second reading, tabled by Mr. Wallace, one of the Coalition Liberals, are obviously drafted so as to secure the support, not only of the convinced Free Trader, but also, if possible, of those who object to all departmental control of our commercial relations.

As regards the Bourbons of the Manchester school, who learn nothing and forget nothing, Mr. Wallace is preaching to the converted; probably no argument will have the slightest effect upon them. They will find nothing in the changed conditions of the world, in the circumstances of the Empire, or in the influence of the war on our home industries to induce them to modify their convictions in the smallest degree. To them the basic principle of Free Trade has something of the sanctity of Holy Writ. It has all the force of a natural law as fixed and immutable as seemed to them the law of gravitation. But they may be reminded, as recent events have shown, that even the law of gravitation may possibly have a less stringent universality than we have hitherto been content to assume. How much more probable is it, therefore, that a so-called economic law depending upon fallible and transitory human conditions may be at least equally invalid and fundamentally more unsound.

The argument against bureaucratic control will no doubt appeal to a considerable body of public opinion. The Legislature, under the direction of the Government, has of late been steadily riveting the chains of this control in a variety of directions, and there is a growing impatience with the policy. It is a sort of aftermath of the war which the country will not tolerate to an indefinite extent. During the continuance of the war, when the free play of individualism might conceivably interfere with a united national effort, guidance and control by a Government which we had entrusted with the safeguarding and direction of our destiny were not only accepted, but also generally recognised as imperatively necessary. But under normal conditions the continuance and possible perpetuation of bureaucratic control is wholly opposed to the genius of the English people, as past experience has abundantly proved, and is certain to be fiercely resented sooner or later.

It may be argued, of course, that the times are not yet normal, and no doubt this consideration will appeal to many who would otherwise be disposed to reject the Bill *sans cérémonie.* The allegation that it is bound to impose an intolerable burden upon manufacturers, traders, and consumers, and that it is calculated to maintain high prices and arrest our rapid industrial recovery and development, of course, begs the question. It is at least arguable that the provisions in the Bill against dumping and for the safeguarding—we purposely omit the word "protecting," as a term of offence to some people—of key industries are really calculated to assist our industrial development, even although they may tend for a time to maintain high prices. Excessive cheapness has not hitherto proved the panacea for all human ills which some, in the past, would appear to have claimed for it.

Although the House of Commons is invited by the amendment to reject the Bill, it will be observed that in the Trade Regulation Committee which it is proposed to set up, and which is to be responsible for the working of the measure, the majority is to consist of members of that House nominated by the House itself. The measure, therefore, is not, strictly speaking, bureaucratic in the sense in which this term is usually understood. It is presumably intended that the representatives of the people, being in the majority, should exercise an effective control of its operations. It rests with the House of Commons to nominate persons of knowledge and experience in commercial and industrial matters, who would keep themselves in touch with the views of the trade organisations in the country, and who may be trusted to check any undue departmental interference or restriction, and to expedite, when necessary, departmental activity. Is the House so distrustful of its power, or of the ability of its members to cope with the permanent departmental officials, that it is to be asked to reject the measure on the ground that it is too "bureaucratic"?

There is much in the Bill of a highly technical character, and even experts are certain to differ as to the true meaning and effect of some of its provisions. Many of its terms are capable of various interpretations, and cases are certain to arise the equitable solution of which will tax the judgment and wisdom of the Committee. But the general sense of the House will, it is to be hoped, perceive that the measure is based upon the requirements and necessities of the times. This consideration ought surely to mitigate the factious opposition with which it is threatened.

No doubt the Bill will be modified in its passage through Parliament. It is certainly capable of amendment in some details. But it is to be hoped that the Government will stand firm in its effort to safeguard the key industries. The list of these named in the Second Schedule is considerably shorter than that drawn up by manufacturers' associations, and much of it is too technical to be within the comprehension of the average member of Parliament, who has little or no knowledge of science. It may be that the events of the last four or five years have made him acquainted with a certain amount of chemical terminology, but the list of articles enumerated in the first two sections of the Schedule dealing with synthetic colouring matters, drugs, "intermediates," and "fine chemicals," is sufficiently deterrent to the lay mind, and scarcely lends itself to effective party debate. It is to be regretted that at the present juncture no acknowledged representative of chemical science is a member of the House—no one of the authority and knowledge, perspicacity and breadth of view, for example, of the late Lord Playfair or of the late Sir Henry Roscoe. It is certain that, whatever might have been the views of these distinguished men concerning the fiscal policy of the Bill, they would be in hearty sympathy with the effort to resuscitate and strengthen an industry which had its rise in this country, and in all probability would never have sunk into partial insignificance had Parliament dealt earlier with the admitted deficiencies in our system of national education.

The Schedule may be said to have its origin in the war, and to embody some of its lessons. It is the direct result of the painful experience of our shortcomings as revealed to us on its outbreak. Some of the industries with which it is concerned are at present not much beyond their initiatory stage, but, as has been proved, they are all more or less necessary to our national welfare, and in the light of our recent experience it would be the height of unwisdom not to do everything in our power to place them on a permanent and independent basis. We are at the parting of the ways, and on the House of Commons rests the serious responsibility of choosing the right path. To neglect the present opportunity, or to be blind to its significance, would be an irreparable disaster.

THE DRAGON OF MYTHOLOGY.

The Evolution of the Dragon. By Prof. G. Elliot Smith. Pp. xx+234. (Manchester: At the University Press; London: Longmans, Green and Co., 1919.) Price 10s. 6d. net.

THE dragon may be regarded as the most venerable symbol employed in ornamental art, and it has been the inspiration of much of the world's great literature in every age and clime. The dragon-myth also represents the earliest doctrine or systematic theory of astronomy and meteorology. The study of dragon-lore thus leads us back to some of the most primitive workings of the human mind, and embraces many subjects which at first sight seem to have little connection with the end in view. Prof. Elliot Smith's work on the evolution of the dragon, indeed, alludes to almost every aspect of primitive thought and myth, and the author discusses questions which vary from the origin of embalming to the worship of the cow, the elixir of life, the swastika, and the reasons for wearing clothes. His volume consists of notes of three lectures delivered in the John Rylands Library, Manchester, illustrated by beautiful reproductions of an appropriate series of drawings. The chapters are entitled respectively Incense and Libations, Dragons and Rain Gods, and The Birth of Aphrodite.

Prof. Elliot Smith maintains that the dragon was originally a beneficent creature, the personification of water. The fundamental element in the dragon's powers was the control of water, whether rivers or seas, pools or wells, or clouds on the tops of mountains. The substratum of its anatomy usually consists of a serpent or a crocodile, with the scales of a fish for covering, the feet and wings (sometimes also the head) of an eagle or hawk, and the fore-limbs (sometimes also the head) of a lion. All the parts are symbols of the various attributes and uses of water in Nature. With various slight additions and modifications, this composite wonder-beast ranges from western Europe to the far east of Asia, and thence across the Pacific to America. It must, indeed, have had a common origin, and Prof. Elliot Smith particularly emphasises the interest of the American version, which he regards as having gradually evolved from several successive importations of ideas from the Old World. He remarks that "one and the same fundamental idea, such as the attributes of the serpent as a water-god, reached America in an infinite variety of guises, Egyptian, Babylonian, Indian, Indonesian, Chinese, and Japanese; and from this amazing jumble of confusion the local priesthood of Central America built up a system of beliefs which is distinctively American, though most of the ingredients and the principles of synthetic composition were borrowed from the Old World."

The lecture notes are unfortunately somewhat scrappy, and Prof. Elliot Smith apologises for the circumstances which led both to this defect and to the not infrequent repetitions. The book also lacks an index, which would add much to its usefulness. It is, however, a veritable mine of information on the subjects with which it deals, with numerous references to literature, and science is indebted to the John Rylands Library for undertaking the publication.

EUGENICS.

(1) *Lectures on Sex and Heredity delivered in Glasgow*, 1917–18. By F. O. Bower, J. Graham Kerr, and W. E. Agar. Pp. vi+119. (London: Macmillan and Co., Ltd., 1919.) Price 5*s*. net.

(2) *Eugenics and Environment.* By Prof. C. Lloyd Morgan. Pp. 82. (London: John Bale, Sons, and Danielsson, Ltd., 1919.) Price 2*s*. net.

(3) *La Sélection Humaine.* By Prof. Charles Richet. (Bibliothèque Scientifique Internationale.) Pp. iii+262. (Paris: Librairie Félix Alcan, 1919.) Price 6.60 francs.

THESE three books illustrate three somewhat different methods of setting the problem of eugenics before the general reader. The aim of the excellent little book by Prof. Bower, Prof. Graham Kerr, and Dr. Agar is to set forth the indispensable facts and principles, and leave the reader to draw the moral. It is not perhaps intended to deal with eugenics at all, but it is one which enthusiasts for eugenic propaganda will find very valuable. It consists of six lectures on the more elementary facts of sex, reproduction, and heredity in plants and animals. The first four lectures, two on plants and two on animals, deal with the subject in the two kingdoms in similar fashion, beginning with examples of reproduction and conjugation (syngamy) in the Protista, and passing through the simpler Metaphyta and Metazoa to the more complex phenomena of the highest plants and animals. No one who has a natural interest in living things, but has had no systematic training in biology, can fail to find these lectures interesting; those on plants are perhaps unnecessarily technical here and there, but with the assistance of the excellent illustrations any reasonably educated person should find them easy and interesting to read.

In the last two lectures Dr. Agar takes up the subject of heredity, begins with the phenomena of fertilisation, cleavage, and the early segregation of the germ-cells in Cyclops as an introduction to the conceptions of soma and germ-plasm and the material basis of inheritance, and then proceeds to give a short but lucid account of Mendel's law. In the last lecture he takes up heredity in Man. He points out that, since the characters in Man which are known to follow Mendel's law are comparatively few, and in general of small practical importance, human heredity must be studied in practice chiefly by the statistical methods of the biometric school. Of these he gives a lucid elementary description, illustrated by actual examples taken from the papers of Pearson, Heron, Schuster, and others, and shortly points out the bearing of the facts on eugenic proposals.

(2) Prof. Lloyd Morgan's little book is frankly an elementary text-book of eugenics. It deals with variation in human characters as illustrated by the normal curve of error, the principles of correlation, and the method of finding the correlation coefficient, very shortly with Mendelian heredity, and finally with acquired characters, selection, and the relation of biological characters to social tradition and civilisation. It is written in a pleasant and almost colloquial style, but suffers not infrequently from a certain obscurity of diction—*e.g.* in describing a correlation table (p. 33): "Along the left-hand vertical side the stature of the sons is given *in ascending order read downwards*" (our italics). Again, on p. 32 a misleading definition of perfect correlation is given, which is corrected at the bottom of the same page, a treatment which does not conduce to clearness. On p. 47 there is, doubtless by a slip, the misleading statement: "If blue eyes mate with brown eyes, one child in four may be blue-eyed." We feel also that the booklet suffers from being illustrated by purely imaginary examples the simplicity of which may give a false impression. Dr. Agar's account of biometric methods compares favourably with it in this respect. Nevertheless, it is in most respects an admirable elementary introduction to the subject, such as might well be used by those who wish to follow it up more fully by further reading.

(3) Prof. Richet's book has more of the character of an essay. It does not profess to set forth specific facts, but takes the facts for granted, and discusses the conclusions to be drawn from them. The main thesis of the author is that if selection can do such great things with domestic animals and plants, it could, if applied, do equally great things with man, and that the only hope for mankind in the future is in its application. The aim of life is happiness; progress is the increase of total happiness; this can be gained through science alone; it is limited only by the limits of the human mind, and these limits might be almost indefinitely extended by suitable selection. Selection must be of several kinds. In the first place, the white race is indisputably superior, and crossing with black or yellow gives bad results. All race-crosses must therefore be prohibited. Within the white race all defectives must be prevented from reproducing; seriously defective infants must not be allowed to live, and those found defective in later life must be segregated. Finally, positive encouragement must be given to marriage of the superior, especially between those superior in the same respect. The author's enthusiasm leads him at times to rather wild statements. He calls deaf-mutes (*sourds-muets*) "ces ébauches d'humanité, ces produits disgraciés . . . ces pauvres avortons," words which can only dis-

gust those who know the brilliant gifts of some who are thus afflicted. He states categorically that the mental improvement due to education is transmitted to offspring, and recommends late marriage of the highly educated in order that the effects of education may be more fully handed on. And neither Prof. Richet nor Prof. Lloyd Morgan seems to realise the extreme difficulty of eliminating an undesirable character if it is recessive in inheritance. In a stable population, if 1 per cent. show a recessive character, 18 per cent. will bear this character concealed by the corresponding dominant, and by preventing the reproduction of the 1 per cent. in which the recessive is homozygous, only very slow progress will be made in eliminating it. Prof. Richet is an enthusiast for eugenics, and has written an entertaining book, but one which is scarcely sufficiently abreast of modern work on heredity.

L. D.

OUR BOOKSHELF.

Essays in Common-sense Philosophy. By C. E. M. Joad. Pp. 252. (London: The Swarthmore Press, Ltd., 1919.) Price 8*s.* 6*d.* net.

If any man of science, perplexed at the disturbing challenge which philosophy throws down to the assumptions as to plain matter of fact on which science rests, wants comfort and support for his intellectual framework from within philosophy itself, he will find and certainly enjoy it in the delightfully clear essays of Mr. Joad. It is a somewhat unusual thing for a young writer to make his *début* in philosophy by rejecting every temptation to paradox and any attempt to startle the "plain man," and setting himself the apparently easy but really very difficult task of convincing the "plain man" that his views about the universe are not likely to be very far removed from truth. Yet this is what Mr. Joad sets out to do.

Mr. Joad is not a very trustworthy guide when he discusses famous philosophical theories. He adopts too easy a classification, with the consequence that we find ourselves in strange company. All philosophers, past and present, are in his view representationists, solipsists, or realists. But this does not in the least spoil our enjoyment of the concise and easy way in which the writer finds himself at home in philosophy, of the keenness of his wit, and of the dexterity of his cut and thrust. There is only one of us who comes in for unstinted praise—Prof. Dawes Hicks—and we believe he does not recognise his theory in Mr. Joad's exposition. The rest of us—Bergsonians, pragmatists, absolutists—are all alike well trounced.

There is one thing in Mr. Joad's own view, however, which is very puzzling, not to say disconcerting. He tells us that sensible objects exist "very much" as we know them. But why not altogether so? If there is any difference at all, why is he so confident it can only be a very little one?

H. W. C.

Modern Engineering Workshop Practice: A Text-book for the Use of Engineering Students, Apprentices, and Engineers engaged in Practical Work. By Herbert Thompson. (Griffin's Scientific Text-books.) Pp. xi+328. (London: Charles Griffin and Co., Ltd., 1919.) Price 9*s.* net.

This book is an attempt to give a fairly comprehensive view of modern engineering workshop practice, and includes sections dealing with general methods and machines, and others dealing with special processes and machines, such as turret lathes, spiral milling, grinding, hardening, tempering, annealing, autogenous and thermit welding, and soldering and brazing. The author is quite at home in these branches. The descriptions are clear, and whilst many of the illustrations are half-tone reproductions of photographs of machines and appliances, there is a sufficient number of line drawings to enable the reader to understand the construction. The author is not so happy in chap. i., which deals with materials. Thus, on p. 3 we read, under the paragraph heading "Malleable-iron Castings": "If an iron casting, made out of the right kind of pig iron, be heated to a red heat in an iron box surrounded by some carbonaceous material for from 12 to 24 hours, the surface of the material becomes converted into a form of steel. The casting then has lost its extreme brittleness, and becomes more or less malleable. The castings are generally embedded in red hæmatite." In view of this statement, it is of interest to note that later on (p. 229), in dealing with case-hardening, the author shows that his knowledge is sound, as regards both the process and the changes which take place during the progress of case-hardening. Despite blemishes of this kind, the young engineering student will find much that is instructive and of interest in the book.

Science and War: The Rede Lecture, 1919. By the Rt. Hon. Lord Moulton. Pp. 59. (Cambridge: At the University Press, 1919.) Price 2*s.* 6*d.* net.

Lord Moulton's lecture gives a striking picture of the manner in which the methods of warfare have been transformed by the application to military purposes of the results of the rapid growth of chemical and physical knowledge and the advances in engineering and medical science during the last half-century. Not unnaturally, a considerable part of the discourse is devoted to the subject of explosives, on which the lecturer can speak with special authority, and the warning which he gives as to the importance of establishing the manufacture of nitric acid from atmospheric nitrogen in this country is one that deserves serious attention. Lord Moulton's final conclusion is that man, "endowed with all the powers that science has given him, will be self-destructive unless his social instincts . . . become sufficiently strong to induce him voluntarily to submit to those powers being fettered." "It is easy to criticise the League of Nations, but let us never forget that some combined action of that type is necessary."

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Progress of the Natural History Museum.

THE admirable survey of scientific progress published in the jubilee number of NATURE on November 6 has received the most cordial appreciation of your numerous readers. May I be allowed to direct attention to one or two omissions, without being supposed to dissociate myself from the universal chorus of approval?

The removal of the natural history collections of the British Museum from Bloomsbury and the increase in their importance afterwards are events which deserve notice, even though the South Kensington branch of the museum was perhaps omitted from your survey on the ground that it was a new home for existing collections, and not an institution which originated during the period under review. The actual removal took place in 1882–83, and the years which have followed have been marked by an extraordinary growth in the collections, associated with a record of scientific research which is equally remarkable. It must not be forgotten that the accurate discrimination of the species of animals, plants, and minerals is a fundamental part of the respective sciences. Even though the philosophical biologist is sometimes inclined to underrate the work of the systematist, he is frequently obliged to turn to him for information with regard to the facts from which he derives his results. The far-reaching conclusions which are based on the study of geographical distribution lose their value if they depend on erroneous determinations of species, while the study of evolution is equally dependent on the labours of the systematist. In bringing together an unrivalled collection of specimens and in publishing a notable series of memoirs dealing with it, the naturalists of the British Museum have taken their full share in the scientific progress of the last fifty years.

The number of specimens in the department of zoology (including entomology), omitting those regarded as duplicates, has been estimated as having been about 1,400,000 at the time of the removal to South Kensington in 1882–83. Successive estimates have been 2,245,000 in 1895, 3,060,000 in 1904, 5,960,000 in 1917, and about 6,000,000 at the time of writing. The other departments of the museum have also increased at a rapid rate. Thousands of forms new to science have been described, and the type-specimens are preserved in the collection. In spite of the magnitude of the task, the specimens have been arranged so carefully that most of them can be found without difficulty when they are required for study.

In addition to this side of its activities, the museum has done much for scientific education by the way in which a part of its treasures have been exhibited in the public galleries. The requirements of visitors who are principally interested in the systematic arrangement of natural history objects are amply provided for; and, to take a single instance, the exhibited series of large mammals is not equalled in any other museum. Other exhibits of a more general nature are shown in the central hall, where may be seen illustrations of the principal types of structure found in the several classes of vertebrates, inaugurated by the late Sir W. H. Flower, a former Director; a series of cases containing objects bearing on the theory of evolution; models and specimens of insects and Arachnids instrumental in carrying diseases; and other exhibits of general interest. The evolution of animals, as illustrated by their geological history, can be studied in the palæontological galleries, and particular attention may be directed to the series of elephants and their presumed ancestors to be found among the treasures of the gallery of fossil mammals. The series of nesting-birds and eggs, arranged on a system which was itself a new departure, deserves special mention. Attention may also be directed to the great development of the collection of domesticated animals, and to the wonderful series of specimens in the mineral gallery.

In noting the progress of the Natural History Museum it is appropriate to refer to the fundamental alteration which has taken place during the last fifty years in the conception of the functions of museums in general. It is now admitted that the museum is a place which ought to exercise an educational influence, and there is an increasing desire to arrange the exhibits in such a way as to teach some definite lesson. It has, moreover, been recognised that the biological sciences are of great economic importance, as is shown, for instance, by the extraordinary advances which have been made in preventive medicine by the discovery that the parasitic organisms giving rise to certain diseases are transmitted by blood-sucking animals. In this field of research the work of the systematic zoologist is of special importance, since it is essential to be able to distinguish the species of insect or other carrier of the pathogenic organism from its near allies which are harmless in this respect. In dealing with economic questions of this kind, and of many others, the Natural History Museum has done its full share, and its function as a consultative body capable of giving valuable information on matters of practical moment has become an important side of its activities.

The action of the then Secretary of State for the Colonies in calling a meeting in 1909 for placing entomological research in our tropical Possessions in Africa on a proper basis is an event which ought not to pass unrecorded. The immediate result was the establishment of the Entomological Research Committee (Tropical Africa), now the Imperial Bureau of Entomology. Short as its life has been at present, the Bureau has fully justified its existence, and it has become an important centre of research, the utility of which is cordially recognised in all parts of the Empire. It already possesses a wide influence, and it may fairly be anticipated that it will become increasingly important in promoting researches tending to reduce the ravages of sleeping sickness, malaria, and many other diseases which have taken a heavy toll of the life of man and domesticated animals in the past. The Trustees of the British Museum associated themselves from the first with this new departure, and provided such accommodation at the Natural History Museum as they were able to spare for the Director of the Bureau and a part of his staff.

May I, in conclusion, direct attention to another side of biological activity which deserves notice? The foundation of the Marine Biological Association in 1884 led to the erection of the Plymouth Laboratory, which has had a most successful career, in spite of the difficulties due to insufficient funds, in promoting the study of marine biology, including practical questions of great importance connected with the fishing industry. Although not the first institution of this kind to be founded in this country, the Plymouth Laboratory, with those on the Clyde, in the Isle of Man, and at St. Andrews and Cullercoats, has become an indispensable part of the biological equipment of Great Britain. S. F. HARMER.

Gravitation and Light.

As I said last week (p. 334), and also in the December *Phil. Mag.* (p. 737), the refractivity $\mu-1$, necessary at every point of a gravitational field to produce the Einstein deflection, is the ratio of the energy of a constant-mass particle fallen there from infinity to the energy of the same particle moving with the speed of light; but it is not permissible to say that the solar gravitational field acts like a lens, for it has no focal length. If the sun were backed by a nebula or any luminous area, the light grazing the rim all round would be brought to a focus at a place seventeen times the distance of Neptune, while light from any larger circle would focus still further off in proportion to the area of the circle. So from a uniformly luminous area there would result a focal *line* of constant brightness. The moon is, unfortunately, impotent to make an annular eclipse interesting.

For an extended solar atmosphere to produce the deflection, its density would have to vary with the inverse distance, which seems unlikely; but this is just the way in which an æther tension ought to vary in order to cause gravitation—as Newton knew. The extra æther-tension factor, μ^2-1, would be twice the refractivity.

Possibly the concluding sentence in the *Phil. Mag.* article above referred to is not expressed with sufficient clearness. Permit me to explain my points thus:—

(1) The quasi-elasticity of æther—the property which enables it to transmit light and to effect electrical discharge—is probably due to exceedingly fine-grained constitutional vorticity with high-speed circulation, as argued in my book "The Ether of Space." Consequently it would have facility for gyrostatic action, yielding a perpendicular result to an acting force.

(2) That a gravitational force acting obliquely on light would probably be unable to alter speed, but, through the co-operation of its transverse and longitudinal components, it might be expected to produce an extra dose of deflection—assuming light to be subject to gravitation, as Newton surmised. So that by the time a beam of light coming from infinity had arrived at its nearest point to the sun, it would already have been deflected as much as an ordinary heavy particle would be deflected along its whole course.

I am aware that these are only suggestions for working out.

Einstein's equations, based on the impossibility of observing motion through æther, seem powerful instruments for extracting results; just as more familiar equations, based on the impossibility of "perpetual motion," have proved themselves effective; but neither set of equations explains, nor attempts to explain, the mechanism of the consequences they deduce. Dynamics have served us so well in the past that it must be still legitimate to try, wherever possible, to apply well-established principles to new phenomena. OLIVER J. LODGE.

Edgbaston, Birmingham, November 30.

The Displacement of Light Rays Passing near the Sun.

THE part of the earth's atmosphere within the conical shadow of the moon during a total solar eclipse may be regarded as approximately a right circular cylinder, the area of the base of which depends on the length of the shadow. Observations have shown that there are temperature and pressure gradients in this cylinder. The latter gradient at the surface of the earth is usually slight, but the temperature gradient may be considerable, so that, assuming that there is equilibrium, we have, roughly speaking, a cylinder of air the density of which decreases outwards in all directions perpendicular to its axis. When we remember that the light from stars at small angular distances from the sun's centre makes small angles with the axis of this cylinder, it is easy to see that a very small density gradient would be sufficient to account for the displacements that were observed in the total solar eclipse of the present year.

Suppose the cylinder to be made up of two parts, an inner and an outer, the common boundary being a coaxial cylinder, and let a ray of light in the outer portion inclined at a small angle α to the axis fall on the boundary, the deviation δ is given by

$$\cos\alpha=\mu\cos(\alpha+\delta),$$

where μ is the index of refraction for rays passing from the outer portion to the inner.

Since δ is very small in comparison with α, we have, approximately,

$$\delta=\frac{\mu-1}{\mu\tan\alpha}=\frac{\mu-1}{\tan\alpha}\ \text{very nearly},$$

since μ does not differ much from unity.

If $\alpha=30'$ and $\delta=1{\cdot}7''$, we get

$$\mu=1+\delta\tan\alpha,$$

δ being expressed in circular measure.

Thus $\mu=1{\cdot}00000007$, and for small values of α it is clear that δ is inversely proportional to the angular distance of the star from the centre of the sun's disc.

If we take μ_1, the absolute index of refraction of the outer portion, to be $1{\cdot}0003$, μ_2, the absolute index of refraction of the inner portion, will be $1{\cdot}00030007$, and consequently

$$\frac{\mu_2-1}{\mu_1-1}=1{\cdot}0002,$$

which will be the ratio of the density of the air in the inside portion to the density of the air in the outside portion. On the assumption that there is no gradient of pressure, this would imply a difference of temperature of about $1/18°$ C., a very small amount when it is remembered that the lowering of temperature at the surface of the earth during an eclipse may be as much as 5° C.

In the actual case the path of a ray will be a curve, but the above remarks will serve to show that the density gradient would probably be sufficient to produce the observed effect. It is clear, too, that the displacement in the actual case will be inversely proportional to the angular distance of the star from the sun's centre, and that it will depend on local conditions, so that the amount of displacement will be different for different places.

I think it is quite likely that if the refraction of the atmosphere of the earth due to density changes during an eclipse could be accurately obtained and allowed for, it would be found that there is no Einstein effect at all. ALEXR. ANDERSON.

University College, Galway.

EINSTEIN'S RELATIVITY THEORY OF GRAVITATION.

I.

THE results of the Solar Eclipse Expeditions announced at the joint meeting of the Royal Society and Royal Astronomical Society on November 6 brought for the first time to the notice of the general public the consummation of Einstein's new theory of gravitation. The theory was already in being before the war; it is one of the few pieces of pure scientific knowledge which have not been set aside in the emergency; preparations for this expedition were in progress before the war had ceased.

Before attempting to understand the theory which, if we are to believe the daily Press, has dimmed the fame of Newton, it may be worth while to recall what it was that he did. It was not so much that he, first among men, used the differential calculus. That claim was disputed by Leibniz. Nor did he first conceive the exact relations of inertia and force. Of these, Galileo certainly had an inkling. Kepler, long before, had a vague suspicion of a universal gravitation, and the law of the inverse square had, at any rate, been mooted by Hooke before the "Principia" saw the light. The outstanding feature of Newton's work was that it drew together so many loose threads. It unified phenomena so diverse as the planetary motions, exactly described by Kepler, the everyday facts of falling bodies, the rise and fall of the tides, the top-like motion of the earth's axis, besides many minor irregularities in lunar and planetary motions. With all these drawn into such a simple scheme as the three laws of motion combined with the compact law of the inverse square, it is no wonder that flights of speculation ceased for a time. The universe seemed simple and satisfying. For a century at least there was little to do but formal development of Newton's dynamics. In the mid-eighteenth century Maupertuis hinted at a new physical doctrine. He was not content to think of the universe as a great clock the wheels of which turned inevitably and irrevocably according to a fixed rule. Surely there must be some purpose, some divine economy in all its motions. So he propounded a principle of least action. But it soon appeared that this was only Newton's laws in a new guise; and so the eighteenth century closed.

The nineteenth saw great changes. When it closed, the age of electricity had come. Men were peering into the secrets of the atom. Space was no longer a mighty vacuum in the cold emptiness of which rolled the planets. It was filled in every part with restless energy. Æther, not matter, was the last reality. Mass and matter were electrical at bottom. A great problem was set for the present generation: to reconcile one with the other the new laws of electricity and the classical dynamics of Newton. At this point the principle of least action began to assume greater importance; for the old and the new schemes of the universe had this in common, that in each of them the time average of the difference between the kinetic and the potential energies appears to be a minimum.

One of the main difficulties encountered by the electrical theory of matter has been the obstinate refusal of gravitation to come within its scope. Quietly obeying the law of the inverse square, it heeded not the bustle and excitement of the new physics of the atom, but remained, independent and inevitable, a constant challenge to rash claimants to the key of the universe. The electrical theory seemed on the way to explain every property of matter yet known, except the one most universal of them all. It could trace to its origins the difference between copper and glass, but not the common fact of their weight; and now the æther began silently to steal away.

One matter that has seriously troubled men in Newton's picture of the universe is its failure to accord with the philosophic doctrine of the relativity of space and time. The vital quantity in dynamics is the acceleration, the change of motion of a body. This does not mean that Newton assumed the existence of some ultimate framework in space relative to which the actual velocity of a body can be uniquely specified, for no difference is made to his laws if any arbitrary constant velocity is added to the velocity of every particle of matter at all time. The serious matter is that the laws cannot possibly have the same simplicity of form relative to two frameworks of which one is in rotation or non-uniform motion relative to the other. It seems, for instance, that if Newton were right, the term "fixed direction" in space means something, but "fixed position" means nothing. It seems as if the two must stand or fall together. And yet the physical relations certainly make a distinction. Why this should be so has not yet been made known to us. Whatever new theory we adopt must take account of the fact.

It was with some feeling of relief that men hailed the advent of the æther as a substitute for empty space, though we may note in passing that some philosophers—Comte, for example—have held that the concept of an æther, infinite and intangible, is as illogical as that of an absolute space. But, jumping at the notion, physicists proposed to measure all velocities and rotations relative to it. Alas! the æther refused to disclose the measurements. Explanations were soon forthcoming to account for its reluctance; but these were so far-reaching that they explained away the æther itself in the sense in which it was commonly understood. At any rate, they proved that this creature of the scientific imagination was not one, but many. It quite failed to satisfy the cravings for a permanent standard against which motion might be measured. The problem was left exactly where it was before. This was pre-war relativity, summarised by Einstein in 1905. The physicists complained loudly that he was taking away their æther.

Let it not be thought, however, that the results of the hypothesis then advanced were purely negative. They showed quite clearly that many current ideas must be modified, and in what direction this must be done. Most notably it emphasised the fact that inertia is not a fundamental and invariable property of matter; rather it must be supposed that it is consequent upon the property of energy. And, again, energy is a relative term. One absolute quantity alone remained; one only stood independent of the taste or fancy of the observer, and that was "action." While the æther and the associated system of measurement could be selected as any one of a legion, the principle of least action was satisfied in each of them, and the magnitude of the action was the same in all.

But, still, gravitation had to be left out; and the question from which Einstein began the great advance now consummated in success was this. If energy and inertia are inseparable, may not gravitation, too, be rooted in energy? If the energy in a beam of light has momentum, may it not also have weight?

The mere thought was revolutionary, crude though it be. For if at all possible it means reconsidering the hypothesis of the constancy and universality of the velocity of light. This hypothesis was essential to the yet infant principle of relativity. But if called in question, if the velocity of light is only approximately constant because of our ordinary ways of measuring, the principle of relativity, general as it is, becomes itself an approximation. But to what? It can only be to something more general still. Is it possible to maintain anything at all of the principle with that essential limitation removed?

Here was exactly the point at which philosophers had criticised the original work of Einstein. For the physicist it did too much. For the philosopher it was not nearly drastic enough. He asked for an out-and-out relativity of space and time. He would have it that there is no ultimate criterion of the equality of space intervals or time intervals, save complete coincidence. All that is asked is that the order in which an observer perceives occurrences to happen and objects to be arranged shall not be disturbed. Subject to this, any way of measuring will do. The globe may be mapped on a Mercator projection, a gnomonic, a stereographic, or any other projection; but no one can say that one is a truer map than another. Each is a safe guide to the mariner or the aviator. So there are many ways of mapping out the sequences of events in space and time, all of which are equally true pictures and equally faithful servants.

This, then, was the mathematical problem presented to Einstein and solved. The pure mathematics required was already in existence. An absolute differential calculus, the theory of differential invariants, was already known. In pages of pure mathematics that the majority must always take as read, Riemann, Christoffel, Ricci, and Levi-Civita supplied him with the necessary machinery. It remained out of their equations and expressions to select some which had the nearest kinship to those of mathematical physics and to see what could be done with them. E. CUNNINGHAM.

DISCOVERY OF A MINOAN PALACE AT MALIA, IN CRETE.

DISCOVERIES of great importance have been made during the course of excavations carried out this year in Crete by M. Joseph Hatzidakis, at a site one kilometre from the shore, near the village of Malia, about twenty miles east of Candia.

The site of a palace of the Middle Minoan epoch has been uncovered, and numerous objects found. The containing walls of the palace, the lower courses of which consist of *poros* stone, can all be traced, the dimensions of the building being 110 metres in length and 80 metres in width. The interior walls, which are of bricks and rubble, are 2·30 metres in thickness, and the floor of the palace is composed of a layer of white earth upon which is a stratum of chalk and sand with a top surface of red chalk paste. The outside of the containing walls was covered with a white chalk wash.

The palace was destroyed by fire shortly after the end of the Middle Minoan epoch, and probably suffered from the depredations of looters for a considerable time after its destruction. In consequence, few objects of value, and nothing intact, have so far been discovered. A very large number of small fragments of gold leaf, however, have been found. For many years past similar fragments have been found by the peasants from time to time, and the site became known as "Chrysolakkos," "The ditch of gold." Capt. Spratt early last century noted the prevalence of such gold fragments on this site. The fragments are derived in all probability from some large bone or wooden objects which were decorated with gold leaf. Bronze was rare, only a dagger blade, a brooch, and a band having been found.

The fields between the shore and the palace show traces of walls, and in one case a complete house, all of the same date as the palace, and clearly belonging to the town in which the palace was situated. The site of a necropolis was found near the shore, where one grave containing pottery of the same date as the palace was opened.

Minoan pictographic or graphic signs were found cut on various stone blocks in the palace. The double-axe occurred on a large tetragonal pillar, which was of the type found at Knossos, but twice the size. A six-rayed star of a known type also occurred; a similar star with a spray at the end of one of the rays represents a sign not hitherto known.

The pottery so far discovered is disappointing, no complete or even well-preserved pieces having been found. The best fragments, mostly of cups of the Middle Minoan periods, were found in what appears to have been a shrine.

Three kilometres to the west of the palace a number of graves of the third Late Minoan or Mycenean period were found. One of these graves was opened, and was found to contain five rectangular "larnakes," in each of which was a skeleton.

The importance of the site lies in the fact that this is the only example hitherto found of a palace of the Middle Minoan epoch without an overlying building of later date. The Middle Minoan parts of the palaces of Phæstos and Knossos are overbuilt with walls of the Late Minoan periods, and the plans and details of the Middle Minoan palaces at these places cannot, in consequence, be definitely ascertained. The existence of a city and necropolis of the same date as the palace increases the importance of the site. The Late Minoan city is clearly to be found some distance away. The excavations will be continued, and promise important results.

NOTES.

THE desirability of fostering scientific research as a result of experience gained during the war was recently urged upon various Government Departments by the British Association. There is reason to believe that measures are being taken to this end in various directions; in particular, the association has received from the Admiralty a communication in the course of which it is stated that the authorities there "are keenly alive to the supreme importance of research in its bearing on naval requirements, and that the organisation of suitable arrangements for this purpose is now engaging, and will continue to engage, their earnest attention. Rapid progress is now being made in the elaboration of a complete scheme which will provide, on one hand, for systematic and continuous development in research and experimental establishments controlled by the Department, and, on the other, for an effective relation between these establishments and scientific institutions throughout the country."

THE collection of precious stones which was formed by the late Sir Arthur H. Church, and presented by his widow to the Trustees of the British Museum, has recently been placed in a special case under the archway leading from the main gallery of minerals to the meteorites pavilion at the Natural History Museum. Sir Arthur Church was for thirty-two years professor of chemistry at the Royal Academy of Arts, and his leaning towards art led him from his early days to take an interest in rare gem-stones. In consequence, the collection was at his death exceptionally rich in specimens of mineral species seldom seen in ordinary jewelry, as well as in unusual specimens of familiar species. The pride of the collection is the brilliant orange-coloured spessartite, which is all but unique, since only one other such stone (cut, in fact, from the same original crystal) is known to exist. The collection is very rich in zircons. Together with the four stones which Sir Arthur Church presented in his lifetime, the collection numbers 207 specimens, without counting the eight diamond points and the twenty-one diamond brilliants used in the setting of a zircon and a peridot ring respectively; of them, 170 are set in 162 gold rings and 37 are unset.

DR. O. HOLTEDAHL is organising a Norwegian exploring expedition to Novaya Zemlya, and hopes to sail in June next year. Dr. Holtedahl, who has had previous polar experience in geological exploration in Spitsbergen, has laid his plans before the Norwegian Academy of Sciences, where they obtained the support of Dr. F. Nansen, who advocated a State grant. According to the *Morning Post*, Dr. Holtedahl will make the base of his expedition on Matochkin Shar, the strait between the two large islands, where there is a small Samoyede settlement. A botanist, a zoologist, and a meteorologist will accompany the expedition, while the leader will devote his time to geology and geophysical problems. Novaya Zemlya is by no means a *terra incognita*; Russian explorers have frequently visited it, particularly in search of minerals. But the results of their work have only partly been published, and the collections and observations have probably been destroyed. In 1916 the Russian Government proposed to erect two permanent meteorological stations in Novaya Zemlya, one at the north end and the other at Matochkin Shar; but nothing has yet been done. Dr. Holtedahl rightly insists on the usefulness of a permanent station. He would also like to see one on the island of Jan Mayen, between Iceland and Spitsbergen.

A LETTER has been received by us from Dr. Th. Mortensen, the distinguished curator of the zoological collections in the Royal Museum, Copenhagen, protesting against the use of the German word "Anlage" in zoological papers written in English. It is rather curious that it should have been left to a friendly neutral to protest against this disfigurement of the English language. Dr. Mortensen suggests that the English word "rudiment" conveys exactly the meaning of "Anlage," and he hazards the supposition that the reason why "rudiment" is not more largely used in this sense is that it has been customary in the past to employ the phrase "rudimentary organ" to signify the disappearing remnant of a once functional structure. In both his views we heartily concur with Dr. Mortensen. Unfortunately, the phrase "rudimentary organ" is found embedded in our great classic of biology, the "Origin of Species," and it is probably for this reason that some years ago leading American zoologists, who disliked the word "Anlage," attempted to replace it by the English word "fundament," an attempt which excited only amusement in the zoological world in general. To us it seems that only a little perseverance is required in order to establish the word "rudiment" as the English equivalent of "Anlage," whilst the equally good English word "vestige" can be used to signify the remnant of a disappearing organ. This usage has already been adopted by some of our most recent writers on embryology, and it is to be hoped that it will spread until it becomes universally recognised.

THE appeal which is being made by the Research Institute in Dairying, attached to University College, Reading, for funds to purchase a suitable farm and to provide research laboratories and a dairy is deserving of support, not only by those connected with the dairying industry, but also by the public at large. A good supply of pure milk at a moderate price is most important for the nation, and it is only by a systematic inquiry conducted with proper equipment by skilled workers that the problem will be solved. The formation of a research institute on dairying dates only from 1912, and, naturally, the work which has been undertaken up to the present has been seriously handicapped by war conditions. Now, however, the staff of the institute is in a position to press forward the various inquiries which have in many cases already been commenced. An excellent start was made with an investigation of the causes which lead annually to heavy losses when milk sours prematurely. As would be expected, cleanliness and a low temperature have been proved to be the chief agents in the prevention of these avoidable losses. The reports already issued from the institute give some very striking illustrations of the high "keeping" properties of clean milk. In cheese-making the Research Institute has also a most promising field of investigation, for although many of the best varieties of cheese in the world have had their origin in this country, very little is known of the details of the processes. The higher price of milk makes it imperative that there should be no avoidable losses either in the milk supply or in the articles made from milk, the high food value (to say nothing of the physiological value) of which is now so generally recognised.

THE death has occurred, at the age of sixty-nine, of Dr. John Vose Hazen, who had recently resigned the chair of civil engineering and graphics at Dartmouth College, New Hampshire, after a long tenure.

DR. W. G. BISSELL, whose death is reported in his fiftieth year, had been chief of the Bureau of Bacteriology in the city of Buffalo since 1894. He was president of the New York State Sanitary Officers' Association.

AT the ordinary scientific meeting of the Chemical Society to be held on Thursday, December 18, Prof. J. Walker will deliver a lecture entitled "War Experiences in the Manufacture of Nitric Acid and the Recovery of Nitrous Fumes."

DR. PAUL SABATIER (Toulouse), Dr. Pierre Paul Emile Roux (Paris), Dr. Jacques Loeb (New York), Dr. Robert Andrews Millikan (Chicago), Dr. Arthur Gordon Webster (Harvard), and Dr. William Wallace Campbell (California) have been elected honorary members of the Royal Institution.

THE death is announced, in his eighty-fourth year, of Dr. Charles Henry Hitchcock, professor of geology at Dartmouth College, U.S.A., from 1868 to 1908. Dr. Hitchcock was widely known as the compiler of several geological maps of the United States, and for his researches in ichnology, geology of the crystalline schists, and glacial geology. During the winter of 1870–71 he established, on the top of Mount Washington, the first high mountain observatory in the United States. Among his many publications were memoirs upon the fossil tracks of the Connecticut Valley. On his retirement he went to live in Hawaii (where he died), and in 1909 he published a book on the volcanoes of that territory.

THE following are among the lecture arrangements at the Royal Institution before Easter, 1920:—Prof. W. H. Bragg, six lectures adapted to a juvenile auditory on The World of Sound; Sir John Cadman, two lectures on (1) Modern Development of the Miner's Safety Lamp and (2) Petroleum and the War; Prof. G. Elliot Smith, three lectures on The Evolution of Man and the Early History of Civilisation; Prof. Ernest Wilson, two lectures on Magnetic Susceptibility; Prof. Arthur Keith, four lectures on British Ethnology: The Invaders of England; Prof. A. E. Conrady, two lectures on Recent Progress in Photography; Prof. A. H. Smith, two lectures on Illustrations of Ancient Greek and Roman Life in the British Museum; Lt.-Col. E. Gold, two lectures on The Upper Air; Sir F. W. Dyson, Astronomer Royal, three lectures on The Astronomical Evidence bearing on Einstein's Theory of Gravitation; and Sir J. J. Thomson, six lectures on Positive Rays. The Friday evening discourses will begin on Friday, January 16, 1920, at 9 o'clock, when Sir James Dewar will deliver a discourse on Low-temperature Studies. Succeeding discourses will probably be given by Sir C. A. Parsons, Mr. S. G. Brown, Prof. W. M. Bayliss, Dr. E. J. Russell, Mr. W. B. Hardy, the Hon. J. W. Fortescue, Prof. J. A. Fleming, Mr. E. McCurdy, Sir J. J. Thomson, and others.

WE learn with regret of the death on November 25 of Mr. Frederick Webb Headley, at the age of sixty-three years. Educated at Harrow and Caius College, Cambridge, where he obtained a First Class in the Classical Tripos, Mr. Headley spent nearly forty years of his life as an assistant master at Haileybury College, where, so recently as June 30 last, he delivered his last lecture to the College Natural History Society on his favourite subject, "The Pedigree and Life of Birds." Through the instrumentality of this society and of the museum he succeeded in maintaining, generation after generation, a body of active boy-naturalists in the college, and few men were better able to fan into enthusiasm the spark of what so often proves but the passing hobby of a young boy. Of Headley's published works two, namely, "The Structure and Life of Birds" and "Life and Evolution," are very largely the finished product of lectures delivered to the boys. The variety of subjects handled is eloquent testimony to the wide sympathy and biological knowledge of the man—a classic by early training. The doctrine of evolution made a powerful appeal to his mind, as is evidenced by his "Problems of Evolution" and by "Darwinism and Modern Socialism." But it was "birds" and "flight" that more than all else attracted him. The war prevented the execution of a projected tour abroad with "birds" as a main object, and kept him at Haileybury longer than he had intended. Another such tour was planned after his final retirement last July. *Dis aliter visum.*

AT the meeting of the Illuminating Engineering Society on November 25, a short address on "Lambert and Photometry" was given by the president, Mr. A. P. Trotter, who raised the question whether Lambert ever devised a photometer, inclining, however, to the view that Bouguer was the first to contrive an apparatus for measuring light. Later in the evening Mr. Haydn T. Harrison exhibited a new form of photometer which had several interesting features, notably the use of an illuminated scale. The greater part of the evening was given up to exhibits, including a new form of "daylight" or colour-matching lamp, shown by Mr. L. C. Martin. This device, which is due to Mr. Sheringham, the well-known artist, involves the projection upwards of light from an electric lamp to a surface carrying a chessboard pattern in various colours. The reflected light closely resembles daylight in colour, and is stated to be well adapted to colour-matching processes. The indirect method thus utilised is considered very suitable for use in picture galleries, etc. Other exhibits included a series of tungsten arc ("pointolite") lamps exhibited by Mr. P. Freedman, of the Ediswan laboratory. This form of lamp utilises an arc between tungsten electrodes within a hermetically sealed bulb, and has proved very suitable for optical projection. By improved methods of manufacture larger tungsten globules, facilitating much higher candle-powers, have been prepared. Lamps giving up to 1000 c.p. have already been used, and a special 4000-c.p. unit, which it is hoped will prove specially suitable for kinema work, was shown at the meeting.

THE retirement of Dr. Cecil Lyster from the position of head of the electro-therapeutic department of the Middlesex Hospital was announced at a meeting of the governors of the hospital. The chairman, Lord Athlone, said that Dr. Lyster was now lying in a critical condition directly due to his self-sacrificing devotion to duty. Dr. Lyster was one of the pioneers of scientific research, and applied himself to the study of X-rays and radium and their use in the treatment of disease, especially cancer. By exposure to the rays in the early days he fell a victim to the disease he sought to conquer. Though suffering, he declined to be set aside from his purpose, and continued his good work until now, when work for a time was no longer possible. Mr. Sampson Handley spoke of the high esteem in which Dr. Lyster was held by his colleagues on the staff of the hospital. Dr. Lyster was president of the section of electro-therapeutics of the Royal Society of Medicine for the year which ended in October last. His colleagues in the domain of X-rays and electro-therapeutics had occasion to appreciate his invariable tact and sympathy at the meetings over which he presided. At the joint meeting of his section with the Institution of Electrical Engineers on March 21 last he remarked, in introducing the president of the institution and asking him to take the chair: "We are amateurs in electricity, and we are at last asking the professional electrician to tell us what we want. I hope meetings of this sort will be continued in years to come, and that we shall be able to interest the Institution of Electrical Engineers in our work as electro-therapeutists and radiologists. It is a fascinating subject, and a far-reaching one for humanity—that is, the future of the electrical and radiological treatment of disease Perhaps my optimism is enormous." It is this spirit of optimism that has buoyed up Dr. Lyster through his times of suffering, and caused him to remain at his post to the last.

DR. J. WALTER FEWKES, Chief of the Bureau of American Ethnology, has recently returned from two months' field-work on the Mesa Verde National Park, Colorado. This park is the only one reserved by the U.S. Government for the protection of aboriginal buildings, and for the last decade the Department of the Interior and the Smithsonian Institution have co-operated in the excavation and repair of ruins in order that they may be preserved for posterity, after having been put in a condition to show their structural features. The field-work of last summer was devoted to a cliff-dwelling called Square Tower House from a high tower situated midway in its length. This tower is 40 ft. high, and is the highest building constructed of masonry by Indians north of Mexico before the coming of the whites. It adds to this unique feature the best-known example of prehistoric masonry, shown in the construction of the roofs of two circular rooms. The original rafters are still in place, showing the marks of stone implements used by the builders. The whole ruin, which measures 136 ft. in length, is most picturesquely situated, and has already become one of the greatest attractions of the park. An unexpected result of the field-work was the discovery of many inconspicuous buildings among the cedars on top of the plateau. The evidences of these buildings before excavating were very obscure, but they are so numerous in certain areas that there is scarcely a square quarter-mile in which one of them does not occur. One of these small buildings when excavated was found to belong to a very ancient type, probably the oldest on the mesa.

WE have received the second number of *Medical Science*, a monthly periodical of abstracts and reviews of medical science published by the Medical Research Committee. The present issue contains, among others, reviews on diphtheria, tuberculosis, gastric ulceration, influenza, and cerebro-spinal fever. In the last-named, Dr. Rolleston surveys the epidemiology, symptoms, and treatment of the disease, particularly with serum. This, in the hands of numerous observers, has proved to be of benefit, reducing the mortality provided it is administered early enough.

A SHORT, but very welcome, account of the courtship of the dabchick, by Mr. Julian Huxley, appears in *British Birds* for November. The author was too late to witness the earlier phases of the courtship, but he contrived to glean much information as to their behaviour after pairing-up had taken place. These birds, lacking the frills and crests characteristic of other species of grebes, display none of the posturing which takes place in the more resplendent species, but content themselves with the performance of duets recalling the neighing of a horse. They also spend much time in long excursions on the water, swimming side by side. It is to be hoped that next year it will be possible to start observations earlier in order that the initial stages of the courtship may be studied. Mr. Huxley's studies on the courtship of the great crested grebe are known to all ornithologists, and his able handling of this theme makes us the more anxious to have the complementary picture.

IN an important memoir on a new type of nephridium found in Indian earthworms of the genus Pheretima (*Quarterly Journal of Microscopical Science*, vol. lxiv., part 1) Mr. Karm Narayan Bahl gives a very interesting description of the excretory system of *Pheretima posthuma*. He finds three distinct kinds of nephridia in this worm: septal, pharyngeal, and integumentary. Although the nephridia are very numerous and all small (micronephridia), the system is not plectonephric, each nephridium being a separate organ. The chief novelty of the author's work lies in the discovery that the septal nephridia open into the intestine, instead of on to the surface of the body, by segmentally arranged apertures, not directly, but through a system of ducts, of which the most important are a pair of longitudinal excretory canals lying above the intestine, one on each side of the mid-dorsal line. The author applies the term "enteronephric" to this remarkable type of nephridial system, and puts forward the suggestion —due to Prof. W. N. F. Woodland—that the discharge of the excretory products into the intestine may be a special adaptation for the conservation of moisture in a dry climate.

THE *Journal of the Board of Agriculture* for October contains a preliminary report on the recent Lincoln tractor trials. The excellent work done by the machines and the large attendance of farmers show that the industry has now passed the pioneer stage. The tendency of the manufacturers is less to novelty of design than to development in accordance with the experience obtained in this country, chiefly as the result of the operation of the Government tractor scheme. Close attention is being paid to the reduction of weight, to the increased accessibility of the vital parts of the machinery, and to the provision of protection from the effect of weather and dirt. Interesting comparisons were made of the ploughing done by tractors fitted respectively with high-speed vertical and low-speed horizontal engines, with wheels and caterpillar-tracks, and between self-contained machines and independent tractors. The use of the tractor is not restricted to ploughing, and there were important haulage tests and threshing demonstrations. Great as is the value of the present trials from the commercial and educational points of view, further trials extending over a considerable interval, and giving greater uniformity of task and conditions, will be necessary before the capacity of the various machines can be defined.

THE *Kew Bulletin* (Nos. 6 and 7, 1919) contains an account of recent investigations by J. Bintner on the symptoms and distribution of silver-leaf disease. There has been much controversy as to the cause of the disease, which is now established as mainly due to the growth in the tissues of the mycelium of the fungus *Stereum purpureum*. Mr Bintner demonstrates the presence of the fungus in the wood of diseased branches, which show the brown coloration beneath the bark characteristic of the disease. No trace of the fungus has been found in the leaves, and it is suggested that the separation of the cells, which gives the silver effect, is caused by the production of some diffusible toxin by the fungus, which is conveyed to the leaves in the water-conducting channels. Infection takes place through open wounds above ground and immediately below ground-level, and inoculation experiments confirm the view that injured superficial roots can be infected. Localised silvering of a branch results from local infection which has not yet spread to the main stem, and excision of the diseased branch may save the tree. On the other hand, silvered suckers springing from a healthy tree indicate root-infection, and where root or stem is infected there is no hope of saving the tree. The disease has been proved to occur on a number of plants besides plum, apple, and other members of the family Rosaceæ, including species of laburnum, horse-chestnut, and cultivated varieties of gooseberries and currants. As a preventive measure good cultivation is recommended; careless pruning, unsatisfactory drainage, and deficiency of lime are especially to be avoided. The author also indicates an apparently distinct disease which he calls "false silver-leaf," which may be mistaken for the disease caused by Stereum, but no trace of this fungus has been found in the plants affected. It is suggested that false silver-leaf, from which plants recover under careful treatment, is due to physiological weakness. It has been observed in cultivated varieties of apple, cherry, peach, and plum.

A NOTEWORTHY addition to our knowledge of Eocene foraminifera is made by the publication of the late Mr. E. Halkyard's "Fossil Foraminifera of the Blue Marl of the Côte des Basques, Biarritz," under the care of Messrs. E. Heron-Allen and A. Earland (Mem. Manchester Lit. and Phil. Soc., vol. lxii., part ii.). Megalospheric and microspheric forms are discussed among the nummulites.

MESSRS. F. F. GROUT and T. M. Broderick (*Amer. Journ. Sci.*, vol. xlviii., p. 199, 1919) describe structures in the Huronian iron-bearing strata of the Mesabie range in Minnesota as due to algæ. In this they have the support of Dr. C. Walcott, who writes that the iron-ore was evidently separated out of marine waters through the metabolism of the algal growths, which he compares with Cryptozoön.

IN the *American Journal of Science* (vol. xlviii., p. 136, 1919) Prof. R. A. Daly replies to recent criticisms of his "glacial-control" theory of the growth of coral-reefs. He urges that the general absence of cliffs on the island spurs may be due to the protection afforded by rapidly growing fringing reefs in late Cainozoic time; these would have to be scoured away before the Pleistocene sea could attack the volcanic masses. Variations in the depths of lagoons, again, may be expected even on a general platform of erosion, owing to the presence of drowned valleys, fault-troughs, and volcanically formed depressions not yet filled with detritus. Lagoon depths greater than 50 or 60 fathoms are, however, rare.

THE *Times* of November 28 contains an article from Prof. Einstein on his generalised principle of relativity. Prof. Einstein remarks at the beginning of the article: "After the lamentable breach in the former international relations existing among men of science, it is with joy and gratefulness that I accept this opportunity of communication with English astronomers and physicists. It was in accordance with the high and proud tradition of English science that English scientific men should have given their time and labour, and that English institutions should have provided the material means, to test a theory that had been completed and published in the country of their enemies in the midst of the war." After a brief account of the general nature of the theory, which does not add anything to what has been summarised by Prof. Eddington in his report to the Physical Society, Prof. Einstein concludes: "The great attraction of the theory is its logical consistency. If any deduction from it should prove untenable, it must be given up. A modification of it seems impossible without destruction of the whole. No one must think that Newton's great creation can be overthrown in any real sense by this or any other theory. His clear and wide ideas will for ever retain their significance as the foundation on which our modern conceptions of physics have been built. . . . By an application of the theory of relativity to the taste of readers, to-day in Germany I am called a German man of science, and in England I am represented as a Swiss Jew. If I come to be regarded as a *bête noire*, the descriptions will be reversed." Prof. Eddington, in the *Contemporary Review*, quotes from Newton's "Opticks":—"Query 1. Do not bodies act upon light at a distance, and by their action bend its rays?"

ON Engler's theory of the origin of petroleum, the oil has been formed out of animal and vegetable fatty matters derived from marine animals and plants. The fats have been hydrolysed by water, and the resulting fatty acids, under the influence of heat and pressure, have then been decomposed into carbon dioxide and hydrocarbons, these latter constituting the petroleum. Whilst this theory would account for the liquid hydrocarbons of the aliphatic series found in petroleum, it does not explain the presence either of solid paraffins or of the aromatic (naphthenic) hydrocarbons which are found in most petroleums, and, indeed, form the whole of some varieties. Engler's distillation experiments in confirmation of the theory were made chiefly on free oleic and stearic acids. It is probable, however, that salts of these acids, rather than the free acids themselves, would be the bodies acted upon during the natural production of petroleum. Following up this idea, MM. Pictet and Potok have carried out a series of experiments on the distillation of sodium stearate and sodium oleate, with the view of ascertaining whether, in operations thus approximating more closely to the natural conditions, aromatic hydrocarbons or paraffins of high boiling points are produced (*Helvetica Chimica Acta*, 2, v., 501). In the result it was found that the chief products were acyclic and unsaturated hydrocarbons closely agreeing with those found in American petroleum, but no trace of naphthenic (aromatic) hydrocarbons was produced. Hence the origin of Baku petroleum, and of the numerous other kinds which contain these naphthenic bodies, is not accounted for by Engler's theory. Further, since many of these bodies show optical rotation, they have probably been produced at relatively low temperatures, and not by the closing up of acyclic compounds, which would demand high temperatures and yield inactive products. No likely source of such optically active bodies suggests itself except the resinous or terpenic constituents of the higher plants. Similar compounds have, in fact, been extracted from coal. For the numerous petroleums containing both acyclic and naphthenic hydrocarbons a twofold origin appears to be indicated.

THE announcements of *Messrs. A. and C. Black, Ltd.*, include "X-rays in General Practice," Alice Vance Knox, with chapters on Instrumentation, Dr. R. Knox; "Cerebro-Spinal Fever: The Etiology, Symptomatology, Diagnosis, and Treatment of Epidemic Cerebro-Spinal Meningitis," Drs. C. Worster-Drought and A. M. Kennedy; "Medieval Medicine," J. J. Walsh; and "The Making of Europe: A Geographic Treatment of the Historic Development of Europe," W. H. Barker and W. Rees. In addition to the books announced for publication by the *Cambridge University Press* (see NATURE, November 20, p. 321) may be mentioned "Physics," Dr. Norman R. Campbell, 3 vols.; "The Theory of the Imaginary in Geometry," J. L. S. Hatton; "Practical Chemistry for Agricultural Students," H. A. D. Neville, vol. i.; "What Became of the Bones of St. Thomas," Rev. Canon A. J. Maron; "From Ritual to Romance" (A Study of Comparative Religion and

Folk-lore), Miss J. L. Weston. *Messrs. Constable and Co., Ltd.*, announce "Physiology and the Nation's Needs," edited by Prof. W. D. Halliburton, containing essays by Dr. M. S. Pembrey, Prof. D. Noël Paton, and the editor on, respectively, "Physical Training and the Open-air Life," "Physiology in the Study of Disease," and "Physiology and the Food Problem." They also promise "Elementary Plane Trigonometry," H. E. Piggott.

MESSRS. DULAU AND CO., LTD., 34 Margaret Street, W.1, have issued a Catalogue (No. 80) of nearly six hundred works on Diatomaceæ, Botany, Horticulture, Agriculture, Natural History, Geology, Palæontology, Voyages and Travels, Astronomy, Physics and Mechanics which will doubtless appeal to many readers of NATURE. It can be obtained upon application.

OUR ASTRONOMICAL COLUMN.

HELIOCENTRIC GROUPING OF PLANETS IN DECEMBER.—The astrologers have been amusing themselves and alarming the timid by predicting violent cosmic convulsions as the result of the planetary grouping on December 17. The actual position is sufficiently interesting to warrant a note. During the five days December 13 to 17, six of the eight major planets will be within a range of 26° in heliocentric longitude, while Uranus will be in the same line on the other side of the sun, the earth alone standing out. In the following list the two longitudes given refer to noon on December 13 and 17 respectively:—Mercury, 130° to 154°; Venus, 135° to 143°; Earth, 79° to 84°; Mars, 152° to 154°; Jupiter, 129°; Saturn, 155½°; Uranus, 331°; and Neptune, 130°. There were similar scares when the four giant planets were all near perihelion together. We may safely predict that they will be as baseless now as they were then.

COMETS.—Finlay's periodic comet passed perihelion about October 15·38. It was a fairly conspicuous object in November, and observations are numerous. It will be much fainter in December, but an ephemeris (for Greenwich midnight) may still be of use:—

	R.A. h. m. s.	N. Decl. ° ′		R.A. h. m. s.	N. Decl. ° ′
Dec. 5	1 33 59	13 14	Dec. 13	2 7 12	16 52
7	1 43 7	14 20	15	2 14 13	17 28
9	1 51 41	15 18	17	2 20 47	17 56
11	1 59 42	16 9	19	2 26 56	18 17

Schaumasse's periodic comet is also fading, but more slowly. Ephemeris for Greenwich midnight:—

	R.A. h. m. s.	S. Decl. ° ′		R.A. h. m. s.	S. Decl. ° ′
Dec. 5	14 9 36	2 2	Dec. 13	14 33 13	3 52
7	14 15 38	2 30	15	14 38 54	4 17
9	14 21 35	2 58	17	14 44 31	4 42
11	14 27 27	3 25	19	14 50 3	5 6

Messrs. Braae and Fischer Petersen announce that their supposition that comet 1919*b* (Brorsen-Metcalf) has made two revolutions since 1847 is not correct; its true period is 72·1 years.

FALL OF A METEORITE IN AMERICA.—The daily papers report that on the night of November 27 last a large meteorite descended into Lake Michigan, and that the object was seen before its fall by many persons over a wide extent of country. If this event is fully corroborated, it seems quite possible that the meteorite may have been a fragment of Biela's lost comet, like the Mazapil meteorite of November 27, 1885, on which date there occurred a great shower of ordinary meteors.

The earth passed through the orbit of Biela's comet on that occasion, and must have been very near, if not involved in, the denser portion of the material forming the remains of the comet. The latter had a periodic time of revolution amounting to about 6¾ years, and if we add five periods to the last return near the end of 1885 we arrive at the present time, so that a display of meteors was rendered quite probable. However, no very conspicuous shower occurred, though from reports sent in by various observers for the period November 19–25 a few meteors, including several of special brilliancy, were recorded from the right direction in Andromeda. In all, seventeen paths appear to be conformable to this shower, and the radiant is indicated at 29°+44° near the star γ Andromedæ.

On the same night, at 9h. 50m., that the meteorite is said to have fallen in America, a fireball was seen at Bristol descending slowly in the north-eastern sky, but the atmosphere was very hazy and few stars were visible. Observations of this object from other places would be valuable.

ANNIVERSARY MEETING OF THE ROYAL SOCIETY.

THE anniversary meeting of the Royal Society was held on Monday, when the report of the council was presented and the president, Sir J. J. Thomson, delivered an address. In the evening fellows and their guests dined together at the Royal Palace Hotel, Kensington, this being the first anniversary dinner since 1913. The assembly received with much satisfaction the announcement of the president that the Prince of Wales is to be admitted a fellow of the society early next year.

The report of the council is largely occupied with an account of the origin and constitution of the International Research Council and the related National Research Council. It is hoped that the British Government will consent to make the annual contribution required from countries forming part of the international organisation, in order to place the Council on a sound financial basis. The report refers also to the increased need of financial assistance for the promotion of research in pure sciences and to developments of the National Physical Laboratory under Sir Richard Glazebrook's directorship. The names of the new officers and council were announced in NATURE of November 13 (p. 295)

In his presidential address Sir Joseph Thomson referred to the retirement of Sir Alfred Kempe (treasurer) and Dr. Schuster (secretary) and to the invaluable services which these officers have rendered to the society. He also announced with regret that the assistant secretary, Mr. R. Harrison, has been obliged to resign his office owing to ill-health. The subjoined extracts are from the president's address.

Einstein's Theory.

I cannot pass over without notice the remarkable result that was announced at our first meeting this session: that the observations made at the eclipse of May 29 showed that light was deflected, when passing close to the sun, by an amount which, within the somewhat wide limits of the experimental error, agreed with that predicted by Einstein.

The deflection of light by matter, suggested by Newton in the first of his Queries, would in itself be a result of first-rate scientific importance; it is of still greater importance when its magnitude supports the law of gravity put forward by Einstein, a law which has explained the long-standing difficulty of the motion of the perihelion of Mercury.

On Einstein's law the velocity of light passing through a field of gravitational attraction depends upon the gravitational potential, and diminishes as the potential diminishes. Thus the gravitational field round the sun acts like a refracting atmosphere, the refraction diminishing as the distance from the sun increases.

Though there are some hundreds of theories of gravitation, Einstein's is the only one which has predicted a result which has been verified by experience. On Einstein's, as on several other theories, changes in gravitational attraction travel with the velocity of light, and also the mass of a body varies with the proximity of other bodies.

In view of the statements in the Press about the overthrow of the Newtonian law, it may be well to point out that it is only in most exceptional cases—cases which are very difficult to realise—that the difference between the effects of the two laws is appreciable.

The modified theory of relativity by which Einstein arrived at this result is of remarkable interest and subtlety. The space around matter is on this theory distorted by an amount which diminishes as the distance from the matter increases, so that an observer in an aeroplane, if he were provided with infinitely delicate instruments, would, as he rose in the air, find the shapes of objects on the ground continually changing; and again the ratio of the circumference to the diameter of a circle would be changed to a minute amount by placing a weight at the centre of the circle. The laws of morality have been said to be a question of latitude; on Einstein's view those of geometry are a question of altitude.

On Einstein's view, gravitation is due to a particle trying to find the easiest way through space distorted and disturbed in this way. We may put it as follows:—The dynamical principle of least action, when applied to a particle moving through a space of this kind, would lead to a different path from that which would be pursued if the space were Euclidean, and this difference in path is that which would be produced if we supposed the space to remain Euclidean and the particle to be acted upon by an appropriate force. This force is what we call gravitational attraction. Thus we can represent the effect of this distorted space by the effects of suitable forces, and I expect it will be found that even the most enthusiastic relativitists will be tempted to think in terms of forces rather than in those of the geometry of non-Euclidean space.

If the distortion of space were very great, the customary methods of dynamics might lose their significance; and the question arises: Will, on Einstein's theory, the space inside an atom be so far from Euclidean that ordinary dynamical methods are unjustifiable? The answer to this question is, "No." There are two lengths which have special significance in connection with the atom; one of these is what we call the radius of the atom, and is of the order 10^{-8} cm.; the other we call the radius of the electron, and is about 10^{-13} cm. Even at the smaller of these distances the gravitational potential due to the mass of the atom, and therefore the distortion from Euclidean space, would be exceedingly small compared with the corresponding quantities due to earth at its surface, so that there is no special distortion inside the atom, except at distances from the centre which are infinitesimal even when compared with the radius of an electron.

One point of interest in connection with any view we take about mass is that, on the electrical theory of matter, the massive part of the atom is invariably positively charged, so that any state of space which we associate with mass ought to involve something corresponding to a positive charge of electricity.

The determination of the consequences of Einstein's theory on the principles of relativity, where the ideas of space and time are so intimately correlated that time has to be treated as a fourth-space dimension, introduces us into a space of four dimensions which we cannot visualise, and the properties of which are very remote from our experience. It is this which makes any general explanation of Einstein methods so difficult. To the analyst the difficulties presented by space of four dimensions are mainly those of an increase in the number of his symbols and equations; his difficulties begin when he has to explain his results to someone who is not an analyst. It is a remarkable and most interesting fact, from the point of view of either physics or metaphysics, that from such transcendental considerations as those I have indicated should have emerged a result so closely connected with such a prosaic thing as that it is more tiring to go upstairs than down.

According to Einstein's theory, the Fraunhofer lines in the sun must be displaced towards the red. This effect, though looked for by several observers, has not been confirmed; but even should it turn out that the theory has greatly to be modified, or even abandoned, its conception and development will, I think, always be regarded as one of the great triumphs of human thought.

Another interesting consequence of Einstein's theory is the exceeding minuteness of structure which it demands from matter. The electron, with a radius of 10^{-13} cm., carried our notions of the minuteness of some constituents of the universe far beyond those associated with the older atomic theory, but the size of the centres of disturbance, which in Einstein's theory are associated with matter, bears to the size of the electrons about the same proportion as the size of the smallest particle visible under the most powerful microscope to that of the earth itself.

I am afraid that the termination of the war has not brought to an end the difficulties in the way of scientific research in this country. Not the least of these is the difficulty and expense of procuring apparatus; it is perhaps surprising that in these circumstances the Government should have put obstacles in the way of the importation of philosophical instruments. Another very real difficulty is that the large increase in the number of students in our universities has greatly increased the educational duties of many of our most active workers, and so diminished the time they can devote to research.

The demands of war required large quantities of substances which previously were obtainable only in small quantities and at great expense. Prominent among these is helium, which can now be procured on a scale which, measured by laboratory standards, is unlimited. Such supplies of helium put cryogenic research on a new footing, and render possible investigations which promise to be of the greatest importance to many different branches of science. It is greatly to be regretted that in this country, the birthplace of cryogenic research, we have no adequately equipped cryogenic laboratory.

The Medallists.

The COPLEY MEDAL is awarded to WILLIAM MADDOCK BAYLISS.

Prof. W. M. Bayliss has been engaged in the investigation of physiological problems for the last thirty-five years. His work has ranged over a wide field. His paper with Starling on the electrical phenomena of the mammalian heart was the first to give the correct form of the normal variation, as confirmed by later investigations with the spring galvanometer. Again, he and Starling showed that the pancreatic secretion was effected by the production of a specific chemical messenger, which travelled by the blood, and not by the stimulation of nerve-endings and the passage of impulses through nerves and the central nervous system. They showed that this secretin was but a type of a whole group of substances which they designated hormones. The discovery of these hormones, and the precise definition of their nature and of the conditions of their activity, mark an important epoch in the development of our knowledge of the organs of the animal body. Prof. Bayliss's researches on the mode of action of enzymes and on the closely related questions with regard to the nature of colloidal solutions have obtained universal recognition. The war led to Prof. Bayliss making a great advance in practical medicine. He studied the condition known as shock, which follows great loss of blood. The condition had previously been treated by the injection of saline solution, but the effect produced was characteristically transitory, and sometimes no benefit accrued at all. Prof. Bayliss, amongst other things, proved that perfused fluid to be effective must contain colloidal matter sufficient to give the osmotic pressure of the normal colloidals of the blood.

A ROYAL MEDAL is awarded to PROF. JOHN BRETLAND FARMER for his researches in botany, especially in the cytology and anatomy of plants.

Prof. Farmer's work is characterised by the fundamental importance of the problems worked upon; thus his memoirs on the meiotic phase (reduction division) in animals and plants are of as great value to zoologists as to botanists, and his conclusions and interpretations of the complex nuclear changes which precede the differentiation of the sexual cells have stood the test of criticism, and remain the clearest and most logical account of these very important phenomena. His papers, in collaboration with his pupil, Miss Digby, on the cytology of those ferns in which the normal alternation of generations is departed from has thrown new light on problems of the greatest biological interest, and especially on the nature of sexuality. In his cytological work on cancerous growths Prof. Farmer has established the close similarity between the cells of malignant growths and those of normal reproductive tissue.

A ROYAL MEDAL is awarded to MR. JAMES HAYWOOD JEANS.

Mr. Jeans has successfully attacked some of the most difficult problems in mathematical physics and astronomy. In the kinetic theory of gases he has improved the theory of viscosity, and, using generalised co-ordinates, has given the best proof yet devised of the equipartition of energy and of Maxwell's law of the distribution of molecular velocities, assuming the validity of the laws of Newtonian dynamics. In dynamical astronomy he took up the difficult problem of the stability of the pear-shaped form of rotating, incompressible, gravitating fluid at a point where Darwin, Poincaré, and Liapounoff had left it, and obtained discordant results. By proceeding to a third order of approximation, for which very great mathematical skill was required, he showed that this form was unstable. He followed this up by the discussion of the similar problem when the fluid is compressible, and concluded that for a density greater than a critical value of about one-quarter that of water the behaviour is generally similar to that of an incompressible fluid. For lower densities the behaviour resembles that of a perfectly compressible fluid, and with increasing rotation matter will take a lenticular shape and later be ejected from the edge.

The DAVY MEDAL is awarded to PROF. PERCY FARADAY FRANKLAND for his investigations in three sections of chemical science.

Prof. Frankland's early work on the illuminating power of burning hydrocarbons was considerable in amount, and had the further merit of inspiring others in the study of combustion. He was one of the first after Pasteur to study seriously the chemical reactions which occur during the vital processes of numerous lower organisms, and to apply such reactions to the preparation of pure products. During the last twenty years he has devoted himself to the elucidation of the relationship existing between the chemical constitution and the rotatory power of optically active substances.

The SYLVESTER MEDAL is awarded to MAJOR PERCY ALEXANDER MACMAHON.

Major MacMahon's researches on the combinatory analysis and on subjects allied to the partition of numbers are of the highest value, and display great originality and invention. He has shown equal power in the discovery and treatment of the wonderful ranges of partition theorems which are derivable from the theory of elliptic functions, and of the similar theorems to be obtained by the application of analysis to purely arithmetical principles.

The HUGHES MEDAL is awarded to DR. CHARLES CHREE.

Dr. Chree has for many years devoted himself to the intimate study of the phenomena of terrestrial magnetism, notably those which are recorded by self-registering instruments. He has investigated the differences which occur in the diurnal variation on quiet or moderately disturbed days, studied the initial stages of magnetic storms, and investigated various problems connected with the relation of solar phenomena and manifestations of terrestrial magnetism. Perhaps the most notable result obtained is that called by Dr. Chree the "acyclic change." This manifests itself on taking the averages of quiet days, when it appears that the mean value of the magnetic force is not the same at the end as it was at the beginning of the 24-hourly period, but shows a difference which is always in the same direction.

THE HYDRO-ELECTRIC SURVEY OF INDIA.[1]

AT a time when so much enterprise and energy are being displayed in collecting facts and data concerning the world's water-power resources, the issue of a preliminary report on the water-power resources of India is an incident of considerable interest and importance. The investigation was commenced in 1918 under instructions from the Indian Government by the late Mr. G. T. Barlow, C.I.E., who was placed in charge of the survey, with Mr. J. W. Meares as his assistant. The untimely and deplorably sudden death of Mr. Barlow in April, 1919, towards the close of the tour of inspection, left the compilation of the report in the hands of Mr. Meares, who was appointed as his successor in the post of Chief Engineer. Mr. Meares has discharged his exacting task in a very able manner. The removal of Mr. Barlow's collaboration was, of course, a serious deprivation, as a number of places were visited by him unaccompanied; and, although he compiled his notes with every care, his unrecorded impressions would have been of great value. Notwithstanding this the report is excellently put together, and full of useful information.

The earliest water-power installation in India was the electric lighting plant of the town of Darjeeling, carried out by Mr. Meares himself in 1897. Five years later considerable power for industrial purposes was developed in Mysore from the River Cauvery. Then nothing of importance happened until the initia-

[1] "Hydro-electric Survey of India." Preliminary Report on the Water-power Resources of India. Ascertained during the Season 1918–19 by the late G. T. Barlow, assisted by J. W. Meares. Compiled by J. W. Meares. Pp. vii+108+iii plates. (Calcutta: Superintendent Government Printing, India.) Price Rs. 3.2 or 4s. 9d.

tion of the great Tata hydro-electric power project at Bombay, which has recently been completed. The country is known to abound in hydraulic possibilities, but, owing to the paucity of important manufacturing industries, no serious attempt has been made to exploit these possibilities, except in a few rare instances.

The difficulty in regard to the promotion of power-development schemes is the erratic incidence of the rainfall. India differs very greatly in this respect from other countries. The rainfall is seasonal, often tremendously heavy, followed by protracted spells of drought. In amount it ranges from 500 to a few inches.

Apart from canals, the mountainous regions, where the rainfall is a maximum, are the natural sources of water-power, but here there is a certain disability in that they lie largely in unsettled districts in the north inhabited by uncivilised tribes. "Except in localities where storage on a large scale is possible, such as the Western Ghats and possibly the uplands of the Central Provinces, the greater part of the monsoon rainfall of India must necessarily pass to the great rivers and canals undeveloped for power purposes." The Jaldaka River in the Bengal Duars is instanced as a case in point. The catchment area is 250 square miles, and the annual rainfall not less than 150 in.—probably 200 in. as an average. In the seven months from April to October the total fall amounts to some 75,000,000,000 cubic ft., giving an average flow of nearly 4000 cubic ft. per second, yet the flow gauged in April this year was only 170 cubic ft. per second. Add to this that a single day's rainfall may reach, and even exceed, 10 in., and the difficulty of controlling such extremes becomes at once apparent.

In consequence of the prevalence of conditions such as these, many Indian rivers during the dry season sink to insignificant streamlets. Storage, therefore, during the monsoon period is the only possible means of obtaining continuous supplies of water. But in most localities this is not economically possible. Certain seasonal industries, such as tea-drying and kindred processes, might be served by intermittent supplies, but the cost would be relatively higher than by a continuous supply.

As indicating the backward state of electrical development in India, the following figures are interesting. The number of watts installed per head of population in Canada is 148, in Australasia 62, in South Africa 57, in the British Isles 33, and in India less than 1.

The total brake-horse-power of all kinds is set down approximately as follows:—

Assam	22,550	
Bengal...	201,518	
Bihar	2,325	(apart from collieries)
Bombay	782,872	
Burma	17,750	(exclusive of rice mills, etc.)
Central Provinces	32,773	
Madras	39,568	
Punjab...	15,734	(steam only)
United Provinces	38,548	
Grand Total ...	1,153,638	

No estimate of the total water-power available for development is given or attempted. Mr. Meares states that it would take several years to ascertain it, even approximately. A statement is set out of existing hydro-electric plants and a number of possible sites for developing water-power are discussed. The report concludes with a series of practical notes and suggestions on methods of collecting and tabulating the necessary data, with a view to the future work of the survey.

BRYSSON CUNNINGHAM.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—A further benefaction of 1000*l.* has been received by Prof. Nuttall on behalf of the institute for parasitology from the executors of the late Lord Strathcona and Mount Royal, in fulfilment of a promise made in 1910 to contribute that sum when the sum of 6000*l.* had been collected from other sources.

Dr. F. H. A. Marshall, fellow of Christ's College, has been appointed reader in agricultural physiology.

Mr. P. Lake, of St. John's College, has been appointed reader in geography.

Mr. W. B. R. King, of Jesus College, has been appointed assistant to the professor of geology, and Mr. T. C. Nicholas, fellow of Trinity College, to be demonstrator in geology.

OXFORD.—On November 2 an amendment to the Responsions statute was moved in Congregation by Prof. Gilbert Murray. This, if carried, would have had the effect of restricting the exemption from compulsory Greek to candidates in the pass schools and in the honour schools of natural science and mathematics. The amendment was lost on a division by 104 votes to 123. This decision will, no doubt, lead to a reopening of the question of exemption before Congregation, with a possible appeal to Convocation before a final settlement can be reached.

ON Friday, December 5, the Marquess of Northampton will distribute prizes and certificates at the Northampton Polytechnic Institute, Clerkenwell, E.C.1.

OWING to the lack of fuel for heating purposes, the University of Budapest has been unable to resume its activities this session. It is not anticipated that the resumption of work will be possible until next spring.

THE RIGHT HON. VISCOUNT HALDANE OF CLOAN, president of Birkbeck College, will receive the college graduates and deliver an address on "What is Truth?" at the celebration of the ninety-sixth anniversary of founder's day of the college on Friday, December 12. The chair will be taken at 8 p.m.

THE Dean of the faculty of medicine of the University of Paris has directed our attention to the reorganisation of the courses of instruction and the reopening of the laboratories and clinics in this faculty. A booklet has been published by Messrs. Masson (price 1 franc) giving a valuable and interesting historical account of the school, together with complete information with respect to the various courses. The booklet is admirably produced, and illustrated with twenty-one well-executed photographic plates. It should be in the hands of all those who wish to make use of the great resources now open to them. There should be many of these. Some of the clinical courses are given in vacation time—a fact which makes them available to those who might otherwise find it impossible to make a visit to Paris.

THE Prime Minister has appointed a Committee "to inquire into the position to be assigned to the classics (*i.e.* to the language, literature, and history of ancient Greece and Rome) in the educational system of the United Kingdom, and to advise as to the means by which the proper study of these subjects may be maintained and improved." The constitution of the Committee is as follows:—The Marquess of Crewe (chairman), Sir George Adam Smith, the Rev. C. A. Alington, Mr. S. O. Andrew, Miss M. D. Brock, Prof. H. J. Browne, Prof. J. Burnet, Mr. T. R. Glover, Sir Henry Hadow, Miss K. Jex-Blake, Prof. W. P. Ker, Mr. J. G. Legge, Mr. R. W. Livingstone, Mr. G. A. Macmillan, Prof. Gilbert Murray, Mr. Cyril Norwood, Prof. W. Rhys Roberts, Mr. C. E. Robinson, Prof. A. N. Whitehead, and Mr. C. Cookson (secretary). Communications intended for the Committee should be addressed to Mr. C. Cookson at the offices of the Board of Education, Victoria and Albert Museum, Exhibition Road, South Kensington, S.W.7.

THE eighth annual Conference of Educational Associations will be held in University College, Gower Street, London, W.C.1, from Wednesday, December 31, 1919, to Saturday, January 10, 1920. Mr. H. A. L. Fisher, President of the Board of Education, will give an address at the inaugural meeting, and the following are among the subjects to be discussed at meetings of some of the associations:—National Association of Manual Training Teachers and Educational Handwork Association: (a) The Measurement of Practical Ability and (b) Handwork and Science. British Psychological Society—Education Section: The Development of Mental Tests. Association of Science Teachers: Anti-gas Fans—with Experiments. Geographical Association: The Present Position of Geography in the Upper Forms—Some Causes and Possible Remedies; Spitsbergen; Islands, Peninsulas, and Empires; and Rainfall Considered as a Geographical Function. The Association of Science Teachers has arranged for a demonstration of Dr. Wilson's astronomical model at intervals throughout Monday, January 5.

THE inauguration of the University of Strasbourg under the new *régime*, which took place on November 22, was naturally an event of importance. The position of Strasbourg as the eastern outpost of French culture gives to its University a position of outstanding prestige. The authorities responsible for its "reconstruction" under the tricolour intend to maintain a very high standard of studies, and are especially anxious to attract students from this country. There are six faculties (law, sciences, letters, medicine, and Protestant and Catholic theology) and a *personnel enseignant* of 170 professors and *maîtres de conférence*. A well-endowed Société des Amis de l'Université (2 rue Geiler, Strasbourg) has just been founded, and one of its chief objects will be that of welcoming students (of either sex) from abroad and of making life attractive to them. Inquiries should be addressed to the society. The cost of living is much to the advantage of British residents on account of the very favourable rate of exchange. The imposing university buildings (opened in 1884 at a cost of 2,000,000*l.*) stand in the centre of the city, and close at hand is the magnificent library of 1,200,000 volumes, so rich in German literature. Strasbourg itself is, without doubt, one of the most attractive and well-governed cities in Western Europe, and its close proximity to the beautiful forests of the Vosges gives it a further advantage as a place of residence for British students.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 20.—Sir J. J. Thomson, president, in the chair.—W. J. **Johnston**: A linear associative algebra suitable for electro-magnetic relations and the theory of relativity. The algebra is based on four fundamental units i, j, k, o. The square of each unit is -1, while the other binary products are polar ($ij=-ji$, $io=-oi$, etc.). This algebra is associative. i, j, k are interpreted as mutually rectangular unit vectors in Euclidean space, while o is a unit vector in the fourth dimension perpendicular to the other three. Let ω be the pure imaginary scalar $ct\sqrt{-1}$ and $W=c^{-1}\phi\sqrt{-1}$, where ϕ is the scalar potential, then if (F, G, H) is the ordinary vector potential the vector

$$U=iF+jG+kH+oW$$

is the fourfold vector potential. If ∇_1 is the operator

$$i\frac{\partial}{\partial x}+j\frac{\partial}{\partial y}+k\frac{\partial}{\partial z}+o\frac{\partial}{\partial \omega},$$

then the electric and magnetic forces are the six components of $c\nabla_1 U$, the scalar part of which vanishes; and the eight scalar equations of the electrodynamic field which connect these forces are expressed by the single equation $\nabla_1(\nabla_1 U)=0$. This equation in the equivalent form $\nabla_1{}^2U=0$, when interpreted in terms of ordinary space, expresses that all the disturbances are propagated from their point-sources with uniform velocity c.—Sir Joseph **Larmor**: Generalised relativity, in connection with Mr. W. J. Johnston's symbolic calculus. If ijk are polar units, so that $i^2=-1$, $ij=-ji$, then $ik+jy+kz$ is a binary form involving the position of a point xyz and that of a trihedron ijk. So far as regards relative position, a displacement of the one is the same thing as a displacement of the other. A vector $iF+jG+kH$ represents an entity independent of the trihedron of reference, so is invariant for changes of the latter. Operations of addition and multiplication of vectors give results which are also invariant. Similar statements apply in geometric algebras of higher dimensions, and the scalars involved may be ordinary imaginaries. With the four dimensions $x, y, z, ct\sqrt{-1}$ of Minkowski, Mr. Johnston has shown that the vector forces of the electro-dynamic field are specified by $\nabla_1 U$, where U is the fourfold vector potential, and the eight equations of the field are summed up in $\nabla_1{}^2U=0$. But a source, naturally conceived as a singular point in ordinary space, complicates now into a Minkowski line. Again, all the geometric quantities natural to any Euclidean hyperspace are those which are evolved immediately from the addition and multiplication of vectors in it. It is proved that the possible types of disturbance propagated through an æther, which conform to the principle of relativity, are restricted to the single one specified by Maxwell's electro-dynamic scheme. In an appendix the Einstein idea of gravitation is developed as a theory of correspondence of modes of action of a physical system; it appears, at any rate on this view, that it does not involve displacement of the solar spectral lines.—G. E. **Bairsto**: The variation with frequency of the conductivity and dielectric constant of dielectrics for high-frequency oscillations.—F. J. W. **Whipple**: Equal parallel cylindrical conductors in electrical problems. Dr. Alexander Russell has recently directed attention to the practical importance of determining the mutual induction between currents of high frequency carried by parallel cylindrical conductors, and pointed out that the problem is mathematically equivalent to that of finding the distribution of static charge on two electrified conductors. The first part of the present paper is devoted to the solution of this problem. The coefficients of mutual and self-induction and the force between the cylinders, regarded as carriers of high-frequency currents, concentrated on the surfaces, are also investigated.—G. A. **Schott**: The scattering of X- and γ-rays by rings of electrons. A crucial test of the electron-ring theory of atoms. This paper investigates the effect of the regular spacing of the electrons of a ring on the scattering of X- and γ-rays, treated as undamped simple harmonic wave-trains of high frequency. The ring, whether at rest or revolving uniformly about its axis, diffracts the waves incident on it in all directions, but not equally. For a single electron the law of distribution is that of Sir J. J. Thomson's simple-pulse theory, but it deviates from it as the number of electrons increases, more energy going forward in the direction of the incident rays than backward. This asymmetry is retained, though to a less extent, by an irregular assemblage of similar electron rings with their axes distributed uniformly in space. An expression is obtained for the scattering coefficient, or mean total energy scattered per ring per unit intensity of the incident radiation, in a finite form, depending upon the number of electrons in the ring and on the ratio which its radius bears to the wave-length of the incident radiation.

Physical Society, November 14.—Prof. C. H. Lees, president, in the chair.—S. **Butterworth**: The self-inductance of single-layer flat coils. Two formulæ are established for the computation of the self-inductance of single-layer flat coils, one for the case when the inner and outer radii are not very different, and the other for the case of small inner radius. The two formulæ are shown to be consistent and capable of including all possible cases.—Dr. N. W. **McLachlan**: An experimental method of determining the primary current at break in a magneto. A method of obtaining experimentally the current at break in a magneto is described. A condenser is connected across the secondary winding to reduce the voltage below that required to cause sparking at the safety gap. The peak voltage due solely to interruption of the current at any speed is found. The interrupted direct current necessary to give the same peak voltage is also found by using a calibrating circuit. The magnitude of this current is equal to that broken in the magneto. The influence of the secondary condenser on the primary current at high speeds is discussed.—F. W. **Newman**: A new form of Wehnelt interrupter.

Royal Meteorological Society, November 19.—Sir Napier Shaw, president, in the chair.—Lieut. C. W. B. **Normand**: Effect of high temperature, humidity, and wind on the human body. The climatic conditions under which a wet bulb, restricted to a certain maximum rate of evaporation and having an initial temperature of 36·5° C., will neither gain nor lose heat are derived from kata-thermometer and wet-bulb formulæ. The application of these results to the human body is then considered, and, on the assumption that conditions resulting in a rise of body temperature above 36·5° C. must be fatal, the upper limits to liveable climatic conditions are deduced. The scorching, and sometimes deadly, simoom of tropical deserts is considered to be a case of the onset of a high wind without necessarily a change of temperature or humidity, converting liveable into unliveable conditions. The suggestion is also made that an essential feature of heat-strokes may be that a portion of the body has been exposed for a time to air conditions which are above the limit for existence. The wet kata-thermometer and wet-bulb formulæ were found to furnish quite discordant results regarding the behaviour of a wet surface under varying wind velocities, and it is suggested that this discrepancy is due to a less efficient wetting of the kata-thermometer bulb and to a consequently restricted rate of evaporation from it.—Capt. A. J. **Bamford**: Some observations of the upper air over Palestine. This paper gives a brief summary of some upper-air observations made in Palestine during the last two years. Tables and graphs are given showing the monthly averages of the horizontal movements at different altitudes over three stations, at one of which (near Ramleh) observations were kept up continuously for a year. The second part of the paper deals with vertical velocities, and includes frequency curves, showing for each of the layers 0–2000 ft., 2000–4000 ft., and 4000–6000 ft. the number of times in each month that the observed velocities differed from the theoretical ones by not more than 10, 20, 30, or 40 per cent., etc. The lowest layer is appreciably the most varied, and in it differences of 50 per cent. are not unusual, although the average velocity differs very slightly from theory. In the other layers there is a distinct increase in the compactness of the frequency curves, while the average velocity changes from slightly above to slightly below the theoretical value.—E. G. **Bilham**: Barometric pressure and underground water-level. The results recently obtained from a study of an experimental well with autographic registration at Kew Observatory, Richmond, Surrey, are compared with some earlier records obtained by Dr. Isaac Roberts at Maghull, near Liverpool, and by Prof. K. Honda in the neighbourhood of Tokyo, in Japan. As at Kew, the sensitiveness of the water surface at Maghull to pressure changes varies considerably, high sensitiveness being associated with saturation of the soil by previous heavy rainfall. In Japan it was found that in surface wells the water-level was not affected by pressure changes, sensitiveness being exhibited by deep artesian wells only. Prof. Honda has pointed out that by determining the sensitiveness of a well to barometric pressure the extent to which pressure changes affect strata at a given depth below the surface can be deduced. Data for Japan and the British Isles obtained in this way show marked points of difference.

CAMBRIDGE.

Philosophical Society, November 10.—Mr. C. T. R. Wilson, president, in the chair.—Dr. **Hartridge**: Colorimeter design.—J. T. **Saunders**: A note on hydrogen-ion concentration and photosynthesis. Spirogyra and elodea during photosynthesis cause the surrounding water to become markedly alkaline. Acids are very rapidly absorbed.—J. **Gray**: (1) The effects of some ions on spermatozoa. A suspension of Echinus spermatozoa in sea-water behaves in an electric field or in the presence of hydrogen ions or trivalent ions in the same way as an emulsion of albumen in alkaline solution. (2) The effects of ions on ciliary movement (gills of *Mytilus edulis*). By far the most potent ions in sea-water which affect ciliary movement are hydrogen ions and hydroxyl ions.—C. **Warburton**: Note on the solitary wasp, *Crabro cephalotes*. A small colony of *C. cephalotes* took possession in August, 1919, of a log in the author's garden, and afforded an opportunity of studying their habits with some accuracy. Observations were made on the time occupied in capturing and bringing home their prey and in packing them in the burrows.—Miss M. D. **Haviland**: Preliminary note on the life-history of a Proctotrypid (Lygocerus sp.) hyperparasite of Aphidius. *Lygocerus Cameroni*, Kieff (Proctotrypidæ), is a hyperparasite of certain Braconid parasites of plant-lice, and not a parasite of the aphides themselves, as has hitherto been assumed.—H. J. **Snell** and W. H. **Tams**: The natural history of Rodrigues, with exhibits. The paper gives a brief account of the island of Rodrigues as it at present exists. Since it was first discovered it appears to have been completely swept by fire, save only for peculiar deep pits in the elevated coral rock which in places overlies the volcanic. Here a certain number of the indigenous plants still survive, but probably the species in the flora are only half as numerous as when the island was first discovered; great damage has also been done by pigs and goats. The fauna previously described was almost in its size that of a coral island, but the present collections reveal much larger numbers of species and more variety, indicating probably a greater age for the island; the fauna also shows a close parallel to that of Mauritius and other volcanic islands in its adaptability to island conditions.

MANCHESTER.

Literary and Philosophical Society, November 4.—Prof. F. E. Weiss in the chair.—Prof. W. H. **Lang**: One of the simplest land-plants, *Hornea Lignieri*. The further results obtained by Dr. R. Kidston and Prof. W. H. Lang in the study of the silicified Old Red Sandstone plants at Rhynie were described. Two species of Rhynia are now distinguished, *R. Gwynne-Vaughani* and *R. major*. The latter is the larger in all its parts, and differs in some details of anatomy. These plants are rootless and leafless, and consist of a subterranean rhizome with rhizoids, dichotomously branched cylindrical aerial stems, and large terminal sporangia. Another equally simple plant, associated with these in the family Rhyniaceæ, has been discovered and investigated. This, *Hornea Lignieri*, consisted of rhizomes, branched stems, and terminal sporangia, without roots or leaves. The rhizomes were lobed parenchymatous structures, suggesting comparison with the protocorm of certain species of Lycopodium. The stems branched dichotomously, and had a simple central cylinder, cortex, and epidermis. No stomata have yet been discovered in this plant, as they have in Rhynia, but its organisation suggests a similar land-habit. The sporangia are remarkable in the presence of a columella-like central region, making the spore cavity dome-shaped. These simple vascular Cryptogams suggest comparisons with Bryophyta and Algæ.

PARIS.

Academy of Sciences, November 10.—M. Léon Guignard in the chair.—M. **Hamy**: A case of diffraction of images of circular stars.—H. **Douvillé**: The geology of Mont Blanc.—A. **Blondel**: A solution of heterochromatic photometry permitting of a physical measurement of the luminous intensity. The instrument proposed is based on the inversion of a spectrograph, the slit being replaced by a thermocouple.—L. **Cuénot**: The coaptation of the anterior femurs and of the head in the Phasmidæ.—E. **Bompiani**: Surfaces of translation and minimum surfaces in curved space.—B. **Baillaud**: Return of the Finlay comet; re-found by M. Schaumasse; compared by M. Fayet with the recent Sasaki comet. The comet discovered on October 25 by Sasaki is considered by M. Fayet, director of the Nice Observatory, as identical with the periodic Finlay comet recently found by Schaumasse.—A. **Véronnet**: Time and temperature of formation of a star. The author concludes that the sun originally could not have had a temperature more than three times its present temperature, or a radius more than double the present one. Even in this case the time of formation would have to be less than a million years. The physical conditions have never been greatly different from the existing ones.—M. **Girousse**: The calculation of the current thrown into the ground by the rails of electric tramways.—H. **Colin** and Mlle. A. **Chaudin**: The diastatic inversion of saccharose: influence of the products of the reaction on the velocity of hydrolysis. In all the cases studied the velocity of hydrolysis is a linear function of the fluidity of the solutions. The reduced velocity of hydrolysis of sugar by sucrase caused by the presence of lævulose or glucose must be attributed to the purely physical effect of increased viscosity.—L. **Chelle**: The detection of hydrocyanic acid in a case of poisoning. Its *post-mortem* transformation into thiocyanic acid. It is well recognised that hydrocyanic acid apparently disappears from the body at a certain period after death. It is now shown that this acid is not destroyed or transformed in an irreversible manner, but takes up sulphur and is converted into thiocyanic acid. The latter resists the action of putrefaction, and can be extracted from the tissues and reconverted by oxidation into hydrocyanic acid.—R. **Levaillant** and L. J. **Simon**: The action of methyl alcohol on sulphuryl chloride and on methyl chlorosulphonate.—J. **Barthoux**: Relation of volcanic eruptions and marine transgressions in Egypt.—A. **Briquet**. The age of the old littoral lines of the Bas-Champs of Picardy.—G. **Mouret**: The prolongation to the north-west of the zone of crushed rocks recognised between Asprières (Aveyron) and Fromental (Haute-Vienne).—Ph. **Glangeaud**: The plateau of Millevaches, its cycles of erosion, its ancient glaciers and peat-bogs.—J. **de Lapparent**: The conglomerates of the valley of la Bruche and the character of the breccias of sedimentary origin.—P. **Garrigou-Lagrange**: The kinematography of atmospheric movements and weather prediction.—C. E. **Brazier**: Relations of wind with gradient in the lower layers of the atmosphere.—A. **Goris** and Ch. **Vischniac**: Characters and composition of primeverose. The new sugar was isolated from two glucosides extracted from *Primula officinalis*. Its physical and chemical properties are given. Glucose and xylose are the products of hydrolysis, and primeverose is the first known biose of this composition.—G. **Tanret**: The *miellée* of the poplar. Melezitose has been isolated from the sugary deposit (*miellée*) found in warm seasons on the upper faces of the leaves of certain species.—J. **Amar**: Mechanism of the cough in respiratory diseases.—J. **Nageotte**: The formation of conjunctive fibres in a non-living medium at the expense of dead protoplasm.—MM. G. **Bertrand**, **Brocq-Rousseu**, and **Dassonville**: Destruction of *Sitotroga ceralella* by chloropicrin.

DIARY OF SOCIETIES.

THURSDAY, DECEMBER 4.

ROYAL SOCIETY, at 4.30.—A. M. Williams: (1) The Adsorption of Gases at Low and Moderate Concentrations. Part I: Deduction of the Theoretical Adsorption Isotere and Isotherm. Part II: Experimental Verification of the Form of the Theoretical Isoteres and Isotherms. (2) The Adsorption of Gases at Low and Moderate Concentrations. Part III: Experimental Verification of the Constant in the Theoretical Adsorption Isotere.—T. R. Merton: (1) The Secondary Spectrum of Hydrogen. (2) The Spectra of Isotopes.—E. F. Armstrong and T. P. Hilditch: A Study of Catalytic Actions at Solid Surfaces, Part II.—F. Horton and Ann C. Davies: An Experimental Determination of the Critical Electron Velocities for the Production of Radiation and Ionisation on Collision with Argon Atoms.

ROYAL SOCIETY OF MEDICINE (Balneology and Climatology Section), at 5.30.—Dr. C. F. Sonntag: The History of Baths and Bathing in Britain before the Norman Conquest.

CHEMICAL SOCIETY, at 8.—H. Henstock: Di-phenanthryl.—B. D. Steele and H. G. Denham: A New Sulphuretted Hydrogen Generator.

ROYAL SOCIETY OF MEDICINE (Obstetrics and Gynæcology Section), at 8.—*Discussion:* On the Recently Published Report on the Teaching of Obstetrics and Gynæcology to Medical Students and Graduates in London. Dr. T. W. Eden will introduce the discussion, and a Criticism of the Report will be read by Dr. H. Spencer.

FRIDAY, DECEMBER 5.

ROYAL SOCIETY OF MEDICINE (Laryngology Section), at 4.

INSTITUTION OF ELECTRICAL ENGINEERS (Students' Meeting) (at the City and Guilds Technical College, Leonard Street, E.C. 2), at 7.—H. M. Barlow: Thermionic Magnifiers.

GEOLOGISTS' ASSOCIATION (at University College), at 7.30.—W. B. R. King: Geological Work on the Western Front.

TECHNICAL INSPECTION ASSOCIATION (at the Royal Society of Arts), at 7.30.—R. D. Summerfield and H. J. Davey: Inspection and Testing of Materials.

ROYAL SOCIETY OF MEDICINE (Anæsthetics Section), at 8.30.—Dr. C. H. Mott: Intratracheal Insufflation of Chloroform; a Report on 357 Cases.

MONDAY, DECEMBER 8.

VICTORIA INSTITUTE (at the Central Hall, Westminster), at 4.30.—A. W. Sutton: The Ruined Cities of Palestine, East and West of the Jordan.

ROYAL GEOGRAPHICAL SOCIETY (at Lowther Lodge, Kensington Gore, S.W. 7), at 5.—Lt.-Col. W. J. Johnston: The New Inch and Quarter-inch Maps of the Ordnance Survey.

BIOCHEMICAL SOCIETY (at the Lister Institute), at 5.30.—B. Moore, E. B. R. Prideaux, E. Whitley, and A. Webster: (1) Season Variations in Reaction of Sea Water Due to Photosynthesis; (2) Fixation of Atmospheric Nitrogen by Marine Algæ.—B. Moore and E. PARASITIC AMŒBÆ AND DISEASE.

The Amoebae Living in Man: A Zoological Monograph. By Prof. Clifford Dobell. Pp. vii+155+v plates. (London: John Bale, Sons, and Danielsson, Ltd., 1919.) Price 7*s.* 6*d.* net.

THIS is a very valuable piece of work, bringing order and critical intelligence to bear in a field of study which, already touched by many observers, has immensely increased in activity and importance during the war. The common freshwater Amœba, living freely in natural pools, has many relatives, some of which have been distinguished by definite characters of the nucleus, form of pseudopodia, cysts, and other characteristics as "good" species and even assigned to distinct genera. But there has been no careful cytological study of the various species, though here and there important observations have been made. When to these forms are added those living in the soil, in sea-water, and, lastly, those parasitic in other animals, we find that there is quite a large group of these "amœboid" organisms which have been recorded from this or that habitat by observers who were hurried by other work or insufficiently trained in cytological methods. As a consequence, without sound method or criticism, specific and even generic names have been given to "Amœbæ," parasitic or free-living, and misleading sketches of them have been published. A perplexing confusion of inaccurate statements obscures the whole subject.

A great source of inaccuracy and vague statement has been the interest excited among medical men by the parasitic species of Amœba-like organisms and their association with dysentery and possibly with other diseases. As a rule the medical observers have not been trained "protozoologists," or attentive to the laws of zoological nomenclature. It is creditable to them that in the midst of other important work they have done so much in directing attention to these parasites. But to give any serious value to a knowledge of the Amœbæ as a guide to the diagnosis and control of disease, it was absolutely necessary that a high standard of accuracy in observation and statement, correct nomenclature, and a severe criticism of the accumulated mass of loose statements published by incompetent though well-meaning writers, should be applied to this subject by a competent authority having not only special experience and understanding of systematic zoology, but also time and opportunity to ensure full examination by him of the organisms in question.

The Government was fortunate in being able to secure the services of Mr. Clifford Dobell, assistant professor of Protistology and Cytology in the Imperial College of Science, for this purpose. Prof. Dobell had before the war made for himself a distinguished name as an investigator of the structure and reproduction of such minute parasites as the Coccidia, the Bacteria, and, amongst others, of the Amœbæ parasitic in frogs. He had carried the discrimination of details in the structure and reproductive changes of the threads and granules of the cell-nucleus of such minute organisms beyond that attained by other microscopists. His careful and precise work was recognised by his scientific *confrères* as certain to lead to sound conclusions when applied with ample time and material to the problem of the relation of Amœbæ to disease in man, and especially to the question of the causation of dysentery (and other diseases) by one, or more than one, species of Amœba.

In 1915 the return to this country of large bodies of troops from the Eastern war area—many afflicted with dysentery—rendered it necessary to examine the stools of a very large number of patients in order to decide whether those returning from Gallipoli and Egypt were suffering, as was supposed (but shown to be erroneously so), from "amœbic dysentery." A large number of trained workers were required for this purpose. Their training was undertaken, at first, by Dr. C. M. Wenyon, but when his services were required elsewhere at the end of 1915, Prof. Dobell took charge of the work and for four years has devoted himself uninterruptedly to the practical study of the intestinal protozoa of man. A large part of his time has been occupied with the routine work of diagnosis, with teaching that routine to others, and with the investigation of methods of treating amœbic dysentery. But, as he says, he has had great opportunities for studying the human intestinal protozoa from the zoological point of view, and probably no zoologist has ever before had such an immense amount of this special material at his disposal.

As a result, in spite of the really formidable difficulties in interpreting the results of many other workers, Prof. Dobell is able to say that almost all his own doubts have disappeared, and he presents to other workers in this field in the present volume a very full and detailed account of the work of his predecessors and of his own work and conclusions—together with the story of his methods of microscopic observation—illustrated by five remarkably well-executed plates.

This book is not for the general reader, and not even for every zoologist. It is addressed to the protozoologist who has some familiarity with the later developments of cytology, and is either already engaged in such studies or qualifying for them. At the same time we may briefly direct attention to some of Prof. Dobell's conclusions which have general interest. For reasons fully set forth, he reduces the number of species of "Amœbæ" ascertained to be living in man to six, which he arranges in four genera, as follows:—

Genus I.—ENTAMŒBA, Cassagrandi and Barbagallo, 1895 (*nec* Endamœba, Leidy, 1879).

Species 1. *E. coli*, Grassi; 2. *E. histolytica*, Schaudinn; 3. *E. gingivalis*, Gros.

Genus II.—ENDOLIMAX, Kuenen and Swellengrebel, 1917.

Species 4. *E. nana*, Wenyon and O'Connor.

Genus III.—IODAMŒBA, *nov. gen.*

Species 5. *I. Bütschlii*, Prowazek.

Genus IV.—DIENTAMŒBA, Jepps and Dobell, 1918.

Species 6. *D. fragilis*, Jepps and Dobell.

Of these only *Entamoeba histolytica* is proved experimentally to be pathogenic; it causes dysentery and liver abscess. None of the other five are pathogenic. *E. coli* is proved experimentally to be harmless. It is held by Prof. Dobell, in agreement with recent investigators, such as Goodrich and Moseley, that *E. gingivalis*, common on the human gums, is innocuous and not a cause of pyorrhœa. He cites their observation of the occurrence of *E. gingivalis* in pus from the mouths of dogs and cats. *Endolimax nana* is a small but well-marked innocuous species common in the human bowel. *Iodamoeba Bütschlii* is a small and uncommon species which produces in its cysts a mass of glycogen, which gives the mahogany stain when treated with iodine. *Dientamoeba fragilis* is a very small form studied only in seven cases. It is typically "bi-nucleate."

Entamoeba coli is as large as *E. histolytica*, and the two have been persistently mistaken for one another and confused in name. Even when occurring together they have not been distinguished. Hence endless misapprehension and trouble have arisen as to which "Amœba" it is that is harmless and which that causes dysentery. Lösch, in 1875, gave the name *Amoeba coli* to what is now by common consent called *Entamoeba histolytica*. Grassi, in 1879, described as the *Amoeba coli* of Lösch, not what Lösch had so called, but the harmless form which to-day passes under that name. Schaudinn (1903) described what Lösch had named *Amoeba coli* under the name *Amoeba histolytica*. Schaudinn *ought* to have recognised what he described as being Lösch's *A. coli*, but he *failed* to do so. Hence *E. histolytica* is to-day the name in use for the dysentery-causing species, and *E. coli* is that applied (contrary to the original use of the name) to the harmless species. Prof. Dobell declines (and we think rightly) to reverse or interchange the two names again, as such a course would cause "endless confusion." The mere citation of this one example of the misunderstandings of former authorities will serve to suggest to the reader how great are the difficulties in regard to nomenclature and identification with which Prof. Dobell has successfully contended. All future workers in this line must be grateful to him for his laborious and judicious treatment of these questions, as well as for his new and accurate observations.

E. RAY LANKESTER.

ASTRONOMICAL LECTURES AND ESSAYS.

(1) *The Adolfo Stahl Lectures in Astronomy. Delivered in San Francisco, California, in 1916–17 and 1917–18, under the Auspices of the Astronomical Society of the Pacific.* Pp. xiv + 257 + liv plates. (San Francisco: D. S. Richardson, 128 Lick Building, 35 Montgomery Street, 1919.) Price 2.75 dollars.

(2) *Planetary Rotation Periods and Group Ratios.* By F. A. Black. Pp. xii + 115. (Edinburgh and London: Gall and Inglis, n.d.) Price 3*s.* 6*d.*

(1) THE Astronomical Society of the Pacific is in several respects an interesting and fortunate body. As Dr. Aitken recalls in one of these lectures, it had its origin in the co-operation of amateur and professional observers of the eclipse of 1889, which crossed California and was the object of an expedition, the first of a splendidly organised series, from the Lick Observatory, then only recently established. The society is essentially an amateur association enjoying the cordial support of professional astronomers, and this means much, for in its province—a thousand miles long—is to be found the most notable part of the instrumental equipment of astronomy in the world, including the three largest reflectors, with an average aperture of nearly 80 in. It bestows the Bruce medal on conditions which make the award the seal of the highest professional approval on the work of the recipient. It grants the Donohoe medal to the discoverer of every unexpected comet. Its "Publications," without having the severity of a conventional learned journal, contain notes on results of the most recent work, and often give an intimate account of observatory life in circumstances of peculiar interest, especially welcome to those who have had personal experience of it.

It was quite in accordance with the aims and spirit of the society that an organised course of six popular lectures should be given in San Francisco by members of the Lick Observatory staff in the winter of 1916–17, and equally fitting, but no less welcome, that a generous benefactor should be found in Mr. Adolfo Stahl to defray the expenses; for the readiness of Californian citizens to help worthy astronomical projects of all kinds with financial support is unequalled elsewhere. And Mr. Stahl's liberality did not stop there; for when the success of the first course suggested a second series in the following winter, this time with the help of the Mount Wilson and the Berkeley staffs, Mr. Stahl again lent the same aid, and when it was very properly felt that the lectures, which had been printed in the "Publications," deserved to be published in collected book form, he undertook once more to guarantee the cost. The result is this handsome volume, beautifully illustrated and containing a dozen lectures, popular in the sense of being simply stated and dealing for the most part with modern aspects of astronomy, by competent authors.

The first two lectures, on the solar system and on comets, are by the director of the Lick Observatory. Surely the time is at hand for an advance in our knowledge of the physics of comets. Dr. Aitken, who has acted as editor of the volume, is responsible for three lectures—on solar eclipses, on the moon, and on recent results from stars and nebulæ. Dr. H. D. Curtis discourses on nebulæ and on some aspects of astronomical discovery. Four single lectures are by Dr. Crawford on epochs in astronomical history, by Dr. St. John on the sun, by Dr. Leuschner on motions in the solar system, dealing mainly with recent computing work at Berkeley, and by Mr. Seares on the brightness, colours, distribution, and motions of the stars. These last three are very useful summaries of current work. The final lecture, on the Mount Wilson 100-in. reflector, was delivered by Dr. Ritchey, but not reduced to writing, and, owing to the lecturer's preoccupation with war work, it has been necessary to substitute an account compiled from other sources.

The book deserved an index. The photograph of the Pleiades (plate xliv.) was not by *Sir* Isaac Roberts. Did space not forbid, one would be tempted to dispute some of Dr. Crawford's views of history. Both he and Dr. Leuschner disparage Kepler's achievements by calling them guesswork. If to be fertile in hypotheses and to submit them instantly to the test of comparison with good observations be guesswork, then a good part of the truest scientific method is guesswork. Of this part Kepler is the supreme and unrivalled example.

(2) A reviewer would be quite justified in declining to take Mr. Black's little book seriously. It is a dreary collection of petty calculations, made with 7-figure logarithms when 4-figure would have been ample and printed *in extenso*. As there is no clear and intelligible summary, it takes no little trouble to find out what is the precise object aimed at, or how successfully that object is attained. But the effect is to set up an empirical relation between the rotation periods of the planets and their masses and radii, which may be expressed by the formula (p. 56)

$$\frac{T_1}{T_2}=\left(\frac{R_2}{R_1}\right)^{\frac{1}{2}}\left(\frac{g_1}{g_2}\right)^{\frac{1}{3}}=\left(\frac{M_1}{M_2}\right)^{\frac{1}{3}}\left(\frac{R_2}{R_1}\right)^{\frac{7}{6}},$$

$g=M/R^2$ being the surface gravity; the corresponding suffix notation is not Mr. Black's. Now among the eight planets the rotation periods of four are practically unknown. Obviously, three assumed periods can be satisfied rigorously by a proper choice of the two exponents. Hence a consistent result for the Earth, Mars, and Jupiter, with a 20 per cent. error for Saturn, has nothing impressive about it. The author then goes on to complicate his formula further by introducing imaginary satellites skimming over the surface of imaginary planets, and the effect (p. 59) can be expressed in the form

$$\frac{T_1}{T_2}=\left(\frac{R_2}{R_1}\right)^{\frac{7}{6}}\left(\frac{M_1}{M_2}\right)^{\frac{1}{3}}\left(\frac{M_2R_1^3}{M_1R_2^3}\right)^{\frac{1}{18}}\left(\frac{M_1R_1^3}{M_2R_2^3}\right)^{\frac{1}{18}}=\left(\frac{M_1}{M_2}\right)^{\frac{1}{3}}\left(\frac{R_2}{R_1}\right)^{\frac{7}{6}}.$$

So the results are naturally the same. In fact, Mr. Black plays on himself a variant of the old game beginning "Think of a number" with a portentous elaboration which may amuse some readers. On p. 59 the Sun should be substituted for the first planet mentioned in the definitions of both M and *m*.

The foundation of a second essay rests on the approximate equality of the mass ratios

$$\frac{\text{Jupiter}}{\text{Mars}}=\frac{\text{Saturn}}{\text{Mercury}},\quad\frac{\text{Uranus}}{\text{Venus}}=\frac{\text{Neptune}}{\text{Earth}}.$$

Of course, the mass of Mercury is really unknown, but it is rather remarkable that Newcomb's masses for Uranus and Neptune only require an adjustment each within 2 per cent. to make the second relation exact. With this slender material the author again builds up elaborate arithmetical combinations and finds an evident delight in results which are nothing more than simple numerical verifications of the laws of proportion.

H. C. P.

THE DOMINION OF MAN.

The Outline of History: Being a Plain History of Life and Mankind. By H. G. Wells. With the editorial help of Mr. Ernest Barker, Sir H. H. Johnston, Sir E. Ray Lankester, and Prof. Gilbert Murray. To be completed in about twenty fortnightly parts. Part i. Pp. 32. (London: George Newnes, Ltd.) Price 1*s.* 2*d.* net.

IN this first part of his "Outline of History" Mr. H. G. Wells has surpassed the old author who carried the Trojan war back to Leda's eggs, for he begins with our solar system as a nebula condensing into sun and planets, and our earth as a mass of glowing matter. He tells how, in the course of cooling, an ocean gathered on its surface, on the margin of which the first structureless organic matter at last appeared, from which, in the course of ages, the earth's living tenants were developed. He describes in graphic terms not a few characteristic members in their succession, some of which are well depicted by Mr. J. F. Horrabin. Once or twice a phrase occurs to which we may demur: for instance, the nautilus is not a genus of ammonite; volcanic eruptions are more often a consequence than a cause of mountain upheaval; and we doubt whether the changes between the Mesozoic and the Kainozoic were so "catastrophic" as he implies. But these are trifles, and we find, after a discussion of the estimates of geological time, a good sketch of natural selection and the changes of species. As these changes in life depend not only on alterations in the world's physical geography, but also on its climate, the causes of the latter are briefly explained.

Next, Mr. Wells, after sketching the strange living tenants of the earth in ages when no creature with a backbone existed in sea or on land, brings before his readers the strange aspects of the earlier vertebrates, such as Pareiosaurus, which, low down as it is among the reptiles, seems as if striving to be a mammal. This leads to the "Age of Reptiles," which is illustrated by such huge forms as Brontosaurus and Diplodocus, Stegosaurus and Triceratops, which might be a first attempt at a Pachyderm, together with Megalosaurus, Tyrannosaurus, and Iguanodon, besides Plesiosaurus and Ichthyosaurus in the sea, with flying creatures like Pterodactyles and Archæopteryx, half bird, half lizard; and then dentigerous birds, which pass on to the Kainozoic, and end the present part of the work, which when completed will be a broad survey of the world throughout time.

Mr. Wells has undertaken a difficult task, and it is not too much to say that no other writer of the present day is so well equipped as he is to bring it to a successful completion. He possesses the rare combination of brilliant literary power with comprehensive and precise knowledge, and this distinctive quality makes his work one in which all intelligent readers will find profit and delight.

OUR BOOKSHELF.

Principles of Electric Spark Ignition in Internal-combustion Engines. By J. D. Morgan. Pp. vii+88. (London: Crosby Lockwood and Son, 1920.) Price 8*s*. 6*d*. net.

In the eighty or so pages of this little book Mr. Morgan gives the result of certain experiments by others and himself to determine the nature of electric spark ignition in internal-combustion engines. A wide circle of readers will feel grateful to the author for providing in this convenient form an account of the more important work along these lines, and for the reference which he provides to the sources from which information in fuller detail may be obtained. Mr. Morgan puts them still further in his debt by the lucidity with which he writes, and his manifest endeavour—almost always successful—to ensure that, even in the more intricate parts of the subject, his phraseology shall be free from the ambiguity which is so often the despair of readers of technical books.

Mr. Morgan explains most ingeniously and simply his view of the double nature of the spark, its important "capacity" component and the less valuable "inductance" oscillation. Experiment so far has failed to show any effect on the resultant gaseous explosion, or on the upper and lower limits of richness at which explosion will occur, of change in the size, temperature, energy, or other feature of the spark. Any one individual spark seems to be as good as any other, provided that explosion is caused; but the apparatus must be unfailing in the succession of sparks which it is designed to provide.

The book is one which should be in the hands of all who are interested in the scientific side of the design of internal-combustion engines in their many forms. That further work along these lines will cause spark gaps to be less sensitive than they now are to short circuiting caused by the inevitable gradual loss of insulation is greatly to be hoped.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Gravitation and Light.

Jupiter ought just to show the Einstein deflection, for if it pass between two stars a couple of diameters of the planet apart, their temporary relative displacement will be a "third" of arc, the sixtieth of a second; and this could be measured with a heliometer.

Oliver J. Lodge.

Mariemont, Edgbaston, December 6.

The Deflection of Light during a Solar Eclipse.

Prof. Anderson suggested in Nature of December 4 (p. 354) a possible source of systematic error in the determination of the deflection of light at an eclipse, owing to lateral refraction caused by a temperature-gradient in the shadow-cone in our atmosphere. Having carefully considered this suggestion, I feel convinced that the effects of any possible temperature-gradient would be small.

Taking the height of the atmosphere as 10 miles, the ray from a star 30′ from the sun's centre would traverse a distance of 150 yards in the direction perpendicular to the shadow-axis whilst passing through our atmosphere. Prof. Anderson estimates a temperature-drop of 1/18 of a degree as required to produce the observed deflection. Thus the lateral temperature-gradient must be 1° C. per $1\frac{1}{2}$ miles. The shadow moves over the earth at about 30 miles a minute, so that for a stationary observer the fall of temperature would have to be at the rate of 20° a minute to produce the observed effect.

In the case of a single surface of discontinuity, considered for simplicity by Prof. Anderson, the displacement by lateral refraction is inversely proportional to the distance from the sun's centre; but this law does not apply in the actual case of a continuous temperature-gradient.

It seems possible that the effect might amount to as much as 1/20 of the Einstein deflection in some cases, and possibly the rather high value found at Sobral has been increased by this cause. At Principe there was no perceptible change of temperature during the eclipse, but the climatic conditions there are exceptional.

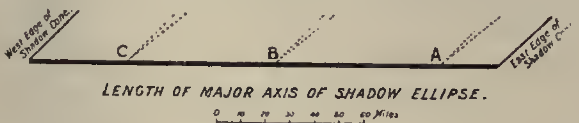
A. S. Eddington.

Observatory, Cambridge.

Prof. Anderson's letter in Nature of December 4 raises a point well worthy of consideration—that is, the possibility of abnormal refraction due to the lowering of temperature in the air by the passage of the shadow cone. I do not, however, think that more than a very small portion of the effect noted at Sobral could be explained in this way. The shadow ellipse was 194 miles long (direction of motion) and 137 miles broad. I have drawn a section in the former direction to scale, taking the height as 20 miles. It is certainly unnecessary to take it higher, as the temperature of the upper air is unaffected by the passage of the shadow.

Photographs were taken at Sobral at uniform intervals throughout totality, and all give tolerably accordant values of the shift.

But at the point A, near the beginning of totality, the left-hand ray, coming from a star about 1° west of the sun, would be travelling from a denser to a rarer medium; the right-hand ray, coming from a star 1° east of the sun, from a rarer to a denser medium. Hence both rays would be deflected towards the east, and the distance between the stars would be unaffected. The same thing would happen at C, the deflection of both being now to the west. It is only at the middle point B that the apparent distance could be altered, and here the temperature-gradient vanishes.



Moreover, at A and C there would be no temperature gradient (and therefore no optical shift) in the plane perpendicular to the plane of the diagram. But the measures showed equal shifts in all directions. In actual fact, the presence of much cloud must have made the temperature gradients irregular; the fall of temperature at Sobral during totality was very small, doubtless owing to the cloudiness before totality.

A. C. D. CROMMELIN.

Sex-Phenomena in the Common Limpet (*Patella vulgata*).

IN the course of investigations on the rate of growth and the age at which breeding begins the common limpet was examined, and the following interesting phenomena were observed:—A preliminary examination of batches of limpets of about 2 cm. long, and later still of smaller specimens, revealed the occurrence of a large proportion of males. The proportion of males was so high indeed as to give strong suspicions of a change of sex from male to female (*i.e.* protandric hermaphroditism), and a sample of about 1000 small ones less than 1 in. was therefore collected from cement piles between 3 ft. and 9 ft. above low-water springs at the Great Western Docks, Plymouth, and the sex examined and recorded. As the common limpet has no penis or uterus, it is necessary to examine the internal sex-organ (the gonad) to determine the sex. Of the 1102 limpets collected, 167 were rejected as being found by experience to be too small to show development of the internal sex-organ; these were mainly about 13 mm. long. Of the remainder, 169 (mostly about 14 mm.) showed no development of gonad on examination, 64 were females mostly about 2 cm. long, and the remaining 702 were males mostly about 15 mm. to 20 mm. long. These males probably comprise the bulk of the limpets in this sample in their first spawning year.

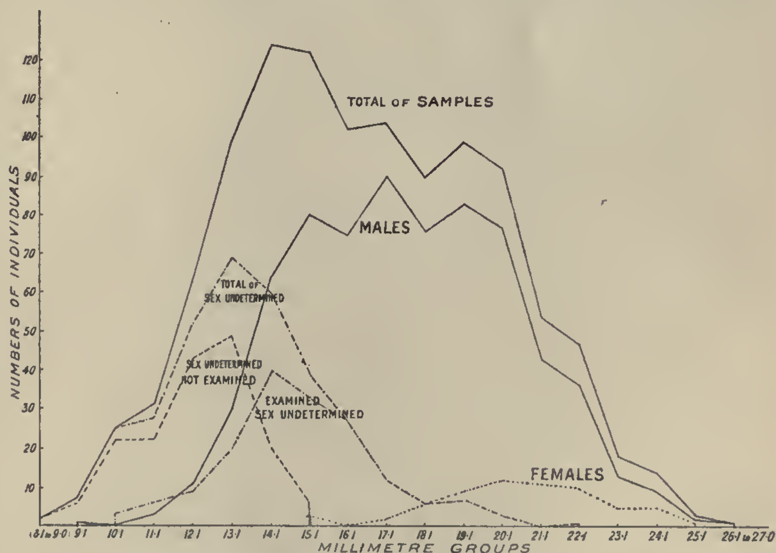


FIG. 1.—Length and sex analysis of a sample of 1102 young limpets under 1 in. in length collected at random at Plymouth, October 31, 1919.

This result confirmed the suspicion that all limpets might be born as males, and to determine whether they all change into females a sample of about 600 larger but medium-sized specimens from 3 cm. to 4·5 cm. was examined from the same locality. Of these 255 were males, 3 of indeterminate sex, and 334 females. These figures indicated sex-change, but were not sufficiently definite; hence a further sample of about 1000 very large limpets, from 5 cm. to 7·5 cm. in length, was obtained from Looe Island and examined, with the result that 693 were found to be females, 18 were of indeterminate sex, and 301 were males. Some of these latter males were very big, ranging up to 6·5 cm. in length; some males, therefore, may live several years before changing into females, if, indeed, these larger males ever change into females. At the same time as these very large limpets were collected a batch of tiny limpets was taken from the same locality and the sex examined. Of this sample of 1233 tiny limpets, 138 were rejected as being too small (*i.e. circa* 13 mm. and less), and of the remainder, all of which were examined, 944 were males (mainly from 16 mm. to 20 mm.); 113 showed no gonad developed, and were mostly small, about 15 mm. in length; and the remainder, only 38, were females, and mostly about 2 cm. long.

Amongst the 102 females recorded in the 2030 young examined, however, 4 were found of a size about 15 mm. long. The writer thinks that this small proportion of small females will be found to be dwarf females analogous to those described by Conklin[1] and by Orton[2] in the slipper limpets (*Crepidula fornicata* and other species). In this investigation so far length of shell has been taken as an indicator of age, and doubtless *on the average* length is a good indicator for a given locality. But the rate of growth is known to be variable from as yet unpublished work, and it is surmised that the smallest female limpets are two-year-old forms in which growth has been stunted, and that such specimens are therefore older than their size indicates. In this case it would appear that sex-change may occur any time after the first spawning season. One ready method of testing this view would be to obtain a large number of young limpets of known age, and this letter is written mainly with the view of obtaining information of any dock-walls, slips,

[1] "The Embryology of Crepidula." By E. G. Conklin. *Journal of Morphology*, vol. xiii., p. 12, 1897.

[2] "On the Occurrence of Protandric Hermaphroditism in *Crepidula fornicata*." By J. H. Orton. Proc. Roy. Soc., B, vol. lxxxi., p. 480 1909.

or other constructions in tidal waters built during the years 1918, 1919, or even 1917. As the examination for sex can be conducted with speed only during the breeding season, which may shortly end in some localities, it is hoped that anyone knowing of suitable constructions will inform the writer at the address given below.

Evidence of sex-change is apparently already available from Gemmill's observations,[3] made so long ago as 1896. Gemmill found that 3 specimens out of 250 examined by him were hermaphrodite. In the samples quoted above no definite hermaphrodite forms were found, but several were suspected and preserved for microscopic examination. These forms were, however, mainly male or female, and are recorded above tentatively as males and females respectively. Sex-change may be seasonal, as is indeed indicated by Russell's observations on the sex of the common limpet.[4]

The sex-phenomena in the common limpet closely resemble in most respects those found in the slipper limpet, where the small females and large males are accounted for, but in which all the tiny ones—some thousands of which have now been examined—have a penis. It is, however, not impossible, on the evidence available at the moment, that sexual dimorphism without sex-change may explain the phenomena in the common limpet, but this explanation does not seem probable. The observations on the sex of the common limpet cannot all be described here; they will be continued and completed and the results published in the Journal of the Marine Biological Association, Plymouth. Fig. 1 shows a length-sex analysis of the sample of small limpets under 1 in. in length collected at Plymouth. J. H. ORTON.

The Hoe, Plymouth.

A Tribute from Prague.

PERMIT me to congratulate you upon the jubilee issue of November 6, which has just reached me and has been received with great pleasure, for the last number of NATURE which reached me before this was that of July 30, 1914!

It may interest readers of NATURE to learn that from that date the Austrian Government prohibited for more than four years the circulation of anything printed in England as a punishment for the regard which, especially during the war, we have always had for your country, to which, with the other Allies, we owe our liberty. To the bodily sufferings of the war was added isolation from nearly the whole civilised world.

In a year's time I shall celebrate the fortieth anniversary of my introduction to NATURE, for while a student of Owens College, Manchester, I purchased in October, 1880, my first copy of the journal, and since that time I have been an ardent reader, contributor, and even Bohemian correspondent. The reading of NATURE's all-round scientific contents has been one of the greatest pleasures of my life in my leisure hours, and the richness of information which I have gathered from it cannot be expressed in better words than those of Dr. Deslandres in the jubilee number. I do not wonder that all attempts at founding a similar scientific and yet popular (in its best sense) journal in other European countries have invariably failed, for there a man of science is usually identical with a professor (a professional worker); and though I am one myself, yet I am of the opinion that the scientific character of NATURE is in no small measure due to the high type of British scientific amateur or student of science for its own sake, which I do not find equalled in any other country in the world.

Even we scientific workers in this remote part of Europe owe sincere thanks to Sir Norman Lockyer, who is a brilliant representative of the "non-professional" English man of science, for providing us with NATURE and conducting it so admirably for so many years. BOHUSLAV BRAUNER.

Chemical Laboratory, Bohemian University,
Prague, November 17.

EINSTEIN'S RELATIVITY THEORY OF GRAVITATION.[1]

II.—THE NATURE OF THE THEORY.

IN the first article an attempt was made to show the roads which led to Einstein's adventure of thought. On the physical side briefly it was this. Newton associated gravitation definitely with mass. Electromagnetic theory showed that the mass of a body is not a definite and invariable quantity inherent in matter alone. The energy of light and heat certainly has inertia. Is it, then, also susceptible to gravitation, and, if so, exactly in what manner? The very precise experiments of Eötvös rather indicated that the mass of a body, as indicated by its inertia, is the same as that which is affected by gravitation.

Also, how must the expression of Newton's law of gravitation be modified to meet the new view of mass? How, also, must the electromagnetic theory and the related pre-war relativity be adapted to allow of the effect of gravitation? With the relaxation of the stipulation that the velocity of light shall be constant, will the principle of relativity become more general and acceptable to the philosophic doctrine of relativity, or will it, on the other hand, become completely impossible?

One point arises immediately. The out-and-out relativist will not admit an absolute measure of acceleration any more than of velocity. The effect, however, of an accelerated motion is to produce an apparent change in gravitation; the measure of gravitation at any place must therefore be a relative quantity depending upon the choice which the observer makes as to the way in which he will measure velocities and accelerations. This is one of Einstein's fundamental points. It has been customary in expositions of mechanics to distinguish between so-called "centrifugal force" and "gravitational force." The former is said to be fictitious, being simply a manifestation of the desire of a body to travel uniformly in a straight line. On the other hand, gravitation has been called a real force because associated with a cause external to the body on which it acts.

Einstein asks us to consider the result of supposing that the distinction is not essential. This was his so-called "principle of equivalence." It led at once to the idea of a ray of light being deviated as it passes through a field of gravitational force. An observer near the surface of the

[1] The first article appeared in NATURE of December 4

earth notes objects falling away from him towards the earth. Ordinarily, he attributes this to the earth's attraction. If he falls with them, his sense of gravitation is lost. His watch ceases to press on the bottom of his pocket; his feet no longer press on his boots. To this falling observer there is no gravitation. If he had time to think or make observations of the propagation of light, according to the principle of equivalence he would now find nothing gravitational to disturb the rectilinear motion of light. In other words, a ray of light propagated horizontally would share in his vertical motion. To an observer not falling, and, therefore, cognisant of a gravitational field, the path of the ray would therefore be bending downward towards the earth.

The systematic working out of this idea requires, as has been remarked, considerable mathematics. All that can be attempted here is to give a faint indication of the line of attack, mainly by way of analogy.

It is no new discovery to speak of time as a fourth dimension. Every human mind has the power in some degree of looking upon a period of the history of the world as a whole. In doing this, little difference is made between intervals of time and intervals of space. The whole is laid out before him to comprehend in one glance. He can at the same time contemplate a succession of events in time, and the spatial relations of those events. He can, for instance, think simultaneously of the growth of the British Empire chronologically and territorially. He can, so to speak, draw a map, a four-dimensional map, incapable of being drawn on paper, but none the less a picture of a domain of events.

Let us pursue the map analogy in the familiar two-dimensional sense. Imagine that a map of some region of the globe is drawn on some material capable of extension and distortion without physical restriction save that of the preservation of its continuity. No matter what distortion takes place, a continuous line marking a sequence of places remains continuous, and the places remain in the same order along that line. The map ceases to be any good as a record of distance travelled, but it invariably records certain facts, as, for example, that a place called London is in a region called England, and that another place called Paris cannot be reached from London without crossing a region of water. But the common characteristic of maps of correctly recording the shape of any small area is lost.

The shortest path from any place on the earth's surface to any other place is along a great circle; on all the common maps, one series of great circles, the meridians, is mapped as a series of straight lines. It might seem at first sight that our extensible map might be so strained that all great circles on the earth's surface might be represented by straight lines. But, as a matter of fact, this is not so. We might represent the meridians and the great circles through a second diameter of the earth as two sets of straight lines, but then every other great circle would be represented as a curve.

The extension of this to four dimensions gives a fair idea of Einstein's basic conception. In a world free from gravitation we ordinarily conceive of free particles as being permanently at rest or moving uniformly in straight lines. We may imagine a four-dimensional map in which the history of such a particle is recorded as a straight line. If the particle is at rest, the straight line is parallel to the time axis; otherwise it is inclined to it. Now if this map be strained in any manner, the paths of particles are no longer represented as straight lines. Any person who accepts the strained map as a picture of the facts may interpret the bent paths as evidence of a "gravitational field," but this field can be explained right away as due to his particular representation, for the paths can all be made straight.

But our two-dimensional analogy shows that we may conceive of cases where no amount of straining will make all the lines that record the history of free particles simultaneously straight; pure mathematics can show the precise geometrical significance of this, and can write down expressions which may serve as a measure of the deviations that cannot be removed. The necessary calculus we owe to the genius of Riemann and Christoffel.

Einstein now identifies the presence of curvatures that cannot be smoothed out with the presence of matter. This means that the vanishing of certain mathematical expressions indicates the absence of matter. Thus he writes down the laws of the gravitational field in free space. On the other hand, if the expressions do not vanish, they must be equal to quantities characteristic of matter and its motion. These equalities form the expression of his law of gravitation at points where matter exists.

The reader will ask: What are the quantities which enter into these equations? To this only a very insufficient answer can here be given. If, in the four-dimensional map, two neighbouring points be taken, representing what may be called two neighbouring occurrences, the actual distance between them measured in the ordinary geometrical sense has no physical meaning. If the map be strained, it will be altered, and therefore to the relativist it represents something which is not in the external world of events apart from the observer's caprice of measurement. But Einstein assumes that there is a quantity depending on the relation of the points one to the other which is invariant—that is, independent of the particular map of events. Comparing one map with another, thinking of one being strained into the other, the relative positions of the two events are altered as the strain is altered. It is assumed that the strain at any point may be specified by a number of quantities (commonly denoted g_{rs}), and the invariable quantity is a function of these and of the relative positions of the points.

It is these quantities g which characterise the gravitational field and enter into the differential equations which constitute the new law of gravitation.

It is, of course, impossible to convey a precise impression of the mathematical basis of this theory in non-mathematical terms. But the main purpose of this article is to indicate its very general nature. It differs from many theories in that it is not devised to meet newly observed phenomena. It is put together to satisfy a mental craving and an obstinate philosophic questioning. It is essentially pure mathematics. The first impression on the problem being stated is that it is incapable of solution; the second of amazement that it has been carried through; and the third of surprise that it should suggest phenomena capable of experimental investigation. This last aspect and the confirmation of its anticipations will form the subject of the next article.

E. CUNNINGHAM.

LORD WALSINGHAM, F.R.S.

LORD WALSINGHAM, whose death from pleurisy took place on December 3, in his seventy-seventh year, was a man very highly esteemed in many circles, and in none more than in those devoted to the study of natural history. As an entomologist he was greatly distinguished, and the work and influence which he brought to bear in promoting the study of insects were widely known, and have borne much good fruit. His work was not of the type associated with the name of Fabre, the famous French observer, but he by no means neglected the study of the living insect, and was keenly interested in every problem on which entomology could help to throw light. He saw also its economic importance, and he had the wisdom to know how greatly its value in every direction depended upon the accurate identification of species, and how this in its turn depended upon good methods of classification and arrangement, and upon an exact and stable system of nomenclature. His own studies, and such influence as he could exert, were, in consequence, largely directed towards the fundamental work of naming and describing species, and improving the means that would lead to their more easy identification.

From an early age Lord Walsingham gave his time freely to a study of the Microlepidoptera, or small moths, and he lost no opportunity to add to his collection of these obscure but very important insects. He maintained his interest in them up to the last, and, a month or so before his death, he was to be seen still working at them in the Natural History Museum, to which his own very large collection, together with a valuable library of entomological works, had been transferred as a gift in the year 1910. He was elected a trustee of the British Museum in 1876, and a fellow of the Royal Society in 1887. As a trustee of the museum, more especially during the time when he was a member of the Standing Committee, he was always actively interested in its affairs, and it was doubtless due to his initiative that the entomological staff was increased, and entomology afterwards made into a separate department. He would like to have seen the staff still further increased, for he was greatly impressed with the necessity of having a large and competent staff to deal with the rapidly accumulating accessions of specimens.

Lord Walsingham was president of the Entomological Society in 1889–90, and in one of his addresses he pointed out that of the more than two million species of insects estimated to be living on the globe, less than a tithe had been named and described, and the vast majority were still altogether unknown. His entomological publications, beginning in the year 1867, were numerous, and always showed careful and accurate work. They appeared in the "Biologia Centrali-Americana," the "Fauna Hawaiensis," in catalogues of the British Museum, and in the transactions and proceedings of the Entomological, Zoological, and Linnean Societies, to each of which he belonged as a fellow; and also in the *Entomologists' Monthly Magazine*, of which he had been one of the co-editors, as well as in other scientific journals. Entomology, however, was not his only interest; ornithology and other branches of natural history shared in his attentions. He was a traveller and a keen sportsman, and in his time was noted as a great shot. He was a graceful and gifted speaker, and as a man of wide knowledge and good judgment was always listened to attentively at the scientific or other meetings in which he used so frequently to take a part. Although he might have made his mark in almost any sphere of life, Science has reason to be gratified that so great a part of his time and work had been devoted to her service.

NOTES.

THE Electricity (Supply) Bill was read a second time in the House of Lords on December 8.

THE council of the Royal Institute of Public Health has appointed Prof. Maurice Nicoll, of the Pasteur Institute, Paris, Harben lecturer for 1920.

WE regret to learn that Prof. A. Werner, professor of chemistry in Zurich University, Nobel prizeman for chemistry in 1913, and foreign member of the Chemical Society, died on November 15 at fifty-two years of age.

SIR RICHARD REDMAYNE, who has been Chief Inspector of Mines since 1908, will shortly resign his post. He proposes to devote himself in the future to the work of the Imperial Mineral Resources Bureau, of which he is the chairman, and to the practice of his profession as a consulting mining engineer.

THE late Dr. John Aitken bequeathed the sum of 1500*l*. to the Royal Society of Edinburgh for the purpose of publishing in book form a collection of his papers read before various societies. He also left to the Universities of Edinburgh and Glasgow any of his dust, colour, or other apparatus which they may wish to possess.

THE Elliot medal for 1918 of the U.S. National Academy of Sciences has been awarded to Mr. C. W. Beebe, of the New York Zoological Society, on the com pletion of the first volume of his work on "The Pheasants." The medal is awarded annually to the author of the leading publication of the year in zoology or palæontology. The first award was made for the year 1917 to Mr. F. M. Chapman for his volume, "The Distribution of Bird-life in Columbia," published by the American Museum of Natural History.

A conference of representatives of research organisations connected with the Scientific and Industrial Research Department will be held at the Institution of Civil Engineers, Westminster, to-morrow, December 12, at 2.30. Mr. A. J. Balfour, president of the Committee of the Privy Council for Scientific and Industrial Research, will preside, and will deliver an introductory address. A paper on "Research Associations and Consulting Work and the Collection and Indexing of Information" will be read by Mr. H. J. W. Bliss, and one on "The Equipment of Research Laboratories" by Dr. W. Lawrence Balls.

Before the war the Royal Institute of Public Health was accustomed to hold an annual congress, which was attended by well-known leaders engaged in the conduct of measures for the prevention and arrest of disease. In 1912 Berlin was the meeting-place; in the following year Paris welcomed the institute; and the last congress was held in Edinburgh in 1914. These annual meetings of the institute are now to be resumed. The president and council have received a renewed invitation from the Burgomaster of Brussels, M. Adolphe Max, on behalf of the city, and from the rectors of the University of Belgium, for the next congress to be held in Brussels. The dates have been fixed for Thursday, May 20, to Monday, May 24, 1920, inclusive. Delegates will, as usual, be invited from all the universities, municipalities, and other public bodies in due course, and full particulars will be issued at an early date. Meanwhile, all desirous of participating in the congress in the spring of next year should communicate with the Hon. Secretaries, the Royal Institute of Public Health, 37 Russell Square, London, W.C.1.

By the death of the Rev. E. S. Marshall at Offa's Dyke, near Chepstow, on November 25, the study of British plants has sustained a serious loss. For at least thirty-five years Mr. Marshall spent nearly all his leisure in excursions to almost every part of the British Isles, studying the flora *in situ* and collecting herbarium specimens. He was fortunate in meeting in early days such distinguished botanists as the late Rev. R. P. Murray, and his diligence and accuracy, aided by a retentive memory, eventually placed him in the front rank of field botanists. Mr. Marshall was an authority on Hieracia, and wrote the article on Betula in the second volume of "The Cambridge Flora." For very many years he spent his summer holidays in remote districts in Scotland, his work in this field winning him his recent election as honorary fellow of the Botanical Society of Edinburgh. Owing to the accident of residence Mr. Marshall was particularly conversant with the flora of the south-east of England and of Somerset. In 1899 he collaborated with Mr. F. C. Hanbury in publishing "The Flora of Kent," and in 1914 he wrote a copious Supplement to Murray's "Flora of Somerset," published in the Proceedings of the Somerset Archæological and Natural History Society. He will, however, be chiefly remembered for his almost unique general knowledge of the whole flora of the British Isles, which gave his identifications exceptional authority. Mr. Marshall contributed largely to the *Journal of Botany* and to other botanical works, and revised the tenth edition of the "London Catalogue" in 1908. He was a member of two exchange clubs, and carried on a voluminous correspondence. He bequeathed his fine herbarium to the University of Cambridge.

After serving as secretary of the Royal Horticultural Society for thirty-two years, the Rev. W. Wilks has felt himself compelled by advancing years to resign his office. It is in large measure due to Mr. Wilks's devotion, energy, and ability that the society has been brought to its present flourishing state. When he became secretary the society's finances were at a low ebb and its membership poor; now, thanks to his prudence and enthusiasm—a rare combination of gifts—the society is in a strong financial position, and its membership large and ever increasing. The development of the gardens at Wisley into a research station had his strong support, and, indeed, not the least of Mr. Wilks's titles to enduring memory is the strenuous help which he has given in effecting that *rapprochement* between scientific and practical horticulture which is undoubtedly destined to bring advantage to both. Mr. W. R. Dykes, who has been nominated by the council as Mr. Wilks's successor, is a keen and accomplished gardener, and the author of an admirable monograph on the genus Iris. It is pleasant to know that Mr. Wilks's long official association with the Royal Horticultural Society will continue, and that he will act with Mr. Chittenden, the director of Wisley, as joint author of the society's publications.

Under the auspices of the Staff Association, a highly successful scientific reunion—the last of the series for the current year—was held in the board room of the Natural History Museum on November 26, and was attended by nearly eighty members and visitors. The Director, Dr. S. F. Harmer, gave a short address, illustrated by lantern-slides, on "Antarctic Whaling," in which he described the enormous development of the industry in recent years and the methods employed, and discussed the danger of extinction that seems to threaten several of the species of whales, adding that the Government was alive to this danger, and was about to dispatch an expedition to investigate the question. A large number of exhibits were placed round the room. In the Haldane Report on the Machinery of Government it is stated that museums may be considered either as centres for diffusing information or as centres providing facilities for research. That the Natural History Museum fulfils the first of these two functions is familiar knowledge, but probably few even among scientific experts are aware what a great centre of research the museum has become. Visitors to these scientific reunions cannot fail to be impressed with the extreme importance and varied nature of the research carried on by the staff of the museum.

The *Contemporary Review* for December contains an article by Prof. Eddington on Einstein's theory of space and time, and the *Nineteenth Century* has secured an exposition of the matter from Sir Oliver Lodge. Clearly the former is interested in the theory, and the latter in the result predicted and confirmed by the Eclipse Expedition. Sir Oliver holds it dangerous to base such far-reaching conceptions as that of a "warped" space on a predicted effect which may be accounted for in simpler fashion, new and striking though that effect may be. Prof. Eddington, on the other hand, attacks directly our current confusions in regard to the meaning of space and time. Both writers are forced to confess the difficulty of translating Einstein's theory into simple language, Prof. Eddington affirming that the whole theory is a revolt against the simple language which here, as in so many regions, implies confused ideas. Apparently we are only at the beginning of a long controversy on the merits and demerits of Einstein's theory. The *Times Educational Supplement* seeks to give some material for its readers to form a judgment upon it; its correspondent, however, devotes the major portion of his exposition to Einstein's earlier theory, and touches only lightly upon the new work.

The Faraday Society, the Royal Microscopical Society, the Optical Society, and the Photomicrographic Society, in co-operation with the Optical Committee of the British Science Guild, meeting in joint session, will hold a symposium and general discussion on "The Microscope: Its Design, Construction, and Applications," on Wednesday, January 14 next. The meeting will be held in the rooms of the Royal Society, Burlington House, Piccadilly, W.1 (by kind permission of the president and council), and it will extend over two sessions—from 4.30 to 6.30 and from 8 to 10 p.m. During the afternoon preceding the meeting, from 2.30 to 4.30, an exhibition will be held in the library of the Royal Society, which will illustrate recent developments in the science of microscopy and the latest applications of the microscope in all branches of industry. The meeting will be presided over by Sir Robert Hadfield, president of the Faraday Society, who will deliver the opening address. Mr. J. E. Barnard, president of the Royal Microscopical Society, will then give a general survey of the subject, and he will be followed by Sir Herbert Jackson. Prof. F. C. Cheshire will speak on the mechanical design of microscopes, and a paper by Prof. A. E. Conrady on microscopical optics will be presented. Further particulars relating to the discussion may be obtained from Mr. F. S. Spiers, secretary, the Faraday Society, 10 Essex Street, London, W.C.2, or Mr. C. J. Lock, secretary, the Royal Microscopical Society, 20 Hanover Square, London, W.1.

Prof. Annibale Riccò, whose death in September last at the age of seventy-five we much regret to see announced, was born at Modena on September 15, 1844. In his early days Prof. Riccò took up engineering. He was present at the Meteorological Congress at Vienna in 1873, when he paid visits to several Austrian and German observatories. In 1877 he was appointed professor of physics at Modena, and shortly afterwards professor of physical technology at the Engineering School at Naples. Prof. Riccò took up astronomical work in 1879, becoming an assistant at Palermo Observatory. His work included observations of sun-spots and prominences, comets, and the planet Jupiter. In 1890 he was appointed director of the Observatory of Catania and Etna, which post he retained until his death. His special subject was solar physics. He undertook regular observations of sun-spots and prominences, and took part in several eclipse expeditions: to Russia in 1887, to Algeria in 1900, to Spain in 1905, and to the Crimea in 1914. On the last occasion he detected a new red band in the coronal spectrum, the principal line of which appeared to conform to a series discovered by Nicholson, having the cube roots of their wave-lengths in arithmetical progression. Work on sidereal astronomy, meteorology, seismology, and geodesy was also carried on under his direction. Prof. Riccò further undertook the laborious task of photographing one of the zones of the Astrographic Catalogue (north declination 54° to 44°). In spite of great financial difficulties, he published the catalogue of the first three hours of right ascension. His published papers are very numerous; a recent one directs attention to the advisability of correlating solar variations with meteorological phenomena, on the lines initiated by Prof. Abbot. Prof. Riccò was elected an associate of the Royal Astronomical Society in 1911, and last July he was chosen as one of the four vice-presidents of the new Union Astronomique Internationale.

In the October issue of *Man* Dr. J. W. Fewkes describes a remarkable carved wooden object from Santo Domingo, now in the collection of the Missouri Historical Society, St. Louis. It is a rude figure of a man found in a cave in that island. The ancient Antilleans are said to have lived in caves, where they performed their religious ceremonies, and the fact that this relic was discovered in a cave accounts for its good state of preservation. It so closely resembles a specimen in the British Museum, described in the Journal of the Royal Anthropological Institute (vol. xxxvii., 1907), that there is little doubt that it represents a Duko or seat used in some religious rite by the prehistoric people of the island.

The report of the Superintendent of the Archæological Survey of Burma for 1918–19 contains a discussion on the origin of the Shan alphabet. From this it appears that it is derived from the Tibetan rather than from the Burman or the Talaiqu alphabet, and its transmission is due to the close connection between Tibet and the ancient Shan kingdom of Nanchao. Mr. Duroiselle is now engaged on the systematic collection of materials for the early history of Burma. The epigraphical records cover a wide period, and these are now being interpreted. This is supplemented by evidence, not only from Burman chronicles, but also from Chinese works and accounts of the voyages of Arab, Persian, and Indian travellers. The pioneer in this work was Father Sangermano, but the fresh material now available will form a useful supplement to the information collected by him.

The Danish *Kommissionen for Havundersögelser* (Copenhagen: C. A. Reitzel, 1918) has published an exhaustive geographical and biological study of Randersfjord, a long inlet on the east coast of Denmark. The volume, which is entitled "Randers Fjords Naturhistorie," is edited by Dr. A. C. Johansen. It contains more than five hundred pages, and has numerous excellent maps and photographs. Among the eleven authors who have contributed to this fine work we note that the editor is responsible for the geology, archæology, and vertebrate zoology, Dr. J. P. Jacobsen for the hydrography, and Dr. C. H. Ostenfeld for a long section on the plants and general features of the vegetation. This section is particularly valuable, as the author has entered into the detailed relationship of the plant-life to its environment, and gives many fine photographic illustrations of different vegetation formations. Among the maps in the volume there is a layer-coloured orographical map of the whole district on a scale of 1 : 200,000.

The habits and economic relations of the guano birds of Peru form the subject of an able Report (No. 2298) by Mr. Robert E. Coker, issued by the United States National Museum. The hordes of penguins, cormorants, gannets, and pelicans which resort to the islands fringing the coast of Peru for breeding purposes are protected by the Peruvian Government for the sake of the vast quantities of guano they deposit. This, owing to the fact that rain never falls, retains its nitrogen, which would otherwise be converted into ammonia and lost by evaporation. The pages of the report are crowded with interesting observations on the habits of these birds, and it is to be hoped that immediate steps will be taken to protect certain species, which the author shows are in grave danger of speedy extermination. A diving petrel is one of these, the penguin another. The first-named is killed remorselessly for food, the other for the sake of its oil and feathers. As an example of what may be done by judicious protection, Mr. Coker quotes the case of the south island of the Chinchas, where the birds were left undisturbed for three years. At the end of that time 22,337 tons of guano were collected.

With the October issue the *Scottish Journal of Agriculture* completes its second volume. The contents are varied and interesting. The first article, "Problems of Animal-breeding," points out the essential factors and principles involved, and pleads for commercial utility as the real end in view. The second article, on "Aberdeen-Angus Cattle," is presumably the first of a series on "Scottish Pure-bred Livestock." Both serve as reminders that home-grown beef, as well as home-grown wheat, should find a place in any sound agricultural policy. The articles on "Rhizoctonia Disease, or Stem-rot, on Potatoes" and "*Nosema apis* in Hive-bees" are of the kind that bring home to the farmer the realisation of the way in which science can minister to his needs and solve many of the problems that puzzle and perplex him and cause him financial loss. "Agriculture in the Outer Hebrides" affords an interesting glimpse of the state of the industry in this remote and little-known "corner" of the British Isles. It is not altogether without significance to read that although the spraying of potatoes is a firmly established custom in parts of Lewis, yet the next advance recommended is the enclosing of the arable land, thereby bringing about a substantial increase in all crops and rendering proper rotations practicable. Other articles are "Oat-growing Experiments in Scotland," "Composition of Linseed Recovered from Home-grown Flax," "Scottish Farm Labour," "Woodlands and Woodland Industries in Relation to Small Holdings," and short notes on various subjects such as "Leaf-stripe of Barley," "Village Industries," "Agricultural Labour in Other Countries," and that ever-important and intricate problem "Farm Bookkeeping and Cost Accounting."

The difficulties appertaining to work done in order to ascertain the changes in chemical composition undergone by fruits during ripening and storage are enhanced by the fact that the fruit-juice may, and generally does, vary in composition with the method of extraction. In the *Biochemical Journal* for November Misses D. Haynes and H. M. Judd describe experiments made to ascertain whether the first runnings obtained from pressed apples after freezing are similar in composition to those obtained later. A uniform sample of apple-pulp was divided into two portions, one of which was immediately frozen in liquid air and pressed so soon as it had re-attained the laboratory temperature, whilst the other was left overnight in a freezing mixture and then treated in the same way. The chemical and physical properties of the two juices were almost identical, thus showing that no more chemical action takes place in the prolonged freezing of an ordinary freezing mixture than in liquid air. In another series of experiments the juice was expressed from apple-pulp in several fractions to ascertain whether the tissues after freezing are freely permeable to all those constituents of the cell-sap present in the expressed juice. It was found that the concentration of acids and sugars is the same in the first fraction as in the last, but the viscosity of the latter is greater than that of the former, indicating that the colloidal constituents of the sap are held back by the tissues. The authors find that the large fluctuations in the samples investigated cause the probable error to be very large, and they point out that neglect of sampling errors by previous estimations made by other workers detracts very seriously from the value of the results obtained.

Some notes on the use of the aeroplane in African exploration by Lieut. L. Walmsley in the *Geographical Journal* for November (vol. liv., No. 5) are valuable in giving the results of experience. Mr. Walmsley points out that "air-pockets" are normally encountered during the daytime in tropical Africa up to a height of about 6000 ft. As a result he had to do his aerial photography in East Africa in the morning and evening, when the light was not very favourable. Above 7000 ft., however, he thinks that operations could be carried out all day long. As regards the location of air-photographs on the map, Mr. Walmsley points out that two adjoining photographs should overlap, showing at least two objects in common. Owing to the absence of definite objects in hundreds of square miles of African landscape, the only satisfactory method is to operate along clearly marked geographical features, such as rivers, mountain ranges, and roads, so that each picture contains part of an easily recognisable feature. Mr. Walmsley made most successful photographic surveys in north-western Portuguese East Africa. He suggests the application of photographic survey to navigable estuaries, such as those of the Rufiji, Rovuma, or Zambezi. The shifting mud-banks can be seen distinctly at a height of 2000 ft.

Mr. P. R. Burchall gives an "Elementary Survey of the Present Position of Aerial Photogrammetry" in the *British Journal of Photography* for November 28. After giving many details, he concludes by stating that many thoughtless people imagine that aerial photographs are all that is required for map-making, while many surveyors rather disdain them. "Meanwhile, inventors are busy improving aircraft and photogrammetric apparatus, and mathematicians are busy working out and simplifying systems of correction." He prophesies that as soon as the cheapness and accuracy of the aerial photographic method have been demonstrated, it will be speedily recognised and appreciated.

The principal results obtained by Mr. H. J. Hodsman and Prof. Cobb in their tests of the expansions of refractory materials were described at the meeting of the Society of Glass Technology held at the University of Sheffield on November 10. On first firing, silica refractories are permanently expanded, while fireclay refractories are permanently contracted. On subsequent reheating both expand, and on cooling contract to their dimensions after firing. It is this type of reversible expansion which has been investigated for a number of materials between 15° C. and 1000° C. Kaolin, carborundum, alumina, alundum, and ball-clay expand at rates which are nearly constant throughout this range. Silica expands up to 500° C. at a rate slightly greater than that of kaolin, between 500° C. and 600° C. at a much greater rate, while between 600° C. and 1000° C. there is practically no expansion. At 1000° C. its total expansion is nearly equal to that of kaolin. A mixture of ganister and clay containing 80 per cent. of ganister expands like silica, while fireclay and pot-clay have expansion curves which lie between those of silica and kaolin, nearer to the former than to the latter.

The *Times Engineering Supplement* for November directs attention to the announcement that advantage is to be taken of the refitting of the White Star liner *Olympia* for mercantile service to equip her for the use of oil-fuel, and gives this fact in evidence of the growing favour with which oil-fuel is regarded by shipping interests. In view of the great advantages of oil-fuel, it is probable that only the cheapness of coal and the comparatively high price, and at times the uncertainty, of oil-fuel supplies have prevented the more rapid substitution of liquid for solid fuel on shipboard. The diminished output of coal, hampering bunkering regulations, and fears of labour troubles have caused shipping interests to give closer attention to the question of using oil-fuel under the boilers of steamships. One unsatisfactory feature of the situation is that the British shipowner is likely for a considerable time to come to be compelled to rely on foreign sources of supply. Many of the leading dock authorities, such as at Avonmouth, Belfast, Liverpool, etc., are taking steps to augment the facilities available for oil-fuel storage, and shipowners ought soon to be able to obtain supplies at all important home ports.

The following works are in preparation for appearance in the Drapers' Company Research Memoirs of the Biometric Laboratory Publications (*Cambridge University Press*):—In the Biometric Series: "Mathematical Contributions to the Theory of Evolution," xvii. "On Homotyposis in the Animal Kingdom": A Co-operative Study, and in "Studies in National Deterioration," "The Health of the School-Child in Relation to its Mental Characters," Prof. Karl Pearson. In the Memoir Series of the Eugenics Laboratory Publications, "The Influence of Parental Occupation and Home Conditions on the Physique of the Offspring," Ethel M. Elderton, is also in preparation for publication by the same firm. *Messrs. Longmans and Co.* have in the press "Diagnosing and Curing of Troubles in Electric Machinery," Prof. Miles Walker.

OUR ASTRONOMICAL COLUMN.

COMETS.—Prof. Crawford and Misses Fairfield and Cummings have deduced the following orbit of Finlay's comet (1919*d*) from observations on November 9, 12, and 15:—

T = 1919 Oct. 15·52 G.M.T.	log q = 0·0056
ω = 318° 15′	e = 0·7146
☊ = 46° 55′	Period = 6·688 years
i = 3° 23′	

Ephemeris for Greenwich Midnight.

	R.A. h. m. s.	N. Decl. ° ′	Log r	Log Δ
Dec. 9 ...	1 46 27	14 41	0·1046	9·5768
13 ...	2 2 24	16 26	0·1155	9·6198
17 ...	2 16 27	17 53	0·1267	9·6621
21 ...	2 29 42	19 6	0·1377	9·7025
25 ...	2 41 16	20 7	0·1486	9·7419
29 ...	2 52 45	21 0	0·1594	9·7796

It is of interest that three perihelion passages occurred within five days, viz. Finlay on October 15, Brorsen-Metcalf on October 16, and Schaumasse on October 20.

Another long-period comet, de Vico's of 1846, is expected within the next year or two.

WIRELESS TIME SIGNALS.—The *London Gazette* of November 21 gives an interesting list of the stations that now send out these signals. There are three in Europe, thirteen in North and Central America, four in South America, four in Asia and Japan, three in Africa and Mauritius, four in Australia and New Zealand, and three in the Pacific Ocean (Philippines and Honolulu). A ship with an equipment suited to the different systems used should be able to pick up her time in almost any part of the ocean; a comparatively small increase in the number of signal stations would make this absolutely the case. This is a development in navigational facilities that would have seemed incredible a few years ago.

LEEDS ASTRONOMICAL SOCIETY.—Vol. xxvi. of this society's Journal has lately been published under the editorship of Mr. C. T. Whitmell, and contains, as usual, much interesting matter. A paper on Nova Aquilæ by Mr. C. L. Brook may be specially noted. There are also descriptive papers on stellar subjects by the Rev. I. Carr-Gregg and Miss A. Grace Cook, and a very useful note on the limits of vision (1) in detecting an object, and (2) in defining its shape, by Dr. A. S. Percival. The occultation of 7 Aquarii by Venus, 1918 March 2, observed at Lick Observatory, and that of Cape (1900) No. 1524, 1918 April 11, well observed in Australia, were both predicted by Mr. A. Burnet, an energetic member of the society, now at the University Observatory, Oxford. It is noteworthy that he made these predictions while on military service in France.

THE JUBILEE OF "NATURE."

FURTHER OFFICIAL MESSAGES.

WE desire to express grateful acknowledgment of the many friendly references made to our jubilee issue by our contemporaries, and of messages of congratulation received from readers and contributors since those published in NATURE of November 13. It is a pleasant duty to print the following messages which have reached us from official representatives of several important scientific societies:—

November 1. ROYAL SOCIETY OF CANADA: *President, Prof. R. F. Ruttan.*—"It affords me great pleasure to offer you the sincere congratulations of the Royal Society of Canada on the completion of NATURE's half-century of service to the English-speaking world. During this period the journal has not only done much to create and maintain popular interest in natural science, it has also been a driving-power in the recent movement in favour of educational reform. We recognise in Canada that its widely quoted articles have been a strong factor in creating that background of public opinion so essential to ensure official support for scientific education and research. Permit me to add my best wishes for its continued success."

November 3. AMERICAN ACADEMY OF ARTS AND SCIENCES.—"The president and secretaries congratulate the Editor of NATURE on the jubilee of this admirable publication. During fifty years NATURE has upheld a high standard and effectively fostered scientific attainment. To-day the study of the mechanism of the universe is recognised by all thinking men as of exceedingly great importance both in peace and in war. The need was never greater that science—a bringer of increased power to humanity—should be guided by high-minded pilots in order that its great possibilities may be directed in beneficent channels. May the helpful and civilising mission of NATURE long continue!"

November 4. CALIFORNIA ACADEMY OF SCIENCES. *Director of Museum, Dr. B. W. Evermann.* "NATURE is a publication which has long held a large place in the reading and thought of the California Academy of Sciences. We depend upon it more than perhaps upon any other single publication for the scientific news and achievements of the world. The American publication *Science* is, of course, of great interest to us for American scientific news, but its field is rather limited, and in its presentation of valuable contributions to science it scarcely ranks with NATURE. Their fields, however, are in a sense quite different, and it is perhaps, therefore, not fair to compare them. It is a matter of very great satisfaction to be able to extend sincere congratulations to NATURE on the completion of its fiftieth year of extraordinarily useful service."

November 8. SOCIETÀ REALE DI NAPOLI: Accademia delle Scienze Fisiche e Matematiche: *Secretary, Senator G. De Lorenzo.*—"Although it is somewhat late, I am glad to express, on behalf of the academy, my sincere congratulations on the important scientific work which your esteemed journal has accomplished during its fifty years of existence, and trust it may have a prosperous future before it."

THE BRITISH ASSOCIATION AT BOURNEMOUTH.

SECTION K.

BOTANY.

OPENING ADDRESS (ABRIDGED) BY SIR DANIEL MORRIS, K.C.M.G., M.A., D.Sc., D.C.L., LL.D., F.L.S., PRESIDENT OF THE SECTION.

IT has been made abundantly clear that in botany, as in other applied sciences, we must rely in future less on chance individual effort and initiative. We must co-operate our efforts and organise them at every stage, bearing in mind that we shall always require the services of the worker in pure science to solve those larger problems of national importance which confront us. We must be armed by science, or we shall be placed at a disadvantage in the great struggle now before us. We are told that it is absolutely necessary for the prosperity and safety of the country that the development of the resources of the Empire and the production of our industries must be on a scale greatly in excess of anything we have hitherto achieved. As an Imperial people it is our duty to develop our resources to the fullest extent. Fortunately, a great change is taking place in the attitude of the Government and the State towards science, and it is noticeable also in the relations of science to industry and commerce. Since we last met we have lost a number of devoted workers in botany. Apart from those who have passed away in what may be called the course of nature, a sad aspect of the losses sustained in the war is the death of so many brave young men for whom it was anticipated that a bright and successful career was open in the domain of science. Their names are inscribed on the Roll of Honour, and we gratefully bear them in memory.

From the point of view of the scientific exploration of the resources of the Empire, it is satisfactory to note that the publications dealing with the floras of tropical and sub-tropical countries have been continued. These, involving, as they do, so much labour and forethought, are of more than passing interest from the fact that they serve to reveal the distribution of plants that may eventually prove of great economic value. A close investigation of tropical plants is necessary, as allied species or varieties of one and the same species sometimes differ appreciably as regards their economic value.

A new branch of botany has lately come into prominence as one of the results of the devotion to Nature-study and the contemplation of the characteristic features of vegetation as we find it distributed over the earth's surface. Ecology is capable of enormously extending the outlook of botany, and it has so largely added to the interest of field work that we may wonder that the phenomenon of vegetation so long displayed before our eyes had not suggested its sociological aspects long ago. Ecology has its society and journal, and bids fair to establish itself fully in the household of botany. It is hoped that it will mitigate some of the admitted drawbacks of purely laboratory work and revive the old natural history spirit of former days.

The remarkable spread of a comparatively new marsh grass (*Spartina Townsendii*) along certain portions of the southern coast deserves careful study. It is supposed to be a hybrid between *S. stricta* and *S. alternifolia*. It is claimed to be pre-eminent among halophytes on account of the extraordinary vigour with which it spreads over mud-flats, and eventually forms meadows to be measured by thousands of acres in Southampton Water and Poole Harbour. It is a question whether it may not develop into a serious menace to navigable waters. On the other hand, it may prove capable of being utilised in suitable localities as a reclaiming agent. Its economic value in providing material for paper-making or as food for cattle may also receive attention.

The critical study of British plants was supposed to be an exhausted field, but with the necessary insight and careful and critical observation there is much work still to be done. Exchange clubs are active, and additions to local floras are continually being made. New species, varieties, and hybrids are published from time to time. As an instance, *Potamogeton upsaliensis*, hitherto only known in Sweden, has recently been found in East Dorset. Hybrid orchids are being keenly studied, and the occurrence of hybrids in this and other classes of plants opens a wide and interesting field of investigation.

A much desired piece of work is a continuance of Starkie Gardner's interesting investigation of the fossil flora of the Bagshot beds so well shown in the Bournemouth and adjoining cliffs. Some of these have proved exceptionally rich in remains of tropical and sub-tropical plants. So far, in regard to these plant remains, we may say with La Place: "What we know is but little; what we do not know is immense."

My distinguished predecessor, whose work has been largely concerned with the systematic and philosophical side of botany, rightly expressed the general desire for a more cordial understanding between botany and its economic applications. "It is certain," he said, "that our outlook must be widely different after the war, and the changed environment must find us ready to respond in the interest of our country and mankind."

With your permission, and acting on a suggestion made to me, I propose to travel a little outside the usual scope of previous addresses and review the many efforts that have been, and are still being, made to promote the interests not only of the homeland, but also of the Empire as a whole. Before the war it was estimated there were about 3,000,000 square miles of British territory within the tropical zone. A portion of this area, including India, was already producing commodities of the estimated value of 230,000,000*l.* sterling. It is, therefore, in the national interest to keep closely in touch with the conditions and prospects of our tropical Possessions in order that we may render them still more capable of supplying the raw material so necessary to the maintenance of our commercial prosperity.

In recent times one of the most important steps taken in this connection was the establishment, on the recommendation of a Royal Commission appointed by Mr. Joseph Chamberlain, of an Imperial Department of Agriculture in the West Indies. The provision for the upkeep of the Department, approved by Parliament, was at the rate of 17,400*l.* per annum.

When fully organised the Department made grants for teaching science at colleges and secondary schools, and for the maintenance of agricultural schools, botanic gardens, and experiment stations. Special attention was devoted to research work in raising new varieties of sugar-canes and other plants, to the investigation of diseases affecting crops, and to the general amelioration of the conditions under which they were grown. At the end of ten years of strenuous effort it was noticeable that, owing to the expansion and improvement of old industries and the introduction of new, the general conditions in the West Indies were greatly improved. This may be illustrated by the fact that the public revenue of the Colonies had increased from 2,546,724*l.* in 1894 to 3,914,434*l.* in 1911, while the total trade during the same period had increased from 16,270,474*l.* to 26,949,086*l.* There was thus an increase of 65 per cent. in the total revenue and of 60·5 per cent. in the total trade. In reviewing the situation in the West Indies, as the result of the activities of the Imperial Department of Agriculture and those associated with it, the late Prime Minister said: "The work of the Department was universally and gratefully acknowledged by the planters to be largely responsible for the improved state of affairs in all branches of agriculture, and he believed—and he spoke with some experience—it would be difficult to find a case in which any analogous experiment made by the Home Government had attained such speedy and satisfactory results."

A gratifying proof of the appreciation of the work of the Imperial Department of Agriculture in the West Indies was the formation of several Departments on similar lines, first at Pusa in India in 1902, and afterwards in all the tropical Colonies in the New and Old World. Further, twenty competent officers trained in the West Indies are now in charge of the Departments of Agriculture in Ceylon, Mauritius, the Federated Malay States, and Fiji, and on the staffs of the Imperial Department of Agriculture in India and the several Colonies in East and West Africa. Another interesting feature of West Indian progress was the wider appreciation of improved methods of cultivation and of the value of science by members of the planting community. For instance, in 1898 the aggregate amount voted by the local legislatures for staffs, laboratories, and botanic and experiment stations was at the rate of 14,000*l.* per annum. Apart from the funds of the Imperial Department of Agriculture, it is probable that, directly or indirectly, the total amount contributed locally for scientific services is now not less than 60,000*l.* per annum.

There can be no doubt that not only in the West Indies, but also in all parts of the Empire, "enlightenment as to the objects, methods, and conditions of scientific research is proceeding at a rapid rate." Perhaps the most interesting feature of the progress made is in connection with the application of the laws of heredity to the improvement of such highly important crops as sugar, wheat, and cotton. The problems associated with these involve both scientific and economic considerations. As regards the scientific side, it is fortunate that with the beginning of the twentieth century came the rediscovery of Mendel's facts and the stimulating energy of the genetic school which has brought us an entirely new point of view in regard to the increased production of field crops.

Great importance is attached to the improvement of the sugar-cane, as the prosperity of many of our Possessions depends upon it. Further, the requirements of this country approach something like 2,000,000 tons per annum. The sugar-cane, although its origin is unknown, has been cultivated in tropical and sub-tropical countries from remote ages. Up to a recent date its propagation was purely vegetative, as it was supposed to have lost the power of producing mature seed.

Sugar-cane seedlings were observed at Barbados in 1858, but it was only in 1888 that Bovell and Harrison were in a position to utilise the discovery and obtain thousands of self-sown seedlings for experimental purposes. Similar seedlings were also available in Java about the same time. As about this period the standard canes in sugar-growing countries were showing signs of being severely attacked by disease, the discovery of seedlings was a fortunate circumstance. In fact, in some cases it may be regarded as having probably saved the industry. In British Guiana it is reported that in the crop of 1918 seedling canes occupied 83 per cent. of the total areas under canes. Similar results have been obtained at Barbados, where Bovell has continued since 1888 in raising canes of great merit.

In India there is probably a larger area under sugar-cane than in any other country. Its production of sugar is more than 2,000,000 tons. The larger proportion of this consists of a low-grade quality known as jaggery or "gur." Palm-sugar is also produced to the extent of 500,000 tons. Speaking generally, the sugar industry in India is not in a satisfactory condition. In spite of the enormous area under cultivation, India is obliged to increase its considerable imports of sugar from Java and other countries. To obviate this, urgent steps are being taken to improve the character of the canes and establish varieties adapted to local conditions and the circumstances of the sugar-growers.

In the considerable literature of sugar-cane breeding in India Barber has brought together a vast amount of information of singular interest and value. In the few years that have elapsed since he has been in charge of the Coimbatore Research Station he has laid the foundation of lines of inquiry that cannot fail to prove of great value in the permanent improvement of the sugar industry in India.

In his presidential address in 1898 Sir William Crookes stated that the prime factor in wheat production was a sufficient supply of nitrogen. As the supply was then showing signs of exhaustion, he warned wheat-growers of the peril awaiting them. Sir R. H. Rew has now shown that, thanks to the chemist, who came to the rescue, there is practically no limit to the resources of nitrogen. During recent years Biffen, by his successful investigations on Mendelian lines at the Plant-Breeding Institute at Cambridge, has shown that the characteristics distinguishing the numerous wheats can be traced, and the building up of a fresh combination of these characters was possible on practical lines. As the losses caused by disease were so serious, sometimes running to millions of quarters annually, Biffen devoted special attention to the possibility of breeding rust-resisting varieties. He found that the power of resisting the attacks of yellow rust, for instance, was an inheritable character. By crossing Gurka, a Russian disease-resisting wheat, with Square Head's Master, one of the most widely cultivated wheats in this country, Biffen eventually produced Little Joss, which, after trials extending over a period of several years, is said to yield four bushels per acre more than any other variety. Further, it possesses distinct disease-resisting qualities.

Another of Biffen's new wheats is Yeoman. This was raised in order to produce what are known as strong wheats. These are in great demand in this country, as they produce a flour which is much superior for baking purposes to the flour of English wheat. In pre-war days Canadian strong wheats commanded in the market 5*s.* more per quarter than the best English wheat. Yeoman not only possesses the superior quality of Canadian wheat, but combines with it the high-yielding character of certain English wheats.

A well-authenticated report, supplemented with full details, of the value of Yeoman as a field crop was lately published (*Journ. Bd. Agric.*, vol. xxv., 1161). It was cultivated under normal conditions, but without artificial manure, on three fields on a large farm near Wye, Kent. The cropped area was a little more than twenty-seven acres. The total yield was 2072 bushels, or an average of about seventy-seven bushels per acre. One field, previously under beet, comprising three acres two rods and eight poles, yielded 340 bushels, or an average of eighty-six bushels per acre. These results may be compared with thirty-two bushels, the average yield of wheat in this country.

A most desirable improvement in wheat-growing in this country is to obtain a spring wheat combining early maturity with a yield approaching that of winter wheat. The establishment of a National Institute of Agricultural Botany for the further development of plant-breeding and the distribution of pure seed may be regarded as essential to the welfare and safety of the nation.

Wheat-growing is a very important industry in India. It was estimated in 1906–7 that 29,000,000 acres were under cultivation in wheat with a yield of nearly 9,000,000 tons. Of this 90 per cent. was consumed in India. A botanical survey of the Indian wheats was undertaken by the economic botanists at the Imperial Research Institute at Pusa in 1910. In the following years, by the application of modern methods of selection and hybridisation, high-grain qualities were successfully combined with high-yielding power, rust resistance, and stiff straw, so that wheats were produced which gave upwards of forty-one bushels per acre.

Among the best of the new varieties are Pusa 4 and Pusa 12. Owing to an organised system of distribution of seed, it is estimated that the area under Pusa 12 during the last wheat season (1918–19) was about 400,000 acres. The area under Pusa 4 was about 100,000 acres.

The important work carried on at Pusa by Howard and his accomplished wife has followed closely on the methods found so successful at Cambridge. It is interesting to note that in obtaining new kinds by hybridisation between Indian wheats and rust-resisting forms in Northern Europe a difficulty in regard to flowering at different periods was overcome by sending the Indian parents to Cambridge for spring sowing and by carrying out the actual crossing with Biffen's new hybrids in England. From the crosses thus obtained Howard reports that a wide range of wheats has been evolved likely to prove superior to Pusa 4 and Pusa 12.

The admirable work done by Biffen at Cambridge and the Howards in India clearly demonstrates the value of thorough acquaintance with pure botany as a qualification for grappling with questions of economic importance.

In reviewing the gain to Indian wheat-growers the director of the Agricultural Research Institute has recently stated that, in view of the favour with which the new wheats have been received and the cordial co-operation of provincial organisations, "it is a modest estimate to assume that in the course of a very few years the area under Pusa wheats will reach 5,000,000 acres. This means an increase in the near future in the value of the agricultural produce of India, in one crop only, of 75 lakhs of rupees or 5,000,000*l*. sterling." Another crop that has received attention is indigo. In regard to this a new method of growing the seed has been worked out, and the cause of the destructive wilt disease has been traced to the destruction of the fine roots and nodules during the monsoon rains. The remedy in this case is the selection of surface-rooted plants which are now in course of being generally grown.

As in wheat, so in cotton, this country is almost entirely dependent on foreign supplies. The uneasiness caused by the excessive dependence of the great Lancashire cotton industry, with exports of the annual value of more than 100,000,000*l*. sterling, on supplies from abroad, and the occasional shortage, have led to general action being taken to encourage the more extensive growth of cotton within the Empire. Next to the United States, which in some years has supplied seven-tenths of our imports, India comes second, but the East Indian cotton is not well suited to the requirements of the English spinner. Egypt, as the third producing country, supplies cotton of great strength and fineness.

The most valuable of all cottons is that known as Sea Island cotton, owing to its introduction and successful cultivation on the coastal areas in South Carolina, Georgia, and Florida. It is interesting to report that in recent years Sea Island cotton has been introduced back again to the West Indies, which was probably its original home. This was effected by the Imperial Department of Agriculture in the West Indies in 1902, when a pure strain of seed raised from plants immune to wilt disease was obtained in quantity from James Island. This ensured that the industry from the first was placed on a firm basis, and with the hearty co-operation of the planters an important West Indian cotton industry was successfully established. For some years the West Indian cotton has obtained a higher price than the corresponding grades of cotton from the Sea Islands themselves. The fine spinners in Lancashire are now practically independent for their supplies of this cotton from the United States. Further, it is not improbable that, owing to the serious attacks of the Mexican boll weevil on cotton plants in South Carolina and Georgia, the West Indies may become the only source of supply of fine Sea Island cotton. The results so far attained may be realised from the fact that the value of the exports of Sea Island cotton from the West Indies in recent years has reached a total of 2,000,000*l*. sterling. The general conditions in the West Indian islands, owing to their small size and comparative isolation, should enable them to maintain a high purity of cotton. Harland, whose services in the West Indies have been provided by a grant from the Imperial Department of Scientific and Industrial Research, has in hand important investigations with the view of placing the work of cotton selection and breeding on scientific lines. He has shown that the yield of lint per acre depends on a number of factors of a morphological and physiological character. In a general way it may be said that the yield is dependent on the climatic conditions, so an effort is being made to produce varieties which will interact with the environmental conditions to the best advantage. Although Harland's work so far is of a preliminary character, he is able to suggest the conclusion that, following certain lines of selection and breeding, and bearing in mind the relative importance of lint index and lint percentage, it is possible to isolate a strain of Sea Island cotton with a weight of lint per boll 31 per cent. greater than that of the ordinary sorts in cultivation.

As already mentioned, India is the second largest producer of cotton. In 1906–7 it was estimated that there were about 20,000,000 acres under cotton, with a production of nearly 5,000,000 bales. It is unfortunate that the quality of East Indian cotton is not high, in spite of the considerable efforts made in recent years to improve it.

Leake's research work in the United Provinces, carried on for many years, is regarded as probably the most complete yet attempted with cotton in India. A variety known as K.22 has been widely distributed, and the produce in 1916 sold at 31 rupees per maund when local cotton was 25 rupees. Further, the ginning percentage has been raised from 33 to about 40, while the lint is of superior quality.

Leake has also been successful in raising an early-flowering form of cotton on Mendelian lines. The new form differed from ordinary cotton cultivated in the United Provinces in that it assumed a sympodial instead of a monopodial habit. It not only yielded cotton of high quality, but was found by its early-flowering habit to suit the special conditions of the United Provinces.

As Egyptian cotton comes next to Sea Island cotton in quality, it may be useful to refer to what has been done, or attempted to be done, on scientific lines to safeguard the industry. Its importance may be gathered from the fact that the area under cultivation is between 1,500,000 and 2,000,000 acres. Balls has fully reviewed the scientific and other problems that had to be solved in placing the industry on a satisfactory footing. According to Balls, the high-water mark of Egyptian cotton-growing was from 1895 to 1899. Since that time, although the actual area under cotton has been increased by 600,000 acres, the benefit measured in terms of cotton alone has been small. It is probable that the attacks of the pink boll-worm and other pests may have affected the results, but Balls and his colleagues drew the conclusion that "the falling off in yield was due to a rise in the level of the subsoil water or water-table of the country brought about by the extension of the irrigation system during the past decade." The roots of the cotton plant were thus adversely affected at a critical period of growth. This recalls what Howard discovered: that one of the causes of the wilt disease in indigo in India was the destruction of the fine roots and nodules during heavy monsoon rains.

Probably the most remarkable instance on record of the successful combination of science and enterprise in the tropics is the establishment of a cacao-growing industry in the Colony of the Gold Coast, West Africa. Thirty years ago no cacao of any kind was produced on the coast. Owing, however, to the foresight of the then Governor (Sir William Brandford Griffith), who sought the powerful aid of Kew, cacao-growing was started in a small way among the negro peasantry, with eventually extraordinary results. After selecting the locality for the experiments, seeds and plants were obtained through Kew, and a trained man was placed in charge (*Kew Bull.*, 1891, p. 169; 1895, p. 11). The first exports in 1891 amounted to a value of 4*l.* only. So rapid was the development of the industry that ten years later the exports reached a value of 43,000*l.* By this time both the people and the Government had begun to realise the possibilities of the situation, and systematic steps were taken to organise under scientific control a staff of travelling agricultural instructors to advise and assist the cultivators in dealing with fungoid and insect pests and improving the quality of the produce. In 1911 the exports had increased nearly fourfold and reached a total value of 1,613,000*l.*, while in 1916 what may possibly be regarded as the maximum exports were of the value of 3,847,720*l.*

It should be borne in mind that this Gold Coast cacao industry, now one of the largest in the world, has been called into being and developed entirely by the agency of unskilled negro labour, and on small plots from one to five or ten acres in extent. The controlling factors were, first, the selection of suitable land for cacao-growing; next, the selection and supply of seeds and plants of varieties adapted to local conditions; and, lastly, the advice and assistance of trained Europeans backed by the resources of science.

Coming nearer home, Henry, well known from his association with Elwes in the production of "The Trees of Great Britain and Ireland," by historical research and experiment has established the fact that many fast-growing trees in cultivation, such as the Lucombe Oak, Common Lime, Cricket-bat Willow, Black Italian Poplar, Huntingdon Elm, etc., are natural hybrids. It was of high scientific importance to discover the origin of these valuable trees. Further, by artificial pollination Henry has succeeded in raising new hybrids which display the extraordinary vigour characteristic of the first-generation cross. Perhaps the most notable so far is a new hybrid poplar (*Populus generosa*), which makes the strongest shoots of all poplars. It is claimed in the case of hybrid trees that "it is possible to produce much greater bulk of timber in a given time." The common belief that quickly grown timbers are of inferior quality is said not to hold good in respect of any quality in ash, oak, and walnut. In fact, according to Dawson, "with oak, ash, and walnut the quicker their growth the better their quality in every way. They are more durable, more elastic, and less difficult to work" ("Science and the Nation," p. 138). It is further claimed that by hybridising it may be possible to produce disease-resisting varieties and varieties carrying with them other desirable characteristics.

In the tropics breeding experiments in the case of india-rubber trees are likely to prove of great value. In the meantime, selection of seed from the best trees is being carefully carried out in the hope of increasing the general yield of the plantations. In Java the proportion of alkaloids in the bark of introduced cinchona trees (yielding quinine) has nearly doubled by careful selection on these lines.

Plant-breeding experiments with india-rubber trees have already been attempted, but they are not likely to be of much value if they are confined to empirical and haphazard lines. Work of this kind must be lengthy and complex, but it is absolutely essential to ensure the safety of an industry which is estimated to be of the annual value in the Middle East of about 50,000,000*l.* sterling. The Agricultural Department in Ceylon, which is fully alive to the fundamental importance of the selection and breeding of india-rubber trees, has already taken some action in the matter.

Another investigation in hand is to determine whether the latex-yielding quality of Hevea trees can be associated with any definite botanical characters and to what extent such characters are transmissible. Twenty trees of the same age growing in a four-acre block have been selected for differences in leaf and bark characters. These are all tapped on the same system, and the yield of rubber from each tree is recorded separately for each tapping (*Kew Bulletin*, 1917, p. 118).

The value of these and other experiments of a like nature may be realised when, according to Varnet, quoted by Johnson, the yield of rubber from different trees of Hevea growing under similar conditions in the same plantation may vary as regards volume of latex from 4 to 48, and in percentage of weight of dry rubber from 1·286 to 14·164 (*Journ. d'Agric. Tropicale*, 1907).

Bateson a few years ago expressed the opinion that nowhere is the need for wide views of our problems more evident than in the study of plant diseases. Biffen and others have shown that under certain conditions the quality inherent in some varieties to resist disease may be utilised to great advantage. The national importance of such work is impressed upon us by the enormous losses sustained every year by rust in wheat, mould in hops, and the widespread disease of potatoes. One of the most striking instances in recent times was the destruction of the valuable coffee plantations in Ceylon. The industry, an exceptionally valuable one, was wiped out in a comparatively few years by the coffee-leaf disease (*Hemileia vastatrix*). In the light of our present knowledge it is not improbable that this disease may have been checked by seed selection or by raising an immune race of plants; or, more probably, as suggested by Armstrong, by regulating the use of essentially nitrogenous manures, which are known in some cases to intensify the attacks of fungoid pests, and substituting the use of phosphates. As illustrating the occurrence of an incidental result arising from a purely scientific investigation, mention may be made of the discovery of a remarkably tall strain of flax at the John Innes Institution. This, if capable of being established on pure lines, may prove of economic value. It is a hopeful sign that the appreciation of the work done at this institution, under the stimulating energy of Bateson, is increasing day by day. We may mention the great success which is attending the establishment of a school of technical education and research by the Royal Horticultural Society at Wisley. This is maintained by liberal funds, and by means of its well-equipped laboratories and extensive trial grounds it offers unique facilities for solving problems of great value as affecting the future of British horticulture. In sympathy with the work at Wisley, private firms are also setting up laboratories of their own and employing men of high standing so that a just balance may be maintained between science and practice. The progress made in the elucidation of problems in tropical plant pathology shows the necessity not only for well-trained and experienced mycologists and entomologists, but also for the correlation and combination of knowledge gained in their several lines of study. It is suggested that research work should be organised on the broadest possible lines, and combine the biological services of the whole Empire. We have a first step in this direction in the Imperial Bureau of Entomology, with its headquarters at the British Museum. Those acquainted with the efficient work done by this bureau and the excellent publications issued by it will very heartily welcome the establishment of the proposed Imperial Bureau of Mycology to carry on work on similar lines.

In this brief review I have endeavoured, however imperfectly, to place on record some of the activities that have taken place in the domain of botany in recent years. It has only been possible to select a few of the most striking incidents where progress has been made. This has been done in the hope of arousing wider interest in work of prime importance as affecting the interests of the home country and the Empire. Botany in its widest aspects affects so largely the welfare of the human race that it is impossible to slacken our efforts. Advance has necessarily been slow, but the creative impulse of science cannot fail to bring in a large harvest of results. This may be possible by encouraging individual efforts, by organising active co-operation, and by associating with us men who are practically grappling with difficulties that seem almost impossible to solve. I have attempted to show in what vast fields of enterprise botanical science has already rendered signal service. As regards the future, if we enlist the best intellects, imbued with the true spirit of progressive research, we shall ensure a continuance of discoveries that have proved so effectual. We must also call to our assistance some of that wonderful energy developed during the war and divert it to the great work before us.

Certainly one of the outstanding features that emerge from a record of botanical research during the last decade or two is the prominent position now occupied by plant-breeding on Mendelian lines. In proof of this we have the numerous well-equipped plant-breeding institutes established and maintained by Government and private funds. Plant-breeding is now in the forefront in relation to the improvement of crops, and the value of it is officially acknowledged as "a vital element in the national policy." According to the Secretary of the Board of Agriculture, what we want "are new races of plants adapted to intensive cultivation," and he adds: "It is my deliberate opinion that an increase in the production of our land is much more easily attainable in that direction than in any other."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—On Tuesday, December 2, in the hall of Trinity College, a lecture open to the University was given by Prof. Eddington on the theory of relativity. Apart from the interest of the lecture, which attempted—sometimes lightly and sometimes almost dramatically—to present a popular account of the subject, the most striking thing about it was the enormous attendance. Fifteen minutes before the lecture began there was a queue half-way across the Great Court of men anxious to obtain admittance, and during the lecture the hall was entirely filled with dons and students listening breathlessly to hear an intelligible account, if one could be given, of the new theory. The keen interest was due, no doubt, largely to curiosity stimulated by the newspaper accounts of the subject, but also partly to the feeling, to which at last some hope of satisfaction can be given, that a further great unifying principle is needed in natural philosophy. Whatever be the reason, however, the size and appreciation of the audience were no less extraordinary than the subject of the lecture and the brilliance of its exposition.

Mrs. Osborn, the wife of the president of the American Museum of Natural History, has presented a striking portrait of her husband to the Sedgwick Museum. It is proposed to hang this portrait of an old student of Cambridge and an honorary doctor of science of the University amongst the fossil mammals, which have been the subject of his life's work, near the portraits of Darwin and Huxley. The portrait, which is recognised by friends in Cambridge as a remarkably good likeness, is inscribed as follows:—"Henry Fairfield Osborn, LL.D., Sc.D. Camb., a student at Cambridge in 1879, contributor to Comparative Anatomy, Palæontology, Biology, President of the American Museum of Natural History. By Orlando Rouland, New York, 1919."

LIVERPOOL.—The council has appointed Prof. E. R. Dewsnup, professor of railway administration in the University of Illinois, to the chair of commerce, recently endowed by the trustees of the late Mrs. A. W. Chaddock.

MR. A. CONNELL has been appointed to succeed Prof. S. White in the professorship of surgery in the University of Sheffield.

CAPT. L. L. BURCHNALL, scholar of Christ Church, Oxford, has been appointed lecturer in mathematics in the University of Durham.

DR. J. CRUICKSHANK, pathologist to the Crichton Royal Institution, Dumfries, has been appointed

Georgina McRobert lecturer in pathology in the University of Aberdeen.

THE College Board of the London Hospital is offering the Liddle triennial prize (value 120*l.*) for an essay on "The Etiology of Epidemic Influenza." The competing essays must reach the Dean of the London Hospital Medical College on or before June 30 next.

THE New York correspondent of the *Times* announces that by the will of the late Henry Clay Frick all his estate, estimated at 29,000,000*l.*, except 5,000,000*l.*, is bequeathed to public educational and philanthropic objects. The benefactions include the following:—Princeton University, 3,000,000*l.*; Harvard University, 1,000,000*l.*; and Massachusetts Institute of Technology, 1,000,000*l.*

THE council of the Institution of Naval Architects offers for competition a scholarship (value 100*l.* per annum for three years) to be awarded on the results of the Board of Education examinations in naval architecture and other subjects. Candidates must be between eighteen and twenty-one years of age. Full particulars and application forms are obtainable from the Secretary, Institution of Naval Architects, 5 Adelphi Terrace, London, W.C.2. Entries will close on January 15, 1920.

THE annual meeting of the Mathematical Association will be held at the London Day Training College, Southampton Row, London, W.C.1, on January 7 and 8, 1920. The address of the president, Prof. E. T. Whittaker, will be on "Some Mathematical Problems Awaiting Solution"; and the papers to be presented are: "A Survey of the Numerical Methods for Solving Equations," the president; "The Use of Symmetry in the Teaching of Geometry," C. Godfrey; "Convention and Duplexity in Elementary Mathematics," Prof. E. H. Neville; "The Place of Common Logarithms in Mathematical Training," Miss H. M. Cook; and "The Teaching of Mechanics to Beginners," Mr. R. C. Fawdry.

AN interesting departure in commercial scientific education has been inaugurated by the directors of the Anglo-Mexican Petroleum Co., who have invited Mr. C. R. Darling, lecturer in physics at Finsbury Technical College, to deliver a course of ten lectures to the senior staff on the commercial applications of physics. These lectures are intended to form a broad basis of information which will lead to a fuller appreciation of the specialised lectures to be given by experts connected with the firm. A lecture-room has been provided on the company's premises at 16 Finsbury Circus, and has been equipped with facilities for experimental illustrations. This recognition of the value of science in commerce is a hopeful sign of the times, and an educational scheme of this character cannot fail to lead to increased efficiency in the staff of an industrial firm.

A SPECIAL committee of the Anglo-American Society suggested in the programme for the tercentenary celebration of the *Mayflower* and the Pilgrim Fathers (1620–1920) the foundation and endowment of a chair in American history, literature, and institutions. The sum of 20,000*l.* was required for the endowment of this chair, and this has now been provided by Sir George Watson. It is not proposed that the chair should be exclusively attached to one university, but that it shall be used for the general purpose of stimulating interest and study of America in all the British universities. Neither will the chair be held permanently by one scholar of a single nationality. The scheme provides that it shall be held, for a period of one or two years, alternately by an American and a British scholar or public man, thus drawing upon the best intellectual resources of the two countries, and securing a variety of treatment of the subjects dealt with. The committee points out that as a permanent memorial of America's loyal partnership with Great Britain in the war, as well as of the historic ties of kinship which unite the two peoples and of which the *Mayflower* celebration is a reminder, nothing could be more fitting than the establishment of this educational foundation.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Anthropological Institute, October 14.—Sir Everard im Thurn, president, in the chair.—Lieut. E. W. P. **Chinnery**: "Dengora baiari" is the ceremony of initiation of young men and women of the Binandere tribe, Memba River, British New Guinea. Pigs are killed, and each candidate stands on the pig contributed by his parents and receives a loin-cloth, *gonga*, various ornaments, and instruction in social conduct. Dramatic plays of a special instructional character, *iaveto*, are performed by the village people and visitors. Ancestral ghosts are said to reside during these ceremonies in the posts, *gusi*, of the men's house, *oro*, and in the *jijima*, properties of the *iaveto*. The *gusi* during such time are said to be *kotembo-kotembo*, but their connection with the dead ends with the completion of the ceremony. Some time afterwards the *jijima* are smeared with pig-grease, decorated with feathers, cast into the river, and implored in the names of deceased ancestors to change into crocodiles and devour the enemies of the tribe. After "dengora baiari" follows a period of seclusion in a house known as *wawa*; this condition, *iawa da vitari*, is removed after some months by a purification ceremony known as *tuna*. The candidates then bathe in the river and enter the normal life of the tribe.

Zoological Society, November 18.—Prof. E. W. MacBride, vice-president, in the chair.—Major J. S. **Hamilton**: Field-notes on some mammals in the Bahr el Gebel, Southern Sudan.—Prof. J. F. **Gemmill**: (1) The development of the mesenteries in *Urticina crassicornis* (Actinozoa), and (2) the Leptomedusan *Melicertidium octocostatum*.—Rev. A. H. **Cooke**: The radula of the Mitridæ.—Dr. C. F. **Sonntag**: The variations in the digastric muscle of the Rhesus macaque and the common macaque.—E. S. **Russell**: The righting reaction in *Asterina gibbosa*, Penn.—Lt.-Col. S. M. **Copeman**: Experiments on sex determination.—M. **Turner**: The Nematode parasites of a Chapman's zebra.

Geological Society, November 19.—Mr. G. W. Lamplugh, president, in the chair.—Prof. J. E. **Marr**: The Pleistocene deposits around Cambridge. This paper deals with the deposits in the immediate vicinity of Cambridge, and contains new records of sections, fossils, and implements. It is pointed out that, owing to alternating periods of erosion and aggradation, relative height above sea-level is not a trustworthy index of antiquity, and modifications of the classification proposed by W. Penning and A. J. Jukes-Browne are indicated.

CAMBRIDGE.

Philosophical Society, November 24.—Prof. **Eddington** and E. T. **Cottingham**: (1) Photographs of a solar prominence taken during the eclipse of 1919 May 29. (2) The theory of relativity and recent eclipse observations.—W. J. **Harrison**: (1) The hydrodynamical theory of the lubrication of a cylindrical bearing under variable load, and of a pivot bearing. (2) The pressure in a viscous liquid moving through a channel with diverging boundaries.

MANCHESTER.

Literary and Philosophical Society, November 18.—Prof. F. E. Weiss, deputy chairman, in the chair.—Prof. T. H. **Pear**: The elimination of wasteful effort in industry. Owing to the impossibility of being able to distinguish sharply between physical and mental effort in the investigation of the problems of economising human energy, physiology and psychology must work side by side. While in many industries improvement of the external conditions of work, such as temperature, ventilation, humidity, and illumination, was rapidly proceeding, less had been attempted in the direction of improving the methods of work themselves. Examples of such efforts illustrated the importance of certain fundamental principles. The first was the adjustment, both in total length and in distribution, of rest-pauses. By introducing suitably chosen rest-pauses and by modifying the working attitude of girls who were engaged in folding handkerchiefs, the output increased 300 per cent., while the folders worked only forty-five minutes in each hour, and were less fatigued than before. The second principle was the substitution of habitual movements for constant acts of decision. By rearranging the method of "assembling" a braid machine, so that the parts were not only put together in a more efficient order, but were more easily found by the workman, sixty-six units were assembled by a man in one day instead of eighteen. The third was the elimination of useless movement. By this means the separate actions required to lay a brick had been reduced from 18 to 5; the output increased from 120 per man per hour to 350.

PARIS.

Academy of Sciences, November 17.—M. Léon Guignard in the chair.—C. **Moureu** and A. **Lepape**: The stabilisation of acrolein. Preparation of acrolein. A mixture of potassium bisulphate (5 parts) and potassium sulphate (1 part) is recommended as the best catalytic agent for dehydrating glycerol to acrolein, and full details of the best method of carrying out the preparation on the large scale are given.—J. **Carpentier**: An account of the presentation (made on November 10) of colour kinematographs of the Gaumont establishment. Progress in the application of three-colour photography to the kinematograph has been rapid, and it is now practicable to take kinematographic views in colour.—Sir J. J. Thomson was elected a foreign associate in succession to the late M. Dedekind.—G. **Bouligand**: Solutions of the equation $\Delta u=\lambda u$, analytic and limited in an infinite domain, zero on the frontier.—N. E. **Nörlund**: The calculation of finite differences.—H. **Dulac**: Limit cycles. O. **Mayer**: Ruled surfaces of the fourth order.—P. **Humbert**: The approximate calculation of the elements of critical Jacobians of a high order.—E. **Belot**: The structure of our stellar universe, deduced from the dualist and vortex cosmogony.—G. **Fayet**: Return of Finlay's periodic comet. This is identical with the comet discovered by Sasaki at Kyoto (Japan) on October 25. From data calculated by the author it was again found by M. Schaumasse at Nice on November 9.—M. **Michkovitch**: Observation of Finlay's periodic comet made at the Marseilles Observatory with the 26-cm. Eichens equatorial. The positions of the comet and comparison star are given for November 10. The comet was well defined and of about the ninth magnitude.—M. **Giacobini**: Observations of the Sasaki (Finlay's) comet made at the Paris Observatory. Positions are given for November 12 and 16.—P. **Chofardet**: Observations of Finlay's periodic comet (1919*e*) made at the Besançon Observatory. Position given for November 13.—A. **Schaumasse**: Observations of Finlay's periodic comet made at the Nice Observatory. Positions given for November 9, 10, 11, 12, and 13.—A. **Baldit**: The effect produced by the electricity of rain on an insulated wire. An insulated wire exposed to rain behaves as a potential equaliser. The disturbances known to occur in electrical systems with air-cables during rainstorms arise from the terrestrial electric field.—A. **Chéron**: An apparatus for the simultaneous examination of the same stereoscopic plate by two persons.—A. **Lartigne**: A new form for the formulæ of line spectra. The formula, deduced from the point of view of general mechanics, is

$$\lambda_m=\frac{4\times 10^8}{N_0}\left(\frac{p}{2}\right)^3\left(\frac{2}{p}+\frac{1}{m}-\frac{1}{m+2p}\right)\text{Angstroms},$$

in which λ is the wave-length, N_0 the Rydberg universal constant, p a constant, and $m=(q-p)$, differing only slightly from consecutive numbers. For $p=2$, and $m=q-2=1, 2, 3 \ldots 29$, the formula is identical with Balmer's original series for hydrogen.—G. A. **Hemsalech**: The luminous phenomena observed in the neighbourhood of a plate of graphite carried to a high temperature by an electric current.—H. **Ungemach**: A remarkable deposit of chalcostibite in Morocco. This mineral is rare, and has hitherto been found in only three localities, in minute quantities and as small crystals. The deposit at Rar-el-Anz, in Morocco, is extensive, and the crystals are large and well formed. One measured 9×4×1 cm.—R. **Souèges**: The embryogeny of the Polygonaceæ. Development of the embryo in Rumex and Rheum.—MM. P. **Mazé**, **Vila**, and M. **Lemoigne**: The transformation of cyanamide into urea by the micro-organisms of the soil. Of the three organisms chosen one, *B. coli*, has no action upon cyanamide; the others, *B. prodigiosus* and *B. cloacae*, convert the cyanamide completely into urea, traces only of ammonia being found.—H. **Bierry**: Carnivora and the three classes of food. It appears improbable, from both observation and experiment, that carnivora can thrive on a diet deprived of both fats and carbohydrates.—F. **Mesnil** and M. **Caullery**: A normal process of fragmentation, followed by regeneration, in a polychetal Annelid, *Syllis gracilis*.—A. **Krempf**: Development of muscular layers in the larva of an Anthozoa (*Pocillopora cespitosa*) at the primitive stage of tetraradial symmetry.—F. **d'Hérelle**: The *rôle* of the protecting micro-organism in bird-typhus.—C. **Nicolle** and C. **Lebailly**: The evolution of the spirochetæ of recurrent fever in the louse, as followed in a series of sections of these insects.

DIARY OF SOCIETIES.

THURSDAY, DECEMBER 11.

ROYAL SOCIETY, at 4.30.—C. F. U. Meek: A Further Study of Chromosome Dimensions.—J. M. H. Campbell, C. G. Douglas, and F. G. Hobson: The Respiratory Exchange of Man During and After Muscular Exercise.—Dr. A. D. Waller: The Energy Output of Dock Labourers during Heavy Work.—C. H. Usher: Histological Examination of an Adult Human Albino's Eyeball, with a Note on Mesoblastic Pigmentation in Fœtal Eyes.—J. Gray: The Relation of Spermatozoa to Certain Electrolytes, II.

LINNEAN SOCIETY, at 5.—Prof. W. A. Herdman: Notes on the Abundance of Marine Animals and a Quantitative Survey of their Occurrence.—J. B. Gatenby: The Fertilisation of the Calcareous Sponges.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Sir Charles A. Ballance: The Surgery of the Heart (Bradshaw Lecture).

ROYAL INSTITUTE OF PUBLIC HEALTH, at 5.—Dr. H. H. Thomson: The Diagnosis and Treatment of Tuberculosis in Relation to Public Health.

MATHEMATICAL SOCIETY (at Burlington House), at 5.—Major P. A. MacMahon: Permutations, Lattice Permutations, and the Hypergeometric Series.—L. J. Mordell: The Generating Function of the Series $\Sigma F(n)q^n$, where $F(n)$ is the Number of Uneven Classes of Binary Quadratics of Determinant $-n$.—H. Steinhaus: Fourier Coefficients of Bounded Functions.—D. Priabandrinsky: Steady Fluid Motions with Free Surfaces.

INSTITUTION OF ELECTRICAL ENGINEERS (at the Institution of Civil Engineers), at 6.—Capt. J. M. Scott Maxwell: Scientific Management—A Solution of the "Capital and Labour" Problem.

OIL AND COLOUR CHEMISTS' ASSOCIATION (at 2 Furnival Street, E.C.), at 7.—The Principle of Application of Paint and Varnish, and How it Affects the Works Chemist of the Paint and Varnish Industry.

OPTICAL SOCIETY, at 7.30.

INSTITUTION OF AUTOMOBILE ENGINEERS (Graduate Section) (28 Victoria Street), at 8.—Debate: Worm *v.* Bevel Drive.

ROYAL SOCIETY OF MEDICINE (Neurology Section), at 8.30.—Certain Late Effects of Injuries of the Nervous System.

FRIDAY, DECEMBER 12.

DEPARTMENT OF SCIENTIFIC AND INDUSTRIAL RESEARCH.—Conference of Research Organisations (at Institution of Civil Engineers), at 2.30.—Rt. Hon. A. J. Balfour: Introductory Address.—H. J. W. Bliss: Research Associations and Consulting Work and the Collecting and Indexing of Information.—Dr. W. Lawrence Balls: The Equipment of Research Laboratories.

ROYAL ASTRONOMICAL SOCIETY, at 5.—Prof. Eddington and Others: Consideration of the Theory of Relativity.

PHYSICAL SOCIETY OF LONDON, at 5.—Prof. W. M. Coleman: First Steps in the Experimental Analysis of a Galvanic Cell.—J. W. T. Walsh: Radiation from a Perfectly Diffusing Circular Disc.—Dr. N. W. McLachlan: A Comparative Method of Testing Thermionic Valves for Passing No Reverse Current at High Voltages.—Dr. A. O. Rankine: Recording and Reproducing Sounds by Means of Light.

ROYAL SOCIETY OF MEDICINE (Clinical Section), at 5.

MALACOLOGICAL SOCIETY OF LONDON (at the Linnean Society), at 6.—Rev. Dr. A. H. Cooke: An Abnormality of Structure in the Radula of Certain Rhachiglossate Mollusca.—H. Watson: The Affinities of Pyramidula, Acanthinula, and Vallonia.

MONDAY, DECEMBER 15.

INSTITUTION OF ELECTRICAL ENGINEERS (Informal Meeting) (at Chartered Institute of Patent Agents), at 7.—R. Rankin and Others: Discussion on Some Reflections on Labour.

FARADAY SOCIETY (at the Chemical Society), at 8.—Lieut. W. A. Macfadyen: Electrolytic Iron Deposition.—A. G. Tarrant: The Measurement of Physical Properties at High Temperatures.—J. G. Williams: The Electrolytic Formation of Perchlorate from Chlorate.—Prof. A. W. Porter: The Vapour Pressures of Binary Mixtures.—S. Horiba: Some Relations between the Solubilities of Solutes and their Molecular Volumes.—Dr. E. J. Hartung: (1) An Accurate Method for the Determination of Vapour Pressure; (2) Some Properties of Copper Ferrocyanide.—Prof. E. D. Campbell: The Solution Theory of Steel and the Influence of Changes in Carbide Concentration on the Electrical Resistivity.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.—S. Perks: London Town-Planning Schemes in 1666.

ROYAL SOCIETY OF ARTS, at 8.—Dr. J. T. Hewitt: Synthetic Drugs (Cantor Lecture).

SURVEYORS' INSTITUTION, at 8.—Discussion on The Future of the Institution.

ROYAL GEOGRAPHICAL SOCIETY (at the Æolian Hall), at 8.30.—Capt. E. H. Keeling: In Northern Anatolia, 1917.

TUESDAY, DECEMBER 16.

ROYAL SOCIETY OF MEDICINE, at 5.—General Meeting of Fellows.

ROYAL STATISTICAL SOCIETY, at 5.15.—J. E. Allen: Some Changes in the Distribution of the National Income during the War.

INSTITUTION OF PETROLEUM TECHNOLOGISTS (at Royal Society of Arts), at 5.30.—A. J. Wilson: The Application of Liquid Fuel to Heavy-Oil Engines.

INSTITUTION OF CIVIL ENGINEERS, at 5.30.—Major E. O. Henrici: Precise Levelling.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN (Technical Meeting), at 7.—N. E. Luboshez: Fancy Lighting in Portraiture.

ILLUMINATING ENGINEERING SOCIETY (at Royal Society of Arts), at 8.—Capt. W. A. Howells: The Art of Camouflage.

WEDNESDAY, DECEMBER 17.

SOCIETY OF GLASS TECHNOLOGY (at Institute of Chemistry), at 2.—J. Connolly, Dr. M. W. Travers, and Dr. W. E. S. Turner: The Position of the Glass Industry in America.

ROYAL UNITED SERVICE INSTITUTION, at 3.—Major-Gen. Sir Lewis Jackson: Possibilities of the Next War.

ROYAL SOCIETY OF ARTS, at 4.30.—C. Grunwald: The Present Economic Position of Russia, and Some Aspects of its Future Development.

ROYAL METEOROLOGICAL SOCIETY, at 5.—F. J. W. Whipple: The Laws of Approach to the Geostrophic Wind.—G. M. B. Dobson: Winds and Temperature Gradients in the Stratosphere.—Capt. C. J. P. Cave: Quotations from the Diary of Samuel Pepys on the Weather.

GEOLOGICAL SOCIETY OF LONDON, at 5.30.—Secretary of State for the Colonies: An Earthquake at Rabaul in May, 1919.—R. R. Lempriere: The Raised Beach at South Hill (Jersey).—Prof. S. J. Shand: A Rift-Valley in Western Persia.

INSTITUTION OF ELECTRICAL ENGINEERS (Wireless Section) (at Institution of Civil Engineers), at 6.—Prof. G. W. O. Howe: High-Frequency Resistance of Wires and Coils.

ROYAL MICROSCOPICAL SOCIETY (at the Northampton Polytechnic Institute), 7.30–10.30.—Conversazione.

THURSDAY, DECEMBER 18.

ROYAL SOCIETY OF ARTS, at 4.30.—P. J. Hartog: Some Problems of Ind an Education.

INSTITUTION OF MINING AND METALLURGY (at Geological Society), at 5.30.—Adjourned Discussion on A Contribution to the Study of Flotation, H. L. Sulman.

INSTITUTION OF ELECTRICAL ENGINEERS (at Institution of Civil Engineers), at 6.—D. M. W. Hutchison and W. J. Wayte: Electricity in Tin Mining.

PHYSIOLOGY AND MEDICINE.

Physiology and Biochemistry in Modern Medicine. By Prof. J. J. R. Macleod. Assisted by Dr. Roy G. Pearce and by Others. Pp. xxxii+903. (London: Henry Kimpton, 1918.) Price 37*s*. 6*d*. net.

TEACHERS engaged in giving instruction in physiology to students of medicine are well aware of the difficulty pointed out in the preface to the book before us. The student, mainly out of ignorance, is apt to regard the subject as of no importance in the practice of his profession, and to devote what attention he gives to it simply to what he believes will enable him to pass some particular examinational test. He rarely acquires real and useful knowledge of the fundamental processes at the basis of all the manifestations of vital phenomena, normal and pathological, a knowledge which he usually regards as purely "academic." He fails to realise how great an assistance in the comprehension of complex states he would obtain by the application of such general principles. It is to be feared that this attitude is too much encouraged by that of some clinicians. The student learns from his friends who have passed on to their hospital work what little value physiology possesses, as judged by the remarks made by his clinical teachers. There are signs, however, that a change is taking place. The work of physiologists in elucidating problems which arose during the late war, such as the action of poison gases, the regeneration of muscle and nerve, wound-shock, and so on, had the effect of demonstrating to many enlightened medical officers the necessity of physiological science.

On the side of the physiologists themselves it is perhaps true to some extent, as the preface to Prof. Macleod's book states, that the laboratory courses fail to give the student the conviction that he is learning what will be of use to him in the future. But this conviction is not an easy matter to give, for the reason that the teacher, naturally enough, is not regarded as an impartial judge when he seeks to impress upon his students the bearing of any particular lesson upon the interpretation of disease. Prof. Macleod holds that the chief remedy of the evil "lies partly in the continuance of certain of the laboratory courses into the clinical years, and partly in the study of medical literature in which the application of physiology in the practice of medicine is emphasised." For the latter of these objects the present book is admirably fitted. The author intends it as "an advanced text-book in physiology for those about to enter upon their clinical instruction, and at the same time a review for those of a maturer clinical experience who may desire to seek the physiological interpretation of diseased conditions."

The practice of continuing some course of physiology during the clinical years is being advocated in certain quarters at the present time. A great difficulty is undoubtedly the enormous bulk of clinical knowledge that the unfortunate student has to learn. It would, perhaps, be a valuable step in this direction if the laboratories would arrange from time to time special lectures or practical exercises on aspects of the subject which happen to attract attention at the time, say, for example, "acidosis" and hydrogen-ion concentration at the present time. Suggestions would be made by the clinical teachers. On the other hand, this practice would not solve the problem of giving the student a vital interest in his laboratory work, and it has been suggested that some opportunity might be arranged for the student to see something of hospital work during his physiological course. A note in NATURE of May 15 last states that Sir Edward Sharpey Schafer objects to any systematic clinical instruction at this time. Doubtless with justice. But might it not serve the purpose if an occasional clinical demonstration, appropriate to the physiological problem under discussion, such as the taking of an electrocardiogram in a case of heart disease in connection with the treatment of electrical phenomena in muscle, were given in the hospital? It would, at all events, serve to show the student what he must learn, and impress upon him how little he knows. At the same time, much caution would need to be exercised to avoid the fatal error of limiting physiological teaching to what is obviously of immediate interest in clinical practice.

The book before us does not claim to supersede the general text-books, or to give instructions for the performance of chemical tests and estimations. These latter are only to be learned by practice. Indeed, it would seem that the word "biochemistry" in the title of the book might be omitted, because the author himself states that it treats biochemical knowledge from the viewpoint of the physiologist. Biochemistry, in fact, can scarcely be regarded as an independent science in the sense that physiology is. Its separate teaching and investigation are rather matters of practical convenience, and, unless guarded against, may lead to unfortunate results. Part of it is included in physiology, animal and plant, while the remaining part is a branch of organic chemistry.

Certain aspects of physiology, such as the phenomena of immunity and the details of reactions of the central nervous system, require the space of special works. Some readers may be inclined to think that the portion of Prof. Macleod's book devoted to the nervous system is somewhat meagre in comparison with that occupied in the usual text-books. It gives, however, an excellent general account of the activities of the nerve-centres, and we may call to mind that a large part of the corresponding sections in many text-books is occupied with pure anatomy. It is curious that Prof. Macleod falls into the common practice of describing the receptor organ for position, the semicircular canals, under the head of the cerebellum; but this is possibly to be accounted for as the result of his intentional omission of details of the sense-organs in general, which would have made the book too unwieldy.

Since a review is scarcely complete without a word of criticism, it may be pointed out that the spelling of "edema" and "hemoglobin" is unwelcome to British eyes, and that "neuron" should have a final *e*.

But these are trivialities, and the work as a whole can be highly commended. Circulation, respiration, digestion, and metabolism are especially well discussed. There are, of course, some aspects of these questions on which our knowledge is more complete than at the time the book was written. These are matter for a future edition. In such an edition a short account of the phenomena of immunity, from a general point of view, would be valuable, although this would not be a particularly easy task. The illustrations and diagrams are by no means the least useful part of the book.

W. M. BAYLISS.

MATHEMATICS, PARTICULAR AND GENERAL.

(1) *Analytic Geometry.* By Prof. Maria M. Roberts and Prof. Julia T. Colpitts. Pp. x + 245. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1918.) Price 7s. 6d. net.

(2) *Elementary Mensuration, Constructive Plane Geometry, and Numerical Trigonometry.* By P. Goyen. Pp. viii + 169. (London: Macmillan and Co., Ltd., 1919.) Price 3s. 6d.

(3) *Lectures on the Philosophy of Mathematics.* By James Byrnie Shaw. Pp. vii + 206. (Chicago and London: The Open Court Publishing Co., 1918.) Price 6s. net.

(1) PROFS. ROBERTS AND COLPITTS have wisely included in a single course on "Analytic Geometry" the most important parts of the theory of conic sections, the theory of curves in Cartesian and polar co-ordinates, and the elements of solid geometry treated analytically, thus representing as a connected whole the parts of co-ordinate geometry in which every university student of mathematics should be thoroughly grounded. The book is very sound pedagogically, the treatment being based largely on the intuitive use of geometrical constructions. The figures are well and neatly drawn, and many of the curves are accurately plotted.

One must, however, point out some of the more serious faults, with a view to their elimination from a future edition. Some of the figures are unsatisfactory—*e.g.* those on pp. 117, 136, 152, 159, 168, 178, and 188. A very important point is missed on p. 38. The student should be informed that in a family of curves like

$$ay^2 = x(x-2a)^2,$$

which can be written in the form

$$(y/a)^2 = (x/a)(x/a-2)^2,$$

the value of the parameter a is to indicate the dimension of any curve of the family, so that the family consists of similar curves with the origin as centre of similitude. The method of § 70 is clumsy.

An interesting feature is the discussion on pp. 83–4 of the difficulties arising from the multiple representation of points in the polar system. A definite point on a plane has definite Cartesian co-ordinates if the axes are given, but it has more than one pair of polar co-ordinates even when the pole and original line are given. Thus the points (ρ, θ), $(-\rho, \theta+\pi)$, $(\rho, \theta+2\pi)$, $(-\rho, \theta+3\pi)$, etc., are all really one and the same point. This may cause confusion and error in the practical use of polar co-ordinates. Unfortunately, the authors do not indicate clearly the steps to be taken in order to avoid the danger. This is done by writing any equation $\rho=f(\theta)$ in the more general form $\rho=(-)^n f(\theta+n\pi)$, in which n is any positive or negative integer.

The book is one that can be unhesitatingly commended to the notice of teachers and students. There are numerous exercises, amply illustrative of the principles taught.

(2) There is no doubt that Mr. Goyen is right in claiming for the experimental method of geometrical teaching the advantage of preparing "the way for such subsequent abstract proofs as will enable learners to reinforce the test of experience by the test of reason." The present book depends somewhat on the "test of experience," and its value lies principally in the information given, and not in the process of proof employed to establish the results. Occasionally, indeed, statements are made without attempt at any justification.

Mr. Goyen's book thus caters for the student who wishes to acquire geometrical knowledge rather than geometrical training. It includes the usual geometry of rectilinear figures and circles, with application to ordinary mensuration; the quadrilateral and regular and irregular polygons; and the use of similar figures and some three-dimensional mensuration. A welcome chapter is that on numerical trigonometry, a subject too much neglected in elementary mathematical teaching. Every student who claims to have "done mathematics" should be able to deal successfully with easy problems in "heights and distances."

There are numerous examples. The tables and the answers add to the usefulness of a very useful book.

(3) One of the great defects of scientific teaching, due no doubt to the high degree of specialisation that recent progress has made necessary, is the restricted outlook of the presentation. The pass student learns a certain amount of two or three subjects; the honours man studies one subject to a higher pitch of excellence; but both the pass and the honours men are generally ignorant of two important aspects of their studies: they know little of the historical development of their subjects, and they rarely acquire a view of the whole of any subject, the correlation of its parts,

its foundations, and the contemporary trend of its development.

The ignorance of the history of any science could easily be remedied. Each head of a scientific department should arrange for a historical course in his subject. The interest aroused by such an adequately prepared and well delivered and illustrated historical course would more than repay the time spent on it.

The acquisition of a competent view of any subject is more difficult, and especially in mathematics, as is illustrated by Dr. Shaw's lectures. No student of mathematics can be expected to be familiar with all or even with the majority of the branches of mathematics mentioned by Dr. Shaw. The pass man would probably lay the book down after reading the first chapter—if he gets thus far. The honours student would perhaps go further, particularly if his speciality is pure mathematics and his reading has been ably directed by a teacher familiar with modern mathematical tendencies. Yet Dr. Shaw has dealt with his theme in a particularly persuasive and very elementary manner.

The author considers the "speculative thinker" who desires "to know the content of mathematics," "to hunt for the central principle that controls its evergreen growth," to explore "the source of mathematical reality," and to discover the "methods pursued in the field of investigation" and the "right of this Queen of all the sciences to rule." These problems are dealt with in a brief and clear exposition, which must be read in order to be appreciated. It would be idle to attempt a summary, as this would not convey much to the uninitiated for whom the lectures were written. Suffice it to say that in Dr. Shaw's opinion there is no *single* principle of mathematics, no *single* source of reality, no *single* mathematical method.

These lectures should be read and re-read by all who desire to fathom the depths of the reality of mathematics. They will be inspired to a view of the subject different from the drab and utilitarian view so often prevalent in our colleges. They will learn at least to give his due share of recognition to the mathematician who "sits with abstracted mien, his mental eye turned inward upon some intricate construction of symbols and formulæ," and to respect, perhaps even to share, his joy when he catches the flash of triumph.

S. Brodetsky.

OUR BOOKSHELF.

The Journal of the Institute of Metals. Vol. xxi. Edited by G. Shaw Scott. Pp. xi+508+40 plates. (London: The Institute of Metals, 1919.) 31*s*. 6*d*. net.

Of the new volume of this important journal, no fewer than 216 pages are occupied by the fourth report to the Corrosion Committee by Drs. Bengough and Hudson and the subsequent discussion. The new report embodies the results of a very large amount of experimental work, and is distinctly helpful in regard to the immediate problem of extending the life of brass condenser tubes. A large array of new facts bearing on the baffling question of the mechanism of corrosion is also included, and illustrated by numerous plates. The authors favour the view that direct oxidation takes place without preceding electrolytic action. As Prof. Armstrong points out in the discussion, the theory of corrosion is in a disappointingly backward state, and no satisfactory explanation has yet been given of some of the most familiar facts. The report is a valuable one, and fully justifies the continuance of the work of the committee.

Messrs. Hanson and Archbutt contribute a most useful account of their methods of polishing and etching aluminium and its light alloys, and of identifying the constituents, a task which has presented difficulties to most metallographers. Another paper from the same laboratory, by Dr. Rosenhain and Mr. Hanson, records the properties of some copper alloys which were devised for war purposes, and incidentally describes a convenient method of obtaining clean castings by working under pressure. A note by Lt.-Col. Jenkin on the metallurgical information required by engineers is followed by a lively discussion, the conclusion being reached that the determination of true physical constants is likely to supersede many of the present empirical tests. There are two papers on the effect of cold work on metals, and an interesting discussion on the relation of science to the industry of the non-ferrous metals, in which the respective views of scientific workers and manufacturers are well and clearly expressed. The volume concludes with the usual abstracts of metallurgical literature.

C. H. D.

Golden Days from the Fishing-Log of a Painter in Brittany. By Romilly Fedden. Pp. xviii+233. (London: A. and C. Black, Ltd., 1919.) Price 7*s*. 6*d*. net.

Here is a book full of quiet charm and humour, written by one who is evidently not only an artist and a sportsman, but also a true lover and observer of Nature and her ways. The angler will be fascinated by the vivid descriptions of trout- and salmon-fishing in Brittany. There are no improbable fisherman's yarns to invite his scepticism, but their place is taken by some delightful stories of saints and miracles drawn from the Breton folk-lore, so that the book appeals quite as much to the general reader as to the piscatorial fraternity. It is a pleasant narrative, well suited to while away a winter evening at the fireside and to conjure up visions of sunlit meadows, fragrant pinewoods, and murmuring streams, though tinged, alas! by that vein of sadness which must colour the day-dreams of all of us at the present time, and especially of those who, like the author, have witnessed at close quarters the tragedy of the last few years.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Power from the Sun.

IN the very interesting Trueman Wood lecture delivered at the Royal Society of Arts on December 10, Sir Oliver Lodge discussed the utilisation of solar radiation, and recommended, as the best method of effecting this purpose, the promotion of agriculture of every kind. According to Sir Oliver Lodge, the green leaves of trees and vegetables generally are able to absorb and utilise solar energy without much regard for any hampering limit to efficiency such as the second law of thermodynamics, but in saying this he appears to be unaware of the researches of Dr. Horace Brown, who has shown that the actual amount of energy stored is less than 2 per cent. of that which reaches the vegetation.

Now the total amount of solar energy intercepted by the earth is prodigious, being in the aggregate some 200 billion h.p., or, on an average, about 4,000,000 h.p. per square mile of that portion of the earth's surface that is exposed not too obliquely to the sun's rays. Absorption by the clouds and by the atmosphere, though important, is not so great as might be expected, with the result that even in this latitude and in this climate the energy constantly received throughout the hours of daylight exceeds 1000 h.p. per acre.

If, then, some method could only be devised for efficiently converting this energy into a form in which it could be readily applied for motive power and other purposes, the gain and the convenience would be enormous; for, to take a single instance, sufficient energy to run all the machinery in a factory throughout the working day could be collected from an area in many cases not greater than that subtended by the factory's roof.

Now, of course, for reasons which Sir Oliver Lodge fully discussed, it is hopeless to expect to be able to effect anything of this nature with the heat engine, for with this we should scarcely reach the 2 per cent. efficiency nearly attained by vegetation. But is there any need to allow the radiation to turn itself into heat at all? Solar radiation, as is well known, consists of electromagnetic waves in the æther—waves exactly similar in kind to those employed in wireless telegraphy. The only difference is that, whereas the length of the waves used in wireless telegraphy is a matter of hundreds or thousands of metres, the wave-length in the case of solar radiation is only a very minute fraction of a millimetre.

Even with wireless waves the resulting frequency is too great to allow of the electric currents they induce being directly utilised. The telephones and other instruments employed offer too much impedance to allow such currents to pass, while, apart from this, no mechanical device could move with sufficient rapidity to respond to such frequencies. In wireless telegraphy, however, a method has been devised for converting these rapidly alternating or oscillating electric currents into currents which, though pulsating, are unidirectional. This is accomplished by the application of thermionic or crystal rectifiers or non-return valves, which only allow the currents in one direction to pass and suppress altogether the currents in the opposite direction. In this way the comparatively useless high-frequency oscillatory currents are converted into rapidly pulsating unidirectional currents which behave like continuous currents, and will operate telephones and other electromagnetic devices. Moreover, though in wireless telegraphy it is customary to use the currents in a single direction only, and to suppress the inverse currents altogether, there is no difficulty about utilising both currents by turning them into separate circuits with valves set opposite ways. Under such conditions, seeing that the separate valves let through their respective currents with but little loss, the efficiency of the conversion from the radiant energy absorbed to that utilisable in the form of electric current is quite high, probably not less than 50 per cent., and perhaps considerably more.

Is it too rash to suggest the possibility of some analogous method being applicable to convert into utilisable electric currents the electromagnetic waves of which the radiant energy from the sun consists? The method is quite successful with wireless waves having frequencies of millions per second, but can it be applied to the sun's waves, the frequency per second of which is of the order of billions? No doubt the problem is a difficult one, but we live in an age of marvels, and what would have been said of modern wireless methods only a few years ago?

One thing seems certain. The energy in the sun's radiation is there, and there, too, in most abundant quantity. To make use of it, moreover, requires no Maxwellian "demon" such as is necessary to render available the general stock of heat energy at uniform temperature. Nor, again, does what is suggested run counter to any thermodynamical law such as would preclude full advantage being taken of the great efficiency that is rendered possible by the enormous temperature of the sun.

Anyway, the problem of the application of solar radiation to the production of power otherwise than by means of heat engines seems worthy of attention, and is a problem that would appear much more likely to meet with a speedy solution than the difficult and obscure question of the liberation and utilisation of the internal energy of the atom.

A. A. CAMPBELL SWINTON.

66 Victoria Street, London, S.W.1,
December 15.

Heat of Reaction and Gravitational Field.

A SIMPLE relation between the variation of mass in a physical change of state or chemical reaction and the rate of variation with gravitational potential of the corresponding change of total internal energy can be deduced as follows:—Let m_1 and m_2 denote the masses of the initial and final states of the chemical system and Q the heat evolved, say at constant temperature and pressure, and at the gravitational potential Z. Considering the following isothermal cycle:

(*a*) State 1 to state 2 at Z,
(*b*) State 2 at Z to state 2 at Z+δZ,
(*c*) State 2 to state 1 at Z+δZ,
(*d*) State 1 at Z+δZ to state 1 at Z,

and equating the total change of energy to zero, we get the equation

$$\left(\frac{\partial Q}{\partial Z}\right)_{p,t} = m_1 - m_2.$$

For all ordinary reactions, experiment has shown that $m_1 - m_2$, if not zero, must be very small. It follows, however, from the theory of relativity that if the reaction be exothermic $m_1 > m_2$, whilst if it be endothermic $m_1 < m_2$. Hence in the former case $\frac{\partial Q}{\partial Z}$ is positive, whilst in the latter case it is negative. If we can apply the energy theory to the highly exenergic radio-active changes, it would follow that the energy given out in such changes must be greater in strong gravitational fields than in weak.

F. G. DONNAN.

University College, London, December 10.

A Helium Series in the Extreme Ultra-Violet.

IN NATURE for November 20 Prof. Lyman reports his observation of a helium line at 1640·1, as well as a weak one at 1215·1, close to the strong one 1216, and refers them to orders 3, 4 in the series $4N\{1/2^2 - 1/m^2\}$. If the correct reading for the strong line is nearer the 1215·1, the whole series $m=4 \ldots 8$ is found in his list of ultra-violet lines given in the *Astro. Journ.* (vol. xliii., p. 89, 1916). The following is the list of observed lines with deviations (obs. − calc.) from the calculated values, with $N = 109720$:—

Order	Intensity	λ	$d\lambda$
3	strong	1640·2	−0·34
4	10	1215·1	−0·11
5	5	1086·1	+1·08
6	4	1026·0	+0·66
7	3	992·0	−0·37
8	1	972·7	+0·59

The line 1084·9 is closer to the calculated with $d\lambda = -0·11$, but its intensity of 2 is not in step with the others. In estimating possible errors, those of standards as well as of observation have to be considered. With uncertainties also of formula, the values of $d\lambda$ do not seem excessive.

W. M. HICKS.

Crowhurst, December 11.

The Constitution of the Elements.

IT will doubtless interest readers of NATURE to know that other elements besides neon (see NATURE for November 27, p. 334) have now been analysed in the positive-ray spectrograph with remarkable results. So far oxygen, methane, carbon monoxide, carbon dioxide, neon, hydrochloric acid, and phosgene have been admitted to the bulb, in which, in addition, there are usually present other hydrocarbons (from wax, etc.) and mercury.

Of the elements involved hydrogen has yet to be investigated; carbon and oxygen appear, to use the terms suggested by Paneth, perfectly "pure"; neon, chlorine, and mercury are unquestionably "mixed." Neon, as has been already pointed out, consists of isotopic elements of atomic weights 20 and 22. The mass-spectra obtained when chlorine is present cannot be treated in detail here, but they appear to prove conclusively that this element consists of at least two isotopes of atomic weights 35 and 37. Their elemental nature is confirmed by lines corresponding to double charges at 17·50 and 18·50, and further supported by lines corresponding to two compounds HCl at 36 and 38, and in the case of phosgene to two compounds COCl at 63 and 65. In each of these pairs the line corresponding to the smaller mass has three or four times the greater intensity.

Mercury, the parabola of which was used as a standard of mass in the earlier experiments, now proves to be a mixture of at least three or four isotopes grouped in the region corresponding to 200. Several, if not all, of these are capable of carrying three, four, five, or even more charges. Accurate values of their atomic weights cannot yet be given.

A fact of the greatest theoretical interest appears to underlie these results, namely, that of more than forty different values of atomic and molecular mass so far measured, all, without a single exception, fall on whole numbers, carbon and oxygen being taken as 12 and 16 exactly, and due allowance being made for multiple charges.

Should this integer relation prove general, it should do much to elucidate the ultimate structure of matter. On the other hand, it seems likely to make a satisfactory distinction between the different atomic and molecular particles which may give rise to the same line on a mass-spectrum a matter of considerable difficulty.

F. W. ASTON.

Cavendish Laboratory, December 6.

The Deflection of Light during a Solar Eclipse.

THE fall of temperature that may occur in the higher strata of the atmosphere during an eclipse is somewhat doubtful, but can scarcely exceed half a degree. An attempt was made to measure it directly during the partial, but nearly total, eclipse in England on April 17, 1912, but of the instruments sent up one only was recovered, so that no comparison could be made.

On the average, the solar heat absorbed by the earth's surface and the atmosphere during one day is capable of raising the whole atmosphere about 1·5° C., and, of course, about the same amount must be lost per day by radiation. There is direct evidence that the daily change of temperature as we know it at the surface does not extend to more than 1 km. or 2 km., and from 2 km. to 20 km. the daily range can scarcely reach 1° C. In these circumstances the fall of temperature of the upper strata during an eclipse must be small, say ¼° or ½° at the outside.

Our direct observations of atmospheric temperature very seldom exceed 20 km., and above that height we know neither the value nor the changes to which it is subject. This is perhaps of little consequence since at 20 km. more than 94 per cent. of the whole mass has been passed.

It must also be remembered that the line of lowest temperature will not be the axis of the shadow-cone, but will lag considerably behind it.

W. H. DINES.

Benson Observatory, Wallingford.

THE correction to the Einstein effect indicated by Mr. W. H. Dines's estimate of the depression of temperature in the eclipse shadow is even less than 10^{-11} radians or 10^{-6} seconds of arc. For a vertical ray the deflection caused by a horizontal temperature-gradient of $d\theta°$ C. in dx cm. is approximately

$$(\mu - 1)_G \,.\, H \,.\, \frac{d \log_e \theta}{dx},$$

where $(\mu - 1)_G = 28 \times 10^{-5}$ is the refractivity of air at normal density, and H is the height of the homogeneous atmosphere. For two rays at a mean distance in the atmosphere of a kilometre apart—a liberal estimate—the difference in deflection would be in c.g.s. units

$$28 \times 10^{-5} \times H \times 10^5 \,.\, d^2 \log \theta / dx^2.$$

If the shadow may be considered to have a radius of 500 km., then $d^2 \log \theta/dx^2$ would be of the order of 10^{-18}. From this the initial statement follows.

That is, assuming $\partial H/\partial x = 0$. But more simply conveniently, and accurately the bending of a vertical ray can be expressed in terms of the surface pressure-gradient because the refractivity is simply proportional to the density. So that five barometers, one at the eclipse station and four distributed around it, would yield the corrections for a single ray. The bending comes to $2{\cdot}3 \times 10^{-4}\ \partial p/\partial x$ radians, where p is the surface pressure in dynes cm.$^{-2}$ and dx is in cm.

LEWIS F. RICHARDSON.

Benson Observatory, Wallingford,
December 12.

I, OF COURSE, admit the force of the remarks in the letters which appeared in NATURE of December 11. But the problem of air refraction during a total eclipse is a very complicated one. The air is not in equilibrium. There is, I imagine, a downward rush of cold air in places deprived of the sun's radiation, as well as a lateral motion of the air from all sides towards such places. The whole refraction effect depends on the shape of the changing surfaces of equal density, and the gradient of density perpendicular to these surfaces. The effect observed would be about equal to the ordinary refraction effect caused by the atmosphere at $1\frac{1}{2}°$ from the zenith, and then the rays of light are nearly perpendicular to the surfaces of equal density.

It is well to remember that, perhaps unfortunately, the stars in the neighbourhood of the sun during a total eclipse must be viewed through air of which the distribution of density must not be assumed to be the same as that of the atmosphere in its normal state.

ALEXR. ANDERSON.

EINSTEIN'S RELATIVITY THEORY OF GRAVITATION.[1]

III.—THE CRUCIAL PHENOMENA.

IN the article last week an attempt was made to indicate the attitude of the complete relativist to the laws which must be obeyed by gravitational matter. The present article deals with particular conclusions.

As Minkowski remarked in reference to Einstein's early restricted principle of relativity: "From henceforth, space by itself and time by itself do not exist; there remains only a blend of the two" ("Raum und Zeit," 1908). In this four-dimensional world that portrays all history let (x_1, x_2, x_3, x_4) be a set of co-ordinates. Any particular set of values attached to these co-ordinates marks an event. If an observer notes two events at neighbouring places at slightly different times, the corresponding points of the four-dimensional map have co-ordinates slightly differing one from the other. Let the differences be called (dx_1, dx_2, dx_3, dx_4). Einstein's fundamental hypothesis is this: there exists a set of quantities g_{rs} such that

$$g_{11}dx_1^2 + 2g_{12}dx_1dx_2 + \ . \ . \ . + g_{44}dx_4^2$$

has the same value, no matter how the four-dimensional map is strained. In any strain g_{rs} is, of course, changed, as are also the differences dx.*

If the above expression be denoted by $(ds)^2$, ds may conveniently be called the *interval* between two events (not, of course, in the sense of time interval). In the case of a field in which there is no gravitation at all, if dx_4 is taken to be dt, it is supposed that ds^2 reduces to the expression $dx_1^2 + dx_2^2 + dx_3^2 - c^2dt^2$, where c is the velocity of light. If this is put equal to zero, it simply expresses the condition that the neighbouring events correspond to two events in the history of a point travelling with the velocity of light.

Einstein is now able to write down differential equations connecting the quantities g_{rs} with the co-ordinates (x_1, x_2, x_3, x_4), which are in complete accord with the requirement of complete relativity.[2] These equations are assumed to hold at all points of space unoccupied by matter, and they constitute Einstein's law of gravitation.

Planetary Motion.

The next step is to find a solution of the equations when there is just one point in space at which matter is supposed to exist, one point which is a singularity of the solution. This can be effected completely[3]: that is, a unique expression is obtained for the interval between two neighbouring events in the gravitational field of a single mass. This mass is now taken to be the sun.

It is next assumed that in the four-dimensional map (which, by the way, has now a bad twist in it, that cannot be strained out, all along the line of points corresponding to the positions of the sun at every instant of time) the path of a particle moving under the gravitation of the sun will be the most direct line between any two points on it, in the sense that the sum of all the intervals corresponding to all the elements of its path is the least possible.[4] Thus the equations of motion are written down. The result is this:

The motion of a particle differs only from that given by the Newtonian theory by the presence of an additional acceleration towards the sun equal to three times the mass of the sun (in gravitational units) multiplied by the square of the angular velocity of the planet about the sun.

In the case of the planet Mercury, this new acceleration is of the order of 10^{-8} times the Newtonian acceleration. Thus up to this order of accuracy Einstein's theory actually arrives at Newton's laws: surely no dethronement of Newton.

The effect of the additional acceleration can easily be expressed as a perturbation of the Newtonian elliptic orbit of the planet. It leads to the result that the major axis of the orbit must rotate in the plane of the orbit at the rate of $42{\cdot}9''$ per century.

Now it has long been known that the perihelion of Mercury does actually rotate at the rate of about $40''$ per century, and Newtonian theory has never succeeded in explaining this, except by *ad hoc* assumptions of disturbing matter not otherwise known.

Thus Einstein's theory almost exactly accounts

[1] Previous articles appeared in NATURE of December 4 and 11.

* The gravitational field is specified by the set of quantities g_{rs}. When the gravitational field is small, these are all zero, except for g_{44}, which is approximately the ordinary Newtonian gravitational potential.

[2] These equations take the place of the old Laplace equation $\nabla^2 V = 0$. Just as that equation is the only differential equation of the second order which is entirely independent of any change of ordinary space co-ordinates, so Einstein equations are uniquely determined by the condition of relativity.

[3] The result is that the invariant interval ds is given by

$$ds^2 = (1 - 2m/r)(dt^2 - dr^2) - r^2(d\theta^2 + \sin^2\theta d\phi^2),$$

the four co-ordinates being now interpreted as time and ordinary spherical polar co-ordinates.

[4] This corresponds to the fact that in a field where there is no acceleration at all the path of a particle is the shortest distance between two points.

for the one outstanding failure of Newton's scheme, and, we may note, does not introduce any discrepancy where hitherto there was agreement.

The Deflection of Light by Gravitation.

The new theory having justified itself so far, it was thought worth while for British astronomers to devote their main energies at the recent solar eclipse to testing its prediction of an entirely new phenomenon.

As was remarked above, the propagation of light in the ordinary case of freedom from gravitational effect is represented by the equation $ds=0$.

This Einstein boldly transfers to his generalised theory. After all, it is quite a natural assumption. The propagation of light is a purely objective phenomenon. The emission of a disturbance from one point at one moment, and its arrival at another point at another moment, are events distinct and independent of the existence of an observer. Any law that connects them must be one which is independent of the map the observer uses; ds being an invariant quantity, $ds=0$ expresses such an invariant law.

This leads at once to a law of variation of the velocity of light in the gravitational field of the sun.

$$v=c(1-2m/r).$$

Here m, as before, is the mass of the sun in gravitational units, and is equal to 1·47 kilometres, while c is the velocity of light at a great distance from the sun. Thus the path of a ray is the same as that if, on the ordinary view, it were travelling in a medium the refractive index of which was $(1-2m/r)^{-1}$. In this medium the refractive index would increase in approaching the sun, so that the rays would be bent round towards the sun in passing through it. The total amount of the deflection for a ray which just grazes the sun's surface works out to be 1·75″, falling off as the inverse of the distance of nearest approach.

The apparent position of a star near to the sun is thus further from the sun's centre than the true position. On the photographic plate in the actual observations made by the Eclipse Expedition the displacement of the star image is of the order of a thousandth of an inch. The measurements show without doubt such a displacement. The stars observed were, of course, not exactly at the edge of the sun's disc; but on reduction, allowing for the variation inversely as the distance, they give for the bend of a ray just grazing the sun the value 1·98″, with a probable error of 6 per cent., in the case of the Sobral expedition, and of 1·64″ in the Principe expedition.

The agreement with the theory is close enough, but, of course, alternative possible causes of the shift have to be considered. Naturally, the suggestion of an actual refracting atmosphere surrounding the sun has been made. The existence of this, however, seems to be negatived by the fact that an atmosphere sufficiently dense to produce the refraction in question would extinguish the light altogether, as the rays would have to travel a million miles or so through it. The second suggestion, made by Prof. Anderson in NATURE of December 4, that the observed displacement might be due to a refraction of the ray in travelling through the earth's atmosphere in consequence of a temperature gradient within the shadow cone of the moon, seems also to be negatived. Prof. Eddington estimates that it would require a change of temperature of about 20° C. per minute at the observing station to produce the observed effect. Certainly no such temperature change as this has ever been noted; and, in fact, in Principe, at which the Cambridge expedition made its observations, there was practically no fall of temperature.

Gravitation and the Solar Spectrum.

It was suggested by Einstein that a further consequence of his theory would be an apparent discrepancy of period between the vibrations of an atom in the intense gravitational field of the sun and the vibrations of a similar atom in the much weaker field of the earth. This is arrived at thus. An observer would not be able to infer the intensity of the gravitational field in which he was placed from any observations of atomic vibrations in the same field: that is, an observer on the sun would estimate the period of vibration of an atom there to be the same that he would find for a similar atom in the earth's field if he transported himself thither. But on transferring himself he automatically changes his scale of time; in the new scale of time the solar atom vibrates differently, and, therefore, is not synchronous with the terrestrial atom.

Observations of the solar spectrum so far are adverse to the existence of such an effect. What, then, is to be said? Is the theory wrong at this point? If so, it must be given up, in spite of its extraordinary success in respect of the other two phenomena.

Sir Joseph Larmor, however, is of opinion that Einstein's theory itself does not in reality predict the displacement at all. The present writer shares his opinion. Imagine, in fact, two identical atoms originally at a great distance from both sun and earth. They have the same period. Let an observer A accompany one of these into the gravitational field of the sun, and an observer B accompany the other into the field of the earth. In consequence of A and B having moved into different gravitational fields, they make different changes in their scales of time, so that actually the solar observer A will find a different period for the solar atom from that which B, on the earth, attributes to his atom. It is only when the two observers choose so to measure space and time that they consider themselves to be in identical gravitational fields that they will estimate the periods of the atoms alike. This is exactly what would happen if B transferred himself to the same position as A. Thus, though an important point remains to be cleared up, it cannot be said that it is one which at present weighs against Einstein's theory.

E. CUNNINGHAM.

THE INHERITANCE OF THE NAVAL OFFICER.[1]

It seems good sense to say that a man who dislikes the sea and all that therein is, who has no spirit of adventure, who is, in short, a low-spirited land-lubber, is not in the least likely to make a distinguished naval officer. You never can tell, of course, for Nelson was always sea-sick and often pessimistic, but the chances are against a man such as we have pictured becoming a bright and shining light in the Navy. And that is what Dr. Davenport and his assistant have said, only they have said it very learnedly with a lot of technicalities about "thalassophilia," "hyperkinetism," "nomadism," and "recessives." The study of heredity does not foster a sense of humour, and we cannot wonder. It is a rather dismal science.

But the memoir before us goes much further than we have indicated. It is argued from sixty-eight biographies that distinguished naval officers have clear-cut special gifts, which are more or less Mendelian characters. They are expressed in the lineage, direct or collateral, and likewise find appropriate expression in early youth. If the number sixty-eight affords a sufficiently broad basis for secure induction, and if such characters as a love for the sea are really crisply defined, non-blending, unit characters, then the conclusions reached are of high interest. Both for theory and for action it is very important to know how much a man is made and how much he is born, and this latest product of the industry and enthusiasm of the Cold Spring Harbour laboratory for the experimental study of evolution and heredity is a contribution to the answer to this question. We should notice that, apart from the non-inclusion of those distinguished officers whose biographies failed to furnish any details of lineage or of boyhood, no selection of names was made. Dr. Davenport set out without any theory save the preconception which previous studies have warranted, that the hereditary make-up of a distinguished man is likely to include definite traits, being not so much a melange as a mosaic.

What, then, are the features which may be regarded as part of the natural inheritance of a distinguished naval officer, as contrasted with, let us say, a distinguished clergyman? The first is a love for the sea, a specific susceptibility to its call, a "thalassophilia." Unless this, or some analogous characteristic, such as nomadism, is in the blood, the chances are against the boy becoming a distinguished naval officer. Such is the verdict of biography. The second feature is some form of the spirit of adventure, a willingness to incur responsibilities, a capacity for rapid decision and action in face of difficulties. A few cases of persistent sea-sickness in admirals may be found—Nelson's is known to all—but there seems to be no instance of a distinguished naval officer without some form of the spirit of adventure. Very rarely has it taken the form of quarrelsomeness, or of pugnacity, or of devil-may-care rashness—though instances of these are well known—but a distinguished naval officer without the quality at all is a contradiction in terms. The third character that is normally present is the sanguine or buoyant temperament, which is technically described as hyperkinetic in contrast to the melancholic and fatalistic hypokinetic. Now, it is an interesting fact that a small minority among the sixty-eight were of the hypokinetic type—reserved, taciturn, melancholic, fatalistic—and that two or three of the greatest were strange mixtures of both, like Nelson, passing from the crests to the troughs of temperamental waves, probably enough correlated with changes in blood-pressure that would kill an ordinary man. But the great majority of the famous sea-captains have been markedly hyperkinetic, not only daring pilots when the waves ran high, but also positively defiant in danger.

As it seems to us, Dr. Davenport is too readily satisfied with the evidence that this or that character exhibits Mendelian inheritance, and that he attaches far too little importance to the family tradition and conversation in defining the lines of a boy's development; but he states a strong case in support of the view, which is more convincing in negative than in positive form, that "unless a love of the sea appears on at least one side of the house, hyperkinesis in at least one parent, or, in the case of an eminent naval man, among the male relatives of the mother, one is justified in doubting if the applicant for a naval commission will become an eminent officer." It is easy enough to make fun of this contribution to "the pedigree of the sea-dogs," but the number of round men in square holes is one of the tragedies of the world, and we wonder gravely how long it will be before wasteful methods of selection are replaced by those suggested by expert study of lineage and of childhood. As Mahan once said—and he had a great knowledge of naval officers—"Each man has his special gift, and to succeed must act in accordance with it." Dr. Davenport's memoir is a contribution to the art of discovering special gifts, or of estimating the probability of their presence.

NOTES.

The newspapers have lately published a big-game hunter's report that a gigantic dinosaurian reptile related to the extinct Brontosaurus and Diplodocus has been seen living in the Congo region of Africa. Palæontologists, however, receive the story with incredulity, and are decidedly of opinion that it must be founded on mistaken observations. The Dinosauria and all their gigantic reptilian contemporaries, whether on land, in the sea, or in the air, disappeared from every part of the world at the end of the Cretaceous period. If any had survived, some fragments of them would ere this have been found in the Tertiary formations which record the progress of life between that period and the present day. It is no contrary argument to quote Sir Harry Johnston's discovery of the okapi in the Congo forest, for this is merely a kind of ancestral giraffe which is known by fossils to have existed so far north as Greece so recently as the beginning of the Pliocene Tertiary. The okapi is a congruous African animal, but a dinosaur would be an anachronism.

In his Trueman Wood lecture delivered before the Royal Society of Arts on December 10, Sir Oliver Lodge dealt with "Sources of Power Known and Unknown." Power or energy, he said, is the most pressing material need of man. His entire material activity consists in moving matter, and food is mainly used by an animal for developing energy before it has assumed the form of heat. The best engines hitherto devised leave much to be desired in that respect. Even the internal-combustion engine is imperfect so long as it requires a cooling jacket. By the second law of thermodynamics, heat is most efficiently utilised at the highest temperatures. The sun's temperature being 6000° C. approximately, its direct utilisation would offer an efficiency closely approaching unity. The leaves of trees, and vegetables generally, are able to absorb and utilise solar energy in producing wood, coal, and food, and they seem to be able to do this without much regard to any hampering law of efficiency. There are two sources of energy not derived from the sun—the internal heat of the earth and the tides. A beginning has been made in utilising volcanic heat in Italy, but the utilisation of tides involves a use of reclaimed land which might be more valuable for other purposes. Dealing finally with atomic energy, Sir Oliver Lodge gave an admirably lucid account of the "planetary" atom on the basis of Bohr's model, showing that electrons can be "evaporated" or ejected with comparative ease, whereas the projection of an α-particle amounts to a veritable explosion. So far, the vast store of atomic energy becomes available only in radio-active substances, and this is already utilised for therapeutic and other purposes. There is, however, the control of electrons emitted from hot bodies, which has been brilliantly applied to the construction of "valves" for many electric purposes, among them being long-distance wireless telephony.

The successful termination of Capt. Ross-Smith's flight from Hounslow to Port Darwin marks a great advance in the history of aeronautics, and is a good omen for the future of commercial aviation. This remarkable accomplishment leaves no doubt as to the possibilities of the aeroplane with regard to rapid transit to distant parts of the earth, especially when it is noted that the weather conditions were by no means good over the greater portion of the route. The machine used was a Vickers "Vimy," fitted with two Rolls-Royce "Eagle" engines of 350 horse-power each, and the greatest credit is due to the two firms for the remarkable endurance of their products under very trying conditions of both flying and landing. The difficulties attending such a flight are very different from those of the trans-Atlantic journey. In the latter case an endurance of 2000 miles without landing was essential, involving the carrying of an enormous load of fuel. The cross-country route to Australia, on the other hand, provided many possible landing places, but endurance of a different kind was necessary, inasmuch as the machine had to fly day after day with little time for attention and repairs, if the flight was to be completed within the specified time limit. Capt. Ross-Smith left Hounslow on November 12 and reached Port Darwin on December 10, having traversed a distance of 11,294 miles, steady progress being maintained throughout the flight. The feat will rank as one of the greatest in the development of the aeroplane, and the heartiest congratulations are due to the pilot and his companions for their remarkable addition to the list of aeronautical triumphs.

On Monday, December 15, one of the galleries of the new building for the Science Museum, South Kensington, was opened for the exhibition of the existing aeronautics section of the collections and for the development of that section by additions which are being selected under the guidance of a number of expert advisers. The occasion was marked by the formal presentation of the Vickers "Vimy" Rolls-Royce aeroplane which crossed the Atlantic. In the absence of the President of the Board of Education, Dr. Ogilvie, Director of the museum, took the chair and referred briefly to the building scheme which had been put in hand for the museum in 1913, but was interrupted by the war. The gallery now occupied was, he said, in the temporary state in which it had been used for war purposes; it was, however, spacious and well-lit, and its use by the museum for a time now would give an opportunity of preparing a more adequate representation of the applications of science in aeronautics. Sir Richard Glazebrook, a member of the Advisory Council for the museum, reviewed recent progress in aviation, and stated that if this country was to hold the place it had taken in the forefront of aeronautics a complete exposition of the subject must be made available for reference in a central museum, such as the Science Museum. It was a matter for great gratification that the Government was giving serious attention to the promotion of research, and one of the functions of the museum was to aid in this by bringing together examples of the ways in which science gave help to industry and commerce. In presenting the aeroplane to the nation, Mr. Douglas Vickers, for Messrs. Vickers, Ltd., explained that it was one of the Vickers "Vimy" machines—bombing machines to carry a crew of three and a ton of bombs for 1000 miles on a non-stop flight. That standard machine had been varied only so as to take, instead, a crew of two with fuel for a journey of 2500 miles.

Mr. W. Walker has been appointed Chief Inspector of Mines in succession to Sir Richard Redmayne, whose impending resignation we announced last week.

Mr. T. W. Reader has been selected by the Geologists' Association as the first recipient of the Foulerton award. The sum of money which has enabled the association to make this award is the recent generous gift of Miss Foulerton in accordance with the wishes of her late uncle, Dr. John Foulerton, who was for many years secretary to the association.

Prof. H. G. Greenish, Dean of the Pharmaceutical Society's School of Pharmacy, has, we learn from the *Pharmaceutical Journal*, been nominated by the Board of Professors of l'Ecole Supérieure de Pharmacie de Paris as one of five foreign men of science upon whom the University of Paris has decided to confer the diploma of "Docteur *honoris causa*" on the occasion of "Une Séance Solennelle de rentrée pour fêter le retour des étudiants des diverses Facultés," on Saturday, December 20.

On Wednesday, December 10, a memorial tablet with a medallion portrait and a suitable inscription was unveiled in memory of Sir William Ramsay in the presence of Lady Ramsay and a large number of friends and members of the University of Glasgow. The address of presentation was delivered by Prof. G. G. Henderson, of the Regius chair of chemistry, and the custody of the memorial was accepted on behalf of the University Court by the Vice-Chancellor. The medallion is the work of Mr. Paulin, and is an excellent likeness; the design of the memorial is due to Sir John J. Burnet. The mural tablet is placed at the head of the great staircase leading to the Bute Hall and the Hunterian Museum. It is set in an arched recess lined with grey marble, and bears reliefs illustrating Sir William Ramsay's numerous decorations and honours.

An influential committee, with Sir F. G. Kenyon as its chairman, has issued an appeal for the foundation of a school of archæology at Jerusalem to conduct exploration in Palestine, Syria, and Mesopotamia. The school will facilitate the work of scholars, train students, excavators, and administrators, and assist in every way the Palestine Exploration Fund. Its researches will extend from the Stone age and the early cultures down to the later Mohammedan period. The school will catalogue existing remains and co-operate with the archæological departments which, it is hoped, the new Governments will establish. It will hold itself aloof from politics and religious controversies. A site has been secured for the necessary buildings at Jerusalem, and Prof. J. Garstang, of the University of Liverpool, who has already visited Palestine, has been provisionally appointed the first director. The scheme is in every way commendable, and the necessary funds will doubtless be provided without difficulty. Communications should be addressed to the Secretary, British School, c/o Palestine Exploration Fund, 2 Hinde Street, Manchester Square, W.1.

A dozen years ago the expressions "newer physics" and "newer chemistry" would have been taken to refer to those branches of the subjects which centred round the words "electron" and "radium" as opposed to those dealing with surface tension, sound, etc., or with atomic weights and constitutional formulæ to which the term "older" might have been applied. It is interesting to note how the last few years have rendered the two terms inappropriate, and how fields which were considered worked out, or at least not likely to produce returns which would justify the time spent on further research, have proved themselves not merely fertile, but also worthy of cultivation for many years to come. A revision of astronomy and physics in the light of the theory of relativity has to be carried out; the hydrophone has brought new problems in elasticity to light; we want more knowledge of atomic weights, of the action of catalysts, and of the synthesis of nitrates. On surface tension and contact angles a whole industry has been founded, some of the problems of which are dealt with by Mr. H. L. Sulman in a paper read before the Institution of Mining and Metallurgy on "Flotation," a summary of which appears elsewhere in this issue.

The foundation of the Salters' Institute of Industrial Chemistry about a year ago was celebrated on December 11 by a dinner given by the Salters' Company to a number of leading representatives of applied chemistry, the Master, Mr. W. B. M. Bird, presiding. Salters or drysalters have for centuries been the recognised dealers in potashes, dyestuffs, and almost every chemical preparation; and their livery of the City of London has taken a prominent part in the promotion of technical education and of research in chemistry. The Company does this because, as Mr. Bird remarked at the dinner, it believes in the progress of chemical industry through scientific knowledge, and considers it a privilege as well as a duty to assist in such development. The institute established last year is not a building or a laboratory, but a foundation for the award of fellowships to enable post-graduate students to continue their studies, or suitably equipped chemists to carry on research in chemical industry. Grants are also made to artisans attending evening classes for the purchase of books and like assistance in their studies. The director of the institute is Dr. M. O. Forster, and under his capable and sympathetic guidance, with the liberal support of the Salters' Company, the fellowships, which are of the value of 250*l.* a year, promise to exert the same effective influence upon chemical science that the 1851 Exhibitions have upon scientific research generally. The scheme was wisely conceived, and its formation gives worthy cause of congratulation to all who are concerned with it.

The appointment of Mr. G. H. Hardy, fellow and mathematical lecturer of Trinity College, Cambridge, to the Savilian professorship of geometry at Oxford reminds us that the present year marks the tercentenary of the foundation by Sir Henry Savile of the first university chairs of geometry and astronomy in Great Britain. Gresham in 1596 had inaugurated similar professorships in London, but the Gresham College never attained the importance it might have done, and London had to wait two centuries for her university. Both the famous Elizabethans, Gresham and Savile, performed valuable services for their Queen and country, and both were favourites at Court. Savile, who was born near Halifax, Yorkshire, in 1549, was, from 1585 until his death in 1622, Warden of Merton College, Oxford, of which he had been made a fellow in 1570. He founded the Savilian professorships in 1619, and the first holders of them were Briggs and Bainbridge, the former of whom had been the first Gresham professor of geometry. Briggs, who, like Savile, was born near Halifax, is best known for his notable works on logarithms and his intimacy with Napier, and the details of his life are generally familiar. Bainbridge did not rise to the same celebrity as his colleague, which may be partly accounted for by the fact that he was trained as a physician, and while Savilian professor of astronomy he was also Linacre reader in medicine. He was born in Leicestershire in 1582, and died in 1643, twelve years after Briggs. Savile, besides being Warden of Merton, was from 1596 Provost of Eton, where he died and is buried. He is commemorated by a monument in the choir of Merton College, close beneath which are the tombs of Briggs and Bainbridge, the former of whom died in the college, and the latter in a house just opposite.

Mr. C. T. Whitmell, the well-known amateur astronomer, who died at Leeds on December 10 after a brief illness, graduated at Cambridge in 1872, being placed in the First Class in the Natural Sciences Tripos and Senior Optime in the Mathematical Tripos. He was a prominent member of the British Astronomical Association, and contributed very largely to its journal. His interests lay in the mathematical rather than in the observational side of astronomy, though his long series of observations of the phenomenon known as the "green flash" are almost unique. Mr. Whitmell acted as director of the expedition to Spain organised by the British Astronomical Association for the purpose of viewing the solar eclipse in May, 1900. He was a fellow of the Royal Astronomical Society and published several papers in the Monthly Notices. His careful determination of the maximum duration of totality of a solar eclipse supersedes De Sejour's erroneous value. On his appointment as H.M. Inspector of Schools in Leeds in 1897 he identified himself with many of the scientific societies in that city. The Leeds Astronomical Society, which owes much to his interest and devotion, elected him as president in 1898–99. In his earlier years Mr. Whitmell did a fair amount of geological fieldwork, both in England and abroad. He was an active member of the Leeds Geological Association, of which he was at one time president.

A notable figure in the engineering world passed away on December 14 in the person of Sir John Jackson. Born in 1851, Sir John was destined to become one of the most potent agencies of his day in directing the forces of Nature and adapting them to the service of man. As a contractor for large public works, he was responsible for the carrying out of gigantic engineering schemes, which have appreciably altered the topography of many lands, and remain a permanent record for the admiration of future generations. His most notable achievements include the great railway across the Andes from Arica to La Paz, the Hindiat barrage across the Euphrates near Babylon, harbours at Singapore and Simon's Bay, the Keyham docks at Devonport, irrigation works in Mesopotamia, the foundations of the Tower Bridge, London, and the last section of the Manchester Ship Canal. Sir John took a prominent part in political life, being M.P. for Devonport from 1910 to 1918. He was a member of the Royal Commission appointed to inquire into the South African War. Another Royal Commission recently exonerated his firm from the charge brought by the Public Accounts Committee that it had unfairly secured contracts which were not thrown open to competition. Sir John was knighted in 1895, and created a C.V.O. in 1911. Educated at York and Edinburgh University, the degree of LL.D. was conferred upon him by the latter. He was also a fellow of the Royal Society of Edinburgh.

A conference of research associations—the second of a series—organised by the Department of Scientific and Industrial Research, was held on December 12 in the lecture-theatre of the Institution of Civil Engineers. The Right Hon. A. J. Balfour, Lord President of the Council, appropriately presided, the Department of Scientific and Industrial Research being a Committee of the Privy Council. Mr. Balfour, who was warmly greeted on his first public appearance in his capacity of head of the Department, delivered a short introductory address on the national need for scientific research, especially in its application to industry. Three points emphasised by Mr. Balfour were that, though man does not live by bread alone, the amelioration of the material lot of mankind can come only through progress in scientific knowledge; that we must not imitate, but follow the example of the Germans in realising a helpful and close alliance between science and industry; and that, in the prosecution of this aim, the paramount interests of pure science must not be overlooked. Papers were afterwards read by Major H. J. W. Bliss, director of the British Research Association for the Woollen and Worsted Industries, on "Research Associations and Consulting Work and the Collection and Indexing of Information," and by Dr. W. Lawrence Balls on "The Equipment of Research Laboratories." There was a general discussion on the subject-matter of the two papers, from which it was clear that, although there is a large common measure of agreement among the different associations, there is also enough variety of circumstance and character to make it desirable for each association to work out its own salvation in many problems of organisation and method. It is the intention of the Department of Scientific and Industrial Research to continue periodically these conferences of research associations. As the Department, in fostering the associations, is engaged in a novel adventure in Government enterprise, the research associations have to set sail on uncharted seas, without maps or precedent experience to guide them, and these periodical conferences must be of great help to them in mapping out their courses and taking their soundings.

The important question of the future of wheat production, with special reference to the Empire, is dealt with at length in the current number of the Bulletin of the Imperial Institute. The annual production of wheat in the world prior to the war amounted to about 110,000,000 tons, the largest producers being the Russian Empire, with an output of 22,000,000 tons, and the United States, which provided nearly 19,000,000 tons. During the war the production in Europe as a whole, and in Russia in particular, decreased considerably, but outside Europe there was a great expansion. The acreage under wheat in Canada, the United States, Argentina, India, and Australia in 1918 was more than 25 per cent. larger than the average acreage for the five years before the war, and it is considered that at the present time there is a sufficiency of wheat, even without the help of Russia, to meet the requirements of the world. As regards the future also there is reason for optimism. There are vast areas of land suitable for wheat-growing yet to be opened up in Canada, Australia, South America, Siberia, and other countries, whilst the present low average yield of thirteen bushels per acre is susceptible of great improvement. In recent years the increase in the world's production has been due to a great extent to an increased yield per acre, and there is every reason to believe that with the introduction of improved drought- and rust-resistant varieties the rise will be even more rapid in the future.

In the current number of *Parasitology* (vol. xi., Nos. 3 and 4) Dr. D. Keilin describes the larval structure and the complete life-history of a species of fly, *Melinda cognata*, Meig., the larvæ of which live as parasites in the snail, *Helicella virgata*, and he gives a short account of various other dipterous larvæ that have been found in living or dead snails and other molluscs. But the most generally interesting part of his paper is, perhaps, the additional note relating to snails and house-fly larvæ, to which Dr. C. J. Gahan has directed attention in a letter to the *Times*. For if the observations made by M. E. Séguy, which are now for the first time made known, turn out to be correct, as they probably will, a solution of the mystery surrounding the hibernation of the house-fly cannot be far distant. That from nine out of fifty snails collected in midwinter larvæ of *Musca domestica* were obtained may be an unexpected, but is not at all an incredible, statement. If true, the fact would at once go far to explain why the search in winter for larvæ or living pupæ of house-flies in or near the places in which they are usually to be found in summer has hitherto always met with failure; for no evidence has ever been obtained to show that house-flies go through the winter in the adult stage, and they must go through it somehow. The larvæ of some flies are known to live only in one species of mollusc, but there is no reason to think that this will be found true of the house-fly. Those who may search for its larvæ this winter would do well not to confine their attention to one or two common species of snail only; and should they look out also for its pupæ they may find them, not inside the body of the snail, as has been absurdly suggested, but in the earth near by, or in the sheltered hole in the wall where the snail itself is found.

A highly interesting paper on "The Direct Replacement of Glycerol in Fats by Higher Polyhydric Alcohols" is contributed to the *Biochemical Journal* for November by Prof. A. Lapworth and Mr. L. K. Pearson. The work described is the outcome of an endeavour to convert the large quantities of fatty acids produced during the war in the manufacture of glycerol into an edible foodstuff. These authors found that when olein or stearin is distilled under reduced pressure with mannitol in the presence of a little sodium ethoxide, almost the whole of the glycerol present in the original fatty compound is expelled, the greatest yield being attained when the proportion of fat to mannitol corresponds with two molecules of the former to three of the latter. The other products of the reaction are chiefly water, a little alcohol, and a substance many properties of which are similar to those of the original fat. The composition of this latter substance corresponds with that of a mixture of the di-oleates (or distearates) of mannitan and isomannide.

THE first number of the *N.P.L. Review*, edited by members of the staff of the National Physical Laboratory, Teddington, appeared in November. Its thirty-six pages contain a large amount of information on the scientific and other activities of the staff, much of which will prove of interest to the general public as well as to those for whom it is primarily intended. Now that the laboratory is a Government institution, it seems reasonable that its work should be more widely known than it has been in the past, and readers of the review will find in it a clear statement of the way in which the laboratory has been fitted into the organisation of the Scientific and Industrial Research Department. From the articles on the old and new directors it appears that the process of fitting has necessitated a decrease in the responsibility of the office, and under Treasury regulations there seem now to be difficulties in the way of rewarding merit by increase of salary. Seven or eight pages are devoted to notes on the most important work passing through the various departments. All are interesting, and show clearly how the scientific problems of the industries are being solved. The staff of the laboratory is to be congratulated on its new publication.

THE power required for actuating the plant and machinery of the Panama Canal is obtained by utilising the flow of surplus water over the Gatun Dam, the height of which above sea-level enables an average effective head of 75 ft. to be realised throughout the year. The power plant at first installed comprised three turbines, each of a rated capacity of 2250 kilowatts when running at 250 revs. per minute and supplied with 500 cu. ft. of water per second. A flow of 500 cusecs, with a fall of 75 ft., produces nominally 3160 kilowatts, so that there is an efficiency margin of 37 per cent. The demand has been found to be much under-estimated, and it has become necessary not only to provide three additional machines of greater capacity, but also to increase the output of the existing generators. Of the three additional machines only one is yet in position, but when the installation is complete there will be three units of 2880 kw. each and three units of 4500 kw. each, totalling 22,140 kw., and requiring a supply of just over 4000 cu. ft. of water per second. The electric energy is employed to drive the machinery of the locks at Gatun, Miraflores, and Pedro Miguel, of the haulage locomotives, of the permanent machine-shops, of the dry dock, and of the coal-handling plant, besides lighting the locks and many towns comprised within the canal zone—a stretch of country ten miles in width across the isthmus. We are indebted for the foregoing particulars to an article in the *Engineer* of December 5.

MR. E. A. MARTIN, the author of "Dew-Ponds," is bringing out through *Messrs. Allen and Donaldson, Ltd.*, 57 Marsham Street, S.W.1, a book entitled "Life in a Sussex Windmill," recounting his experiences of three years in a somewhat unusual dwelling, and giving particulars of his observations of Nature on the Sussex Downs. The portions of the book which will be of special interest to readers of NATURE are the chapters devoted to the geology of the Downs, the problem of the dry combes, prehistoric man and marling, water-supply, fossil oysters, Sussex iron and wood, and the possible discovery of coal in the county.

THE *Cambridge University Press* has in preparation "The Cambridge Ancient History," the general plan of which will be similar to that of the Cambridge Modern and Medieval Histories. It will be in eight volumes, and, beginning with an account of archæological discovery, will trace the history of Egypt and Babylonia, Assyria and Persia, Greece and Rome, to 324 A.D. The work will be edited by Prof. J. B. Bury and Messrs. S. A. Cook and F. E Adcock.

OUR ASTRONOMICAL COLUMN.

THE DECEMBER METEORIC SHOWER.—Mr. Denning writes that this display was well observed at Bristol on the night following December 13. The early evening was overcast, but after a storm of rain at 10 p.m. the sky cleared, and between 10h. 30m. and midnight meteors were observed to be falling at the rate of thirty-five per hour. The moon rose just before 12h., and during the next hour, when her light and films of thin cloud obscured some of the smaller meteors, the horary rate decreased to seventeen. There were two radiants, viz. at $114^\circ+33\frac{1}{2}^\circ$ (eighteen meteors) and at $107^\circ+24^\circ$ (twelve meteors), but the marked differences in aspect of the members of the two streams were very pronounced. The first-named radiant represented the true Geminids, and they are of moderate speed, with short paths sometimes stellar in aspect, and of a sparkling silvery-white colour.

A brilliant Geminid was seen at 11h. 40m. falling from $131^\circ+10^\circ$ to $138^\circ+0^\circ$, and giving a succession of flashes. It lit up the foggy, humid atmosphere, and was much brighter than Jupiter, slightly to the east of it. This meteor must have been a splendid object as seen from the Eastern Counties of England, and it is hoped that further observations will come to hand. A very conspicuous lunar halo was visible during the early morning hours of December 14.

DISCUSSION ON RELATIVITY.—The meeting of the Royal Astronomical Society on December 12 was entirely devoted to the consideration of the theory of relativity. The discussion was opened by Prof. Eddington, who said that while on the first relativity theory time was adopted as the fourth co-ordinate merely as a convenient system, in Einstein's theory the time-space continuum was inextricably blended, so that what was pure time to one observer was resolved into partly time, partly space for another, differently circumstanced. The distinction between past and future was, however, for sentient beings somewhat greater than that between right and left. If space were re-entrant and finite, the section of the continuum in the time direction would be hyperbolic, so that time would not repeat itself after an enormous interval.

Dr. Jeans said that physicists had other than astronomical grounds for asserting that the foundation-stone of the new system was "well and truly laid." It was originally built on experiments, and since its enunciation further experiments had confirmed its truth. He gave the expressions for a wave-front of light, stating that an observer initially at its source remained central in spite of his own movement.

Sir Oliver Lodge referred to some of the apparent paradoxes that had been uttered, and said he preferred to take the æther, not the observer, as his base of reference, instancing the confused idea of the landscape that one obtained when travelling by train.

Dr. Silberstein pointed out that the star displacements on the plates were not exactly radial, which he took to mean that they were not due to gravity, but to some irregular refracting medium. He further said that Einstein himself regarded the shift of the solar spectral lines as vital to his theory.

Prof. Lindemann and Dr. Jeffreys agreed in thinking that the experiments were by no means decisive against the existence of the spectral shift. The latter further stated that a medium capable of producing the observed shift of the stars by refraction would reflect a great deal of sunlight, whereas the plates showed no trace of such matter near κ Tauri.

FLOTATION PRINCIPLES OF ORE EXTRACTION.

AT the meeting of the Institution of Mining and Metallurgy, held on November 20, a paper entitled "A Contribution to the Study of Flotation" was presented by Mr. H. Livingstone Sulman. After giving a brief historical review of the development of flotation as applied to ore extraction, with the problems that arose in connection with successive phases of the process, Mr. Sulman dealt principally with froth flotation, which he characterised as the final link in a long chain of effort. The essentials of this process are that an aqueous pulp shall be agitated with certain reagents which may be classified as a "froth-producing" material, a "froth-stabilising" substance, and a "gangue-modifying" addition.

The explanation of flotation may be based on the differences shown by various substances in the degree to which they are "wetted" by water and other liquids. "Wetting" is a condition of wide variability, and a theory of flotation must be based largely upon the physics of wetting. The degree of wetting may be influenced by the molecular porosity of the solid surface, and indicated more or less quantitatively by the "contact angle" made between the free surface of the liquid and that of its interface with the solid.

Reviewing the various problems encountered in dealing with flotation, Mr. Sulman devoted considerable attention to the molecular constitution of liquids and solids, gravitation and molecular forces, surface energy and surface tension, interfacial tension which involves consideration of the effects of complete wetting and differential wetting, hysteresis, adsorption, the *rôle* played by immiscible oil, and the action of modifying agents such as acids. In this last connection the theories of flocculation and deflocculation have to be taken into account, including their electrical relationship. Film flotation and differential flotation receive separate attention.

The general summary of the paper gives prominence to the following findings:—Flotation reactions result from the molecular forces acting at the surfaces of solids and liquids; these arise from unbalanced molecular attractions in the surface layers, which in turn are in functional relation to the balanced molecular attractions constituting cohesion for a solid or a liquid. Every solid or liquid, therefore, possesses excess energy at its surface, which may be exhibited in adhesion effects. Liquid-solid adhesion is broadly reciprocal to interfacial tension. The degree of wetting can be relatively quantified within certain limits by the contact angle made between the free surface of the liquid and that of the solid. Contact angles have a minimum and a maximum value; the angular difference between these values is the hysteresis of the contact angle, which permits a wider range of equilibrium for a floating particle.

The dynamical aspect of the subject is concerned with the molecular constitution of the interfaces, with the kinetic effects of molecular motion at the surfaces and interfaces of solids and liquids, and with those in the interior of liquids. Solid surfaces are probably penetrable by the molecules of liquids, which enhances the adhesions between them; such penetrations may give rise to a persistent tendency for the solid to be again wetted by the same liquid. Concentration of foreign molecules at the surface of a pure or homogeneous liquid (positive adsorption) reduces the surface tension of the liquid and confers upon it the property of "frothing."

Frothing reagents useful in flotation produce a froth with water, yet leave a partial strain (mineral-adsorptive energy) at the bubble surface. The mineral adsorption now stabilises the film, especially if the mineral be minutely oil-filmed; still more so if flocculated. To be employed effectively the bubble system must be disseminated throughout the mass of ore-pulp. When water-strain is completely removed from the surface of suspended particles, deflocculation results. Flocculation is greatly increased by mechanical agitation, by minutely oiling the particles, and by contact with air; these are factors necessary to produce standard mineralised froths. Generally, if a substance can be flocculated it can be floated. Electrical phenomena are concomitants of minor order. Flotation depends on bringing about the most advantageous selective adhesions, selective adsorptions, and selective flocculations between the complex of particles in an ore-pulp.

THE BRITISH ASSOCIATION AT BOURNEMOUTH.

SECTION L.

EDUCATIONAL SCIENCE.

OPENING ADDRESS (ABRIDGED) BY SIR NAPIER SHAW, LL.D., Sc.D., F.R.S., PRESIDENT OF THE SECTION.

Educational Ideals and the Ancient Universities.

A PRESIDENTIAL address before the Educational Section of the British Association is an undertaking that might fairly daunt the bravest of those who are really acquainted with its difficulties. The vast range and variety of the problems of education; the enormous amount of effort that is already expended upon them; the torrents of advice and criticism that are offered by those who are familiar with the details of the various curricula, who know how things ought to be done—if I had had time and capacity to become acquainted with all these things, I suppose I must have avoided the duty of making an address. It is, perhaps, the detachment of my present position from any responsibility for details which gives me the courage to recall experiences, now twenty years old, acquired during a lengthy service in various capacities at Cambridge, and matured by twenty years of the consciousness of the dire need of educational discipline and training for those whose business it is to use science in the service of the State.

With a certain amount of assurance I can even be glad that I am not in touch with the educational controversies of the hour, and confidently trust that my deficiencies will be made good by the contributions of those who know to the discussions which will take place in the Section, but the difficulty that I cannot get over just now is that, from the unavoidable circumstances of the present time, a presidential address is a "back number" before it is delivered, for the simple reason that, according to tradition, it must be printed in advance. In this particular year there is an almost immeasurable gulf of experience between the time of my appointment in 1917 and the delivery of this address; the president himself is in many ways a different person from him who undertook the duty of addressing you two years and a half ago.

At that time I had been a good deal moved by the wearying controversy about the relative merits of classics and science in education, because the physical sciences as taught were such a doleful misrepresentation of the spirit of inquiry about the universe which has moved men in all ages and is as clamant to-day as ever. The mysteries of the firmament, the midnight sky, the storm and calm, the earthquake and the thunder, the sunshine, the rainbow and the halo, the intolerable heat and the pitiless cold, the mariner's compass, the aurora and the mirage, are still as wonderful as ever to the wayfarer and the seafarer, and even the dweller in towns wants to know more about them. Yet our educational system, as I knew it, passed all these subjects by and offered instead the determination of the specific heat of copper, with other things that the specific heat of copper stands for. The same, I believe, is true for many of the most interesting subjects of scholarship in ancient and modern civilisations, learning, and languages. And if an inquirer, young or old, should ask whether, if he went there, the great universities could tell him all about the things of wonder or of beauty that he is conscious of, or about the reminiscences of past generations that he finds around him as he travels through life, he could only be told that in consequence of the perverse malignity of external circumstances they had no money to devote to his enlightenment. The capacity would be there in abundance, but not the means. In three years they would put him in a position to pursue intelligently for himself if he pleased any of the subjects in which his interest had been excited, but the facilities for education would extend only to the point where his interest began.

So I wrote a little pamphlet on "The Lack of Science in Education, with Some Hints of What Might Be," and when I was invited to occupy this chair I thought I might be of some service to education if I pressed the subject further and endeavoured to show how, in spite of the good will of nearly everybody concerned, the peculiar constitution of our chief universities was really standing in the way of the lofty ideal of higher education which must find expression if the education which we all want is really to come to pass in this country.

Circumstances have already vastly changed. Committees have sat upon the teaching of science and the teaching of modern languages. A great Education Act has been passed, and the poverty of the universities has overstepped the limits of starvation and a Commission of Inquiry is promised. So we are now on the high road to making presidential addresses matters of quite subordinate interest. Still, you may be interested to hear what I wrote two years and a half ago in explanation of the peculiar difficulties of our educational system; so here it is. It makes a good deal of play of a certain scene in "The Merchant of Venice," which I shall beg you to regard, for a few minutes only, as a satire upon the state of the universities in the spacious times of Queen Elizabeth, after a period of magnificent activity on the part of founders and benefactors and after a succession of statutes for the universities made by successive monarchs for the governance of those institutions, which were then recognised as of the highest importance in the State. Such a period of reconstruction seems to have come again in our time, and the satire, if it be one, is as true to-day as it was three centuries ago.

I was arrested by the curious sentiment, "If to do were as easy as to know what were good to do, chapels had been churches and poor men's cottages princes' palaces." I wondered whether Portia was in fact intended to personify a liberal education. For other subjects of human activity her statement is palpably absurd. All the experience of the British race indicates to us that the acute divisions between people arise in discussions as to what were good to do; the actual doing is easy if the preliminary question "what were good to do" is really decided. Can anyone doubt that after our experience of the war?

But if it were education that Shakespeare was thinking about, chapels and churches, poor men's cottages and princes' palaces are not inappropriate in that connection; the sentiment stimulates the imagination. Certainly in education to know what were good to do does seem in practice to be infinitely easier than to do. From time to time the newspapers are full of reports of conferences, meetings, congresses, and assemblies all fully assured that they know what were good to do, yet very little happens. Our scheme of education is still unsatisfying. Why?

That is the question which I propose for your consideration. Why is it that all the pious opinions about education come to nothing or to so little?

First of all it must be noted that the resolutions and proposals are not addressed to anybody in particular. Presumably they are intended to form public opinion, but public opinion has no authoritative voice with those who are in charge of the higher educational institutions. The resolutions are sent out like wireless signals from a ship at sea. Any educational institution with a receiver tuned to the proper wavelength can take them in, but if the receiver is not tuned or the operator is inattentive, nothing happens. There is no corporate responsibility for the aggregate of our higher educational institutions.

We may, I think, agree that if we wish for ideals in education in this country we must find them in the universities. If the universities give the encouragement of their example and their licence to teach only to men and women who are really educated in the best sense of the word, their influence will leaven the whole of education throughout the country; and, on the contrary, if when they leave the universities the men and women who have to teach, or to control teachers, are themselves imperfectly educated, it is hopeless to expect a well-balanced, living educational system. Among the universities, for reasons good or ill, into which I need not enter, the older Universities of Cambridge and Oxford have a preponderant influence.

And, to my mind, the outstanding characteristic of the organisation of the older universities is the lack of any recognised door by which their corporate responsibility can be reached. In each case the university is itself a corporate educational institution which includes some twenty colleges, which are also separate corporate educational institutions. You never can tell whether the persons with whom you have business are the university or the colleges, and it is quite possible that when you think to address the one you find yourself confronted with the other. The universities in their corporate capacity are constrained by statutes and traditions handed down by our forefathers to look on in comparative impotence while their ideals are distorted or concealed by the interplay of the interests of the many corporations of which they are composed. The whole complex scheme of management forms a sort of craft or mystery which very few even of the initiated really comprehend.

In January of 1917 the Headmasters' Conference (which consists of men with some academic experience) passed a resolution to the effect that Greek should no longer be required for the entrance examination of the Universities of Oxford and Cambridge, and thereupon the Master of University College, Oxford, spent half a column of the *Times* in explaining that the University of Oxford had no entrance examination at all.

This veil of mystery about matters of national concern is very perplexing for those who want things done in education, but do not know the technicalities of the universities. What is true, for Cambridge at least, is that the university *qua* university has no examination for entrance; it is obliged by its statutes to accept as a member without any question anyone presented by the recognised authority of a college, regardless altogether of his qualification or disqualification for a university career. It is a very remarkable arrangement. The university makes no inquiry as to a student's fitness to profit by its educational system; it leaves all that to the colleges, and many, if not all, of the colleges have an entrance examination. So I offer this paradox for the logician who is interested in higher education.

The university consists of the members of its constituent colleges and a few others. At the discretion of the several colleges, or the non-collegiate students' board, 75 per cent. of the members of the university are required to pass an entrance examination before they are accepted for presentation to the university for matriculation. There are at least four examinations of the university which are accepted by colleges on occasions in lieu of their own entrance examinations. Yet there is no entrance examination for the university.

And this does not end the matter. With the power of selecting its students vested in twenty different bodies, the university becomes a controlling body rather than an educational institution with a definite purpose and programme. The regulations for its students are nearly all of them of a negative character. The discipline and the regimen of the university rest upon the assumption that a student desires to secure from the university not so much attainment as a stamp for his attainments. A member of the university cannot be admitted to a degree unless he has satisfied certain conditions of residence, and also satisfies certain examiners; his name is not accepted for the final examination unless he has satisfied certain other examiners. There is nothing in the regulations or administration of the university to secure that a matriculated student shall study or aspire to take a degree. He might live on in idleness and ignorance for the rest of his natural life; the university has no choice in the matter so long as his college pays the periodical fees. It trusts to the colleges to see that idle or unsuitable undergraduates are invited to go elsewhere.

Here we have one of the many instances of the division of jurisdiction between the colleges and the university which hides the ideals of our system of higher education in an impenetrable fog.

The university is governed by the colleges according to a system which goes back to the time when "The Merchant of Venice" was written, so let us revert to the conversation between Portia and Nerissa which expounds the lottery of the caskets in the well-known scene. The position of the university in the matter of the selection or rejection of its members is exactly that which Portia bewailed to Nerissa. Let me invite you to regard the episode of the caskets as a figurative representation of the lottery by which the University of Cambridge selects those upon whom she bestows her inherited riches—*lucem et pocula sacra*. Cambridge, like Portia, the heiress of all the learning of the good and the great, bound by the fantasy of her ancestral tradition never to choose for herself.

Let us think of Portia as the Vice-Chancellor of the University of Cambridge, desiring above all things the advancement of learning, and of Nerissa as a proctor, whose duty it is, as representing the Senate, the collective body of members of the colleges, to see that the statutes and ordinances are duly attended to. Listen to the conversation:—

"*Portia* [*V.-C.*]: O me, the word 'choose'! I may neither choose whom I would nor refuse whom I dislike; so is the will of a living daughter curbed by the will of a dead father. Is it not hard, Nerissa, that I cannot choose one nor refuse none?

"*Nerissa* [*Proctor*]: Your father was ever virtuous; and holy men at their death have good inspirations; therefore the lottery that he hath devised in these three chests of gold, silver, and lead, whereof who chooses his meaning chooses you, will, no doubt, never be chosen by any rightly but one who shall rightly love. . . .

"*Portia* [*V.-C.*]: If I live to be as old as Sibylla, I will die as chaste as Diana, unless I be obtained by the manner of my father's will."

I need scarcely say that I should not spend so much time over what may seem to many of you far-fetched, and perhaps unseemly jesting, if I did not believe that this fantastic view of the lottery of the caskets contains the suggestion of an element in the governance of our highest educational institutions which deserves your gravest and most serious consideration. What I have in mind at the moment is the unforeseen and undesired result of the competition of the colleges within the university itself as quasi-independent educational institutions. It is this small matter, from some points of view of quite minor importance, which, so far as I can see, prevents our great universities from taking the leading part which they might take in exemplifying the ideals of a co-ordinated national system of education, and makes the success or failure of those great institutions something of the nature of a lottery. They may offer ten thousand different avenues from matriculation to a degree, and yet the student may find himself imperfectly educated in the end.

One may, indeed one must, picture to oneself the idea of the colleges as a number of educational institutions co-operating in an avowed and transparent common purpose of the university to display the highest educational ideals. So I think, if they were willing, they might be, without any sacrifice of their individuality or of those magnificent traditions which have fulfilled the high purpose of their pious founders and benefactors. Let us keep that picture for a while in mind.

I have taken from the Cambridge University Calendar for 1918 a list of subjects selected for teaching in the university and colleges, with the number of professors, readers, lecturers, or teachers assigned to the several subjects.

I find that there are 175 university teachers (professors, readers, lecturers, etc.) and 176 college lecturers. I find that the 175 university teachers between them deal with 73 subjects, an average of $2\frac{1}{3}$ per subject, and are distributed between subjects in the following manner:—

Number of university teachers assigned for a subject

9 8 7 6 5 4 3 2 1

Number of subjects which have the number of teachers specified in the upper line

2 3 1 4 1 3 8 10 42

The 176 college lecturers deal with only 23 subjects, an average of $7\frac{1}{2}$ per subject. They are distributed as follows:—

Number of college lecturers assigned for a subject
33 30 23 18 17 10 5 3 2 1 ?
Number of subjects that have the number of teachers specified in the upper line
1 1 1 1 1 1 3 1 3 9 6

Here we see at once a great difference between the educational systems. The university is obviously striving to meet so far as possible its higher educational responsibilities. There is great differentiation of duty; 42 teachers are responsible each for a single subject; there are only two cases in which a subject has so many as nine teachers, whereas in the colleges the tendency is for the same subject to have a great number of exponents. The favoured subjects are:—Classics 33, mathematics and natural philosophy 30, history and economics 23, natural sciences 18, and divinity 17. All those subjects are also provided for, to some extent at least, in the programme of the university. There may be, and indeed must be, some differentiation within these totals, but it is a differentiation which the college authorities do not think it necessary to disclose. Whatever allowance may be made for that, I think it is obvious that the colleges tend to repeat many times over a stereotyped form, and not to distribute their energies over subjects which, for lack of funds or some other reason, are not represented in the university list. Three subjects appear in the college list and not in the university list, namely, modern Greek, Celtic, and military history. We may be sure that the 176 college lecturers are in themselves fully competent to represent subjects of profound human interest which the university disregards for want of means. That it is the system and not the lecturers that account for this convergence upon a few subjects was evident enough during the war, when Cambridge lecturers were to be found among the most proficient and successful workers with their brains in many departments of activity. The needs of peace are not less urgent than the needs of war.

No one can think that the distribution of teachers and subjects would be what it is if the educational system of the university and the colleges were under the control of a single competent body bent upon manifesting a true ideal of the use of educational endowments, whether in money or men.

Suppose, for example, that the council of the Senate were recognised as responsible to the country for the educational system of the university and the colleges jointly; that, once appointed, they were freed from the referendum of every item of their procedure to the lottery of a vote in the Senate. Imagine what would happen if the university really had an entrance examination and the colleges had to select their members from among the successful candidates. One may speculate upon what such a body would produce, but it is scarcely imaginable that they would plump for concentrating so much of the college teaching in general terms upon classics, mathematics, history, and divinity.

And, in support of the contention that diversity of intellectual effort is a pertinent consideration, I would point out that if recondite subjects are to be studied at all it must be at our own great centres of learning. If there is any part of the world where old customs are dying out, or interesting species becoming rare or extinct, it is for highly centralised countries like ours, at a distance from the scene of action, to take care that the subject is studied while there is yet time. On the spot, where no doubt the material is more readily available, people are too much preoccupied to notice the ultimate effect of their own personal activity. If we should, for example, set about exterminating the vermin of London houses (which, by the way, is above all things a most urgent question of rehousing), it is not from any Londoner, or even from our near neighbours in Cambridge, however interesting the minor horrors of war may be to their biologists, that any protest will be raised about the outrage which the extermination would entail upon the province of natural history.

I have looked through that interesting volume "The Yearbook of the Universities of the Empire, 1914," to see whether the older universities of this country and the Empire had a notably extended or different range of subjects. The differences are mostly in name or in the differentiation of medical and theological subjects. It is interesting to note the gradual formation of university teaching in new lands. It seems to begin with medicine and theology, law, engineering, architecture, commerce, and banking; and next to take in our old college friends mathematics, classics, and natural sciences, but it seldom shows any particular characteristics of local scholarship or specialised learning; in the older institutions there are some suggestive subjects, as Assyrian and Babylonian archæology, classical archæology, African languages (Swahili and Bantu), Irish language and literature, Dutch language and literature, Japanese, Portuguese, Scandinavian languages and Thibetan, phonetics, library science, ancient Indian history and culture, Colonial history, Irish history, Scots history, civic design and civic law, scholastic philosophy, Zend philosophy, rhetoric and oratory, geodesics, acoustics, meteorology, and epidemiology in various forms.

Among the subjects which I have noticed in other connections as not represented by name in any of the universities of the Empire, but still claiming attention from those who would help to make the facilities for education complete, there are, in the first place, the history of the various arts and sciences and of medicine, for which some provision has recently been made at Oxford under Dr. Singer; oceanography, which, through the generosity of Prof. Herdman, has now obtained a footing in Liverpool; geodynamics, for which Cambridge wishes to make provision, historical geography and exploration; Malay and Polynesian languages and antiquities, aerodynamics, meteorological optics, now neglected in this country; terrestrial magnetism, seismology, climatology (past and present), particularly of the Empire; illumination and photography, metrology, the science of precision, British archæology and dialects; and perhaps the technical subjects of radio-telegraphy, ballistics, and ventilation. These are subjects with which alone a fully equipped university is competent adequately to deal, and the country is ill-provided until the educational authorities co-operate to supply between them what is needed. To secure this object I am not at all convinced that State aid is the only possibility. The pious benefactor is no more extinct than he was in the days of Henry VIII. and Queen Elizabeth, but while the universities and their colleges speak with two voices and leave us uncertain as to their ideals, it is impossible that he should not be discouraged.

As one passes in review our own educational institutions, one may judge of their ideals by their results. Judging in that way, and looking at the education of our public schools, we may fairly say that the social or ethical ideal is splendid. It expresses the principle of excellence which I take to mean success in fair competition. It is no doubt Hellenic rather than Christian; it is based upon the literature of the ancient Greeks, and has still strength enough to call forth the most devoted self-sacrifice. In the universities also the same ideal is quite easily recognised. There, if anywhere, you can see the worship of success in fair competition developed into a real religion. For a long time I have thought that we should be much nearer understanding our real position in these things if we could persuade the classical scholars to do for Greek religion what the compilers and translators of the Bible did for the Hebrew—that is, to collect together in the best available translation the literature of the Greeks which formed the basis of their guides to conduct. The appropriate contents of such a collection were sketched out by Dr. James Adam, a college colleague of mine at Cambridge, whose untimely death is still deplored, in his Gifford lectures on the religion of the Greeks. With him the subject was a source of unbounded enthusiasm, and his lectures are a series of sermons on the Testament of the Greeks. But we ordinary readers, unlearned in the Greek literature, are in the position of those who are offered sermons on the Old Testament instead of the Old Testament itself. If you imagine where we should stand if the Old Testament were denied to us except in the original Hebrew, you will understand the position the vast majority of us must occupy with regard to Greek ethics, which are, in fact, the ethics of our ruling classes in the old sense. Therefore I use this opportunity to beg those who are enthusiastic for Hellenistic studies to give us such a Testament. I feel sure it will enable us to understand the ideals of the public schools and universities, and throw an entirely new light upon the supposed conflict of classical and scientific studies, which is possibly only another phase of the other perennial dispute about religious education.

The ethical ideals of our schools and universities are clear, excellent in themselves, and appreciated everywhere. They manifestly excite enthusiasm and develop the spirit of self-sacrifice for their maintenance. But what of the intellectual ideals? The subject is important, because the cultivation of the intellect is the avowed purpose of academic institutions, and the part of education which is necessary for carrying on the world's work. Looking at the actual practice of the universities, we can see that the intellectual ideals are obscured, confused, and enfeebled by the very process of competition between colleges which is so eminently successful in developing the ethical spirit.

But the opportunity for strengthening and clearing our intellectual ideals is now. It may require some sacrifice of prejudices and traditions as between colleges and the university, but the reward will certainly be great.

I suppose that the character of any distinguished educationist a century ago would be summed up in the words, "He spared not the rod"; and to-day perhaps the highest praise is expressed by saying that "He spared neither the ratepayer nor the taxpayer," but even that is not enough. Money without motive power does not make education. We may reserve our highest praise for those educational establishments of which it may be said that in the pursuit of a true ideal they spared "neither their prejudices nor their inherited privileges." It may sound sacrilegious, but it must be said: the Portia of our dreams will not become the *alma mater* that the nation needs if she can never be obtained except after the manner of her father's will.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

SHEFFIELD.—Prof. C. H. Desch has been appointed professor of metallurgy in succession to Prof. J. O. Arnold. Since September, 1918, Prof. Desch has been professor of metallurgy in the Royal Technical College, Glasgow, and he was previously Graham Young lecturer in metallurgical chemistry in the University of Glasgow.

VISCOUNT HALDANE, as president of Birkbeck College, was in the chair at the founder's day celebration on December 12. Fifty-eight of the graduates of the college who have taken their degrees at the University of London since 1914, totalling 138, were presented to the president. The Principal (Dr. George Senter), in his report, said that 600 Birkbeck men were known to have been on active service. Of these 331 obtained commissions, and 87 names were on the roll of honour. During the war the chemistry department of the college provided certain drugs needed for war purposes, and the physics department tested more than two thousand optical instruments. Four-fifths of the students in normal times were evening students. Lord Haldane gave an address on "What is Truth?" He said this was a topic on which he had been reflecting for forty-five years—ever since he first entered a university. This question was bound up with another, the same thing in another form, the relativity of knowledge, of which we had heard a great deal just lately. Einstein had told them about it, but he had dealt only with a fragment of the problem of relativity, which covered the whole field of knowledge. The problem of relativity went far beyond the mathematics of astronomy. What was it that Einstein had been trying to tell the world? Even when you could put truth into a nutshell, it was not always possible to keep it there. The problem which Einstein had raised was not new. People had thought of time and space as something they knew all about, of a straight line as the shortest distance between two points. He then explained that to answer the question "What is Truth?" we must realise that the principle of relativity had shown us that the reality and our conception of it are not wholly separate. The observer and the observed could not be separated, and account must be taken of the observer. Sir Frederic Kenyon moved a vote of thanks, which was seconded by Mr. James C. N. White.

THE Manchester Municipal College of Technology is making an appeal to the industrial and commercial community of Manchester and of south-east Lancashire for the sum of 150,000*l.*, with a view to the extension of the present building and equipment on land adjoining the college bought some years ago for that purpose at a cost of 44,000*l.* The present teaching resources of the college are taxed to overflowing with full-time day students, who now exceed five hundred, the majority of whom are proceeding to degrees in the faculty of technology in the University, whilst others are engaged in whole-time post-graduate scientific industrial research. There is every prospect that this number will be considerably augmented in the near future, and the governing body is desirous of making the fullest preparation for the increase, having regard to the serious competition of the chief foreign nations, notably America, Germany, Switzerland, and Japan, in the overseas markets. The urgent need for this extension has been commended by several important firms representative of the chief industries of the area, notably those engaged in the chemical, engineering, and textile trades; and at a recent meeting of the local branch of the Federation of British Industries held in the city the following resolution was unanimously passed:—"That, having regard to the fact that the Manchester College of Technology was the first technical institution of university rank to be established in this country, and being firmly of opinion that the development of the invaluable work of the College of Technology" is of vital importance to the well-being of the industries of the district and county, the executive committee of the Manchester District Branch of the Federation of British Industries confidently commends the appeal for 150,000*l.* (of which 26,000*l.* has been promised absolutely and conditionally) to extend the College of Technology to the sympathetic consideration of all Lancashire producers, being of opinion that lack of whole-hearted support will be to the prejudice of Lancashire industry." This welcome change in the attitude of great industrial firms towards technical training and research leads to the hope that this appeal may meet with the cordial support which its serious and essential importance demands.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 4.—Sir J. J. Thomson, president, in the chair.—A. M. **Williams**: The adsorption of gases at low and moderate concentrations. Part i.: Deduction of the theoretical adsorption isostere and isotherm. Part ii.: Experimental verification of the form of the theoretical isosteres and isotherms.—A. M. **Williams**: The adsorption of gases at low and moderate concentrations. Part iii.: Experimental verification of the constant in the theoretical adsorption isostere.—T. R. **Merton**: The secondary spectrum of hydrogen. It has been found that the presence of a large quantity of helium in vacuum tubes containing hydrogen modifies the secondary hydrogen spectrum in the sense that the relative intensities of the lines are completely altered, some lines being extremely weak in the spectrum of the mixture, whilst others are greatly enhanced and a number of new lines appear. Measurements have been made of the lines which are enhanced or unaffected by the admixture of helium; the changes are shown in a reproduction of a photograph of the two spectra in juxtaposition with a wave-length scale, by means of which the lines which are weaker in the spectrum of the mixture can be identified by reference to Watson's measurements of the spectrum. The secondary hydrogen spectrum is of such complexity that the segregation of its lines into series of mathematically related lines is a task which offers great difficulties. These difficulties can doubtless be lessened by the aid of physical methods of separating the lines into different classes.—T. R. **Merton**: The spectra of isotopes. (1) Interferometer measurements of the principal line in the spectrum of ordinary lead and lead from pitchblende show that in the latter case the line is less refrangible by 0·0050 A. ± 0·0007 A., in close agreement with the results of Aronberg. (2) In the case of lead from Ceylon thorite it has been found that the line is more refrangible than in ordinary lead by 0·0022 A. ± 0·0008 A. (3) The positions of the lines are arranged in the order of their atomic weights. (4) Spectroscopic measurements seem to provide a favourable method of distinguishing isotopic elements. (5) A comparison has been made of the wave-lengths of the principal line in ordinary thallium and thallium from pitchblende residues. The wave-length of the line in the spectrum of thallium from pitchblende has been found to be more refrangible than the line in ordinary thallium by 0·0055 A. ± 0·0010 A. In the case of thallium the measurements may possibly be affected by certain disturbing factors which do not apply to the measurements of the lines of lead. Unless the results are affected by these disturbing factors, it would seem likely that the thallium in pitchblende is an isotope of ordinary thallium.—E. F. **Armstrong** and T. P. **Hilditch**: A study of catalytic actions at solid surfaces. Part ii. It is shown that the catalytic action of metals, like that of certain enzymes, is reversible; in other words, compounds which are saturated in the ordinary sense are capable of interacting with the metal to form a system which breaks down into a more stable equilibrium consisting of hydrogen and a less saturated compound. This is readily demonstrated in the case of cyclohexanol; when a mixture of cyclohexanol and methyl cinnamate is heated at 180° in presence of nickel, a considerable transference into cyclohexanone and methyl β-phenyl propionate is effected. It is necessary that both components of the system should be present in the liquid state. Dehydrogenation has also been effected in the case of hexahydroxylene and dihydropinene mixed with methyl cinnamate in presence of nickel; in these cases a temperature of 230° is required. At this temperature small quantities of an ethyl oleate of unknown structure are obtained from ethyl stearate.—F. **Horton** and Ann C. **Davies**: An experimental determination of the critical electron velocities for the production of radiation and ionisation on collision with argon atoms. The critical velocities for electrons in argon were investigated by methods similar to those employed in a previous research for the determination of the corresponding values in helium, the earlier form of apparatus being modified somewhat to facilitate the detection of the beginnings of radiation and ionisation. As the result of many experiments under different conditions, the values 11·5 volts and 15·1 volts were obtained for minimum radiation velocity and minimum ionisation velocity respectively. No sudden increase of radiation at the second critical velocity was detected, and it was shown that no detectable amount of ionisation was produced at 11·5 volts. The limiting wave-length of the argon spectrum, calculated from the value, 15·1 volts, found for the minimum ionisation velocity, is in agreement with the limit observed spectroscopically in the recent experiments of Lyman.

Royal Microscopical Society, November 19.—Mr. J. E. Barnard, president, in the chair.—H. M. **Carleton**: Note on the Cajal formalin-silver nitrate impregnation method for the Golgi apparatus. The theory of silver impregnation in general was briefly outlined and the technique of the Cajal method described. Mention was made of the impregnation of cell-constituents other than the Golgi reticulum, while the problem of the production of artefacts by the various methods used for demonstrating the Golgi apparatus was discussed. Finally, mention was made of the various changes undergone by the Golgi apparatus during certain physiological processes, *i.e.* glandular secretion, intracellular fat formation, ossifraction, etc.—F. I. G. **Rawlins**: Report on the collection of metallurgical specimens recently presented by Sir Robert Hadfield, Bart. In 1918 a suggestion was made that the society might further interest, and perhaps research, in metallography. To this end Sir Robert Hadfield presented the society with a collection of specimens. These were polished at the Royal School of Mines by permission of Prof. Carpenter, and it is intended that they shall be available for microscopic examination by fellows, in much the same way as the general collection. A catalogue is being prepared, which will be ready shortly, giving brief details of the microstructures, etc.

Linnean Society, November 20.—Dr. A. Smith Woodward, president, in the chair.—Dr. G. C. **Druce**: The occurrence in Britain as native plants of *Ajuga genevensis* and *Centaurium scilloides*, Druce, var. *portense* (Brot.). Although there are previous records of *Ajuga genevensis* from Britain, the records are probably mistakes for *pyramidalis* or other species, and in one instance due to a garden-escape of the true plant.

This discovery of *genevensis* on the Berkshire downs is an undoubted evidence of it as a British species. *Centaurium scilloides* is the *Erythraea diffusa* of Joseph Woods, who discovered it near Morlaix, in Brittany. It occurs on the edge of a headland near Newport, Pembroke.—Prof. R. C. **McLean**: Sex and soma. The author enlarged upon the recently discovered phase of multinucleosis in the developing soma cell of higher plants. The genetic interest of the phenomenon has not received sufficient consideration, and the present paper was designed to direct attention to the possibilities involved.

Aristotelian Society, December 1.—Prof. Wildon Carr, vice-president, in the chair.—G. **Cater**: The nature of inference. The logic of the concrete universal as the medium of judgment and inference was criticised. It was shown by analysis of examples that it does not really succeed in making contact with its differences; their content is only *imputed* to it. On the other hand, the instrument of inference is always an intermediating representation, particular and not universal. Absolutism, the outcome of the theory that the active dominant concrete universal is the instrument of inference, ends in the concept of reality, under the form of eternity, as an exhaustive system of differences, without character, a contentless limit.

PARIS.

Academy of Sciences, November 24.—M. Léon Guignard in the chair.—L. **Maquenne** and E. **Demoussy**: The richness in copper of cultivated soils. The soils examined were in two classes, ordinary arable soil and soil on which fruit-growing had been carried out, and which was therefore liable to contain copper from the liquids used for spraying. All the soils contained copper, but the arable soils some millionths only of their weight. The soil from vineyards was compared with soil from the same district untreated with preparations, and the results from a considerable number of districts are tabulated. One fact was brought out by these investigations: the copper applied in spraying is mainly found in the surface layers, and penetrates the ground with great difficulty. At 30 cm. below the surface the soil of a vineyard contains no more copper than soil from a similar depth in a field growing cereals.—A. **Blondel**: The amplitude of the oscillating current produced by audion generators.—Ch. D. Walcott was elected a foreign associate in succession to the late M. Metchnikoff.—E. **Kogbetliantz**: The unicity of ultra-spherical developments.—L. E. J. **Brouwer**: The classification of closed ensembles situated on a surface.—M. **Portevin**: Study of the influence of various factors on the creation of internal longitudinal strains during the rapid cooling of steel cylinders. The determination of the internal longitudinal strains was carried out by measuring the variations in length produced during the removal of concentric layers of the cylinder by turning. The strains produced depend on a number of factors, including the temperature of immersion, the nature of the liquid (oil, water), the temperature of the water, time of immersion, and diameter of the cylinders. The results are summarised qualitatively in the present communication; full numerical data will be published elsewhere.—R. **Bayeux**: The ozogenic power of the solar radiation at the altitude of the Mont Blanc Observatory. At an altitude of 4360 metres sunlight does not produce ozone from oxygen. Hence it is concluded that the ozone found at lower altitudes is not formed by the direct action of the sun, and the therapeutic effects of the suncure cannot be attributed to ozone.—E. **Henriot**: The calculation of double refraction.—M. **de Broglie**: The X-ray spectrum of tungsten.—MM. **Ledoux-Lebard** and A. **Dauvillier**: The reticular distance of calcite and its influence on the determination of *h*. A recalculation of some data given in an earlier communication.—G. **Baume** and M. **Robert**: Some properties of pure nitrous anhydride and of its solution in nitrogen peroxide. The fusibility diagram of the system ($N_2O_3-N_2O_4$) is normal, with a single eutectic near the freezing point of pure nitrogen peroxide. Pure nitrous anhydride does not appear to be capable of existence except at very low temperatures in the solid state, or in the liquid state under a pressure of nitric oxide. At temperatures above $-100°$ C. N_2O_3 dissociates, the liquid phase containing N_2O_4, and the gaseous phase NO.—W. A. **Noyes**, jun.: The potential necessary for electrolysing solutions of iron. In a cell composed of iron anode and cathode and a solution of a ferrous salt absolutely free from ferric salt, it is impossible to deposit iron with a lower voltage than 0·66 volt. This is reduced by increase of temperature, falling to a minimum value of 0·13 at 109° C.—L. **Chelle**: The detection and estimation of traces of hydrocyanic and thiocyanic acids in a complex medium. Hydrocyanic acid can be completely removed by a rapid current, and retained by washing the air with alkali. Chromic acid converts thiocyanic acid into hydrocyanic acid. The results of quantitative experiments are given.—A. **Goris** and Ch. **Vischniac**: The constitution of primeverose, primeverine, and primulaverine.—J. **Bougault** and P. **Robin**: The oxidation of the hydramides. A study of the oxidation of benzhydramide, anishydramide, and piperhydramide by iodine and sodium carbonate. The corresponding cyanidine is produced in each case.—G. **Mouret**: Some effects of the lamination of rocks observed in the western part of the Central Massif of France.—P. **Morin**: The coefficients of flow of the watercourses in the Central Massif.—M. **Dechevrens**: Modification and complement to the method of observation of telluric currents with the aid of naked subterranean conductors.—L. **Daniel**: Experimental researches on the causes of the immersion of the leaves of the water-lily. The immersion of the leaves instead of floating on the surface is not due, as has been suggested, to the effect of the depth of water.—M. **Molliard**: The action of acids on the composition of the ash of *Sterigmatocystis nigra*.—H. **Guilleminot**: The second postulate of the calculus of probabilities and the law of option in the evolution of living matter.—L. **Boutan**: The rotation of the anal region of the larval shell in Gasteropods.—A. **Pézard**: The modifying factor of normal growth and the law of compensation.—M. **Barthélémy**: The definite survival of dogs bled white, obtained by a means other than blood transfusion. The solution injected was a 6 per cent. solution of gum arabic containing 6 parts of sodium chloride per 1000.

SYDNEY.

Linnean Society of New South Wales, September 24.—Mr. J. J. Fletcher, president, in the chair.—K. G. **Blair**: Notes on the Australian genus Cestrinus, Er. (fam. Tenebrionidæ), and some allied genera. The paper discusses the synonymy of the somewhat obscure genus Cestrinus, Er. (fam. Tenebrionidæ), as well as Achora, Pasc., and Adelodemus, Haag.—Dr. H. S. H. **Wardlaw**: The venous oxygen content of the alkaline reserve of the blood in pneumonic influenza. The skin of persons suffering from pneumonic influenza often assumes a distinctly bluish or plum-coloured tinge, and several hypotheses have been put forward to account for this. One question which arises is whether this colouring of the skin is a cyanosis in the generally accepted sense of the word, *i.e.* whether the colour is due to an abnormally large proportion of reduced hæmoglobin in the blood. In the paper the results are given of investigations involving determinations of the oxygen capacity and degree of oxygen saturation of the venous blood of persons suffering from pneumonic influenza; in some cases the acidity and reactivity were determined by means of the hydrogen electrode. The samples of venous blood from cases of pneumonic influenza showed no indication of decreased oxygen capacity or of deficient oxygenation. The concentration of hydrogen ion produced by the addition of a measured quantity of acid showed no indication of acidosis; the alkaline reserve was not reduced.—Dr. R. J. **Tillyard**: The Panorpoid complex. Part 3: The wing-venation. Amongst the new discoveries may be mentioned the proof that the basal cell of the forewing in the butterflies is an *areocel* of very specialised construction, and that all the higher groups have had the venation of the anal area of the hindwing reduced, not by loss of 3A, as hitherto supposed, but by loss of 1A after fusion with 2A to form a Y-vein. A summary is given of the phylogenetic results, and a phylogenetic table with the positions of the more important fossils marked along the lines of descents. The Trichoptera and Lepidoptera are shown to be very closely allied, being a true dichotomy from a common ancestral stem, probably in the Trias. The Megaloptera and Planipennia are even more closely allied, and can only doubtfully be kept as separate orders. The Diptera are traced back to the Triassic Paratrichoptera, themselves an early offshoot of the older Mecopterous stem. The three orders Mecoptera, Paratrichoptera, and Diptera differ from all the rest in having the cubitus only two-branched, and thus lie outside the main line of advance of the complex.

THE PROFESSION OF CHEMISTRY.

The Profession of Chemistry. By Richard B. Pilcher. Pp. xiv+199. (London: Constable and Co., Ltd., 1919.) Price 6*s*. 6*d*. net.

THE late Sir Henry Roscoe, in his autobiography, relates that when he had made up his mind to follow chemistry as a profession his decision caused astonishment and even dismay among his friends and relations, who asked him if he intended to open a shop with red and blue glass bottles in the window. This, he added, was not an extraordinary question in the early 'fifties. Some persons would consider it as not more extraordinary to-day. Fairly well informed people have gradually learned to understand that there is a distinction between the professional chemist and the pharmacist, but the general community still regards the shopkeeper who dispenses medicines and sells drugs and anything else that he thinks may appeal to his clients as a chemist, because he calls himself such. This needless confusion in the public mind exists nowhere else in Europe, and would not exist here if our Legislature and the Public Departments concerned with the issue of Royal charters, and, it may be added, our lay Press, were better acquainted with the functions and aims of the science of chemistry as distinguished from the art and craft of pharmacy.

An eminent foreign physicist, passing through one of our country towns in company with the writer of this review, chanced to see, on the facia of the local druggist, the term "Family Chemist," whereat he was considerably astonished and perplexed. The appellation was wholly unintelligible until it was suggested, as the only way of escape from a laboured explanation, that it might possibly mean a "chemist with a family." As he glanced in turn at the heterogeneous objects in the window—the photographic appliances, hot-water bottles, weed-killers, toilet soaps, electric torches, safety razors, vanishing cream, egg-preservatives, hair-brushes and sponges—and commented on the character of the show-cards his wonder grew. Why a man who dealt in such articles should term himself a *chemist* was incomprehensible to a fellow-countryman of Scheele, who, by the way, always called himself an *Apotekare*; and, further, why the *soi-disant* chemist should advertise himself for the purposes of business as "a family man" was still more inexplicable, unless, as was surmised, he considered it as some justification for his charges. But he was evidently a man of enterprise, since, in addition to his other activities, he traded in spectacles and sheep-dips, sold British and foreign wines, developed photographs, and was the local agent of one of the smaller insurance companies.

That the misunderstanding as to the true vocation of a chemist is widespread is the common experience of teachers when consulted by the parents of boys who have developed a taste for scientific chemistry. The "man in the street," as a rule, has a very hazy idea of the department of knowledge or of human activity with which chemistry is concerned. He cannot be wholly ignorant of its applications, but he seldom knows them as such. Even generally well-informed people are unaware what the profession of chemistry comprehends. It is to meet this lack of knowledge that the registrar and secretary of the Institute of Chemistry has been induced to put together this book.

In a special chapter Mr. Pilcher deals with the claim of pharmacists to the title "chemist," and shows how it has arisen. They base it apparently on the teaching of Paracelsus—no very reputable authority—that "the true use of chemistry was not to make gold, but to prepare medicines." But chemistry was studied, as an art, long prior to the fifteenth century, and was applied to industry and manufacture by the ancient Egyptians and Far Eastern nations centuries before the Christian era. Many of the earliest chemists, it is true, were physicians, and practised their art, like Paracelsus, in connection with their profession. But there was never any exclusive association of chemistry with medicine, and there is no justification, therefore, for the vendors of drugs on this score to assume the title of chemist. Strictly speaking, the pharmacists are the direct descendants of the Apothecaries, who in their turn were descended from the thirteenth-century Spicers, who dealt in galenicals —*i.e.* roots, herbs, and other vegetable products. The Apothecaries gradually took upon themselves the functions of the physicians, whilst the drug-vendors usurped those of the Apothecaries in preparing and compounding medicines. The Apothecaries were originally incorporated with the grocers, and down to the beginning of the reign of James I. such drugs and medicines as were then in use were sold in common by the grocers. In 1617 the Apothecaries obtained their charter, which enacted that the grocers should no longer keep an Apothecary's shop, and that no surgeon should sell medicines. The Society of Apothecaries then proceeded to take action against the frauds and artifices of the grocers and drug-vendors, and established a manufactory of medicinal preparations for the use of their own members. Although Robert Boyle drew a clear distinction in his writings between chemists and the druggists or drugsters, as he indifferently calls them, by the middle of the eighteenth century the popular confusion was such as to draw forth a protest from Berkenhout, who complained that "persons, who know nothing more of chemistry than the name, naturally suppose it to be a trade exercised by shopkeepers called *Druggists* and *Chemists*, who are thought to be chiefly employed in preparing medicines. . . . Chemistry, therefore, they imagine belongs exclusively to physic."

Space will not permit us to follow Mr. Pilcher's historical account in further detail, but it is interesting to note that it was only after the Chemical Society was established in February, 1841, that the "Chemists and Druggists" began to organise themselves, and "at a public meeting of the Trade held at the Crown and Anchor Tavern on April 15th" of the same year, it was resolved "that for the purpose of protecting the permanent interests, and increasing the respectability of Chemists and Druggists, an Association be now formed under the title of the Pharmaceutical Society of Great Britain."

Notwithstanding the various Pharmacy Acts, it cannot be seriously contended that the pharmacist has established any prior or prescriptive rights to the title "chemist." Scientific chemists existed in this country long before 1852, and were so termed: we have only to name Boyle, Black, Priestley, Cavendish, Dalton, Davy, and Wollaston in proof of this fact; pharmacists themselves could only designate such men as *chemists*, but they were in nowise pharmacists or druggists. Perhaps, therefore, the pharmacists would still further increase their respectability by dropping their pretensions to a title to which they have no valid right.

The chemist, properly so-called, will find little in Mr. Pilcher's book with which he is not already familiar, or will not wholly agree. The work, indeed, is not specially addressed to him. It is primarily intended for those who intend to take up chemistry as a profession, and to practise ultimately either as a consultant or as an analytical chemist, research chemist, or works chemist, or who seek to enter one of the Government Departmental or Municipal Laboratories, etc., and on leaving school wish to begin the necessary training. The book may be recommended to parents and also to schoolmasters, who are often the best judges of a boy's aptitudes, but, from their lack of knowledge of the many openings that chemistry affords, and of the proper course to pursue in order to enter the profession, are at a loss to offer sound advice.

Mr. Pilcher has a pleasant literary style; his book is eminently readable, and contains many facts of general interest. It is not often that he will be found tripping, but the sentence at the bottom of p. 120 concerning the appointment of Medical Officers of Health as Public Analysts requires amendment. Certain of the lines have apparently been transposed either in the galley or during the paging of the book.

FLOWERING PLANTS AND FERNS.

(1) *A Dictionary of the Flowering Plants and Ferns.* By Dr. J. C. Willis. (Cambridge Biological Series.) Fourth edition, revised and rewritten. Pp. xii+712+iv. (Cambridge: At the University Press, 1919.) Price 20*s.* net.

(2) *The Living Cycads.* By Prof. C. J. Chamberlain. (University of Chicago Science Series.) Pp. xiv+172. (Chicago: The University of Chicago Press; London: Cambridge University Press, 1919.) Price 1.50 dollars net.

(3) *British Ferns and How to Identify Them.* By J. H. Crabtree. Pp. 64. (London: The Epworth Press: J. Alfred Sharp, n.d.) Price 1*s.* 6*d.* net.

(1) IN the fourth edition of his "Dictionary of the Flowering Plants and Ferns," Dr. Willis has achieved the ideal form in arrangement, the sweeping together of the whole of the material into one alphabetical sequence. Part i. of the original edition, a somewhat sketchy and unequal account of the morphology, natural history, taxonomy, distribution, and economic uses of the phanerogams and ferns, has been eliminated, and the gain of space has been usefully employed in enlarging the scope of the main portion of the work. Dr. Willis claims that he has now found it possible to include all the genera, and though the expert in taxonomy may note a few omissions, the general botanist or student for whom the work is intended will not be critical on this heading. The book is, in fact, a remarkable compendium of botanical information, including not only the genera, which are referred to their family, and accorded some descriptive matter varying from a bare statement of geographical distribution to a paragraph, but also the families, which are treated in detail according to their relative size and importance. A useful feature is the inclusion of a great many popular names of plants and a large number of botanical terms, though the latter are much more exhaustively treated in Dr. Daydon Jackson's classic work. There are also a few general articles, such as one on "Collecting," and on concepts such as the leaf, inflorescence, fruit, etc., in which numerous cross-references are given to other headings.

There are occasional suggestions that the author might perhaps have spread his net a little more widely for his sources of information; and a brief list of standard works of reference, such as Dr. Jackson's "Glossary of Botanic Terms," Britten and Holland's "Dictionary of English Plant Names," and others, might with advantage have occupied one of the blank spaces at the beginning or end of the volume.

(2) The little volume entitled "The Living Cycads" is one of the University of Chicago Science Series, which aims at providing a medium of publication intermediate between the short article of the technical journal and the elaborate treatise; the volumes are written not only for the specialist, but also for the educated layman. Prof. Chamberlain has travelled round the world in order to study in their native habitats the widely separate genera of this group, remarkable for the peculiar habit, form, and structure of the plants, and for their great botanical interest as the surviving remnants of a line which reaches back through Mesozoic into Palæozoic times. During the last fifteen years the author has spent long periods of study in Mexico, Cuba, Africa, and Australia, and the work in the field has been continued in the laboratory by himself and his pupils. The subject-matter is divided into three

parts. Part i., "Collecting the Material," gives an eminently readable account of the different genera and species in their homes, illustrated by some excellent photographs. It will interest the educated layman as well as the botanist. Part ii., "The Life History," is a concise account of the Cycads in their various stages, including vegetative structures, reproductive structures, fertilisation, and the embryo and seedling. It is written with great clearness and is also well illustrated, but the mere educated layman will not get far beyond the first chapter. In part iii., "The Evolution and Phylogeny of the Group," we pass from the record of fact to speculation. This will interest the botanical student, who will follow easily at any rate the development of the different types of female sporophyll from the foliage-leaf, while he will be struck with the comparative uniformity of the male cone throughout the group. The evolution of the gametophyte and of embryogeny presents greater difficulty. Botanists will look forward to reading the much more extended technical account of the living Cycads on which the author has been at work for many years; and the results of this work will be of the greatest interest to those who are investigating the evolution and phylogeny of the Gymnosperms.

(3) Mr. Crabtree's little book on the British ferns makes a delightful introduction to their collection and study. The habitat and form are described in twenty-eight species (about three-fourths of the British species), and each description is accompanied by a full-page photographic reproduction of the plant as it grows and of a portion of a fertile leaf showing the sori on the pinnæ. The latter are sometimes wanting in clear definition. An introduction gives a very brief account of the life-history of a fern, and also directions for collecting, drying, and mounting. The author recommends mounting in a book. This was the custom in the old herbaria, but the plan of mounting on separate sheets which may be kept in a box or portfolio is much to be preferred. It allows intercalation of additional specimens or replacement of old ones, as well as alterations in arrangement, all of which are impracticable with the book-form.

OUR BOOKSHELF.

Ireland: The Outpost. By Prof. Grenville A. J. Cole. Pp. 78. (London: Oxford University Press; Humphrey Milford, 1919.) Price 3*s*. 6*d*. net.

A BRAVE and poetic effort is here made to present what Vidal de la Blache would call the personality of Ireland. The country is viewed as an outpost of Eurasia, from which her people and her civilisation have been derived in successive and overlapping waves. Prof. Cole's name assures the picturesque interest of the structural sections, and the maps and views are most helpful. A laudable effort is also made to set forth the present state of the problem of the peopling of Ireland, and this chapter is a welcome change from the too common fanciful remarks about Celts. No two writers would make the same sketch on this subject, and several would dissent from Prof. Cole's identification of the archæologically named Beaker folk with the "Bronze age" invaders of Ireland and with the monuments of New Grange. Nevertheless, Prof. Cole has made a suggestive summary that may well make a basis for discussion. The very short mention of Roman times and of the days of the saints is a little disappointing perhaps, as the story of those days emphasises the initiative of Ireland.

Separate accounts of the barrier of Leinster and the Irish plain, the uplands of the north and the Armorican ranges of the south, are full of interest with many a picturesque phrase and much fine human sympathy. The section on exits and entrances and communications hints at future developments of train ferries and of trans-Atlantic services from the West, while it gives a fresh criticism of the railway system.

The book should promote a more sympathetic understanding of Ireland's problems, and must be useful to the student and teacher, as well as to the general body of British citizens.

H. J. F.

British Rainfall, 1918. On the Distribution of Rain in Space and Time over the British Isles during the Year 1918. By Hugh Robert Mill and M. de Carle S. Salter. The Fifty-eighth Annual Volume. Pp. 242. (London: Edward Stanford, Ltd., 1919.) Price 10*s*.

TABULAR matter of great precision and of considerable scientific value as recorded by about 5000 observers constitutes the bulk of the information set out in this volume. The British Rainfall Organisation is to be congratulated on the high standard of the work which for the last time is produced under practically private management. Dr. H. R. Mill, after acting as director of the Organisation for nearly twenty years, has given over the control, which has now passed to the Meteorological Office.

An article on the development of the British Rainfall Organisation since 1910 shows considerable activity in the production of rainfall maps. A series showing the annual rainfall of the British Isles from 1865 to 1914, on a scale of nineteen miles to an inch, has been completed. A map on the scale of half an inch to a mile, showing the relation of rainfall to geographical features, is stated to be in contemplation.

Mr. Carle Salter contributes an article on "The Relation of Rainfall to Configuration," and he deals with the physical processes of rain formation.

Rainfall maps are given for each month, showing the actual fall in inches and the percentage of average. A coloured map shows the relation of rainfall in 1918 to the average of 1875–1909. The rainfall was more than 30 per cent. above the average in Merionethshire, Central and North Lancashire, North Dumfriesshire, and part of co. Kerry. The areas of deficient rainfall during 1918 occurred chiefly in the east of Great Britain.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Polarisation of Light Scattered by Helium Atoms.

ABOUT a year and a half ago I published an experimental investigation of the *degree of polarisation* in the light scattered at right angles by various dust-free gases (Proc. Roy. Soc., A, vol. xcv., p. 155). I believe the results then obtained to be in the main quite correct, but there is an important point on which I have completely to withdraw what I then said. This refers to the results on helium, which was then found to behave differently from the other gases, giving much less complete polarisation than any of them. The result given was that the weak image (vibrations parallel to incident beam) had 42 per cent. of the intensity of the strong image (perpendicular vibrations). This was given on the results of two independent series of photographs, which were, indeed, obtained under conditions much more difficult than those for the common gases, but were considered at the time to give adequate evidence. I do not even now know what was wrong with them; but on repeating the work with a much improved apparatus, which it has taken many months to design and construct, I have obtained an entirely different, I might say opposite, result.

I now find no intensity large enough to be observed in the weak image, and certainly not 3 per cent. of the intensity in the strong image. It may be possible to lower this limit still further; but, in any case, if helium is outstanding at all, it is in the direction of polarising more, and not less, completely than the generality of gases. The details will be published later, but I write to make the correction as soon as possible, so that no one who speculates theoretically on the subject may be misled by reliance on my former result.

RAYLEIGH.

December 21.

Gravitation and Light.

IT should perhaps be stated, in connection with Mr. Cunningham's remarks (NATURE, December 18, p. 395), that my difficulty with regard to Dr. Einstein's theory must extend to the deviation of light by the sun as well as to its change of period. According to the theory, the velocity of light *diminishes* near the sun; on the other hand, the scale of time is increased, so that the wave-length is not altered. Now, the space being nearly flat, the path of a ray is, with such heterogeneous time, determined fundamentally by minimum number of waves, and not by minimum time; therefore, it should not be altered.

On the other hand, passing from kinematics to dynamics, Dr. Einstein requires in another connection that light should consist of discrete bundles or *quanta* of energy. Let it also be granted that inertia and gravitation are attributes of all energy. It seems to follow that each of these bundles of energy will swing round the sun in a hyperbolic orbit, and that its velocity will be *increased* when near the sun. It is well known that this would account for half the observed deflection. But, again, physical optics could not exist without the idea of transverse waves and their phases, which must be grafted on somehow to the bundles of energy. Now the supposed gravitational derangement of the fourfold extension from the flat being very slight, it can be agreed that the change in extent of each element of it is of the second order. The expansion of scale of time near the sun requires thus a compensating shrinkage of radial lengths; and this second-order effect, the cause of the adjustment for Mercury, will, on the phase-principle of Huygens, just double the previous result. This would amount in all to the observed deflection of the rays.

But amid these uncertainties and apparent contradictions the view asserts itself that the very important astronomical determination is to be regarded as a guide towards future theory rather than as the verification of the particular theory which suggested it.

JOSEPH LARMOR.

Cambridge, December 20.

Radio-activity and Gravitation.

IN connection with the interesting letter of Prof. Donnan in NATURE of December 18, it may be of interest to mention some experimental results which have a bearing on this question. Some years ago Dr. Schuster suggested to one of us that it would be of interest to test whether the rate of transformation of radio-active substances was influenced by the intensity of gravitation. An accurate method of testing the rate of decay of radium emanation over a period of about a hundred days was developed, and it was intended to compare the rate of decay of samples which had been transported to suitable portions of the earth's surface. The outbreak of the war interfered with this plan.

Since, according to Einstein's theory, a gravitational acceleration is in no sense different from a centrifugal acceleration, experiments have been performed in the Cavendish Laboratory to test whether the rate of decay of radio-active substances is affected by subjecting them to the high centrifugal acceleration at the edge of a spinning disc. For the purpose of measurement the γ-ray activity was determined by a sensitive-balance method. Although the radio-active material was subjected to an acceleration of more than 20,000 times gravity, the change observed, if any, was certainly less than one part in a thousand.

This result is not in disaccord with the relation deduced by Prof. Donnan, for a simple calculation shows that his relation predicts an effect very much smaller than can be detected by measurements of this character.

Mortality among Snails and the Appearance of Blue-bottle Flies.

THE residential parts of Calcutta are remarkably free, as a rule, from both house-flies (Musca, spp.) and blue-bottles. This is doubtless due to the excellence of the municipal sanitary arrangements, for at Sibpur, a few miles away, blue-bottles (*Pycnonoma* or *Lucilia dux*) are not only extremely troublesome in the houses, but are also probably connected with frequent epidemics of enteric, unknown in the better parts of Calcutta. For some years past I have noticed in the compound of the Indian Museum that Pycnonoma from time to time becomes relatively numerous, and on several occasions I have been able to trace the flies to their breeding-ground. This has always been the dead bodies of the snail *Achatina fulica*, the largest land mollusc in Bengal.

A. fulica, the shell of which may attain a length of at least 4 in., is not an indigenous species, but was introduced for purposes of dissection by a keen malacologist some sixty-five years ago from Mauritius, whither it had been brought in some unknown manner from tropical Africa, its original home. Col. Godwin Austen [1] has told the story of its introduction into Calcutta, while Mr. E. E. Green [2] has published a report on its prodigious increase in Ceylon, when once its eggs had been carried (accidentally on a cabbage-leaf) into a suitable locality. Fortunately, it is largely a feeder on decaying vegetable and animal matter, and therefore does little harm to crops or gardens, and has even its value as a scavenger. Since, however, I found the maggots in the dead snails, I have noticed that the appearance of blue-bottles in this part of Calcutta invariably coincides with a heavy mortality in the mollusc, which appears to be subject occasionally to some kind of fatal epidemic and also perishes in large numbers after egg-laying at the beginning of the rainy season and during dry spells in and at the end of that season. In one instance investigated the mortality was due not to disease or weakness or to meteorological conditions, but merely to the fact that the snail was enormously abundant and that large numbers of individuals were crushed by people walking on garden paths in the evening.

I have thought these facts worth putting on record as illustrating the delicate balance of Nature and the danger of introducing apparently harmless or even seemingly beneficial animals into a new country.

N. Annandale.

Indian Museum, Calcutta, November 19.

Remains of a Fossil Lion in Ipswich.

In 1910 I discovered a rich bone-bed in a section of Stoke Hill at Ipswich, the deposit in which it occurred being 30 ft. below the surface. The results of the researches then undertaken were published in vol. xiv., part 1, of the Proceedings of the Suffolk Institute of Archæology and Natural History.

As a portion of Stoke Hill is now being cut away for railway sidings, a continuation of the same section is exposed, and with the permission and kind assistance of Mr. A. Woolford, G.E. Railway District Mechanical Engineer, I have been able to work for the past month upon it.

To the animal remains found in 1910, which included large cave-bear, mammoth, large horse, *Bos primigenius*, smaller ox, deer, and bird, I have now added teeth of the largest cave-lion yet discovered, with the exception of the Crayford specimen in the Spurrell collection. These were identified for me by Dr. Smith Woodward and Dr. Andrews, who also examined and named a large assortment of teeth and bones from the site. The list of remains is daily being added to, and a massive skull of deer, with other bones, a tooth, and an antler with a base measuring 10 in. in circumference, still await identification. The position of the tines suggests reindeer. With the help of a grant from the Percy Sladen Research Fund, I am able to continue the work with the care that it requires, and am employing special workmen for the purpose.

The question of the relation of Glacial deposits to these ancient land-surfaces is, of course, of paramount importance, especially as a small number of worked flints have been found closely associated with the animal remains. For this purpose pits are being dug to a considerable depth below our present ground-level in order to ascertain the constituents of the strata below.

Nina F. Layard.

Rookwood, Ipswich, December 17.

Promotion of a Plumage Bill.

May I announce through the columns of Nature the formation of a "Plumage Bill Group," designed to fight the plumage trade by means of publicity to the facts and of pressure upon the Government to bring in a Bill forbidding the importation of all birds' skins for millinery purposes, except poultry, ostrich, and eider-duck? Sir Charles Hobhouse is the president of this group; Lt.-Col. Swinburne, of 23 Eaton Place, S.W.1, its treasurer; and Mr. W. Dewar, of 8 Kenilworth Court, Putney, S.W.15, its hon. secretary. The group is in need both of funds and of assistance, and the former will be very gratefully received by the treasurer, and the latter as gratefully considered by the secretary and the committee.

We feel that a vigorous effort must be made to end the yearly massacre of the world's most beautiful and interesting species of wild bird—a massacre so merciless and extensive as seriously to threaten the extermination of a large number of species, and thus to throw out of gear the great work of evolution. Nor is there any honest or valid argument for the traffic, since this immense drain upon natural resources is for no other purpose than to feed the profits of a small band of East End traders and to satisfy the frivolity of some women.

H. J. Massingham.

December 17.

The Deflection of Light during a Solar Eclipse.

There can scarcely be a downward rush of cold air in places deprived of the sun's radiation during an eclipse as suggested by Prof. Anderson. This would happen only if the upper layers of the atmosphere were cooled more than the lower, and if the cooling were sufficient to bring the temperature-gradient near to the adiabatic. As it is, however, the effect of an eclipse should be to cool the lower layers more than the upper, and so to decrease the temperature-gradient. Moreover, if cooling caused convection movements, we should have upward currents as well as downward, and a development of cumulus clouds would result from the passage of the moon's shadow.

Ditcham Park, Petersfield, December 19.

INDUSTRIAL RESOURCES OF INDIA.[1]

As explained in a preface by Sir Thomas H. Holland, the president of the Indian Munitions Board, this handbook was originally prepared in connection with the exhibit of the Board at the exhibitions held in Bombay and Madras in the winter of 1917–18. It was intended to show what had been done to develop India's industrial resources for war purposes. It has now been enlarged so as, in some measure, to indicate the general industrial development which has taken place during, and on account of, the war, and it discusses the possibility of future progress.

The Board was created in 1917 with the view of relieving the United Kingdom, so far as possible, from the necessity of meeting India's demands for war purposes, and particularly for the supply of the forces in India, Mesopotamia, and Egypt. Its functions consisted not only in utilising Indian resources to the utmost extent, but also in controlling and regulating imported

[1] Indian Munitions Board. Industrial Handbook, 1919. Revised Edition. (Calcutta: Superintendent, Government Printing, 1919.) Price 2s. 3d.

material so as to avoid waste and overlapping on the part of different departments of the public service.

After a short account of the history and organisation of the Board and of its relations to indigenous industries, we have a series of reviews of industrial development in Bengal, Madras, Bombay, the United Provinces, the Punjab, Burma, and the Central Provinces. The book then deals with specific industries, viz. the chemical and metallurgical industries; the future of hydro-electric power in India; electrical and engineering manufactures; hides, tanning, and leather; tan-stuffs and tannin extracts; the supply of timber and bamboos; textiles; shipbuilding; railway material; petroleum; calcium carbide; paper-making; paints; glass; the coconut industries of the west coast of the Madras Presidency; soap; bitterns; Portland cement; lac; glue and gelatine; industrial alcohol; medical and surgical appliances; jute, hemp, and flax; pine resin; magnesite and mica; hardware; sandalwood oil; and it concludes with an account of miscellaneous articles purchased by the Indian Munitions Board, and a description of the Tata iron and steel works at Jamshedpur (Sakchi).

With regard to the reports of development in the several presidencies and provinces, each has been entrusted to a member of the Indian Civil Service, usually the Director of Industries or the Controller of Munitions. With one exception, all tell the same story of the strong stimulus which has been given to native industry by the war. "It has taught India its dependence on other countries and the danger of such dependence," writes Mr. Peterson; "it has tended to make the Presidency (Madras) more self-supporting and less dependent on the United Kingdom"; while it has arrested temporarily the development of some industries, it has opened up new possibilities, and diverted energy into new channels (Mr. Innes); Mr. Mead reports that the cotton mills in Bombay, Ahmedabad, and other places in the Presidency have prospered exceedingly during the war; glass-works have been established, and there have been considerable increases in the export of castor, ground-nut, and sesamum oils, and of castor and ground-nut cake; large quantities of casein are being exported, mainly to the United Kingdom and America, and the industry is rapidly extending; chemical manufactures have been established, with the result that many products formerly imported are now made successfully in India. There has been a great development in the utilisation of indigenous timber, and the ample deposits of suitable clays have been turned to increasing account in the production of tiles, bricks, and pottery. Mr. Silver states that "the war has given a strong stimulus to various industries in the United Provinces. The mills and factories of Cawnpore have been engaged almost entirely on war work," working continually, night and day, providing the many woollen and cotton items required for Army purposes. In spite of the very large call for men for the Army, "the Punjab has undoubtedly developed some of its industries very considerably" during the war, writes Mr. Townsend. This is especially seen in the manufacture of textiles, wood and metal work, cutlery, glass, leather, and certain minor industries. The Controller is sanguine that "the experience gained by many thousands of unskilled labourers in the manufacture of useful articles will prove to be not without its value to them after the war." "The effect of the war in developing industries in Burma was less marked than in some other Indian Provinces," reports Mr. Hardiman. This was due partly to its distance from war theatres, but mainly to the small extent to which its raw material is worked up owing to the shortage and high cost of labour, the lack of cheap fuel, and the paucity of roads and railways. The chief assets of Burma are its exportable surplus of rice; the large area of its reserved forests; its minerals and oil-bearing regions. Burma is largely undeveloped, but it has evidently great possibilities; at present it suffers from lack of capital and the reluctance of the Burman to submit to the discipline of an organised industry.

The effect of the war on the industrial development of the Central Provinces has, in the opinion of Mr. Corbett, been adverse, owing, he thinks, to the depletion of staffs both in the Government service and in private employment, the impossibility of recruiting experts, the difficulty of procuring machinery and stores, and the shortage of fuel and of transport. It has retarded the growth of agriculture, and has not permanently benefited forestry. On the other hand, the collection of tanstuffs has undoubtedly derived great impetus from war demands, and has been put on a more scientific and permanent basis. Cement and pottery works are now established as very profitable industries, but a number of smaller industries have suffered from the lack of expert supervision and the impossibility of obtaining adequate plant.

The general impression one derives from the reports of the provincial controllers is confirmed and amplified by the reports of the experts on the present condition and future prospects of the main industries of India. These latter reports constitute a very valuable feature of the book, and are of great interest. We would specially indicate the detailed account of the chemical industries of India by Profs. Sudborough and Simonsen; the report on the metallurgical industries by Dr. Leigh Fermor; that on the leather industry and on tanstuffs by Mr. McWatters and Mr. Fraymouth; on petroleum by Mr. Watt; on Portland cement by Messrs. Musgrave and Davy; and the several reports on lac products, glue and gelatine, and industrial alcohol by Dr. Gilbert Fowler, of the Bangalore Institute of Science. Lastly, we would refer to the account of the Tata iron and steel works at Sakchi (Jamshedpur) by Mr. Tutwiler, the general manager. These were started in 1912. They are on a very large scale, properly organised and laid out, and fitted with modern appliances and labour-saving machinery. They are being rapidly extended and developed, and are certain to exert a profound influence on the industry of the East, not only in India, but also in Ceylon, Java, Manchuria, China, Japan, Australia, the United States, the Argentine, etc., with all of which countries they are building up an export trade in iron and steel castings, machinery, fencing wire, nails, tools, galvanised products, tinplate and enamel ware, etc. An interesting feature is the description of what is being done to promote the intellectual and physical well-being of the workers by the provision of hospitals, convalescent homes, schools, co-operative stores, credit societies, an industrial bank, a concert hall, a restaurant, a reading room, etc.

There can be no question that India is on the eve of most momentous changes, political, social, and industrial—changes which have been largely affected and accelerated by the war. All who are interested in her future will do well to study carefully this official account of her present industrial position. It will amply repay perusal.

THE REFORM OF THE CALENDAR.

THOSE who have concerned themselves with the question of a reformed calendar will find much interesting matter in a report[1] published by a committee which was appointed early in the year by the Paris Société d'Encouragement pour l'Industrie nationale. In 1884 the Abbé Croze, chaplain of La Roquette prison, suggested a competition of schemes to M. Flammarion's journal, *L'Astronomie,* and presented anonymously prizes to the value of 5000 francs, with the rather incompatible conditions that the first day of the year should be always a Sunday, and that the week of seven days and the year of twelve months should be retained. From that time until the outbreak of war, enthusiasts had been making proposals, and, though they had reached little agreement among themselves, they had succeeded in 1910 in inducing the International Congress of Chambers of Commerce at London to pass a resolution in favour of reform, and the Swiss Government to promise diplomatic action. The projects have been reported from time to time in these columns. Since the close of the war, proposals of the kind have been renewed, and the report of the French committee is a useful document.

For the Western world there are two calendars of importance existing. There is the Gregorian calendar and there is the ecclesiastical calendar, founded on the Council of Nicea, which rules the movable festivals of the Churches. Hence there are two quite distinct questions before the reformers. One is to remove the conventional luni-solar element from the latter, and to fix Easter so far as possible relative to the Gregorian calendar. Another is to reform the Gregorian calendar itself, more or less drastically. But yet a third plan has been proposed by a French engineer, M. Paul Delaporte, which consists practically in ignoring these questions and in using a special subsidiary calendar purely for the purposes of industry.

The French committee, under Gen. Sebert, has formulated a number of resolutions which appear sensible and on the whole conservative. This is perhaps natural, in view of the peculiar French experience of ill-considered calendars. It supports the proposal to keep the variation of Easter within the narrowest possible limits—a week instead of a lunar month. This view has the assent of all lay opinion, and it is believed that it is no longer opposed by any ecclesiastical authority. On this point agreement in detail should be reached quickly and carried into effect without delay. Another resolution favours the substitution of the Gregorian for the Julian calendar, a hope which political events may have brought nearer to realisation. On the general manner of reform the committee expresses itself in favour of the continuity of the week. This excludes at once a number of schemes, the latest of which was proposed by M. Deslandres. At the same time, it threatens to make the change so slight as scarcely to be worth making at all. But it leaves open such a possibility of a perpetual calendar as the succession of thirty-five, twenty-eight, twenty-eight days in the month, with thirty-five days in December when the date ends in 0 or 5 generally and twenty-eight days in all other years, with the addition of those dates ending in twenty-five and seventy-five and those divisible by 400. This rule is not more complicated than the corresponding Gregorian rule, and the objection lies not so much to the variation in the length of the year as to the unequal months. Of course, a symmetrical calendar is out of the question, and no change in the present system can offer serious advantage without raising some such objection and meeting with firm opposition in consequence.

M. Delaporte, mentioned above, is properly impressed with the difficulty of ousting the present calendar, and suggests his scheme as an auxiliary, not as a substitute for it. Strictly speaking, his project does not seem to be a calendar at all, because it lacks continuity. He takes the Gregorian year as he finds it, and divides it from the beginning into thirteen months of four weeks each. This is the Comtist calendar without trimmings, but the one or two days at the end of the year must be provided for "à part." He furnishes in the report different mechanical and tabular modes of exhibiting the correspondence between his scheme or "Chronos" and the Gregorian calendar for a year. He claims that the method of reckoning weeks continuously through the year has proved itself advantageous in industrial practice. It is very possible. No doubt the advantage would be increased by uniformity of practice secured by agreement over a wide area. But the ordinary diary gives for each date the number of days elapsing from the beginning of the year, and if on this basis a business man cannot divide up his year to suit the requirements of his calling, suggestions from outside will scarcely help him.

[1] "Commission pour la réforme du calendrier." Bulletin de la Société d'Encouragement pour l'Industrie nationale, tome cxxxi., p. 70.

At any rate, no scientific liability is involved if he persists in the use of the necessarily unequal calendar month when a more convenient uniform period might be substituted. The French committee approves of M. Delaporte's economic calendar for its own special purposes, and recognises that it stands apart from the question of a civil calendar properly so called. H. C. P.

NOTES.

PROMINENCE has been given in the daily papers to an interview with Dr. J. O. Arnold, who has recently resigned from the chair of metallurgy at the University of Sheffield, relating to a new alloy tool-steel, the cutting powers of which are claimed to be far in advance of those of any rapid-cutting tools at present in the market. The element conferring this property is stated to be molybdenum. It was reported in the interview that Dr. Arnold had taken out British and American patents, but that, owing to the veto of the War Office, the Admiralty, and the Ministry of Munitions, he was not allowed to exploit his discovery, and that he was forbidden to communicate its details except under censorship to anyone in Great Britain. Meanwhile, representatives of the United States Government were said to be conducting inquiries in Sheffield. On December 19 it was announced, however, that Dr. Arnold had received notice from the Government that the restrictions had been removed. Until more information is forthcoming as to the precise chemical composition of the steel tools in question it will be well to suspend judgment on the matter. That rapid-cutting tools can be made with molybdenum as the alloy basis has been known for many years. Such tools, however, have hitherto been regarded as peculiarly sensitive to heat conditions, and therefore liable to injury by improper treatment. This has stood in the way of their exploitation in practice.

MORE than ninety years ago alcohol was synthesised from ethylene gas by Hennel. The gas was absorbed in sulphuric acid, with which it combined to form ethyl hydrogen sulphate. On distilling this with water alcohol was obtained in the distillate. Until recently the process has remained a purely laboratory operation. During the war, however, investigations were made into the practicability of utilising for the commercial production of alcohol the small proportion of ethylene present in the gas given off from coke-ovens. A good deal of progress was made and the possibility proved, but the process was not fully worked out. It appears that this has now been successfully accomplished. In a paper read at a meeting of the Cleveland Institution of Engineers, Middlesbrough, Mr. E. Bury, of the Skinningrove Iron and Steel Works, states that practical working has given a yield of 1·6 gallons of alcohol per ton of coal carbonised. The best results were obtained by absorbing the ethylene at a temperature of 60°–80° C. It is calculated that the coal used for coke-making in this country would yield more than 23,000,000 gallons of alcohol yearly, and the ethylene present in ordinary coal-gas, if similarly treated, would supply a further 27,000,000 gallons.

WE have received from the Royal Statistical Society a copy of a petition which has been forwarded to the Prime Minister urging the immediate appointment of a Royal Commission or Select Committee to inquire into the existing methods of the collection and presentation of public statistics and to report on the means of improvement. The lack of co-operation between the different Departments charged with the preparation of statistics, and the consequent lack of co-ordination between their publications, excellent though these are in many respects, and the absence of any sufficient information on points that are now of the first importance (*e.g.* wages, incomes, and home production), are so notorious that some action in the direction indicated is most urgently called for. Adequate information is the very basis of right reform, but in scarcely any case is it forthcoming. The petition received the most widespread support from members of both Houses, from learned societies, from county and municipal authorities, and from those interested in social questions and the use of statistics generally—support which will, we hope, secure its acceptance.

THE Electricity Supply Bill has had many vicissitudes in its passage through Parliament. In its final form it elicited little opposition, if no great enthusiasm. The appointment of Commissioners is universally welcomed. They can do much to co-ordinate the working of new schemes, and can effect great economies by standardisation. They will erect one or two super-stations which will effect an economy of fuel. They will probably also use a certain number of internal-combustion engines, which, theoretically at least, have a higher economy than steam turbines. The appointment of district boards with powers of compulsory purchase was strongly opposed by the electric supply companies, mainly on the ground that it was a breach of the Parliamentary bargain made in 1888. It was pointed out that electric supply was initiated by private enterprise, and that many of the pioneer companies had an anxious and unremunerative time in their early days. To take away the opportunity they had of bettering their financial position in the few remaining years of their concession was not just. The Government, influenced by the strong opposition to the suggested district boards, and possibly also by the approach of the end of the session, dropped all the contentious proposals. There is now a golden opportunity for the companies, both private and municipal, to enter into combination as "joint electricity authorities" for themselves, and it would be good policy for them to make a move in this direction, but at present we see no signs of such a movement. The proposals for district boards, which were all thoroughly discussed in Committee, will doubtless be revived either in this or in a future Parliament.

THE report of the Council of British Ophthalmologists on the desirability of a special qualification in ophthalmology presents a strong and well-considered case. The qualifications required by the principal hospitals of candidates for the post of ophthalmic surgeon—usually the fellowship of the College of Surgeons of England, Edinburgh, or Ireland—furnish no evidence of special knowledge of ophthalmology. The council concludes that there should be a special examination for those who propose to devote themselves to this branch of medicine; and that, owing to the importance of a sound knowledge of the general principles of surgery, pathology, etc., this examination should form part of the examination for a higher degree or diploma, such as the M.S. or F.R.C.S., rather than that it should be a special examination in ophthalmology alone. The council rightly lays stress upon an exhaustive curriculum, including anatomy, pathology, optics, systematic and clinical ophthalmology, and operative surgery. The Council of British Ophthalmologists is doing excellent work in striving to improve the teaching and practice of ophthalmology. It has already reported upon the teaching of these subjects to undergraduates, the lighting of test types, and other matters. It deals with aspects of medicine which are not catered for by the ordinary medical societies, but are of great importance to medical men in their relationship to the general public. It is eminently desirable that the excellent example which the council has set should be followed by other branches of medicine.

THE last day of this year marks the bicentenary of the death of John Flamsteed, first Astronomer Royal of England, and the rector of the parish of Burstow, Surrey, where he is buried, uncommemorated, we understand, by any monument. Flamsteed was born four years after Newton, and was a native of Derbyshire, being the son of a well-to-do maltster. Though prevented by illness from attending a university, he was devoted to mathematical studies, and in 1671 sent a paper to the Royal Society. Three years later he published his "Ephemerides," a copy of which, being presented to Charles II. by Sir Jonas Moore, led to Flamsteed being appointed on March 4, 1675, "our Astronomical Observer" at a salary of 100*l.* per annum, his duty being "forthwith to apply himself with the most exact care and diligence to the rectifying the tables of the motions of the heavens and the places of the fixed stars, so as to find out the so much desired longitude of places for the perfecting the art of navigation." The observatory at Greenwich, constructed partly of brick from old Tilbury Fort and of timber and lead from the Tower of London, was designed by Wren and built at a cost of 520*l.*, the money being derived from the sale of spoilt gunpowder. The struggles and disputes, the dogged perseverance, and the memorable achievements of Flamsteed have their place in the history of astronomy, but it may safely be said that never has king or Government made a better investment than when Greenwich was built and Flamsteed made passing rich on 100*l.* a year.

AT the general meeting of the Association of Economic Biologists on December 10 and 11 more than seventy new members were proposed, and Sir David Prain was elected president for the forthcoming year. Exhibits were made by Messrs. W. F. Bewley, E. E. Green, A. D. Cotton, and W. B. Brierley. Papers were read by Mr. W. F. Bewley on "Sleepy Disease, or Wilt of Tomato," Mr. W. E. Hiley on "A New Instrument for Measuring the Light Intensity in Woods," and Mr. F. R. Petherbridge on "The Life-history of the Strawberry Tortrix, *Acalla comariana*." December 11 was devoted to a symposium on "The Integration of Mycological Research with Practice in Agriculture, Horticulture, and Forestry." Sir Daniel Hall discussed the administrative problems involved and the organisation which the Board of Agriculture proposes in this connection. The training of investigators was treated by Prof. V. H. Blackman. The special needs and difficulties of agriculture were dealt with by Dr. E. J. Russell, of horticulture by Mr. F. J. Chittenden, and of forestry by Prof. W. Somerville. Sir David Prain discussed the part which the newly formed Imperial Bureau of Mycology will play in linking the investigator with the practical man. The meeting was presided over by Prof. F. W. Keeble, and in the discussion following the principal speakers a large number of members took part. The symposium was of great value in co-ordinating many divergent lines of thought, and there can be little doubt that the more frequent adoption of this method at scientific meetings would be conducive to that synthesis which is so great a desideratum in all natural science.

AN interesting and valuable gift which has more than a local interest has just been received by the Plymouth Institution. This is the fine vase presented to Sir William Snow Harris in 1845 by the Emperor Nicholas I. of Russia. Harris, who was born in Plymouth and educated at the Grammar School there, was trained as a doctor in Edinburgh, and for a time practised in his native town. After his marriage in 1824, however, he abandoned his profession to devote himself to the study of electricity. From 1819 onwards he was a frequent lecturer at the Plymouth Institution, where in 1822 his subject was "The Application of Fixed Conductors to Ships' Masts." In 1827 the Lord High Admiral—afterwards William IV.—while on a tour of inspection to the dockyards, visited the institution, and with some naval officers witnessed Harris's experiments. Two years later a Royal Society committee under Davy reported favourably on the proposals, but it was not until 1839, when the matter was referred to another committee, that Harris's new conductors were introduced into the British Navy, although the Russian Navy was already using them. The Copley medal had been given to Harris in 1835, and other honours followed. He was awarded a Civil List pension in 1841; the Emperor of Russia gave him a valuable ring and the vase in 1845; two years later he was knighted, and the Government afterwards made him a grant of 5000*l.* He died in the house overlooking the Hoe in 1867, and his name is inscribed on one of the panels in the Plymouth Guildhall. Harris's fixed conductors replaced the temporary conductors introduced by Watson in 1762, and led to a great diminution in the loss of ships through lightning. His scientific work and his improvements are a notable instance of the benefits conferred upon the community by local scientific societies, and no fitter place for the preservation of the beautiful vase presented to Harris could be found than the institution which saw the birth of his discoveries.

IT is announced in *Science* that Dr. Frank Schlesinger, director of the Allegheny Observatory of the University of Pittsburgh, has been elected director of the Yale Observatory.

THE Physical and Optical Societies' annual exhibition, to be held on Wednesday and Thursday, January 7 and 8, 1920, at the Imperial College of Science, South Kensington, will be open both in the afternoon (from 3 to 6 p.m.) and in the evening (from 7 to 10 p.m.). Prof. F. J. Cheshire will give a discourse on "Some Polarisation Experiments" at 8 p.m. on January 7 and at 4 p.m. on January 8, and Prof. A. O. Rankine will give a discourse on "The Use of Light in the Transmission and Reproduction of Speech" at 4 p.m. on January 7 and at 8 p.m. on January 8. Admission in all cases will be by ticket only, obtainable by members of various societies through the secretaries. Others interested should apply direct to the Secretary of the Physical Society, National Physical Laboratory, Teddington, S.W.

THE weather of the past autumn was so abnormal that a few facts concerning it are worth recording. At Greenwich for the whole autumn the mean temperature was 47·7°, which is 3·0° below the normal. There are only three autumns in the last hundred years with lower means—46·8° in 1829, 47·4° in 1840, and 47·0° in 1887. The autumn rainfall was 3·23 in., which is 49 per cent. of the average. There have been only two autumns in the last hundred years with a smaller rainfall—1834 with 2·84 in., and 1858 with 2·80 in. October was the driest month of the year with the exception of May, whereas it is normally the wettest of the twelve months. From October 26 to November 16 inclusive, twenty-two days, the maximum temperature at Greenwich was below 50°, and from November 10–16, seven days, it was below 40°. There has been no similarly long period without a temperature of 50° at the corresponding time of year during the last seventy-eight years. This cold period was due to an abnormal distribution of atmospheric pressure, the barometer being high over Iceland and the neighbourhood, whilst it was low to the south-east and south of England, causing a steady drift of cold north-east and east winds over the British Isles.

In the Journal of the Bihar and Orissa Research Society for September last Mr. M. H. Shastri discusses the contributions of Bengal to Hindu civilisation. In the religious sphere western Bengal was the scene of origin of Buddhism and Jainism. It was the aborigines of Bengal who taught the Vedic Aryans how to tame the elephant and to manufacture silk and cotton cloth. It was from the local performances of mystery plays that the Indian theatre was founded in Bengal. The writer's views in some instances may be open to comment, but the article is an interesting contribution to Indian history.

We have received the annual report of Livingstone College for the year 1918–19. The college gives training in elementary medicine, surgery, and hygiene to missionaries going to spheres of work abroad far from medical aid. During the war the college was transformed into an auxiliary hospital, but has now resumed its proper work. The fees of students do not suffice to cover expenses, the deficit being met by donations, and further donations to the college funds are urgently needed.

In the *Quarterly Journal of Experimental Physiology* (vol. xii., No. 3) Sir E. Sharpey Schafer shows that the fatal result of section of both vagus nerves is due not to pneumonia, resulting from absence of sensation in the parts supplied by these nerves and lack of protection from foreign matter entering the lungs, but to paralysis of certain muscles of the larynx, leading to obstruction of the glottis and slow asphyxia. If this obstruction is prevented, animals live indefinitely with scarcely any abnormal symptoms. In the same journal Prof. Halliburton points out that the waves in the blood-pressure seen during asphyxia are correctly designated as "Traube" waves. Those described by S. Mayer are of a different nature, and being artificial have no physiological significance.

The *Veterinary Review* for November (vol. iii., No. 4) provides a valuable summary of literature on current veterinary science and practice. Among the reviews is one giving a full *résumé* of the methods employed in the examination of milk at the Intercommunal Laboratory at Brussels, with details of the method of scoring. A maximum of 150 points is given for all kinds of milk, and samples of sterilised and pasteurised milk must obtain not fewer than 120 points; aseptic raw milk, 115 points; and ordinary milk, 100 points. The scoring is based upon number of bacteria present, catalase test, reduction test, fermentation test, microscopic characters of films, and kind of bacteria present.

The Thomas Vicary lecture on "The Surgical Tradition" was delivered in the Royal College of Surgeons of England on December 3 by Sir John Tweedy. In 1646 Mr. Edward Arris, and in 1655 Mr. John Gale, gave sums of money to the Company of Barbers and Surgeons for the purpose of lectureships. In 1745, on the dissolution of the union between the Barbers and the Surgeons, these funds became vested in the Surgeons, and afterwards in the Royal College of Surgeons, and "Arris and Gale" lectures have been delivered ever since 1810. Early in the present year the Barbers' Company founded a lectureship at the Royal College of Surgeons to perpetuate the memory of Thomas Vicary, Master of the Barbers' Company in 1540, and the former association between the Barbers and the Surgeons. Sir John Tweedy, who is a past-president of the Royal College of Surgeons and a past-master of the Barbers' Company, first reviewed the life of Vicary, who was Serjeant-Surgeon to Henry VIII., Edward VI., Mary, and Elizabeth, and also resident surgical governor to St. Bartholomew's Hospital. Sir John Tweedy then surveyed the progress of surgery from the period of Egypt and Greece, dealing in succession with the times of Celsus and Galen, the Arabian writers, Lanfranc and Ambroise Paré, concluding with a notice of Dr. J. F. D. Jones, who discovered the true principles of the ligature of arteries in 1805.

Some very interesting notes on the migration of birds over the Mediterranean Sea, by Mr. C. Suffern, appear in *British Birds* for December. The author holds that there are at least three main routes of migration, apart from the Gibraltar line. One of these runs from Cape Bon to Sardinia, Corsica, and the Riviera. Another from Egypt to Crete and Greece. The third seems to run from Africa to Malta, Sicily, and Italy.

Mr. M. A. C. Hinton, in the *Scottish Naturalist* for November-December, describes a new species of field-mouse from Foula, thus adding another to the list of insular forms which have been brought to light by an intensive study of these northern islets. The Foula field-mouse (*Apodemus fridariensis thuleo*)—one of the *Apodemus sylvaticus* group—most nearly resembles the field-mouse of Fair Isle, from which it differs in its smaller size and conspicuously larger feet. Very carefully prepared tables of external and internal measurements enable an exact comparison to be made with other British species of the *sylvaticus* group.

The 1918 Report of the Agricultural and Horticultural Research Station, Long Ashton, Bristol, states that, as is the case with all such stations, the normal work has been considerably interrupted owing to war conditions, and its place has been taken by technical and advisory work, as well as by some few instruction courses for officers. This outside work included investigations into the utilisation of cider-fruit by the jam trade and for other purposes, miscellaneous experiments in connection with fruit and vegetable preservation, and an extensive series of experiments on potato-spraying for the prevention of potato disease. The last-named experiments include investigations into the use of Burgundy mixture and of other copper sprays, and discuss what proportions of soda and copper sulphate are most advantageous in the former mixture. The normal experimental work with cider for the season 1917–18 had to be reduced considerably, and the varieties tested were those which had been examined in former years. The trial orchards for cider-production have received rather scant attention, though some new orchards have been added. Other work includes the study of "reversion" and resistance to "big bud" in black currants; the preserving value of various spices and essential oils; the influence of concentration of sugar solutions upon the growth of micro-organisms; as well as a large amount of advisory work and several special investigations which arose out of it.

Some improvements on his well-known classification of climates are proposed by M. W. Koppen. A summary of his suggestions, without a map, is given in

Revue générale des Sciences for October 15. The three main divisions are tropical or *zone mégathermique*, temperate or *zone mésothermique*, and cold or *zone microthermique*. These are based on considerations of temperature. Two other divisions are placed on the same level, one embracing hot deserts and the other cold deserts, but in their case amount of precipitation is an important determining factor. Subdividing these zones, M. Koppen finds eleven principal climates, which he names as follows: (1) Tropical forests, (2) savannas, (3) steppes, (4) deserts, (5) temperate with dry winter, (6) temperate with dry summer, (7) temperate humid, (8) cold with wet winter, (9) cold with dry winter, (10) tundra, and (11) perpetual ice. In addition to these main climates M. Koppen recognises a large number of secondary and transition climates. With the help of these lists he gives two or three reference letters to every climate on the globe. We gather from the summary that he distinguishes some fifty different climates. Thus the climate of Brisbane is indexed as *Cfa*, which designates a warm temperate climate with rainfall at all seasons, and the mean of the warmest month not above 22° C. Cairo is indexed BW*h*, which means an arid climate of the desert type, with a mean annual temperature above 18° C.

IN a paper read before the London Mathematical Society in 1903 Sir Joseph Larmor showed that when the disturbance propagated into a medium is determined by considering each element of an advancing wave-front to constitute a source of disturbance, as Huygens did two centuries ago, the problem of finding the strengths of these sources was indefinite from an analytical point of view. Many distributions could be found over the wave-front which would give the same total effect. In a further paper read before the society on November 13 Sir Joseph shows that, although analytically the problem is indefinite, physically one specification only is permissible.

IN the *Biochemical Journal* for November Prof. W. D. Halliburton and Messrs. J. C. Drummond and R. K. Cannan describe some experiments made to ascertain the food value, if any, of the synthetic product prepared from olive oil and mannitol by Lapworth and Pearson. The synthetic oil possessed a taste and odour recalling those of olive-oil, but somewhat less pleasant; insufficient oil was at hand to make experiments on the higher animals, so rats were employed in the work described. From the results so obtained Halliburton, Drummond, and Cannan conclude that "mannitol olive-oil" is utilised by the animal organism practically to the same extent as olive-oil itself, and no toxic action was observed to follow its prolonged administration to rats.

A SHORT account of the methods used in France at the present time for the production of radium bromide and other radio-active substances is given by M. Demenitroux in *La Nature* for November 1. Pitchblende from Joachimsthal being no longer obtainable, the industry is dependent on carnotite from Colorado, autunite from Portugal, and certain rare-earth minerals from Madagascar. These contain fewer than 15, and in some cases not more than 4, milligrams of active material per ton. The first operation consists in the separation of the barium, and this process is a long and costly one. The radio-active materials are separated with the barium, and the second operation is the separation of the two from each other. This is done by fractional crystallisation, a tedious but certain process which involves, as a rule, 500 successive crystallisations of the material. Finally, one of the tubes used in medicine containing 100 milligrams of radium bromide is obtained from 12 tons of the ore, 3 tons of hydrochloric and 1 ton of sulphuric acid, 5 tons of carbonate of soda, and 10 tons of coal. The present cost in France of the hydrated bromide of radium, $RaBr_2,2H_2O$, is 500 francs per milligram.

HITHERTO it has been stated in the literature that chloropicrin can be distilled unchanged at ordinary pressure. Messrs. J. A. Gardner and F. W. Fox have observed, however (Journal of the Chemical Society for October), that when the pure anhydrous substance is distilled at atmospheric pressure a small amount of a yellowish-red gas, resembling diluted nitrous fumes, is invariably produced, and can be seen in the atmosphere of the condenser and receiver. These authors show that this is due to a slow decomposition of the boiling chloropicrin into carbonyl and nitrosyl chlorides, according to the equation

$$CCl_3.NO_2 = COCl_2 + NOCl.$$

If 200 c.c. of the substance are boiled gently, the rate of decomposition is approximately 2 c.c. per day. This observation will account for the divergence between statements made on the physiological activity of chloropicrin. Further, the experiments of Frankland, Challenger, and Nicholls, showing that under some conditions chloropicrin is quantitatively reduced to methylamine, and under others to ammonia, would be explained by the reduction in the first case of chloropicrin *per se*, and in the second of its decomposition products. In some reactions chloropicrin seems to act as a nitro-compound, *e.g.* it can be substituted for nitrobenzene in Skraup's method of preparing quinoline; whilst in others the results can be explained as due to the carbonyl and nitrosyl chlorides.

THE latest catalogue of second-hand books of Messrs. W. Heffer and Sons, Ltd., Cambridge (No. 184), comprises a number of works on history and economics from the library of the late Rev. Dr. W. Cunningham; also books on architecture and archæology, and old travels to the East.

MR. FRANCIS EDWARDS, 83 High Street, Marylebone, W.1, has just circulated a Catalogue (No. 396) of autograph letters, historical documents, and manuscripts. Many of the letters are the work of explorers and men of science. The section devoted to manuscripts contains several items of great historical value.

AMONG forthcoming books of science we notice the following:—A "Peat Industry Reference Book," the late F. T. Gissing (*Charles Griffin and Co., Ltd.*); "The Life and Inventions of Sir Hiram S. Maxim," P. F. Mottelay (*John Lane*); "Military Psychiatry in Peace and War," Dr. C. S. Read (*H. K. Lewis and Co., Ltd.*); "The Life and Letters of Silvanus Phillips Thompson, F.R.S.," Jane S. and Helen G. Thompson (*T. Fisher Unwin, Ltd.*); and "The Life of Sir William White, K.C.B., F.R.S.," F. Manning (*John Murray*).

IN reference to our notice of the *Daily Telegraph* Victory Atlas (November 13, p. 276), Messrs. Geographia, Ltd., take exception to the remark that "a mistake is made in the area of the Slesvig plebiscite." This criticism, which had reference to the course of the frontier of that area, was based on the abstract of the Treaty of Versailles published in Treaty Series, No. 4, and our reviewer wishes to examine the German large-scale maps of Slesvig before accepting the boundary shown by Messrs. Geographia, Ltd. Meanwhile, we regret if his reading of the text and maps of the abstract gave a wrong impression of the accuracy of the *Daily Telegraph* Atlas.

OUR ASTRONOMICAL COLUMN.

BARNARD'S PROPER-MOTION STAR.—It was shown in *Mon. Not.* for November, 1916, that this star was observed by Lamont at Munich in 1842, being Mun. (1) 15040. Further confirmation of this is given by K. Graff in *Ast. Nach.* (4989 and 5007). He has surveyed the region with the 60-cm. refractor at Bergedorf, and gives visual magnitudes on the Harvard scale, and colour on the Osthoff scale, of twenty-eight stars in the region. The Barnard star is of mag. 9·37 and colour 3·4, being the reddest star in the field. There are nineteen individual measures of its magnitude, ranging from 9·22 to 9·60, but they are not grouped in a manner suggesting variability. The magnitude of the star Mun. (2) 6966, which Bauschinger observed in 1886 in an unsuccessful search for Mun. (1) 15040, is 10·79 and colour 2·0. Its proper motion is small, and it must have been extremely near the Barnard star in 1843. As there was some doubt whether the star B.D. +4° 3561 was the Barnard star or Mun. (2) 6966, Prof. Kustner has re-examined the original zones at Bonn, with the following interesting result. Zone 462 was observed on 1854 May 30, the air being very clear. The following two stars were recorded in the region:—

	Mag.	R.A. 1855·0 h. m. s.	N. Decl. 1855·0 ° ′
(a)	... 9·5	17 50 43·8	+4 16·5
(b)	... 9·5	17 50 44·3	+4 17·9

Zone 472 was observed on 1854 July 24, the air again being clear; on this night a single object was recorded in the place, thus:—

(c)	... 9·3	17 50 41·9	+4 17·3

In editing the B.D. it was assumed that objects (*a*) and (*c*) were the same, and their mean was taken as the position of +4° 3561, while object (*b*) was omitted as insufficiently observed. However, making use of our later knowledge, it is fairly certain that (*a*) is Mun. (2) 6966, (*b*) is the Barnard star, while (*c*) is probably the two objects observed as one (the telescope was small and the magnifying power low). This would account for the greater brightness recorded on July 24, which is unquestionably too high for Mun. (2) 6966. In view of these facts, the two stars must divide the claim to the title B.D. +4° 3561, but another early observation of the Barnard star (1854 May 30) has been established with tolerable certainty.

Mr. Graff estimates the diameter of the Barnard star as 1/20 of the sun's, or half that of Jupiter. This is based on its absolute magnitude and an estimate of its surface brightness from the character of the spectrum. It seems, however, unlikely that so small a body could ever attain the temperature necessary for a sun-like state. Prof. Eddington considered that a mass 1/8 of the sun was the minimum for the attaining of a sun-like condition. If we assume a density eight times the sun's, or twice that of the earth, this would give a diameter 1/4 of the sun's. It seems unlikely that the actual value is less than this.

THE GREAT SOLAR PROMINENCE OF LAST MAY.—Several reproductions of the photographs of this object, taken by the eclipse expeditions, have recently appeared (*Observatory*, November, and the British Astronomical Association's Journal, October). The Monthly Notices for June contained some photographs taken with the Cambridge spectroheliograph. The *Astrophysical Journal* for October gives some beautiful photographs taken at short intervals with the Yerkes 40-in. refractor. The first photograph was taken at 1h. 17m. G.M.T., about midway between the Sobral and Principe pictures. The prominence then formed a great arch, extending from −42° to +6° in latitude, and 4·5′ high. It was rising rapidly, and 1¼h. later it had broken away from its terminal columns. Successive plates show that the rising continued steadily, and at 7h. 57m. G.M.T. its height was 17′, or more than a solar radius. It rose from 200,000 km. to 760,000 km. in 6h. 40m. Mr. Evershed also secured many photographs of the object at Kodaikanal, but the longitude of Yerkes was more favourable for securing its most dramatic stage. The prominence had been in existence since March, but on the eclipse day it suddenly changed from the quiescent to the eruptive type. The Yerkes observers direct attention to a claw-like marking at the base of one of the columns, from which they infer that this base was exactly on the sun's limb.

ATOMIC DISINTEGRATION AND HEAT ENERGY.

SIR OLIVER LODGE, in the Trueman Wood lecture to the Royal Society of Arts, referred to last week, asked whether atomic energy may not already be being unconsciously utilised. The recognition of radio-activity as a process of natural transmutation, in which a large and previously unknown store of energy associated with the atomic structure is released in the disintegration of the atom and its change into totally different kinds of atoms, dates, of course, from the early years of the century. The natural conclusion is that, before this energy can be rendered available, artificial transmutation must be possible, and that this transmutation certainly does not occur in any other case than in that of the radio-elements, and then only spontaneously and in a manner not to be altered by artificial means.

Sir Oliver Lodge appears, however, to think that internal atomic energy may be being already unconsciously made use of, and cites two possible cases. The first is vision. The retina is supposed to contain a substance the atoms of which are capable of accumulating a few million impulses of æther-waves of luminous frequency. This causes the atom to eject one or more electrons, and it is these electrons rather than the original light-waves which stimulate the nerve-endings. Even accepting this as an interesting and suggestive new photo-electric theory of vision, which accounts satisfactorily for the extreme sensitiveness of the eye, the energy involved is surely the energy of the exciting radiation rather than internal atomic energy. Photo-electric effects in general are not supposed to be different from or more fundamental in character than other electro-chemical effects.

In the other example it is the energy of the electrons emitted by an incandescent wire which is in question. It is possible to welcome and recognise the very great advance which the use of this phenomenon, by means of the thermionic valve, has achieved in wireless telegraphy and telephony, without accepting the view that any new form of energy is utilised. The emission of electrons is, indeed, described as analogous to the evaporation of molecules from a surface, the velocities being distributed in accordance with Maxwell's law for a monatomic gas. It would seem sufficient to ascribe the energy of the electrons to heat energy, at least until it is proved that it is not so derived. The mere latter-day interpretation of many of the changes studied by the chemist and electro-chemist in terms of the electron does not alter their character, which is well understood by chemists not to be of the type they would regard as transmutational, or to involve the kind of energy disclosed by radio-activity, or, indeed, any other kind than what has been familiar in chemical, electro-chemical, and physical changes since these subjects began to be studied.

THE BRITISH ASSOCIATION AT BOURNEMOUTH.

SECTION M.

AGRICULTURE.

OPENING ADDRESS (ABRIDGED) BY PROF. W. SOMERVILLE, D.SC., PRESIDENT OF THE SECTION.

DURING the past four years—or since the ploughing programme began to take shape—grass-land has been officially cold-shouldered in no small degree. The cause was obvious and the reasons were good. The result of compulsory and voluntary ploughing has been that, whereas in 1914 the total area in Great Britain under temporary and permanent grass (hay and pasture) was practically 21.500,000 acres, it was barely 19,500,000 acres in 1918, a reduction, namely, of about 2,000,000 acres. During the same period the arable area, other than temporary grass, increased from about 10,500,000 acres to 12,500,000 acres. In Ireland during these years the area under grass (permanent and temporary) fell from about 12,500,000 acres to less than 11,250,000 acres. The United Kingdom at the present time comprises about 30,500,000 acres of permanent and temporary grass and 15,500,000 acres of land under crops other than grass and clover. This is over and above some 16,000,000 acres of mountain land used for grazing.

A considerable proportion of the grass-land of this country is of so high a quality that any improvement, and certainly any economic improvement, is hard of accomplishment. Satisfactory as are the high-class pastures of this country, it by no means follows that there is nothing more to learn about them. It is often very difficult to determine the factor or factors that go to the making of high-class pastures. Such pastures are to be found on most of the geological formations of this country; they are met with north, south, east, and west; and even altitude, within the limit of at least 700 ft., seems to have little effect. An immense amount of attention has been given to the botanical composition of the herbage of the more famous of the pastures of Britain. The result that emerges most conspicuously from these researches is that one may have a dozen pastures which are about equal in feeding value and yet may vary widely in respect of botanical composition. Thus Fream found that in the case of forty-eight English and eight Irish pastures, each of which was the "best" in the district selected, the Gramineæ might be as low as 11 per cent. and as high as 100 per cent.; Leguminosæ might be entirely absent or as high as 38 per cent.; while of miscellaneous herbage, most of which would be designated as "weeds," there might be none or up to 89 per cent. As regards individual genera and species, Fream found, for instance, that Agrostis was almost always present, and on five occasions was the most abundant plant; while *Holcus lanatus* gave an almost identical result. By a different method Carruthers arrived at a very similar conclusion. The latter also found that *Hordeum pratense* was the most abundant species on what is perhaps the finest grazing in England, namely, Pawlett Hams, near the mouth of the Parret, in Somerset. This investigator even found that on one of the "famous ancient pastures of England" the predominant grasses were Fiorin and Hassock, and in this connection makes the following remark, "In this field the hassock-grass, which made up a large proportion of the pasture, was freely eaten, and the cattle were in good condition."

In Hall and Russell's investigations Agrostis and Holcus might on occasion each exceed 20 per cent., and it is stated that "wherever *Holcus lanatus* occurs it is more abundant on the fatting fields." Even miscellaneous herbage could bulk more than 29 per cent. on a pasture so good that it could fatten five bullocks on four acres without cake. Armstrong found in a field representative of "the richest type of old grazing land found in the Market Harborough district" that, amongst grasses, *Poa annua* came second (12·3 per cent.) in point of abundance. There will be general agreement that four of the grasses just mentioned, Fiorin, Yorkshire Fog, Squirrel Tail, and Hassock, are accounted "bad," and yet it is hard to apply this term to plants which are the most abundant constituents of some of the finest pastures in England. While there is much that is disconcerting in these investigations, some facts do emerge with satisfactory consistency:—(1) That the great majority of high-class pastures contain a large proportion of perennial ryegrass and white clover; (2) that crested dogstail is almost always present, though rarely predominant; (3) that meadow fescue is practically negligible; and (4) that of the two Poas, *pratensis* and *trivialis*, the former is very rare, while the latter is very common.

The obvious deduction to be drawn from these investigations is that the quality of a permanent pasture is only in a minor degree determined by the relative abundance of its constituent plants, or, in the words of Hall and Russell, "We can only conclude that the feeding value of a pasture is largely independent of the floral type." Factors of much greater weight are depth and physical character of the soil, soil moisture and temperature, density of the herbage, and the natural or induced composition of the soil as regards plant-food, and especially in respect of phosphoric acid.

It seems that the lesson that may be learned from a study of the old pastures of England is that we need not include in a seeds mixture for permanent purposes plants which never bulk to any considerable extent in old grass-land, but that we should include all those which are usually naturally abundant. Take, as an illustration, the case of perennial ryegrass. In the eighties of last century, when much interest was taken in the subject of the best way to lay down land to grass, an almost violent controversy arose over the desirability or otherwise of including perennial ryegrass in a seeds mixture for permanent pasture. The main opponents of ryegrass were Faunce de Laune and Carruthers, who would have excluded this species in all circumstances. It is a common experience of those who have laid land away to grass with ordinary commercial seed that perennial ryegrass does not persist, but neither, for the matter of that, does white clover. And the probability is that the cause in both cases is to be found in the same direction. Both these plants, as usually grown in this and other countries for seed, are the progeny of a long line of cultivated ancestors, grown under somewhat forcing conditions which may be said to undermine the "constitution." They have adapted themselves to their artificial environment, and such adaptation has taken the form of early maturity and the production of a large yield of "bold" seed which is easily marketed. Gilchrist has, of late years, directed attention to the merits of wild white clover, which, as regards persistency, is on an altogether different plane from the cultivated or Dutch white. The price that farmers are willing to pay for the seed of wild white clover is the best proof of the sharp distinction which they draw between the two varieties. What we now want is similar work on grasses, and particularly on perennial ryegrass, and it is satisfactory to know that such work has actually been started.

Important as is the position of the fine old pastures of England in the agricultural economy of the country, and interesting though it may be to examine questions of seeding, a much more important line of inquiry is opened up by the problem of the improvement of our second- and third-rate pastures. What proportion of the grass-land of the country falls into the lower categories it is impossible to say, but the most superficial acquaintance with rural England is sufficient to carry conviction that the aggregate area of such land is enormous. Most of the poor grass-land of the country is associated with the heavier classes of soil, and has been abandoned to grass on account of the high costs of cultivation, including, in many cases, the necessity of drainage. It is, for arable purposes, essentially wheat-land, with an occasional crop of beans, and the regular intervention at comparatively short intervals of a bare fallow. Other areas of poor pasture, smaller in aggregate extent than the clays, but still of much importance, are to be found on all the geological formations of the country. Of the 14,500,000 acres of permanent grass in England and Wales, 70 per cent. is under pasture and only 30 per cent. under hay, and of the poorer classes of grass-land it is certain that the proportion that is grazed is still greater. It is evident, therefore, that the improvement of pasture is relatively a more urgent matter than the improvement of meadows, though with more than 4,250,000 acres of permanent grass made into hay in England and Wales during 1918, the latter problem is also one of enormous importance. The most famous experiments on the effects of manure on permanent hay are those started in 1856 by Lawes and Gilbert on the meadow at Rothamsted, and continued ever since on the lines originally laid down. The results have thrown a flood of light on the principles of manuring, which has been of the greatest assistance in the elucidation of problems in agricultural chemistry and soil physics. They have also shown unmistakably the effects of the more important elements of plant-food on the yield of hay and on its botanical composition, but, even supported as they were by elaborate chemical analysis of the produce, they leave us uncertain in regard to the feeding value of the herbage.

A very large number of experiments have been carried out which had for their object the determination of the quantitative results attributable to the use of manures, singly and in combination. In many cases these experiments were supported by a botanical, and not infrequently by a chemical, analysis of the resultant herbage, but it was felt that we were still in a state of much uncertainty in respect of the quality of the hay—that is to say, its effect on animals consuming it. This induced Middleton in the winter of 1900–1 to carry out a feeding experiment with sheep at Cockle Park, and in 1905–6 and 1907–8 Gilchrist continued and amplified this work. The sheep were accommodated in a special house. The various lots of sheep all got equal quantities of roots, cake, and hay. The hay employed was the produce of variously manured plots on old grass-land which I laid out in 1897. The soil is a clay loam on a boulder clay subsoil. This set of experiments includes the eight-plot test, and it may be interesting to see what influence nitrogen, phosphoric acid, and potash respectively have on the produce. The quantitative figures refer to the average annual yield for twenty-one years, 1897–1917, while the figures which indicate the relative values of the produce, as determined by the live-weight increase of sheep, are based upon the feeding tests already specified. The hay from the unmanured plot, No. 6, is assumed to be worth 4l. per ton. The results are set out in the accompanying table:—

Plot	Manuring per acre per annum	Average annual yield of hay	Value per ton of hay as determined by feeding
		cwt.	s. d.
6	Unmanured	19¼	80 0
7	30 lb. N in Sulphate of Ammonia	23	72 0
8	50 lb. P_2O_5 usually in Basic Slag	20	93 0
9	50 lb. K_2O in Muriate of Potash...	16	80 0
10	30 lb. N + 50 lb. P_2O_5	30½	84 0
11	30 lb. N + 50 lb. K_2O	21	72 0
12	50 lb. P_2O_5 + 50 lb. K_2O	26	101 9
13	30 lb. N + 50 lb. P_2O_5 + 50 lb. K_2O	30½	89 2

Nitrogen derived from sulphate of ammonia, and used at the rate of 30 lb. per acre per annum, has consistently increased the yield and as consistently reduced the quality. When used alone the nitrogen has increased the crop by 3¾ cwt. per acre, and reduced the feeding value of the hay by 8s. per ton. When added to phosphates, the nitrogen has increased the yield by 4¼ cwt. and reduced the quality by 9s. per ton. When nitrogen was added to potash the yield has been raised by 5 cwt. per acre, and the value lowered by 8s. per ton. When used as an addition to both phosphates and potash the nitrogen has increased the yield by 4½ cwt. per acre, while the value has fallen by 12s. 7d. per ton. Even if the quality of the hay be disregarded, the use of nitrogen has always been attended by an adverse financial balance; when quality is taken into account this undesirable result is greatly emphasised.

As regards phosphoric acid, an increased yield has been consistently obtained by its use, accompanied in every case by a marked improvement in the quality of the hay. Taking the arithmetical mean, the increase in quantity has been nearly 8½ cwt. per acre, while the increase in quality is represented by 16s. per ton.

The behaviour of potash is rather peculiar. It has quite distinctly reduced the yield when used alone or when used in combination with nitrogen only, while in both these sets of circumstances it has had no influence one way or other on the quality of the hay. When added to phosphates it has proved powerless to increase the yield, but it has raised the feeding value of the hay by 8s. 9d. per ton. When added to both nitrogen and phosphates the potash has been practically inoperative so far as yield is concerned, but it has improved the quality by 5s. 2d. per ton.

These results show that very erroneous conclusions may be reached if, in experimental work on meadow hay, attention is given only to the weights of produce secured. Thus, in these Cockle Park experiments, on the average of twenty-one years, if quantity alone be regarded, sulphate of ammonia used by itself has involved an annual loss of 6s. 4d. per acre, whereas, if the reduced quality of the hay be taken into account, the loss is increased to 15s. 7d. per acre. On the other hand, a quantitative gain of 4s. 2d. per acre per annum from the use of phosphate and potash is raised to one of 32s. 5d. owing to the superior quality of the hay. While there is a certain relationship between the chemical composition, the botanical analysis, and the feeding value of the hay, there will probably be general agreement with Middleton when he says that "without an appeal to the animal, the relative values of samples grown under different treatment cannot be measured." In my view, this form of research may, with advantage, be largely extended.

Turning now to the improvement of pastures, as contrasted with meadows, it may be remarked that while no sharp line can be drawn between these two classes of grass-land in respect of ameliorative treatment, there are certain distinctions which must be kept in view. In a meadow the plants are allowed to grow up to full maturity, whereas in a pasture they are cut over daily, or at least very frequently, by the grazing of the animals. It is difficult to arrive at a decision as to whether a larger gross weight of dry material is got from a given area treated as pasture, in contrast to being hayed, but the probability is that the aggregate quantity is greater. Take the analogy of a patch of lucerne. Cut three or four times in the season, it may yield six tons of dry matter per acre, cut once it would certainly yield much less. Or take the case of cocksfoot; this springs so quickly in the aftermath that the foliage may shoot up 6 in. almost in as many days, whereas there would be no such growth were the hay not cut over. It is a matter of observation, too, how quickly red clover springs up after cutting, and trees and shrubs which may be growing only a few inches annually when unrestrained may send up stool shoots several feet in length if cut over. It is difficult, however, to bring the question to the test of figures.

If there is any doubt as to the greater weight of dry matter produced under a system of grazing, there can be none in respect of its digestibility. This would appear to be the reason why sheep and cattle will fatten on a pasture, whereas the animals would only remain in store condition on the herbage if made into hay.

At one time experiments on the improvement of pasture took the form of temporarily enclosing an area, to which different methods of treatment were applied and of determining the results in terms of hay. Supplementary to such quantitative determination, chemical analysis and botanical separations were often made, but it is evident from the work of the investigators already quoted that the results so obtained may be a very untrustworthy index of the feeding value of the herbage. In any case, the competition between the various classes of plants may be very different in a hay field and in a well-grazed pasture. Again, in a hay field the produce is reaped and cleared off with all the plant food which it contains. In a pasture, on the other hand, there is the daily conversion of vegetable substance into manure and its immediate return to the land. Reflections of that sort induced me in 1896 to arrange a series of experiments where a direct appeal was made to the animal. We all know that among a lot of animals there are certain individuals which possess idiosyncrasies which result in their thriving better or worse than the others. By careful selection, however, and especially by keeping them under observation for a probationary period, this objection may be largely eliminated. The greater the number of animals, the more completely is any disturbance due to individual peculiarities got rid of, and for this reason sheep are usually employed in preference to cattle. No one who looks into the details of these "manuring for meat" experiments can doubt that, not only in broad outline, but even in the finer details, the results are perfectly trustworthy. Involving as they do considerable outlay on fencing, water, weighing machines, etc., and necessitating the use of large areas of uniform land, such experiments were not likely to be undertaken with great frequency, but I have been able to find reports of nine in England, twelve in Scotland, two in Ireland, and one in New Zealand. Two of them are situated at Cockle Park, of which the original in Tree Field has now completed its twenty-third season, while the other in Hanging Leaves has a record of sixteen years.

The outstanding feature of these experiments is the great and profitable effect of phosphates. In this material the farmer is placed in possession of an agent of production the effects of which on the output of meat, milk, and work from the pastures of this country are only limited by the supplies. In many cases the increase of meat is trebled, and even quadrupled, with a return on the original outlay that runs into hundreds per cent. As between the various sources of phosphate there is unmistakable evidence that basic slag is the most effective, not only in respect of aggregate yield of meat, but also, and more particularly, when the net financial return is considered. This conclusion is also reached by Carruthers and Voelcker in a long series of pasture experiments carried out in 1896–99 for the Royal Agricultural Society of England. In these experiments, however, the effects were only estimated by ocular inspection. The primary effect of phosphates is due to the marked stimulus that they give to the growth of clovers and other Leguminosæ, and as these plants revel in a non-acid soil the alkaline character of basic slag appears exactly to suit their requirements.

In regard to the quantity of phosphatic manure that can most effectively be employed per acre, it would appear that in the case of inferior pasture a heavy initial dressing, say 200 lb. of phosphoric acid or more per acre, is likely to be nearly twice as effective as half this dressing, and therefore actually much more profitable. To secure the best results the Leguminosæ must be rapidly brought up to their maximum vigour, so that they may fully occupy the ground before the grasses have had time to react to the effects of the accumulated nitrogen.

One of the most striking results of these pasture experiments is the long period over which the action of phosphates persists. Even at the end of nine years the meat-producing power of half a ton per acre of basic slag is far from being exhausted. It is not suggested that this persistent action of slag—and no doubt this applies also to any other effective phosphate—is due to unappropriated residues. It is much more probably due to two other causes: (*a*) to the fact that on a pasture, in contrast to a meadow, manurial elements are kept in circulation from the soil to the plant, and from the plant to the animal, and so, to a large extent, back to the soil again; and (*b*) to the accumulation of nitrogen in the form of humus. Poor, unprofitable grass is chiefly associated with clay, and it is fortunate that it is precisely on such land that clover responds so markedly to phosphatic manuring. But conspicuous results have also been obtained on deep peat, on light stony loam, on thin chalk, and on chalk covered by clay with flints. Middleton has very fully discussed the conditions under which phosphatic dressings may be expected to give results, and ascribes an important place to soil moisture, on which white clover is directly very dependent. The only conspicuous case of failure of phosphates to improve pasture was encountered in Norfolk, where a "manuring-for-mutton" experiment was started in 1901. The soil at that station was a hot, dry, sandy gravel containing 60 per cent. of sand, and there both the basic slag and superphosphate were unable to produce any improvement. Wood and Berry attribute this result partly to the presence of abundant natural supplies of citric soluble phosphoric acid, but chiefly to lack of moisture. In reporting on the R.A.S.E. experiments Carruthers and Voelcker in 1900 had already directed attention to the dependence of basic slag on soil moisture.

We may now look at the effect of supplementing phosphates with certain other substances. And, first of all, as regards potash. At most of the manuring-for-mutton stations, both in England and Scotland, there was a plot devoted to the elucidation of the effect of this substance, and although in the great majority of cases the phosphate-*plus*-potash plot has shown more live-weight increase than phosphates alone, it is only in very rare instances that the gain has been a profitable one. Even on thin soil overlying chalk, potash has had little action on pasture. There are several rather conspicuous instances of quite moderate dressings of potash doing positive harm. Thus, at Cockle Park, whereas potash gave an appreciable increase in live-weight in the first nine years, it proved positively and progressively injurious during the next two six-year periods. Even on a "light stony loam" in Perthshire, Wright found that, although in the first two years potash when added to slag gave a conspicuous return, in the next three years "the advantage was wholly with the slag-alone plot." The most notable beneficial effect of potash was obtained in Dumfriesshire on a station where the mineral soil was overlaid by 10 ft. of peat. There the use of kainit supplying 100 lb. of potash per acre at the beginning of the experiment has in seven years produced 70 per cent. more meat than phosphate (slag) alone, while the financial gain has been improved by nearly 50 per cent.

Potash has had great influence both on the yield and composition of the hay on the meadow at Rothamsted, and it would seem that this substance has more effect on a meadow than on a pasture. The reason is probably to seek in the fact that in a pasture the top layers of the soil are constantly being enriched by the potash brought from the subsoil by plants and returned through their excreta. In any case, pasture plants on clay soil are in possession of abundant supplies of potash, and it is only where pasture occupies sandy, gravelly, or peaty soil that this manurial element need be seriously considered.

Lime as an addition to superphosphate was tested at the three original manuring-for-mutton experiment stations, a total of 30 cwt. per acre being applied in three dressings in nine years. A noticeable effect was produced at all stations, and at two of them the gain was a profitable one. The effects of lime can be followed for twenty-one years at Cockle Park, where the soil naturally contains 0·59 per cent. of calcium carbonate. During that period an aggregate of 5½ tons per acre was applied in seven dressings, the phosphate to which it was added being superphosphate in the first nine years and basic slag in the next twelve. The area receiving the lime was the same throughout. The action of the lime has proved to be a progressively decreasing one. On the average it produced an annual increase of 22 lb. live-weight in the first nine years, and of 8 lb. in the next six years, whereas in the concluding six years of the period it has actually caused a reduction in live-weight of 8 lb. per acre per annum.

The addition to superphosphate of moderate dressings of nitrogen in the form of sulphate of ammonia or of nitrate of soda was tried at the three main manuring-for-mutton stations, and at two others. There is no need to go into a detailed discussion of the results. The evidence is overwhelmingly against the use of nitrogen on pastures. It undoubtedly stimulates the vigour of the non-leguminous herbage, but this reacts on the growth of the clovers, with the result that the production of meat is sometimes, as at Cockle Park, actually and substantially reduced.

At the three original stations dissolved bones were also tried, the comparison being with equal quantities (200 lb. per acre in nine years) of phosphoric acid derived respectively from basic slag and superphosphate. The dissolved bones supplied in addition from about 30 lb. to 40 lb. of organic nitrogen. All manures were applied as to half in the first year, and, as to the other half, at the commencement of the fourth season, the experiment being continued for nine years at Cockle Park and Sevington (Hants) and for eight years at Cransley (Northants). At Cockle Park slag acted substantially better than dissolved bones, though the latter surpassed the effect of superphosphate; at Sevington dissolved bones proved inferior to both the other manures; while at Cransley the position was reversed. But when the cost is considered there is no question of the superior merits of basic slag. This superiority is continued and emphasised at Cockle Park, where the experiments are now at the end of their twenty-third year. A similar result was also obtained in the series of pasture experiments conducted by the Royal Agricultural Society of England already referred to. There dissolved bones or bone-meal was tried at ten centres, with the result that "in Herefordshire some benefit was observed, but in the other places no real improvement could be detected as compared with the unmanured part of the field. So far as these investigations go, therefore, they indicate that no further experiments need be made with bones on pasture land."

With these results before us it is needless to pause to consider whether the comparative failure of bones, dissolved or raw, is due to the inferior quality of their phosphate or to the fact that they supply the land with nitrogen.

A form of pasture improvement which has had, and still has, much support amongst farmers is feeding with cake. The manure applied to the land through cake residues is a "general" manure, supplying nitrogen, phosphates, and potash, of which that which has the highest value attached to it is the nitrogen. At eleven of the stations in England and Scotland reported on in the Supplement to the *Journal of the Board of Agriculture* in 1911, linseed or cotton cake, or a mixture of these cakes, was used for two, four, or five years, and at every one of them the live-weight gain secured was insufficient to pay for the outlay, the debit balance per acre per annum being in one case nearly a pound. In connection with the improvement of pasture, however, it is the residual effect of the cake that has most interest. This matter was put to the test at eight of the manuring-for-mutton stations in the following manner. At the three original stations cake was fed all through the season for two years, and none given for the next four. At five of the other stations cake was fed for two or four years, and was then suspended for one, two, or three years. In this way the improvement of the herbage effected during the years when cake was fed had an opportunity of manifesting itself in the form of live-weight increase in the years immediately succeeding, when no cake was given. In every case the residual effect was found to be appreciable, having a money value per ton of cake consumed of as much as 4*l*. 14*s*. at one station, and 3*l*. 11*s*. at another, the average for the three stations where the residues were followed for four years being fully 3*l*. per ton, a figure which is of the same order as, though somewhat higher than, those adopted by Voelcker and Hall in their revised table of 1902.

A method of improvement of poor pasture that deserves notice consists in scattering the seed of a "renovating" mixture over the surface, usually with concurrent harrowing, rolling, and manuring. This procedure was practised in the series of experiments conducted by the Royal Agricultural Society of England, the seed mixture consisting of four natural grasses in addition to white clover and yarrow. In their final report Carruthers and Voelcker stated that re-seeding had not been successful, a result which they thought was "entirely due to the prevalence of dry seasons, the germinating plants being killed before they could get hold of the soil." A more successful result is reported by Middleton, who on a poor pasture on clay soil in Essex sowed, in the spring of 1903, 12 lb. per acre of wild white clover seed, with and without basic slag, kainit, and lime, this treatment being unaccompanied by harrowing. There were no Leguminosæ naturally present in the field. Helped by abundant rain in the summer of 1903, the seed germinated well, and "in 1904 the results were very marked." It was, however, only when the seeding had been accompanied by basic slag that "there was the luxuriant growth which one expects in pastures where Leguminosæ are present." I also have reported on an experiment where renovating a thin, poor pasture with 6 lb. per acre of wild white clover seed was entirely successful, and here, too, the beneficial effects were only secured in the presence of basic slag.

When a responsive pasture is treated for the first time with, say, half a ton of basic slag per acre, the effects reach their maximum usually in the third season. From then onwards there is a steady diminution in the yield, though even after nine years from the time of the initial dressing the improvement is far from being exhausted. At Cockle Park, for instance, the plot dressed once with half a ton of slag was, at the end of nine years, producing three times as much mutton as the continuously unmanured ground, while at Sevington and Cransley the yield at the end of nine and eight years respectively was 70 per cent. to 80 per cent. greater. None of the other stations was carried on for so long a period, but up to the end of the sixth year most of them show residual fertility which is as great as the original rental value of the land. That is a very important result, but in the interests of the country it is still more important to endeavour to secure that the level reached at the period of maximum productivity shall be maintained.

From this rapid survey of grass-land experiments the following conclusions may legitimately be drawn:—

(1) That the quality of a pasture is not primarily dependent on its botanical composition, though, as a rule, the presence of white clover and other Leguminosæ is indicative of high feeding value.

(2) That poor pastures, especially on clay soil, can be rapidly and profitably improved by the use of phosphates, especially basic slag.

(3) That, as a rule, phosphates alone are necessary to effect and maintain the improvement, and that, of supplementary substances, potash and lime are occasionally worthy of attention.

(4) That the improvement of poor pasture is very dependent on the presence of Leguminosæ, and especially of white clover.

(5) That renovating with the seed of wild white clover may, in the absence of natural Leguminosæ, be a necessary preliminary or concurrent operation.

(6) That cake can rarely be used at a profit, and that, as an agent in improving poor pasture, it occupies an unsatisfactory position.

(7) That nitrogen, whether in the form of artificial manure or as cake residues, when added to phosphates for pasture, is always unnecessary and frequently detrimental.

(8) That in the case of hay on permanent grass-land, equal weights of produce may have very different feeding values.

(9) That few forms of agricultural expenditure are more certain in their results than the judicious use of manures on grass-land, and that the meat- and milk-producing capacity of the country can be largely and rapidly increased, with great pecuniary gain to the farmer, and still greater economic advantage to the nation.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BIRMINGHAM.—Mr. C. Grant Robertson, tutor in modern history since 1905 to Magdalen College, Oxford, and a stimulating lecturer upon national development, has been appointed to succeed Sir Oliver Lodge as Principal of the University.

CAMBRIDGE.—Mr. K. J. J. Mackenzie has been re-appointed reader in agriculture. Other appointments are:—Mr. W. J. Harrison, University lecturer in mathematics; Mr. A. Wood, University lecturer in experimental physics; Mr. A. G. Tansley, University lecturer in botany; and Mr. F. Balfour Browne, University lecturer in zoology.

DURHAM.—Members of the University are invited to help in compiling the definitive edition of the Roll of Service and Roll of Honour. The latest date for receiving forms framed to include all details of military service is December 31. The address of the University offices is 38 North Bailey, Durham.

EDINBURGH.—The University Court has made the following appointments to three newly instituted chairs:—Dr. G. M. Robertson to the professorship of psychiatry, Dr. J. H. Ashworth to the professorship of zoology, and Mr. T. P. Laird to the professorship of accounting and business method.

The following appointments have also been made:—Dr. F. E. Jardine as lecturer on applied anatomy, and Dr. David Lees as lecturer on venereal diseases.

The Right Hon. Lord Lyell of Kinnordy has presented to the geology department forty-six volumes which had formed part of Sir Charles Lyell's library when he was preparing his "Principles of Geology."

The late Mr. Samuel Elliott, of New York, has bequeathed to the University Court the sum of 1500*l.* to be held in trust by it for the purpose of applying the income in providing scholarships or prizes in connection with the classes of the professors of rhetoric and English literature and of ancient history and palæography, the scholarships or prizes to be known as the James Elliott scholarships or prizes, in memory of the testator's brother, James Elliott, who was a student and graduate of the University.

At the last meeting of the Munitions Committee, South-East of Scotland Area, a sum of 500*l.* was set aside to be expended in providing additional equipment for the engineering laboratory.

LIVERPOOL.—Mr. T. E. Peet has been appointed to the Brunner chair of Egyptology, and Dr. J. Share Jones to the chair of veterinary anatomy.

LONDON.—Dr. Sydney Russell Wells has been elected Vice-Chancellor in succession to Sir Cooper Perry, who has been appointed to the post of Principal Officer.

Sir Richard Glazebrook has been appointed to the Zaharoff chair of aviation tenable at the Imperial College of Science and Technology, founded by Sir Basil Zaharoff, who gave to the University the sum of 25,000*l.* for this purpose.

Dr. A. P. Newton has been appointed, as from September 1, 1920, the first occupant of the newly established Rhodes chair of Imperial history tenable at King's College.

Prof. W. Bulloch has been appointed, as from January 1, 1920, the first occupant of the newly established Goldsmiths' Company's chair of bacteriology tenable at the London Hospital Medical College.

The following doctorates have been conferred:—*D.Sc. in Applied Statistics:* Mr. E. H. Chapman, an internal student, of the Sir John Cass Technical Institute, for a thesis entitled "The Application of Statistical Methods to Meteorological Problems." *D.Sc. in Botany:* Mr. S. C. Harland, an internal student, of King's College, for a thesis entitled "Manurial Experiments with Sea Island Cotton in St. Vincent." *D.Sc. (Engineering):* Mr. N. A. V. Piercy, an internal student, of East London College, for a thesis entitled "On the Flow in the Rear of Aerofoils."

Dr. Thomas Lewis, of the cardiographic department of University College, has been awarded the William Julius Mickle fellowship, of the value of 200*l*., in recognition of the important work which he has carried out on the nervous mechanism of the heart.

OXFORD.—Dr. F. W. Keeble, who has been elected to the Sherardian professorship of botany in succession to Prof. S. H. Vines, was formerly professor of botany and dean of the faculty of science at University College, Reading. In 1914 he was appointed Director of the Royal Horticultural Society's gardens at Wisley, and in the following year became concurrently Director of Horticulture in the Food Production Department of the Board of Agriculture. Since last year he has been Assistant Secretary to the Board.

DR. FRITZ PANETH has recently been appointed to a professorship in chemistry at the University of Hamburg, which was founded in the spring of this year. After obtaining his doctorate at the University of Vienna Dr. Paneth proceeded to England, and worked for some time in the laboratories of Prof. Soddy at Glasgow, and of Sir Ernest Rutherford at Manchester. Later he was chemical assistant in the Radium Institute at Vienna, and after the appointment of Prof. Hönigschmid to a chair of chemistry at the University of Munich in 1917, Dr. Paneth directed the work of the chemistry department of the German Technical High School in Prague.

THE University of Manchester, which before the war was preparing to issue an appeal for funds to enable it to make due provision to meet its expanding needs, has now made, in addition to that of the College of Technology, which requires 150,000*l*. for its much needed extension, an appeal for a sum of 500,000*l*., towards which 76,000*l*. has been promised, in addition to 10,000*l*. for a chair of colloid chemistry as announced at the public meeting held in the Town Hall on December 9, to meet the urgent demands which, among other claims, the great influx of students in all departments has made upon its resources. There was recently opened a large new building for the faculty of arts (languages, literature, history, and philosophy), which, as a consequence, enables the departments of chemistry, engineering, medicine, and commerce to be accommodated more adequately. But the pressure, especially in respect of students in medicine and chemistry, and the growing need for facilities in economics, sociology, and courses of training for social work, cannot be satisfactorily met in present circumstances. A new system of post-graduate training has been instituted and a new degree therein established, which is certain to retain and attract a large body of well-prepared students to the great advantage of the University and of all concerned. The provision of hostels is an urgent need, together with that of extra-mural teaching in tutorial classes, for which there is a strong demand on the part of working men and women throughout the area covered by the University. A considerable increase in equipment, and especially in that of the teaching staff, in all departments is a pressing requirement, and altogether, having regard to the supremely and increasingly important place the University takes in the life of the city and district, makes this appeal for a large addition to its financial resources one that should commend itself to the liberal support of the great and wealthy community which it so effectively serves.

A DEPUTATION of members of the governing body of the Imperial College of Science and Technology, introduced by Lord Crewe, and received on December 15 by Mr. Balfour and Mr. Fisher, put forward the request that the college should be empowered to award degrees, either by being constituted a university or by granting its own degrees as a college. At present each of the constituent colleges of the Imperial College grants its own diplomas in the form of associateships of the Royal College of Science, the Royal School of Mines, and the City and Guilds' Institute respectively, while the Imperial College itself awards a diploma for a course of advanced work. There is, however, a great difference in the market values of a diploma and a degree, and it is on this account that the movement to make the college a degree-conferring institution has the support of most past and present students. The question of constituting another university in London has already been considered by two Royal Commissions and adversely reported upon, and the demand for the foundation of the new university will need to be strongly supported before it can have the promise of success in the face of these two reports and of the certain opposition of London University. The simplest course, and the one that would arouse least opposition, would be to grant the college the power of conferring degrees. Whichever plan is adopted, it is to be hoped that the position of past students of the constituent colleges will be effectively safeguarded. We assume that, whether the Imperial College grants a degree or a diploma, adequate provision will continue to be made for the study of pure science. It is becoming increasingly difficult to obtain the necessary funds for carrying on scientific research not directly concerned with industry, and the neglect of this part of the work of the college would eventually have a disastrous effect on technical education and industrial progress. A strong case can, no doubt, be made out for several distinct universities in London, and the appeal made on behalf of the Imperial College has been followed by a letter from Profs. W. H. Bragg and E. H. Starling in the *Times* of December 22, in which like claims are made for the freedom of King's College and University College "as regards teaching, research, and the granting of degrees."

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 11.—Sir J. J. Thomson, president, in the chair.—C. F. U. **Meek**: A further study of chromosome dimensions. The degree of somatic complexity of an animal cannot be correlated with (*a*) the lengths of the chromosomes composing its complex; (*b*) the diameters of the chromosomes composing its complex; (*c*) the total volume of the chromosomes composing its complex; and (*d*) the number of the chromosomes composing its complex. There are many different chromosome diameters. The chromosomes composing the spermatogonial complex of an animal are not necessarily identical in diameter with those composing its secondary spermatocyte complex. All chromosomes composing an individual complex are not necessarily of the same diameter.—J. M. H. **Campbell**, C. G. **Douglas**, and F. G. **Hobson**: The respiratory exchange of man during and after muscular exercise. Support is given to the view that muscular work may involve the metabolism of a higher proportion of carbohydrate to fat than is the case during rest. In the case of the severer degrees of work, serious shortage of oxygen, as indicated by the production of lactic acid, may lead in the earlier stages of the exercise to temporary great exaggeration of the hyperpnœa, accompanied by washing out of preformed CO_2 from the body and an abnormally high respiratory quotient, phenomena which are absent in the case of lighter work.—A. D. **Waller**: The energy output of dock labourers during heavy work. Part i. The paper contains the results of observations on dock labourers by a simplified method, which consists in measurements of the CO_2 discharge at convenient intervals throughout the working day or night with the least possible interruption of work.—J. **Gray**: The relation of spermatozoa to certain electrolytes (ii.). The paper embodies an attempt to apply the facts of recent chemistry to the behaviour of the living cell.

Royal Anthropological Institute, December 9.—Sir Everard im Thurn, president, in the chair.—J. H. **Hutton**: Leopard-men in the Naga Hills. The Naga tribes generally regard the tiger as having the same origin as man, in that the first tiger and the first man were brothers, sons of one mother. No clear distinction is drawn between leopards and tigers, the same word being ordinarily used for both animals. The practice of lycanthropy among the Naga tribes differs from that followed in India, Burma, and Malaysia, in that no actual metamorphosis is believed to take place, in which respect it seems to differ from the form which lycanthropy takes in most parts of the world. The Naga method is to project the soul from the human body into the body of a leopard, usually, but not necessarily, during sleep. By this process the two bodies become intimately associated, and violent emotions affecting the one body are perceptible to the other. On the death of one, the other dies. The acquisition of the powers of a lycanthropist is not desired, but feared and disliked. The practice is assumed involuntarily at the dictation of spirits whose will the subject of it is more or less powerless to resist. The closest parallel to the Naga practice seems to be found in Nigeria, where there are beliefs ("Golden Bough," vol. ix.) which resemble those of the Naga tribes closely. In the Naga Hills and Assam this particular form of lycanthropy seems to be connected with migration from the north as distinct from other immigrations from the east and south.

Linnean Society, December 11.—Dr. A. Smith Woodward, president, in the chair.—Prof. W. A. **Herdman**: Notes on the abundance of marine animals and a quantitative survey of their occurrence. On a former occasion the author considered the plankton food-supply of edible fishes for the purpose of showing the fundamental importance of a very few organisms, about half a dozen kinds of diatoms and the same number of Copepoda. In the present paper he extended the same conclusions to the shallow-water and littoral common animals which are the food of our bottom-feeding fishes.—J. B. **Gatenby**: The germ-cells and early development of *Grantia compressa*. The spermatids of Grantia are described for the first time. They lie inside chambers formed of mesogleal cells. The mitochondria (chromidia) and Golgi apparatus of oocytes and other cells are described.

MANCHESTER.

Literary and Philosophical Society, December 2.—Prof. F. E. Weiss, deputy chairman, in the chair.—C. E. **Stromeyer**: A method by which roots of numbers can be easily and rapidly found by division sums.—L. V. **Meadowcroft**: A discussion of the theorems of Lambert and Adams on motion in elliptic and hyperbolic orbits. Lambert's theorem (1761) on the motion of a body in an elliptic orbit, under the influence of a central gravitational force, can be stated in the following purely geometrical form. The area of any focal sector of an ellipse can be expressed in terms of the focal distances of its extremities, of the chord which joins them, and of the axes of the ellipse. To J. C. Adams is due the most elegant form of the proof. The present author shows that this can be translated from analytical into geometrical terms. An independent proof based on geometrical considerations is thus suggested. Such a proof is given, and also an analogous proof for the corresponding theorem on the area of a focal sector of a hyperbola.—W. E. **Alkins**: Morphogenesis of *Reticularia lineata*. After a *résumé* of earlier work (including Day's) on variation in Brachiopoda, by using Day's specimens the author had constructed skeleton solid figures showing the distribution of length and width, and of length and depth, among 945 individuals of *Reticularia lineata*, Martin, from a restricted locality in the Carboniferous Limestone of North Derbyshire. Day's conclusions were confirmed. The ratio of width to length and of depth to length throughout the series showed that in the development of the individual shell the width and length were connected by a linear function, whereas the depth and length, though related by a linear expression up to a certain size, were connected by a logarithmic function over the greater portion of the range covered by the specimens. The transition from the linear function to the logarithmic relationship was perfectly gradual and continuous.

DUBLIN.

Royal Dublin Society, November 25.—Mr. R. Ll. Praeger in the chair.—T. G. **Mason**: Electrolytes in the leaf-sap of *Syringa vulgaris*. Determination of the dissolved electrolytes of the cell by means of conductivity measurements is largely vitiated by the influence of the viscosity of the solvent. Correction by means of direct measurement of the relative viscosity of the sap is shown to be unsatisfactory. By introducing a known concentration of an electrolyte into the sap and by comparing its conductivity in the sap with that in water, it is possible to obtain a closer estimate of the amount of electrolytes in the sap corresponding with the observed conductivity of the sap. Fluctuations in the electrolyte content of the sap appear to be in the inverse sense of those of the soluble carbohydrates. It is suggested that the concentration of the dissolved electrolytes may be directly or indirectly controlled by the osmotic pressure of the sap.—L. B. **Smyth**: The Carboniferous coast section at Malahide. Between Malahide and Portmarnock, Co. Dublin, an outcrop of Carboniferous Limestone rocks occurs, extending for about a mile along the sea-shore, and having a general dip to the north. This exposure was mapped by the Geological Survey. One fault was shown, separating a smaller southern portion from the rest. This southern part was considered to be older than the remainder, and to have been brought *up* by the fault. It was assigned, chiefly on lithological grounds, to the Lower Limestone Shales. The author maintains, on both structural and faunal grounds, that it is really the youngest part of the section, and belongs to Vaughan's "C" zone, the part north of the fault being assigned to the "Z" zone and the base of "C." The throw of the fault was estimated to be at least 780 ft. Two other faults are pointed out. One, in the middle of the exposure, causes a repetition of "Z" beds, and has a downthrow of 330 ft. to the south. The other, to the north of this, throws in the opposite direction, and is probably slight. Three new species of corals are described of the genera Michelinia, Zaphrentis, and Endophyllum.—J. J. **Dowling**: An apparatus for the production of high electrostatic potentials. The apparatus is an influence machine which transforms a battery voltage of, say, four hundred to, say, five hundred volts. The ratio of transformation can be adjusted, and the high potentials are remarkably steady. An earthed disc is carried to and fro, being fixed to the end of a rod which is given a reciprocating motion by an eccentric device. A contact-maker is mounted on the eccentric shaft, and this alternately connects a fixed insulated disc, mounted opposite the earthed disc, alternately to the battery and to the apparatus which is to be maintained at the high potential. One pole of the battery is, of course, earthed.

BRITISH IRON ORES.

Special Reports on the Mineral Resources of Great Britain. Vol. viii., *Iron Ores: Haematites of West Cumberland, Lancashire, and the Lake District.* By Bernard Smith. Vol. ix., *Iron Ores* (continued): *Sundry Unbedded Ores of Durham, East Cumberland, North Wales, Derbyshire, the Isle of Man, Bristol District and Somerset, Devon and Cornwall.* By T. C. Cantrill, Dr. R. L. Sherlock, and Henry Dewey. Vol. x., *Iron Ores* (continued): *The Haematites of the Forest of Dean and South Wales.* By Prof. T. Franklin Sibly. (Southampton: Ordnance Survey Office, 1919.) Prices: Vol. viii., 9*s*. net; vol. ix., 3*s*. 6*d*. net; vol. x., 4*s*. net.

AS is well known, one of the effects of the recent war has been to direct the attention of the British people to the wealth of the mineral resources of their own country, whereupon it soon became apparent that accurate official information as to the nature and extent of these resources was conspicuous only by its absence. Fortunately, the Director of the Geological Survey, Sir Aubrey Strahan, took immediate steps to rectify this deficiency, and a series of volumes on the mineral resources of Great Britain has been issued under his direction; the last three of these have just been published. These are the opening volumes of a set dealing with British iron ores, and Sir Aubrey Strahan has written a short preface to the first of them, in which he indicates the general scheme which it is proposed to follow. He divides the British ores into "three classes, namely, those products, mostly hæmatites, which occur as replacements, in lodes, etc.; the bedded ores of Mesozoic age; and the bedded ores of Palæozoic age."

This classification is a quite satisfactory one, though the use of the word "lodes" in the above description may well be objected to if it is intended to imply that replacements and lodes are equivalent terms. A typical replacement deposit is certainly not a typical lode; the latter term is identical in meaning with vein, and ought to be restricted definitely to mineral deposits filling fissures, which show for the most part well-defined walls, and have a fairly regular form, so much so that authorities like, *e.g.*, Sir Clement Le Neve Foster, have made them a subdivision of the tabular or sheet-like deposits. It is quite true that the walls of a lode generally show more or less alteration due to the same causes that brought about the filling of the lode itself, and that this alteration may take the form of impregnation or of more or less complete replacement of the country rock, but this fact does not justify calling the lode a replacement deposit. The typical replacement deposit, on the other hand, is, as a rule, quite irregular in outline, and if it does at times assume a tabular form, this is due to accidental conditions, and is certainly not a genetic characteristic.

The three volumes now issued cover the first of Sir Aubrey Strahan's classes, and form geologically the most interesting, but economically the least important, of the three; in fact, it is only the ores described in vol. viii. that possess any economic importance whatever. As regards the economic aspect, it may be considered unfortunate that the authors of the three volumes have put forward statements as to what they consider the probable ore reserves contained in the mineral fields that they have investigated. In the case of irregular deposits, such as are here dealt with, this is a problem of exceptional difficulty, seeing that the data for its solution do not exist, and sound estimates of quantity are impossible; the best that can be done is to make a more or less intelligent guess, and under these conditions the best possible guess is likely to be very wide of the mark. Such speculations are somewhat out of place in an authoritative Government publication, and it is greatly to be feared that heavy money losses may be incurred by adventurers who do not discriminate between the geologist's idea of the quantity of ore that may be supposed to exist and the miner's view of the amount that can be economically extracted.

Apart from his attempt at estimating the probable ore reserves, Mr. Bernard Smith's volume on the West Coast hæmatites is in every respect a very satisfactory one; here the difficulty of forming any opinion as to quantity is peculiarly striking. Owing to the soft nature of the ore and to its highly irregular mode of occurrence, ore reserves cannot be blocked out for any length of time in advance, and there is rarely, if ever, any "ore in sight" in the accepted sense of that phrase, although mines have continued for many years, and will doubtlessly continue in the future, to produce considerable quantities of ore by the hand-to-mouth methods of exploitation which the nature of the deposits renders necessary in the great majority of cases. The volume gives a short but sufficient and very clear description of the geology of the district, and the mode of formation of the ore bodies is described in very convincing terms. It seems impossible to doubt that the ore was deposited metasomatically, as Mr. Smith asserts; he has, however, avoided the more difficult question, namely, whether the ore was first deposited as a carbonate or as a hydrate, and afterwards metamorphosed to red hæmatite, or whether it was deposited in practically the same form as we now find it. He concurs in the generally received opinion that the iron-bearing solutions were introduced from above, but says nothing as to the theory strongly held by many that these solutions were the result of the leaching out of iron from the New Red Sandstone, which may be presumed at one time to have overlain the whole of the iron-bearing region. The greater part of the book is taken up with a careful, detailed description of the mines, the area being, for the sake of convenience, divided into the Egremont and Whitehaven districts of Cumberland, the Furness district of Lancashire, and the far less important occurrences in the Lake district. Existing mines are fully described under the heads of geological occurrence and mining details, whilst information as to the old and abandoned mines has also been collected. The volume forms a very valuable and welcome addition to our knowledge of this important mineral area.

Vol. x., by Prof. Sibly, is geologically the most important of the three, as it has involved a careful geological study of the Forest of Dean coalfield, with which the iron ores of the Forest are necessarily closely connected. Much new matter has thus been brought to light, and as a result of his work Prof. Sibly has succeeded in proving two important geological facts—one that the Millstone Grit of the Geological Survey is in fact a sandy facies of the dolomitised upper portion of the Carboniferous Limestone, and the other that there is an important unconformity between the Coal Measures and the underlying rocks; it need scarcely be said that there is a close connection between these two facts. This is the first time that a systematic study of the iron ores of the Forest of Dean has been attempted, and Prof. Sibly deserves the highest praise for the manner in which he has unravelled the complex problems that the geology of the district presents. Unfortunately, this field cannot pretend to any economic importance commensurate with its geological interest. The ores, as Prof. Sibly shows, are of relatively shallow occurrence, and have been practically worked out; it is indeed fortunate that the study of this field has not been deferred much longer, for in that case there would probably have been no mines open for the geologist to consider. Prof. Sibly guesses the total amount of ore reserves still existing at about a million tons, but it is very doubtful whether anything approaching this figure will be produced here, and his conclusion "that the Forest of Dean is not far from exhaustion as a source of iron ore" is fully warranted by the facts. The second part of the volume is taken up with a description of a small group of iron-ore mines in the Carboniferous Limestone that forms the south-eastern margin of the South Wales coalfield, extending between Taffs' Well and Llanharry; out of the five mines that have been active in this area, only one, the Llanharry mine, is now at work, producing 50,000 to 60,000 tons yearly; this mineral occurrence is fully described, and particulars are given of the abandoned mines also. In a concluding chapter Prof. Sibly discusses the genesis of all the ores dealt with, and in agreement with most other authorities he looks upon them as undoubtedly of metasomatic origin, due to descending iron-bearing waters; he seems inclined to seek the source of the iron in the Triassic rocks that once probably covered the Forest of Dean area and in the Conglomerates and Red Marls of the Keuper in the South Wales district. The volume contains a mass of interesting information upon the area studied, and as regards the Forest of Dean must rank high as a piece of first-class geological research.

Vol. ix. includes a number of miscellaneous occurrences in different parts of the country, of very various character. It is greatly to be regretted that it falls very far below the high standard to which the other two volumes have attained. It is not improbable that the time allotted to the investigation of each deposit was insufficient, but, whatever be the cause, there are no signs of the painstaking thoroughness which characterises the work already discussed. This volume leaves the impression that the authors merely accepted what they were told in each case, and did little actual field work, or, at the best, only looked at what was shown them. They have thus in many cases arrived at a wholly exaggerated opinion of the importance of the deposits they describe. For instance, in describing the Sharkham iron-ore mine, the authors state that "the amount of ore in sight is considered to be large," whereas as a matter of fact there is very little ore in sight, and they seem never to have heard of the deep adit driven in below the deposits, which runs wholly in barren limestone, and shows that the occurrence is strictly limited in depth. It would serve no useful purpose to multiply examples of such oversights; it is, however, fortunate that none of the occurrences described in vol. ix. have any real economic importance.

The Geologial Survey and the country may both fairly be congratulated on the continuation of Sir

Aubrey Strahan's special reports, and it need scarcely be said that the further volumes dealing with the other two classes of iron-ore occurrences will be eagerly awaited by the large body of workers interested in British iron ores.

H. LOUIS.

ALCOHOL.

Alcohol: Its Production, Properties, Chemistry, and Industrial Applications. With Chapters on Methyl Alcohol, Fusel Oil, and Spirituous Beverages. By Charles Simmonds. Pp. xx+574. (London: Macmillan and Co., Ltd., 1919.) Price 21*s.* net.

MR. SIMMONDS, one of the senior analysts in the Government Laboratory, is well qualified by his position to undertake the compilation of this book, since his duties have rendered him familiar with his subject in all its aspects—its production and industrial applications, its chemistry, and its special relations to the revenue.

The work treats of the early history of alcohol; its origin and composition; its production by fermentation and by synthetic processes; the nature of the materials employed; the biochemical agents involved; and the general operations of distillation and rectification. The author devotes a chapter to the general chemistry of the homologues with which ordinary or ethyl alcohol is associated, either as a product of fermentation, or in industry as methylated spirit. He is, by virtue of his office, naturally concerned with the analytical chemistry of these alcohols, especially of ethyl and methyl alcohol, and with the subject of alcoholometry, in this country and abroad, and he writes with special knowledge and authority. He gives a sufficiently full account of the fiscal relations of ethyl and methyl alcohol and of the different forms of "denatured" alcohol, as used in industry; treats of various spirituous beverages, their origin, nature, and chemical examination, and concludes with a concise statement of what is definitely known concerning the physiological properties of alcohol. It will be seen from this short summary that the book constitutes a comprehensive treatise in which practically everything relating to alcohol finds a place. It is, of course, essentially a compilation from numerous sources, the range and extent of which may be inferred from the excellent bibliography appended to the work. But the compilation was well worth making, and has resulted in a complete and well-arranged monograph; it is eminently readable, and the information is sound, accurate, and up to date.

Although the practical brewer and distiller will find much in it that will be of use to them at times, the book is not primarily intended for use in the brewery or the distillery. Technical details, such as are to be found in standard treatises on brewing and distilling, and which are the subjects of the trade journals, would be out of place in a work of this kind, where alcohol, as such, is the main consideration.

For the commercial production of alcohol from wood by Classen's process, or some modification of it, there is apparently no future in this country, and it would seem to be doubtful whether any permanent success will be possible even in countries where wood-waste is more plentiful than with us. Alcohol from sulphite-waste liquor in the manufacture of wood-pulp is, however, being produced in considerable quantities in Sweden and elsewhere, and bids fair to become an important industry. Synthetic alcohol from acetylene, derived from calcium carbide, has been made in Germany by methods which were largely developed during the war, mainly in consequence of the shortage of potatoes. It remains to be seen whether the manufacture will become permanently established. The synthetic production of alcohol, if greatly extended, would be certain to produce considerable economic disturbance in Germany, and would also occasion much perturbation in agrarian circles. The danger was foreseen by the late Government, which, by the Spirit Monopoly Act of 1918, placed the manufacture of synthetic alcohol under the control of the State.

In describing the properties of methyl alcohol, the author rightly lays stress on its toxic character. It is far more dangerous than is generally known. It is alleged that the shortage of whisky during the past four years has led to a great increase in the drinking of methylated spirit. Ordinary mineralised methylated spirit, which is the only form to which the public has ready access, contains wood naphtha and a certain amount of mineral naphtha, in addition to ketones and other substances, and is a very noxious beverage; its habitual consumption quickly results in blindness, paralysis, and death. The detection of the presence of methyl alcohol in mixtures containing ethyl alcohol has naturally received much attention in the book. The matter is of fiscal importance, in view of possible illicit attempts to use "denatured" alcohol instead of duty-paid spirit. It has given rise to an abundant literature, a critical synopsis of which is given by the author, to whom the problem has a special professional interest. Many of the methods described are highly sensitive and characteristic, and there is no practical difficulty nowadays in recognising the presence of methyl alcohol in alcoholic mixtures or in ascertaining its amount.

The author deals with the question of alcohol as a fuel, especially in the internal-combustion engine, and gives details of the results of special investigations which have been made in America and in Australia to elucidate its relative advantages as compared with other forms of motor spirit. Lastly, his chapter on the physiological effects of alcohol gives a careful summary of our present knowledge of its action on the human organism, mainly based upon the report (published in 1918) of the Committee appointed by the Central Board (Liquor Traffic) of the United Kingdom. It is a well-balanced and impartial account of established fact concerning a most important subject, intimately related to the national welfare.

The book is well illustrated; indeed, this, perhaps, constitutes its only demerit; the necessity to use so-called "art" paper throughout in order to reproduce the large number of "process" figures adds greatly to its weight, and thus detracts from its general utility. We would willingly have dispensed with many of the pictures, some of which add little or nothing to the attractiveness or usefulness of the book. Its convenience in handling, and as a work of reference, would thereby have been increased.

A GREAT ARTIST OF NATURE.

A Naturalist's Sketch Book. By Archibald Thorburn. Pp. viii+72+60 plates. (London: Longmans, Green, and Co., 1919.) Price 6 guineas net.

ALL artists are more or less influenced by the work of some previous craftsman whose technique they admire, and it is no detriment to the achievements of so superb an artist as Archibald Thorburn to say that on him has fallen the mantle and style of Joseph Wolf, the greatest artist of bird and mammalian life the world has ever seen. Thorburn himself admits this influence, and renders an adequate tribute to the bygone master. Yet, whilst the care and delicate handling of birds, mammals, landscape, and natural features bear some similarity in their rendition to Wolf in treatment of form and sense of beauty, Thorburn's style is all his own and distinctly original. In one respect, at least, and that a most important one, he excels even Wolf for the beauty, accuracy, and strength of his colour. This has never been surpassed by any artist of ancient or modern times in water colour.

In the work before us we are presented with a series of finished sketches, mostly in colour, and drawn direct from life. Having for his models the most restive and elusive of all sitters, the average artist is content to draw roughly in pencil characteristic poses, and then has to rely for colouring in his details of feather and fur on such skins or stuffed specimens as he is able to procure. Thorburn, it is true, uses only such aids *afterwards* to correct the coloured sketches he makes direct from Nature, and thus he obtains the proper lighting and the real effect of fur and plumage as it is in Nature. Thus he gives us a perfectly satisfactory representation of the creature depicted, and with all the effect of true colour without ultimate studio work, which is always liable to inaccuracy. No one, unless he is an artist himself in this difficult line, has any idea of the rapidity, skill, and accuracy of observation that are required to be *always* successful, and whilst it may be said that even Thorburn occasionally fails slightly in his drawing, 99 per cent. of his work is beyond criticism, and perfectly successful.

In no family of birds is Thorburn more complete in his knowledge than in the case of the game birds and raptorials. His eagles, falcons, grouse, partridges, and black game are drawn from life with a dexterity that is amazing. He puts a wealth of colour and a "bloom" on his plumage that we who know these birds best are left in wonder at his skill. There are just the right softness and rotundity all done with a few unlaboured washes. Details of the plumage in the form of primaries, secondaries, scapulars, and tail are, in the case of each species, rendered with exactly the right number of feathers. No point that is characteristic of any species is lost. A golden eagle in repose shows just the one fluffy feather on the flank, and in flight the striking whites of the under-feathers, which show only when the bird is in movement. We do not need to be told that the series of sketches of game birds, hawks, owls, and smaller perching birds are drawn direct from life, because here, in this beautiful volume, we who are naturalists see them as they really are in all the beauty of life and movement. Perhaps Thorburn is more successful with creatures in repose than in intense action, but this may be due to the fact that the public prefers birds and mammals in their quieter moods, and he likes to render them so.

Probably the artist's work is most successful because he takes such infinite care with all his details before attacking his finished pictures. If he has to do a plate for some work, one or two coloured figures from life are not sufficient. He draws carefully all the "soft" parts, such as feet, bills, and eyes, directly from some dead or living specimen, and thus gains a first-hand knowledge of the whole creature before commencing his final essay.

The text which the artist supplies of how and when he made his sketches, supplemented with original observations of the habits of birds and mammals, is both adequate and interesting. At the end of the volume are some beautiful studies of landscape and plant life, notably the exquisite sketch of a thistle (plate 60), snow-covered furze and pines (plate 58), the eagle's hunting-ground (plate 57)—a perfect handling of the high tops—and pheasant covert (plate 56).

The volume will do much to enhance the reputation of Archibald Thorburn as an artist, and those possessed of the necessary wealth have the opportunity of purchasing something that will live as long as the taste for Nature, high art, and beauty continues—and that remains for ever.

It is an unfortunate truism that few men, least of all artists, are recognised as supreme craftsmen during their lives. The day is coming shortly—if it has not already arrived—when the public, and even art critics, will awake to the fact that this century has produced two great artists of Nature—namely, Joseph Wolf and Archibald Thorburn—and those who possess a complete set of the work of these two masters will be very fortunate.

In the volume under review we notice only two slight errors. We have never seen a white-tailed eagle (plate 4) so dark as the specimen figured, nor have we observed a green cormorant (plate 36) with a "bushy" crest of the shape depicted.

J. G. M.

SUBMARINES AND SEA POWER.

Submarines and Sea Power. By Charles Domville-Fife. Pp. viii + 250. (London: G. Bell and Sons, Ltd., 1919.) Price 10*s.* 6*d.* net.

The author has already written several books dealing with the development of submarines and also with their exploits on actual service under war conditions. In the present volume an attempt is made to discuss the influence of the submarine, now an important weapon in naval warfare, "on national life in time of war in order to awaken those who administer the empires of to-day and to-morrow to the need of provision against a new and growing menace which has changed the older theories of sea power."

Much of the matter in this book has already been covered in the author's previous publications, particularly that in the chapters on the evolution of the submarine. The difficulties of navigating the submarine, the restrictions imposed by limited depth of water and other hydrographical features, the conditions for favourably attacking an enemy and for escape from one, and other factors dealing with the employment of submarines, are dealt with in some detail, particularly in so far as they affect the use of naval power. The immediate effect of the German submarine menace upon our "sea power" during the Great War is discussed, and the author makes some suggestions based on our recent unpleasant experience for the guidance of future administrators.

So long as details of construction and of working the submarines are under review, the author is on safe ground, but in developing general arguments, in stating his premises, in the marshalling of his facts, and in selecting his language, he is not so happy. A plaintive appeal is made in the preface that the book may be read to the end before any definite opinion is formed. The appeal is necessary.

The author has not considered his subject on broad lines. When one has defined a submarine as a mobile ambush which can be set not only on this side of an enemy, so that he will have to encounter it in his advance, but also well within the enemy lines without incurring any serious risks, and with a considerable degree of protection by reason of its power of submergence, whilst retaining its powers of observation, the serious restrictions it imposes upon the movements of a surface fleet become almost obvious. The submarine affects enormously the tactics of a surface fleet, but the experience of the war has not shown that the submarine has appreciably altered the application of naval strategy. It will alter types of ships.

A picture is drawn or suggested of what might have happened to our sea-borne commerce had Germany possessed at the outbreak of war 1000 high-powered submarines. Such a picture is not instructive in any way in regard to the future aspect of the submarine question. The success of the German submarine—for it was undoubtedly a most successful weapon for harassing our sea power—as a matter of fact lay in its surprise application contrary to the Hague Convention. Had Germany possessed 1000 submarines Britain would have had in all probability 10,000 partial antidotes. Fortunately, such favourable conditions for surprise by submarine cannot occur again. A measure of the success of submarine activities is obtained from the book, in which it is stated that 600 merchant ships and fifty warships were destroyed, and that 1500 patrol ships, with guns and ammunition and depth-charges, and 2000 minesweepers had to be built or used in combating submarines.

The chapters at the end of the book dealing with sea power and some economic and international problems should be read. Attention is directed to the necessity for the revision of international law and to its enforcement in regard to matters affecting the mercantile marine. International law as developed from previous war experience must of necessity be inapplicable to wars such as that just concluded, in which, instead of small navies and armies, we had nations in arms when every import is almost certain to be contraband.

The title given to the book brings disappointment, for the author does not give a general treatment of the effect of the submarine upon sea power in the future. He pictures many trees, some of the soil, much undergrowth, but one never seems to see the forest. A. B. T.

OUR BOOKSHELF.

Studies in the Construction of Dams: Earthen and Masonry. Arranged on the Principle of Question and Answer for Engineering Students and Others. By Prof. E. R. Matthews. Pp. v+43. (London: Charles Griffin and Co., Ltd., 1919.) Price 4*s.* 6*d.* net.

We gather from the preface that this little book is intended to be of assistance to students preparing for the examinations of the Institution of Civil Engineers, the B.Sc. (Engineering) of our universities, or other similar examinations. The text is arranged in the form of "question and answer," and includes references to some of the more important dams constructed in different parts of the world. Students who are pursuing systematic courses in the principles of engineering will find a good many statements open to criticism. Thus, at the foot of p. 1, we read: "In a low dam BC may be taken as being equal to AB." ABC is the pressure diagram, and surely this statement regarding BC is not independent of the scale of pressure employed. Again, on p. 1: "The centre of pressure passes through the centre of gravity of this triangle"; and on p. 9: "The centre of pressure acting at a point H/3 above base." On p. 3, r^bH^2 should read rbH^2, and there are several other misprints. On p. 4 the reader is told that the weight of the wall will act through the centre of gravity of the section, but receives no directions as to how to find this point, although space is wasted on p. 25 in answering the questions how to find the centre of gravity of a triangle and parallelogram. We hope that questions such as No. 7, p. 15, do not occur often in professional or university examinations: "What are the suggestions made by Molesworth relative to the thickness of high and low masonry dams?" On p. 16 we read some curious statements, and quote a typical one: "g=specific gravity of the masonry=for light masonry 130 lbs. per square foot=2·08." It is not possible in the limits of a short notice to deal with every point which might be criticised, but probably enough has been said to justify the conclusion that it would be well to give the book a thorough revision.

Immune Sera: A Concise Exposition of our Present Knowledge of Infection and Immunity. By Dr. C. F. Bolduan and J. Koopman. Fifth edition, thoroughly revised. Pp. viii+206. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1917.) Price 7*s.* net.

The present edition of this book has been revised throughout, and fresh details have been inserted where necessary. It gives an excellent and, on the whole, a simple account of the salient facts connected with infection and immunity, antitoxins and other sera, cytotoxins, opsonins, vaccines, and other reactions of immunity, and the practitioner will find it a trustworthy guide to modern views on these subjects. We suggest that the details of the partial saturation method and of "toxin spectra" in connection with antitoxins are somewhat beyond the general scope of the work, and that the space devoted to them might be better employed in extending the more directly practical subject of agglutination. The technique of the Wassermann test for syphilis has been included in this edition in response to many requests for information concerning it. Here, again, we think that the description is too technical for the average reader, and might be simplified with advantage. These, however, are minor faults, if faults they be, and do not in any way detract from the general excellence of the book. Several figures serve to visualise the descriptions given in the text, and the book is very readable.

R. T. H.

Handbook of Mineralogy, Blowpipe Analysis, and Geometrical Crystallography. By Prof. G. Montague Butler. Pp. ix+311+v+80+viii+155. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1918.) Price 16*s.* 6*d.* net.

This book is in three parts, which are separately paged. They are also on sale separately. The first part consists of concise, clearly printed descriptions of the different mineral species, and should prove useful for their recognition by the student or prospector. This will be facilitated by the use of the folding tables of the physical characters of the different minerals, which are a special feature of the work. The second part deals with the blowpipe analysis of minerals. Here also the results are set out in a convenient tabular form. The third part, which is devoted to crystallography, is not so satisfactory. The author has a system peculiar to himself of describing crystal symmetry which is by no means clear. He is also exceptional at the present time in retaining the Weiss system of notation of crystal faces.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Atomic Energy.

REFERRING to the notice of my recent Trueman Wood lecture on p. 420 of NATURE of December 25 last, let me explain that I admitted that we could not at present tap or utilise intra-atomic energy except what is given us spontaneously. But we may claim to be utilising intra-atomic properties, since without some kind of disintegration the right kind of projectiles would not be available. I say clearly in the lecture "it is atomic properties rather than atomic energy that are at present being utilised" in wireless telephony.

Furthermore, although the excitation of healthy retinal nerves is primarily dependent on the energy of incident light, yet the action is as if the atoms of a retinal substance acted as accumulators, storing up an æther disturbance of quite unphysiological frequency until a quantum has been collected, when a stimulating projectile is liberated. If anything like this happens, the energy actually utilised is atomic energy; for if that had no existence, the light-waves would be powerless. There may be pathological cases where optic-nerve stimulus is independent of received luminous energy, but that is a highly undesirable state of affairs.

OLIVER J. LODGE.

Metamorphosis of Axolotl caused by Thyroid-feeding.

THE fact that a diet of mammalian thyroid will induce frog-tadpoles to metamorphose precociously into the adult form is now well established. It is of some interest to find that this diet produces a similar effect in a form which usually does not metamorphose—the Axolotl. This is the larva of a salamander known as Amblystoma, but is remarkable in being neotenic, *i.e.* it normally fails to metamorphose, and attains full size and sexual maturity while keeping its larval characters. Chief among these are the external gills and the fin along the back and both borders of the tail, but the adult also differs from the larva in colour, in shape of head, in the development of eyes and eyelids, in the rounded form of the tail, and, of course, in the use of its limbs for progression on land.

Marie von Chauvin in Germany (*Zeitschr. f. Wiss. Zool.*, vol. xxvii., 1877, and vol. xli., 1885) and E. G. Boulenger in this country (Proc. Zool. Soc., 1913 (2)) have succeeded in getting Axolotls to assume the adult form by forcing them to breathe air, either by keeping them in damp moss or in a gradually diminishing quantity of shallow water.

In conjunction with Mr. D. F. Leney, I have been trying the effect of thyroid diet on Axolotls. Two young specimens, 11·5 cm. and 12·7 cm. long, and therefore presumably between six and twelve months old, were kept in a tank at an average temperature of 15°–16° C. in a depth of water (more than 2 in.) considerably greater than that needed to induce air-breathing. They were fed on ox thyroid, at first three times, and later twice, a week.

The thyroid diet began on November 30 last. On December 15 distinct alterations were visible in colour and in resorption of gills and fin, and on December 17 the stage which is critical in metamorphosis induced by air-breathing (see Boulenger's paper) had been passed, the animals being in Boulenger's stage 6, with only vestiges of gills and fin. On December 19 the next or penultimate stage, with scarcely a trace of larval characters, was reached. The larger specimen, the metamorphosis of which was slightly more advanced, had climbed out of the water up a platform provided for the purpose, and its skin was as dry as an ordinary salamander's. When placed on the table they both walked well, thus differing markedly from the larva, which cannot use its legs efficiently if placed on land. Curiously enough, on the succeeding day the larger animal had returned to the water, where it remained until December 23. It then again left the water of its own accord, and up to the time of writing (December 24) has remained in air. Two other specimens of similar size, fed on worms and kept in shallow water, according to Boulenger's method, have so far shown only minimal changes.

Two points are of special interest. First, the time of metamorphosis—just over three weeks—is much shorter than any previously recorded. Boulenger's larvæ took from twelve to sixteen weeks, Marie von Chauvin's from seven to forty weeks. Secondly, the "critical stage" in the metamorphosis was reached apparently without the animals breathing air at all; *i.e.* two entirely different causes, forced air-breathing and a thyroid diet, can produce the same result—metamorphosis. It was not until December 19 that they were observed to come to the surface for air; and even after that, although possessing no functional gills, they spent much time at the bottom of the water, only occasionally rising to float suspended close below the surface with limbs outspread, after the fashion of newts.

Many interesting problems present themselves, which it is hoped to work out as opportunity offers. Meanwhile, this note is published in the hope that others who possess Axolotls will repeat and develop experiments along these lines. I should be glad to enter into correspondence with anyone intending to work on the subject, with the view of preventing useless overlapping in the working out of the problems that arise; and, further, I should be very grateful if anyone possessing Axolotls, whether young or old, would give me the opportunity of purchasing some, as they are at present very difficult to obtain in the market.

JULIAN S. HUXLEY.

New College, Oxford, December 24.

The Hibernation of the House-fly.

M. DE SEGUY'S discovery of larvæ of *Musca domestica* in the bodies of snails, Dr. J. C. Gahan's observations thereon in the *Times*, and the note in NATURE of December 18 last are very interesting to biologists, but it is most improbable that a winter crusade against the Helicidæ would have any appreciable effect in diminishing the summer swarms of flies.

I am led to this conclusion by circumstances under my immediate observation. Round my house is a large flower-garden in which I work constantly at all seasons, desperately worried in summer by legions of house-flies. In the course of forty years I have never come across one of the larger Helicidæ in this garden; and my head gardener, a very intelligent man and a good observer, assures me that in thirty years he has never seen one in the kitchen-garden, which is distant half a mile from the flower-garden. Slugs abound in both, but the only one of the Helicidæ that is found is a very small species with a thin, flattened shell (? *Helix cellaria*, Müller) and a body too small to accommodate the larva of a house-fly. It is also the reverse of abundant. There must, therefore, be other kinds of *nidus* to harbour the larvæ of *Musca domestica* through the winter.

Monreith. HERBERT MAXWELL.

The Magnetic Storm of August 11–12, 1919.

THE Kodaikanal Observatory magnetographs recorded the "sudden commencement" of this storm on August 11 at 6h. 58m. G.M.T., horizontal force showing an instantaneous rise of 149 γ and vertical force about 35 γ, while the declination magnet was deflected about 1′ towards west. I have measured the three traces, and, after making due allowance for the errors affecting the hour-marks, the following values were obtained:—

	h.	m.
Horizontal force	6	58·0
Vertical force	6	58·7
Declination	6	57·9

Greater weight may be given to the declination result because of the more sharply defined hour-marks in this trace.

It is of interest to compare this result with the times recorded in England in view of the fact that at Kodaikanal the sun at 6h. 58m. G.M.T. was barely three minutes past meridian passage and only 5° north of the zenith. In other words, this observatory was almost at the centre of the earth's disc as seen from the sun, and it might be supposed that the disturbance would have been recorded here earlier than at other places if it is directly due to emanations from the sun.

Apparently the sudden commencement was recorded at Kew "at about 7h. G.M.T.," and at Stonyhurst at 6h. 50m., while at Eskdalemuir the time is given definitely as 6h. 58m., in exact agreement with my result (NATURE, vol. ciii., pp. 483, 505 and 506).

It seems probable that the impulse is simultaneous over the earth to within a fraction of a minute, but it would be interesting to know the limits of error to which the above times are subject, and particularly whether allowance has been made for the rather large error which may be produced by the mechanism for cutting off the light from the sensitive paper at each hour. J. EVERSHED.

Kodaikanal, S. India, November 25.

Deflection of Light during a Solar Eclipse.

DURING a total eclipse of the sun there will be, as I suppose, an increase of density of the air at the central portion of the shadow. If we imagine the normal atmosphere removed, we are left with a residual atmosphere the refraction effects of which will be changes in the normal refraction effects. The whole point is whether, on reasonable suppositions, this residual atmosphere can produce refraction effects of the order of the observed effects that have been attributed to the gravitational field of the sun.

Let us suppose with Prof. Eddington that the portion of this residual atmosphere concerned corresponding to a star near the edge of the sun's disc has a radius of about 150 yards, and let the index of refraction of the residual atmosphere at the central part be μ_2, and that at the circumference μ_1. Then, as I have shown, the displacement will be accounted for if

$$\mu_2=\mu_1\left(1+\frac{7}{10^8}\right).$$

Assuming that the change of density depends only on change of temperature, we have

$$\frac{\rho_2}{\rho_1}=\frac{\theta_2}{\theta_1}=\frac{\mu_2-1}{\mu_1-1},$$

where ρ_2, ρ_1, θ_2, θ_1 are the increases of density and falls of temperature at the centre and circumference.

Thus we have, approximately,

$$\frac{\theta_2-\theta_1}{\theta_2}=\frac{7}{10^8(\mu_2-1)};\quad \frac{\theta_2-\theta_1}{\theta_1}=\frac{7}{10^8(\mu_1-1)}.$$

We must now make some assumption as to the gradient of temperature, and this is a very important point. It would not, I think, be right to make it uniform or approximately uniform throughout a distance of 150 miles. We will assume that in a distance of 150 yards the increase of temperature is 1/100th part of θ_2. This does not seem to be unreasonable.

We then have $\mu_2=1{\cdot}000007$ for the index of refraction of the residual atmosphere at the centre, corresponding to a lowering of temperature of 6·28° C. at the centre and of 6·22° C. at a distance of 150 yards. If we assume that the increase of temperature at a distance of 150 yards is 1/10th of θ_2, we get the fall at the centre 0·63° C. and that at 150 yards' distance 0·57° C. It will be seen that the greater $\frac{\theta_2-\theta_1}{\theta_2}$, the smaller is the necessary fall of temperature at the centre. ALEXR. ANDERSON.

University College, Galway, December 28.

Entente Scientific Literature in Central Europe during the War.

I WAS much interested in reading Prof. Brauner's letter from Prague in NATURE of December 11. Like Prof. Brauner, I was unable to obtain NATURE during the first two years of the war, and I fully appreciate his joy on obtaining your invaluable journal again, after an interval of more than five years.

Prof. Brauner states that from July 30, 1914, "the Austrian Government prohibited for more than four years the circulation of anything printed in England as a punishment for the regard which, especially during the war, we [the Czechs] have always had for your country."

This statement is misleading, for "enemy" periodicals were withheld from the whole of the Austrian Empire, and not from the Bohemians alone. Prof. Brauner is apparently unaware of the fact that, from 1916 onwards, it was possible for institutes of the Austrian universities and technical high schools to obtain scientific periodicals and publications from Entente countries. The enactment which made this possible did not appear to be generally known, but I am aware of two institutions at least, which made application for, and obtained from the Austrian Foreign Office, the necessary permission; and in neither instance was any difficulty experienced.

The Radium Institute of Vienna was one of the institutions concerned, although at that time several Poles (one of them a Russian subject) and the writer of this letter were working there. What is more, the Austrian Foreign Office was not unaware of this "quasi-international" character of the Radium Institute!

Books were also obtainable, and I know of several men of science of Vienna, Budapest, and even of Prague, who were granted permission and obtained books from France and England through neutral countries.

A few months before the armistice I remember sitting in a Viennese restaurant at the same table as a gentleman, who was voraciously devouring the contents of the *Sketch* and the *Illustrated London News*. To judge from his frequent unsuppressed laughter, one would have thought he was scanning the pages of *Punch*. Not having seen these periodicals for nearly five years, my interest and curiosity were aroused, and I asked this gentleman's permission to see them. His reply was very emphatic: "Das ist ja ganz unmöglich!" I gathered from his further conversation that he belonged to the Intelligence Bureau of the Austrian Foreign Office, and that his work consisted in reading such journals. I envied him, but could not suppress my feelings of astonishment at his reading such "ganz geheimen Dokumente" in a public restaurant.

It may be mentioned in conclusion that Germany was much more liberal than Austria about the circulation of Entente publications. At least until the later months of the war, it was possible to go into any of the larger *cafés* of the German cities and enjoy a cup of coffee-substitute over a copy of the *Times, Le Temps, Secolo,* and various other newspapers of the Allied countries.

ROBERT W. LAWSON.

The University, Sheffield, December 17.

Royal Meteorological Society's Phenological Returns.

WITH 1920 the phenological returns complete the thirty years, which period is a recognised critical epoch in meteorological records.

In consequence of the war, our observing stations fell to 110 in 1918, against the high-water mark of 132 in 1914. We are most anxious now to recover lost ground, and would in this respect like to make 1920 preparatory to the years to follow.

A reasonable total would include at least 220 stations, an average of twenty only for the eleven Meteorological Office districts. At present we are short of this in all but South-east England and the Midlands. The six districts forming Scotland, Ireland, and North-east England average only 3½ each. Wales has two stations only, both in the south-west.

The observations asked for refer to the blooming of thirteen common flowers and the appearances of six birds and six insects. Other migrant records and notes are also invited, but these are of secondary importance.

A copy of the observing form and of a recent report will be sent with pleasure (the reports so far as they are available) to any readers of NATURE who would be interested to help.

We especially suggest the value for all interested in Nature-study and regional survey classes.

Inquiries should be addressed to one of us, or to the Assistant Secretary, Royal Meteorological Society, 70 Victoria Street, S.W.1.

Einstein's Theory and a Map Analogue.

I AM grateful to the Director-General of the Ordnance Survey for directing my attention to an inaccuracy in my article in NATURE of December 11, p. 375. It was there stated that it is not possible to strain a map of the earth's surface so that all great circles become straight lines.

This is clearly contrary to the known fact of the central projection. As a matter of fact, the sphere is one of the limited class of surfaces for which it is possible to strain all geodesics into straight lines. For an arbitrary surface this is not true. The difference between the properties of the sphere and of the general surface gives a fair indication of the geometrical notions at the back of Einstein's theory.

E. CUNNINGHAM.

THE SUN DANCE OF THE TETON SIOUX.

AS man advances in the scale of culture he loses his dependence on Nature. The dweller in a modern city relies chiefly on artificial means for his pleasure and comfort, but the American Indian realised that his whole success depended on his co-operation with natural forces. He studied his surroundings and evolved a system of reasoning by which he attempted to explain them. A thoughtful Sioux Indian said to the writer: "When we see the changes of day and night, the sun, moon, and stars in the sky, and the changing seasons upon the earth, with their ripening fruits, anyone must realise that it is the work of someone more powerful than man. Greatest of all is the sun, without which we could not live. The birds and the beasts, the trees and the rocks, are the work of some great power."[1] Having recognised a creative power with the sun as its most important manifestation, it was a natural step in native logic to regard the sun with a reverence that is best expressed by the word "worship."

While the worship of the sun, in various forms, was widespread among the Indians of North America, the sun dance was a ceremony the observance of which was limited to certain plains tribes. The sun dance among the Santee Sioux differed in some respects from that of the Teton Sioux, which is herewith presented, but the underlying idea is the same. The sun dance was "the first and only religion of the Sioux," and even at the present time it is considered too sacred a subject for ordinary conversation. At the opening of the writer's study a member of the tribe said: "If we were to talk of the sun dance there should be at least twelve persons present, so that no disrespect would be shown, and no young people should be allowed to come from curiosity."

The purpose of the sun dance was the public offering to Wakaŋ'taŋka (Great Mystery) of what was strongest in the nature and training of the Indian—namely, his ability to endure physical pain. He did this in fulfilment of a vow made in time of great anxiety or danger, usually when on the warpath. The time of the sun dance was the full moon of midsummer, "when all Nature and even man is rejoicing." Into this joy and beauty, as though to give a greater contrast, the Indian projected his personal suffering. For a month before the sun dance it was customary for the medicine men to "pray for fair weather," singing their songs of magic power, burning sweet grass, and offering their pipes to the sky, the earth, and the cardinal points as they made their petitions. It is said that the oldest men cannot remember the falling of rain during a sun dance.

From long distances the people came and made their camp in a great circle. The dance enclosure was in the centre of this circle, and was about 50 ft. in diameter. Around it was erected a shelter

1 "Teton Sioux Music." By Frances Densmore. Bulletin 61, Bureau of American Ethnology, Smithsonian Institution, Washington, D.C., p. 96. Other direct quotations, as well as the facts herein presented, are from the same work. The Bureau of American Ethnology has kindly given permission to reproduce the illustrations used in this article.

for those who witnessed the ceremony. The sun-dance pole was placed in the centre of the dance enclosure, and near its entrance, which was toward the east, a large drum was placed, the singers being seated around this drum. About 15 ft. west of the pole a square of exposed and finely pulverised earth was located. This was called the "sacred place," and its preparation, as well as the securing and erection of the sun-dance pole, were accompanied by ceremonial songs and action.

The tree for the sun-dance pole was sought as men seek an enemy. It could be cut only by a virgin selected carefully from the tribe, and the song while it was being felled was a song of war. The branches were cut off, and in a triumphal manner the pole was carried to the camp, where it was painted in vertical red stripes by the leader of the ceremony. The people watched the painting and erection of the pole with deep reverence, and listened while the leader sang the sacred songs that had come down to him through many generations—the songs of Dreamer-of-the-Sun. In one of these songs the pole speaks, saying: "Sacred (made holy) I stand"; and after the pole was in position the words of the song were: "Grandfather, at the places of the four winds may you be reverenced. You made me wear something sacred. The tribe sitting in reverence, they wish to live." The "sacred place" was then prepared, the earth being finely pulverised and two intersecting lines drawn in it, forming a cross. In these lines tobacco was placed, then covered with vermilion paint-powder, and over this was spread powdered gypsum, shining white in colour. At the intersection and ends of the lines were placed bunches of downy white eagle feathers. West of this was spread a bed of fresh sage, on which a buffalo skull would be laid during the ceremony, and between the two was a "pipe-rack" to support the stem of the ceremonial pipe. The people watched this also in silence, and the leader sang the following song: "Four times to the earth I prayed. A place I will prepare, O tribe, behold."

The sun-dance pipe (Fig. 1) was decorated in a prescribed manner by one of the most skilful women of the tribe. This pipe was carried by the leader of the dancers. Those who took part in the dance wore their hair loose after the custom of men who had recently killed an enemy. Each man wore a deer-skin apron that extended to his knees back and front. An eagle-bone whistle was hung around his neck, and on this whistle he blew as he danced.

FIG. 1.—Sun-dance pipe.

FIG. 2.—Knife used in inflicting sun-dance torture.

The torture of the sun dance was inflicted by the insertion of a short stick or skewer through the flesh of the chest or back, and placing a strain upon this until the flesh tore, releasing the man. While the word "flesh" is commonly used as suggesting the severity of the ordeal, the Indians said that "the stick was put through the skin." It probably penetrated also the subcutaneous fascia. A knife used in making the incisions is shown in Fig. 2, together with the shield covering the point of the knife when not in use. A man accustomed to the work lifted a small portion of the man's flesh (or "skin") between his thumb and finger, thrust the knife through it, following this with the pointed stick. The strain on the stick was secured by tying to it the ends of thongs that hung from the cross-bar of the sun-dance pole, the length of these being such that the man was only relieved from the strain by rising on his toes. He was, however, expected to dance until the flesh gave way. Others dragged buffalo skulls attached to their backs, and a man might request that the stick be tied to his horse. Another form of torture consisted in the cutting of gashes in arms and body. A man when making his vow designated the manner of its fulfilment, and those who witnessed the vow were expected to see that it was carried out.

After a man released himself it was customary to apply a powdered herb to the wound, which healed in a short time; it is said that even a swelling of the wound was unknown among the Sioux. The man then resumed dancing with eyes steadily fixed upon the sun, and continued dancing without food or water during that day and the following night. As the sun rose on the second day it was greeted by the leader with this song: "Here am I, behold me. I am the sun, behold me."

The scene of a sun dance, while the men are still dancing, is shown in Fig. 3, a drawing by a man who had taken part in the dance. The suspension from the pole and the carrying of buffalo skulls are seen, though the buffalo skulls were usually allowed to drag on the ground. The pole is decorated with streamers, and from the cross-bar are hung two effigies cut from raw hide, one representing a man (an enemy), and the other a buffalo. The drum is seen at the right with two singers beside it, and in the upper left-hand corner two women are carrying kettles of food. Feasts were often given in honour of young men taking part in the sun dance for the first time, and in the camp there were various events taking place during the dances.

Fig. 3.—Native drawing of sun-dance.

During the second day the men fell from exhaustion, and after being carried into the shade they gradually regained consciousness. The evening of that day saw the sun-dance ground deserted, as it was the custom that all the people take their departure before sunset of that day.

While the element of pain forces itself on our thought, it is interesting to note the unselfishness underlying it. As the men were dancing they "prayed for all in the tribe, especially the sick and the old," believing that "an act performed publicly is more effective than the same thing done in private." The men who had taken part in the sun dance were men of fine character. White-buffalo-walking (Fig. 4) was one of those who fulfilled a vow in the last sun dance ever held by the Teton Sioux, that splendid tribe of the rapidly vanishing race.

FIG. 4.—White-buffalo-walking, who took part in a sun-dance.

FRANCES DENSMORE.

THE INTERNATIONAL HYDROGRAPHIC CONFERENCE.

THE International Hydrographic Conference, which was held in London between June 24 and July 16, will, it is believed, mark a new era in hydrography. The revival of trade, with the consequent increased traffic on the high seas which will accompany it, makes the present time most opportune for the discussion of the methods of charting the seas and the publication of information to ensure safe navigation. Thanks to the initiative of the Admiralty, it was found possible to bring together most of the chief hydrographic experts of the world, and the decisions they have arrived at in the conference, and the general interchange of ideas which took place, will be fraught with good to the seamen of the world. Twenty-three countries were represented at the conference, amongst the representatives of which were the Hydrographers of Denmark, France, Great Britain, Greece, Holland, Norway, Sweden, and the United States of America.

The subjects to which the conference devoted its attention were "Charts," "Sailing Directions," "Light Lists," "Notices to Mariners," "Time Signals, Distance Tables, and Other Miscellaneous Hydrographic Publications," "Tide Tables," "Instruments Used for Surveying on Shore and at Sea," "Time-measuring Instruments," "The Interchange of Publications," and "The Establishment of an International Hydrographic Bureau."

The subjects, it will be seen, practically covered the whole field of hydrography, and the main object of the conference was to compare the practices of all countries, with a view to the adoption by all of the best methods, and so more or less to standardise the hydrographic publications of the world. All seamen will appreciate the benefit which must accrue from the adoption of common methods of producing all information required for their use to ensure safe navigation. The conference therefore divided itself into committees on the various subjects, and from day to day these committees pursued their investigations, finally reporting to the conference the agreements at which they had arrived. The conference, after discussing the committees' reports, recorded its decisions in a series of resolutions, to which the hydrographic authorities of each country will, it is hoped, give effect without delay. The result will be practically to standardise all published hydrographic works, and will amply justify the holding of the conference.

It is not possible in this brief account to enumerate all the decisions of the conference, and only a few of the most important can be noted.

Under the head of "Charts," agreement as to the use of a common set of signs and abbreviations which denote the various features on a chart was arrived at. The adoption of the metric system of measurement for depths and heights was discussed at length, but whilst the conference unanimously expressed the opinion that all nations should, as soon as convenient, adopt it in their charts and publications, it was recognised that it was not possible for the countries not using it in their charts to do so until the metre had been adopted as the general standard of measurement in their respective countries, and it was therefore agreed that those countries not using the metre should insert on their charts tables for the conversion of the measurements used to the equivalent measurements of the metric system, and that in their sailing directions, light lists, etc., the metric measurements should follow the national measurements. The transcription of names received attention, and it was agreed that generally the literal, and not the phonetic, transcription was desirable.

Under the head of "Sailing Directions," the general arrangement of these important addenda to the charts was discussed, and the necessity for the publication of an annual supplement to each volume to bring it up to date was recognised. An improved method of describing tidal streams and currents was adopted. Bearings, it was agreed, should be given as "true" only, and from 0° to 360° measured clockwise.

The arrangement of the British "Notice to Mariners" met with universal approval, and its form was adopted as the standard for all countries.

With regard to the "Light Lists," the principal alterations and additions agreed to were the inclusion in the lists of "light buoys," "wireless direction-finding stations," and "sound-ranging signal stations." The desirability of finding a satisfactory formula for describing visibility as limited by the intensity of light was recognised, and it was agreed that each nation should make observations and collect data in order that the matter might be dealt with by the International Hydrographic Bureau if ultimately established.

The subject of "Tides" was carefully considered, and the necessity recognised for the adoption of a uniform zero from which heights should be measured, which should also be the datum for soundings on the charts, and of uniform methods of publishing tidal information. A rule for determining a "universal datum plane," to be called "international low water," was suggested for the further consideration of hydrographers, and decisions were reached regarding information to be published in tide tables, and on charts at places where the semi-diurnal tide predominates, but it was unfortunately found that modern tidal knowledge was insufficient for any recommendation to be made as to information which should be given on charts at places where the semi-diurnal is not the predominating tide-wave; this question was therefore left for further investigation.

Interchange of publications, a most important matter to all countries, as each country freely copies the publications of the others, received consideration, and steps were taken to put the matter on a more satisfactory footing.

A number of instruments used by various countries in hydrographic surveying were exhibited, and useful comparisons made and information exchanged.

The adoption by all countries of a system of "time zones" to regulate the time kept at sea, such as have already been adopted by France, Great Britain, and Italy, was recommended.

The last item on the programme of the conference was the establishment of an "International Hydrographic Bureau," and as the work of the conference progressed, the necessity for such an institution became more and more evident. Questions arose upon which an agreement in principle was arrived at, but time would not permit of the necessary details to give effect to the decisions being worked out by the conference, nor was such a large body as the latter found to be a suitable medium for doing so. On the necessity for the establishment of a bureau, which should be a purely advisory body with no executive powers, and of the existence of sufficient work to employ it, there was unanimous agreement. Such a body, it was felt, was urgently required to consider and make proposals for the co-ordination of the work of the whole of the Hydrographic Offices, to study the numerous questions not fully solved by the conference, to act as an authority to which questions could be submitted for advice, to take steps as required to obtain the assistance and co-operation of Governments and Hydrographic Offices when required for the execution of any particular work or research desirable in the common interests of all countries, and generally to watch over and advance the science of hydrography. As a result of its deliberations the conference decided to appoint a committee consisting of Rear-Admiral Sir J. F. Parry, K.C.B. (then Hydrographer of the British Navy), Monsieur J. Renaud, the French Hydrographer, and Rear-Admiral E. Simpson, the Hydrographer of the United States Navy, to prepare for presentation to the various Governments the case for the establishment of a bureau, and to take the necessary steps for its formation when the various countries should have signified their approval of its institution.

With this final act the conference concluded its labours, which, from a hydrographical point of view, cannot be over-estimated, and the results of which will, it is hoped, speedily be apparent in the publications of the various Hydrographic Offices.

A SHAKESPEAREAN GARDEN.

WE learn with interest that the trustees and guardians of Shakespeare's birthplace are laying out the "Great Garden" attached to his house, "New Place," as an Elizabethan garden. The trustees are naturally anxious to plant the garden with those old-fashioned flowers which were grown in English gardens in Shakespeare's day, and they appeal to lovers of Shakespeare and of gardens to help them by contributing the flowers needed to restore the garden, so far as possible, to its original aspect.

Such a garden of old-fashioned flowers is much to be desired in these days, when so many of the old-fashioned, beautiful, sweet-scented flowers are almost lost to cultivation in gardens, owing to their being ousted by the modern creations of florists. No doubt present-day flowers are larger and more brilliant, but we have to a great extent lost the charm, scent, and elegance of the old garden flowers as a result of what may be termed the vulgarity of present-day tastes.

The desire for masses of colour and for magnificence of form no doubt accounts for the lack of interest in the old-fashioned plants, many of which are now scarcely known. Among the plants which the trustees desire to obtain are "sweet musk roses," "roses damask'd red and white," the "crimson rose" and "milk-white rose," all alluded to by Shakespeare. Crown imperials, "lilies of all kinds"—but those known in Shakespeare's time were only a tithe of what are now found in gardens; daffodils—again only a few—and "fleur-de-luce" are all referred to by Shakespeare, and may be sent. Of shrubs, rosemary, lavender, lavender cotton, box, woodbine, and many others should be planted.

The trustees, in their circular, refer to several early gardening books which give accounts of the plants in cultivation in the latter part of the sixteenth century, but they omit to mention the excellent book by the late Canon Ellacombe, a keen student of Shakespeare, whose "Plant-lore and Garden Craft of Shakespeare" is a mine of useful information on the plants in cultivation in Shakespeare's day. The list of plants grown in the garden at Bitton vicarage in 1831, reprinted in the recently published memoir of Canon Ellacombe, might also well represent what would have been found in a garden three hundred years ago, and should be referred to by those anxious to assist in the good work.

Fortunately, there are still collections of the old roses from which it may be possible to supply plants for the "Great Garden." Anyone having any of the old-fashioned plants suitable for the garden should send them to Mr. Frederick C. Wellstood, secretary to the trust, Shakespeare's Great Garden, New Place, Stratford-on-Avon, by whom they will be gratefully acknowledged. The names of the donors will be preserved at Nash's House, adjoining New Place, which was once the property of Thomas Nash, the husband of Shakespeare's granddaughter Elizabeth.

There are probably many people who would wish to take part in this interesting tribute to Shakespeare's memory, but have no flowers to send; contributions in money from such will be equally acceptable, and should be sent to the secretary to the trust.

A RESEARCH INSTITUTE FOR NEW ZEALAND.

UNDER the will of the late Thomas Cawthorn, of Nelson, New Zealand, the sum of 240,000*l.* was left for the founding of a technical institute. The trustees were unanimous in desiring that the Cawthorn Institute should be a research institution, and appointed a private commission of scientific men to advise as to the best method of procedure. The commission consisted of Sir J. C. Wilson, President of the N.Z. Board of Agriculture, Profs. Benham, Easterfield, Marshall, and Worley, and Dr. Leonard Cockayne. At the request of the trustees, the commissioners have consented to become an honorary advisory board. The main recommendations of the commission have been adopted by the trustees. The chief work of the institute is to be "instruction in and performance of scientific research; such research to be definitely related to the industries of Nelson and of the Dominion."

A beautiful, well-wooded site overlooking Tasman Bay has been secured, the area being approximately 20 acres and the distance from Nelson about three miles. It is expected that the buildings will be commenced at an early date. At the last meeting of the trustees it was decided, with the approval of the advisory board, to offer the position of director to Prof. T. H. Easterfield, professor of chemistry at Victoria College (University of New Zealand), Wellington, who has accepted the position. Mr. T. Rigg, of the Cambridge School of Agriculture, a New Zealand 1851 Exhibitioner, has been appointed agricultural chemist; other staff appointments will be made shortly.

A liberal scheme of scholarships and fellowships is arranged, so that university graduates may be attracted to carry out investigations under the guidance of members of the staff.

An annual "Cawthorn Lecture" has been established. The 1917 lecture was delivered by Prof. Easterfield on "The Aims and Ideals of the Cawthorn Institute"; the next lecturer was Prof. Benham, and the lecturer in 1919 was Dr. L. Cockayne.

Questions having been raised as to the legal right of the trustees to establish a research institute, an originating summons was taken out under the Declaratory Judgments Act. The decision of Mr. Justice Chapman was to the effect that the scheme set out in the report of the commissioners falls, in its main features, within the terms of the testator's intentions. It is proposed to introduce a Bill embodying the chief points of the judgment in the New Zealand Parliament next session.

Though it is intended that the work of the institute is to have a distinct economic bearing, it has been made clear that the trustees recognise that no sharp line can be drawn between technical and scientific research, and that the term "technical" will be understood in a broad and liberal sense.

DR. CYRIL G. HOPKINS.

STUDENTS of agricultural science in all countries will learn with regret of the death on October 6 of Dr. Cyril G. Hopkins, the distinguished head of the department of agronomy in the University of Illinois. Dr. Hopkins had for the past twelve months been studying the exhausted soils of Greece under the auspices of the American Red Cross. He had written his report, seen it translated into Greek, and received a decoration from the King of the Hellenes. He was on his way home, but when three days out from Gibraltar was suddenly struck down with congestion of the brain, with malarial complications.

Dr. Hopkins's chief service to agriculture was his urgent and persistent advocacy of the need for the honest and adequate use of fertilisers. His region of operations was the State of Illinois, of which he had a very extensive knowledge. It was the present writer's privilege to accompany him on an agricultural tour through this State in 1912, and to learn at first hand some of his interesting agricultural deductions and conclusions. Dr. Hopkins's critical scientific outlook was manifested in his lectures and writings. Besides being popular with his students, he had a great faculty for getting on well with farmers, and was obviously a welcome guest in their homes. English agricultural students will remember with pride his high opinion of the work of the Rothamsted Experimental Station, with which he was unusually well acquainted. The Rothamsted data were constantly used by him in lectures and writings, and he maintained his personal interest in the work right up to the time of starting for Greece.

Two of Dr. Hopkins's books are well known in this country. One—"The Story of the Soil"—was written in the main during his long railway journeys in the States; it is an attempt to introduce scientific facts about the soil into the dialogue of a novel. It is not less attractive than other novels written with a purpose, and it is light reading. His more serious book is entitled "Soil-Fertility and Permanent Agriculture"; it contains valuable summaries of the results of the more important field experiments, and an interesting and illuminating discussion. His own view was narrower than would be usually accepted by the younger generation of workers in America or in this country; he considered soil fertility to be essentially a matter of nitrogen, phosphate, and potash, and to be expressible in the terms of the actual weights of these substances in the soil. There are cases where this view would suffice, and many appear to have come within Dr. Hopkins's experience. These, however, would now be regarded as limiting rather than as normal cases, and more generally fertility would be considered to be the outcome of many factors, some chemical, some physical, others, again, biological. But Dr. Hopkins did much good work, training a splendid body of students, and developing a department which has added lustre to the great University of Illinois.

E. J. Russell.

NOTES.

We announce with deepest regret the death on Monday, December 29, at seventy years of age, of Sir William Osler, Bart., F.R.S., Regius professor of medicine in the University of Oxford.

Mr. R. Nathan, late Indian Civil Service and author of works on the history of plague in India and the progress of education in India, has been promoted by the King to the rank of K.C.S.I.; and Mr. G. S. Sankey, Inspector-General of Forests to the Government of India, has been given the honour of K.B.E.

Dr. F. Broili has been appointed professor of geology and palæontology in the University of Munich in succession to the late Prof. A. Rothpletz. Dr. Broili was a pupil of the late Prof. K. A. von Zittel, and is well known for his numerous contributions to vertebrate palæontology.

We learn from Dr. Tolmatcheff, a Custos of the Russian Academy of Sciences, who is now in London, that when he left Petrograd early last summer the collections and libraries of the Academy, the School of Mines, and the Geological Survey were intact, and scientific men were being sympathetically treated by the Bolshevik Government. The most important specimens of the Permian reptiles collected by the late Prof. Amalitsky in northern Russia had been removed from Warsaw to the museum of the Academy of Sciences at Petrograd.

The death is announced, in his sixtieth year, of Dr. Louis Valentine Pirsson, who had been professor of physical geology since 1897 at the Sheffield Scientific School at Yale, where for several years previously he had held various minor posts. Prof. Pirsson was a geologist on the staff of the U.S. Geological Survey and an associate editor of the *American Journal of Science*. He was the author of numerous scientific memoirs, text-books, and papers on geological and mineralogical subjects.

The Photographic Arts and Crafts Exhibition, which was held annually until the war intervened, is to be resumed in the coming spring. It is renamed the Photographic Fair, and will be held at the Horticultural Hall, Westminster, on April 16 to 24. As usual, the Professional Photographers' Association will hold a congress at the same time in connection with the exhibition, while the Photographic Dealers' Association will, for the first time, organise a congress of photographic dealers. It is intended to afford dealers special facilities for examining the exhibits. The organising secretary of the fair is Mr. Arthur C. Brookes, Sicilian House, Southampton Row, W.C.1.

The death of Mr. J. Hartley Wicksteed on December 16, at seventy-seven years of age, is announced. *Engineering* for December 19 gives some particulars of his career. Probably his inventions which have had most bearing on engineering progress are his vertical single-lever testing machine and his horizontal universal testing machine. Mr. Wicksteed was connected with the Institution of Mechanical Engineers for more than fifty years, and was president in 1903–4. He was one of the first members of council of the Yorkshire College, Leeds, afterwards becoming a life governor of the University; and through this and other local activities he exercised a wide influence. He became a member of the Institution of Civil Engineers in 1889.

By the death of Dr. Harold Cecil Greenwood a few weeks ago, at thirty-two years of age, British engineering chemistry has lost one of its most promising younger members. Dr. Greenwood was always a careful and accurate worker, and applied that characteristic to even the smallest detail in every problem which he took up. As a result his work was exact; his data on the boiling points of metals, published in 1909, are generally accepted as the most accurate existing upon the subject. During the last three years of his life Dr. Greenwood was engaged on behalf of the Government on an extremely laborious undertaking: the construction of an experimental synthetic ammonia plant for the preparation of ammonia from its elements. In this work his training with Prof. Haber at Karlsruhe stood him in good stead, but it was no easy matter to translate laboratory experimental work to the semi-technical working-plant model producing 1 kg. per hour of ammonia, desired by the authorities. It was at this stage that his industrial experience with Messrs. Hutton at Sheffield aided him both in the choice of suitable materials and in the proper design of apparatus. No member of Dr. Greenwood's staff had had previous experience with the operation of gases under very high pressures or with the design of suitable plant, yet he not only brought his work to a successful issue, but he also effected the training of the staff in such a way that they could operate the extremely complicated plant unaided. This in itself is a tribute to his technical and executive abilities; and his work on "Industrial Gases," published since his death, is a worthy record of his knowledge of an important department of applied chemistry.

The loss of that keen geologist, Prof. Joseph Barrell, of Yale, who died at the comparatively early age of fifty on May 4 of last year, will be felt far beyond those who met him and appreciated at first hand his mental energy and accuracy of perception. A sympathetic memorial of Prof. Barrell's work, with a portrait and bibliography, appears in the issue of the *American Journal of Science* for October last, and it is followed by two important papers by him on the theory of isostasy. An obituary notice of Barrell by Prof. Schuchert appears in *Science* (vol. xlix., p. 605, 1919). It is here pointed out that his reasoning powers were applied to the relations of climate to organic evolution, as well as to those problems of earth-structure that he made peculiarly his own.

The Government of India has appointed a Committee, consisting of European and Indian experts, to inquire into the conditions and prospects of the sugar industry. At present most of the sugar produced is locally consumed in the crude form of "jaggery," but there seems little doubt that if capital and modern methods of manufacture could be introduced India might become one of the great sugar-producing areas in the world. The annual consumption of sugar in India, as elsewhere, has rapidly increased. India until recent years stood first of all the countries in the world in its area under sugar-cane and its estimated yield of cane-sugar, and even now ranks second only to Cuba. Yet it is notorious that the yield both of cane and raw sugar per acre and the available sugar extracted from the cane are undesirably low. In view of the conservative habits of the Indian peasant, the Government, in inducing him to adopt improved methods, has a difficult task to encounter.

At a conversazione of the Eton College Scientific Society, held on December 15, a presentation from past and present members was made to the retiring president, Mr. W. D. Eggar, who, in returning thanks, referred to the losses which the society had suffered since the last conversazione in 1914, and in particular mentioned the names of W. S. Stewart, A. G. Parsons, and H. G. J. Moseley. Henry Moseley was "in college" with a brilliant band of classical scholars. He obtained his scholarship at Trinity, Oxford, in chemistry and physics, but the only paper which he contributed to the society was on deep-sea fishes. At the 1905 conversazione he demonstrated the simpler properties of those X-rays which afterwards he investigated to such purpose that his name, like that of Robert Boyle, links Eton with a law of Nature. After attending the British Association meeting in Australia, Moseley hurried back to join the Army, and fell in Gallipoli on August 10, 1915. Dr. Leonard Hill, who demonstrated in an amusing and instructive lecture the advantages of oxygen for athletes, deplored the loss to science in Moseley's death. Dr. R. Whytlaw Gray is the new president of the society.

The council of the Scottish Meteorological Society proposes to hold a series of meetings, mainly in Edinburgh, at which lectures on popular lines will be given or discussions opened on questions of meteorological interest. The first of these lectures has, indeed, already been given in Glasgow by Capt. Franklin, who opened the winter session of the Royal Philosophical Society of Glasgow by an address on "The Study of Meteorology in Schools and Universities." The report of the council, adopted at the annual business meeting on December 19, refers to climatological stations maintained by voluntary observers, and says it has become evident that the country should no longer depend so largely on voluntary effort for a record of important economic factors. It is felt that those who may be in charge of any scheme of reconstruction should regard it as a vital matter that there should be a sufficient skeleton network of stations the permanence of which is guaranteed by some local authority or by some Government Department the interests of which are directly concerned. The president of the society for the ensuing year is Dr. C. G. Knott; vice-presidents, Prof. T. Hudson Beare and Mr. D. A. Stevenson; and hon. secretary, Dr. E. M. Wedderburn.

The executive committee of the National Union of Scientific Workers has appointed Major A. Church to be whole-time secretary of the union, the appointment to date from January 1, 1920.

A new era of prosperity for the Zoological Society of London seems to have dawned. At the last monthly general meeting, held on December 17, it was announced that the number of visitors to the gardens from January 1 to November 30 showed an increase of 653,187 as compared with the previous year, while the money received for admission in the gardens during the same period showed an increase of 22,977*l*. as compared with the corresponding period in 1918.

We are glad to note that vigorous measures are to be taken to suppress the practice of bird-liming in Lower Egypt. The Ministry of Public Works, Egypt, has just issued a report by Mr. J. Lewis Bonhote setting forth the hideousness of this traffic and the grave results to agriculture which must follow unless it is speedily stopped, for the victims are almost exclusively small, insectivorous birds. In an introduction to the report Major Stanley Flower, Director of the Zoological Service, remarks that in the past, in every normal year, practically the whole surface of the country was flooded, so that both the insect and rat population was swept away and drowned, with the exception of such comparatively small numbers as could survive by taking refuge in villages, in the tops of banks and trees, and on the desert fringes. The conditions within the last century have changed, and are becoming increasingly favourable for the spread of pests of agriculture. But there are serious difficulties to be overcome in certain districts in enforcing the law, as at Damietta, Fuwa, and Rosetta, owing to the "unpatriotic and uncivilised behaviour" of the local authorities.

MR. T. SHEPPARD has reprinted from the Transactions of the East Riding Antiquarian Society (vol. xxii.) a paper on Danes' Dyke, the remarkable earthwork stretching across the triangular Flamborough headland from north to south. It is certainly much more ancient than the Danish period. Its shape and mode of construction demonstrate that it is not Roman. But in the same area, and associated with the earthwork, are numerous barrows, the implements, weapons, and ornaments found in them belonging to the Bronze age, though they also contain many fine stone implements, the use of which continued into the Bronze age. The results of some excavations made by Major-Gen. Pitt Rivers in October, 1879, are published in the Journal of the Anthropological Institute for 1880.

SIR W. RIDGEWAY describes in the November issue of *Man* a remarkable Irish decorated and socketed bronze axe, of which the provenance is doubtful, but it probably came from Co. Westmeath. The axe, 60 mm. ($2\frac{2}{5}$ in.) long, is remarkable because the maker made a careful scheme of ornamentation for the whole of its surface, dividing it into four compartments by means of four fine curved lines in relief, and adding the main feature, a band or frieze of chevrons, in refined and delicate relief running along the top of each side immediately under the delicate line running below the mouth of the socket. There is no similar specimen in the Irish National Museum or in the British Museum collections, now enriched by that of the late Canon Greenwell, nor does Sir John Evans describe any such in his "Bronze Implements." But Canon Greenwell possessed an Irish socketed axe with elaborate and refined decoration. This agrees fairly well with Sir W. Ridgeway's specimen, which is said to have come from Rathowen, Co. Westmeath, and there is at least some probability that the Ridgeway axe may have been made in that area.

THE progress of boundary delimitation in Europe is the subject of a short article and a useful sketch-map by Mr. A. R. Hinks in the *Geographical Journal* for December (vol. liv., No. 6). The Treaty of Versailles delimited the boundaries of Germany, subject, of course, to the result of the plebiscites in Schleswig, East Prussia, Silesia, and, in fifteen years' time, in the Sarre basin. The Treaty of Saint-Germain-en-Laye delimited the boundaries of Austria subject to the result of the Klagenfurt plebiscite. The new frontier of Italy is not yet fixed in the north-east; the frontier of Hungary is fixed only in the west. Czecho-Slovakia's and Poland's frontiers are incompletely delimited. In Eastern Europe the frontiers are still vague. It is proposed to revise the sketch-map and reissue it from time to time in the *Geographical Journal*.

THE Ordnance Survey decided in 1911 to undertake the levelling of an entirely new network in the British Isles to form the basis for a new series of bench marks and heights shown on the map. Experience has shown that many of the bench marks have altered their heights, either from subsidence or actual displacement; others have disappeared. The instruments and methods decided on for this work were described in a paper on "Precise Levelling" by Major E. O. Henrici read at the Institution of Civil Engineers on December 17. The new lines are laid out so that it is possible to erect special "fundamental" bench marks at intervals of about twenty-five miles. The marks of these will be fixed on solid rock or on concrete founded on rock. These marks have three reference points, one consisting of a metal bolt let into the top of a granite pillar, for general use, and two lower marks which are buried, and are for the use of the Survey only; they will serve in time to come to check the height of the upper mark. The probable error of the difference of height between any two consecutive "fundamental" marks may be about 0·01 ft. Intermediate bench marks take the form of gun-metal plates let into the surface of walls.

IN his new pamphlet ("The Stanton Drew Stones," Bristol, 1s.) Mr. E. Sibree returns to the theme of his former publication ("Stanton Drew: A Calendar in Stone"), treating it in greater detail and with an abundant wealth of literary scholarship and interesting folk-lore. The circles of 30, 12, and 8 stones respectively are referred to the days of the month, the months of the year, and the years of the Venus cycle of intercalation. Eight years of 12 months, each of 30 days, contain 2880 days; if to these are added 12+30 days we get 2922 days, very nearly eight solar years. Mr. Sibree shows that the same number is obtained from the Carnac stone calendar in Brittany. He draws the conclusion that the Stanton Drew calendar was erected by Romans or by Romanised Britons in about the fifth century. Some confirmation is afforded by the fact that the diameters of the circles are 375, 150, and 100 Roman feet respectively, proportional to the numbers of stones in the circles, and by the presence of the Guild of Calendaries at Bristol in about A.D. 700. Much of the lore of Merlin and of the Welsh mythology is invoked to support this conclusion. It must be urged, however, that the lateness of the author's date is surprising. The geometrical interpretation of the construction of the circles is very artificial and too complicated to be accepted as the intention of the erectors; in any case, it is really irrelevant to the main theme of Mr. Sibree's pamphlet.

MR. A. L. SHEATHER describes a malaria-like parasite found in the blood of an Indian buffalo. The animal suffered from irregular attacks of fever and anæmia, and eventually died. The parasites occurred in considerable numbers and in three forms—small, large, and dividing (Agricultural Research Institute, Pusa, Bulletin No. 90). Malaria-like parasites in the blood of ruminants seem to have been recorded only by Bruce, who found two antelopes infected in Nyasaland in 1913.

IN the recently issued fascicle iv. of "Contributions à la faune des Indes néerlandaises" (vol. i.), published by the Instituts scientifiques de Buitenzorg, Dr. Paul van Oye gives an account of the Chætognatha found in fifty-one samples of plankton taken off the north coast of Java. He describes five new species of Sagitta and one of Krohnitta, and founds a new genus Zahonya. Details are given of the horizontal distribution of the various species. Dr. A. L. J. Sunier has examined the collection of Stomatopoda in the fishery station and in the museum at Buitenzorg. The specimens prove to belong to known species of Squilla, Pseudosquilla, Odontodactylus, and Gonodactylus. Notes are given on seventeen species, the known geographical range of several of which is considerably extended.

IN the paragraph in these columns on September 25 (p. 78) referring to a paper by Mr. E. W. Vredenburg on "Observations on the Shells of the Family Doliidæ," the statement that "it appears that the genus Dolium is not known in formations older than the Oligocene" is in need of correction. Mr. E. A. Martin writes to point out that a Cretaceous Dolium is mentioned in Mantell's "Medals of Creation" and in the same author's "Geology of Sussex" (1822, p. 196). This was described and figured as *Dolium nodosum* by Sowerby in 1825 ("Mineral Conchology," vol. v., p. 34, pls. 426, 427). The figures represent casts of a large species of this genus. An analogous, if not identical, species of Dolium is recorded by W. C. Williamson from the Cretaceous formation of Mount Gebeel Suneen, part of the Lebanon range, immediately above Beyrout (Proc. Geol. Soc. Lond., iii., 1840, p. 291).

DR. NATHAN MUTCH describes in the Journal of the Royal Microscopical Society (pt. 3, September, 1919, p. 221) a comparatively simple procedure for the isolation of a single bacterial cell. It consists essentially in making a very dilute emulsion of the culture and transferring a minute drop of this to a sterile cover-glass, which is quickly mounted on a cell so as to form a hanging-drop preparation. A ring of filter-paper moistened with saline solution is placed on the bottom of the cell, and serves both to prevent evaporation from, and addition of moisture to, the hanging drop, which thus maintains a constant size. The preparation is then examined microscopically, and if a single cell only is found to be present, a drop of melted sterile agar is added to the drop on the cover-glass, the preparation remounted on the cell, incubated, and a growth is thus obtained.

WE learn, from *California Fish and Game*, vol. v., No. 4, that in 1919, for the first time in several years, squid were caught in abundance at Montery, California. Three Chinese firms have dried, in the past season, about 1,772,000 lb. of this mollusc. Three tons of wet furnish one ton of dried squid. Practically the whole of the harvest was sent to China. But, apparently by way of experiment, a small percentage of the catch was canned, while some was put upon the market in a fresh state, and is, it would seem, slowly winning favour as a table delicacy. Squid tentacles are said to rival the oyster in flavour. The kelp industry, which was started during the war to furnish potash, seems, from this number, to have come to an end. But it is hoped that the plant will be re-started on a paying basis by the sale of certain by-products which are obtainable during the process of extracting the potash. No hint, however, is given as to the nature of these promising substances.

THE *Journal of Agricultural Research* for October 15 contains two interesting contributions to the study of plant nutrition. By determining the composition of barley at successive stages of its growth in soil, Mr. J. S. Burd demonstrated considerable losses of potassium and nitrogen from the plant at the beginning of ear-formation, at which period the water-extract of the soil has a minimum concentration. The author considers that the most important condition of the soil solution for a high yield is an adequate supply of nutrient elements during the first half of the growth-period; subsequent high concentration is unnecessary, and may be undesirable. Similar results were obtained by Mr. D. R. Hoagland in carefully controlled sand and water cultures. Marked absorption of all nutritive elements occurred throughout growth if suitable concentrations of the medium were continuously maintained, but the absorption in the later stages of growth led to no important increase in yield. Attention is directed to the necessity of clearly distinguishing between the concentration and the total supply of essential elements in the nutrient solution, since rapid absorption by the plant may produce considerable alterations in the composition of the solutions.

A REPORT of the Meteorological Committee for the year ended March 31, 1919, has recently been issued. This is the first report since the Armistice, and much interesting information is given in it. Immense strides have been made in meteorology, and the Meteorological Office has expanded accordingly, dependent on the necessities of the war. Whereas the sum available, including many costs for the Services, in the year 1913–14 was 29,380*l*., in 1918–19 it was 66,371*l*. A much greater demand was made on the office for meteorological instruments, and for forecasts of all descriptions, including the upper air. The marine division, on the other hand, which is dependent for its information on the Royal Navy and mercantile marine, experienced a great falling off in the number of documents received from observers at sea, the documents numbering 2738 in the year 1913–14 and only 43 in 1918–19. Throughout the war there was great activity in the supply of data to the Army, Navy, and Air Service, and the work commonly undertaken in times of peace was greatly augmented, although most of the information was considered private and was withheld from the general public. The restrictions upon the circulation of meteorological information were removed after the signing of the Armistice.

Reports for the several branches of the office show the variety and extended work now undertaken. Any future report will presumably be made through the Air Ministry, to which the Meteorological Office is now responsible.

EXPERIMENTS have been carried out by Prof. Garelli, of Turin, on behalf of the Italian Government, with the view of extracting nitrate of ammonia from surplus stocks of explosives. According to *La Nature* of November 29 last, the explosive mixture is placed in special receptacles, a fixed quantity of water added, and the whole allowed to stand. A dense solution of nitrate of ammonia is then formed, which is separated by decantation. Powdered peat is then added to this solution, and after mixing and drying the product thus obtained it becomes a species of manure which is called "nitric peat." This material, which has the appearance of a blackish powder, has the following composition:—Water, 17·8 per cent.; ash, 18·8 per cent.; nitrate of ammonia, 42·8 per cent.; and organic matter, 20·6 per cent. Tests for ascertaining its value as a fertiliser have been carried out in the Alba district of Italy, and the results show that the action of this fertiliser is nearly equal to that of nitrate of soda.

DR. A. E. H. TUTTON has recently published in the Proceedings of the Royal Society (A, vol. xcvi., pp. 156–84) the results of an exhaustive study of the crystallographic properties of the monoclinic double selenates of the cobalt group, $R_2Co(SeO_4)_2,6H_2O$, where R stands for potassium, rubidium, cæsium, and ammonium successively. Only the potassium and ammonium salts of the group had previously been studied. The results fulfilled expectation, and fully accorded with those obtained for the zinc, magnesium, nickel, and iron groups, and for the eight known groups of the analogous double sulphates. The dominating facts brought out are, first, the progressive character of all the crystallographic and physical properties following the alkali metals concerned, potassium, rubidium, and cæsium; and, secondly, the almost perfect isostructure of the crystals of the ammonium and rubidium salts of the group.

THE Australian Institute of Science and Industry has published at Melbourne a pamphlet on "Engineering Standardisation," by Mr. Gerald Lightfoot. The objects of standardisation in cheapening manufacture and reducing maintenance charges and stocks, and in securing interchangeability of parts, are discussed. The British Standards Association is described, and under its influence other similar bodies are being formed in various countries. It is argued that if Australia neglects to take action, it will be impracticable to develop her engineering industries at the same level as in other countries. The institute desires to carry out research work on lines similar to those in the case of the U.S. Bureau of Standards and the National Physical Laboratory. The outline of a scheme for the formation of a Commonwealth Engineering Standards Association is given. It is mentioned that there is a multiplicity of voltages in electrical supply in Australia, and that merchants have to stock lamps for about twenty different voltages.

VOL. XIII. of the Transactions of the Rochdale Literary and Scientific Society contains the papers that have been read before the society during the years 1917–19. These papers, some fifteen in number, are entirely devoted to local subjects, and are mainly concerned with the history of the town and its institutions. There is a short article by Mr. E. L. Taylor on the Rochdale Grammar School (an old foundation dating back to 1564), two papers on the old Rochdale roads by Dr. Ashworth and Mr. A. P. Wadsworth, an annotated list of Querns found in the Rochdale district by Mr. J. L. Maxim, and a topical contribution by Mr. G. E. Leach on the connection of Rochdale with Peterloo in 1819. Of immediate interest to scientific readers we may note the interesting presidential address by Dr. Ashworth, in which he gives a brief but clear statement of the great and important part which Lancashire men and institutions have played in the striking advances which have taken place in electrical science during the last hundred years. The Rev. T. A. Jefferies contributes a short but suggestive paper on the natural transformations in the vegetation of Blackstone Edge, in which he traces the life-cycle of its plant associations. Dr. Ashworth's paper on atmospheric pollution in Rochdale provides the local authorities with a valuable mass of facts on which to base legislative action to mitigate the evils of smoke, unfortunately inevitable in large industrial areas. Altogether, the volume is an excellent example of the kind of research work, both historical and scientific, which it is the peculiar province of local societies to undertake.

A VOLUME devoted to the "Life and Letters of Silvanus Phillips Thompson" has been prepared by his wife and his daughter, Miss Helen G. Thompson, and will be published by Mr. T. Fisher Unwin in the spring. Many of the letters relate experiences on journeys abroad, some record adventures of the antiquarian in pursuit of early scientific literature, while others tell of battles for truth in some field or other. A few chapters deal solely with Thompson's scientific and public work, and contain appreciations of his books and original papers. Throughout the work there are many indirect testimonies to the warmth of personal regard which the frank geniality of his nature won for him and to the influences he exerted on the lives of those he met.

Messrs. George Bell and Sons, Ltd., will publish almost immediately "The Year-book of the Universities of the Empire" for 1920, edited by W. H. Dawson. The latest list of the *Cambridge University Press* includes:—The late Prof. J. H. Poynting's "Collected Scientific Papers," edited by Dr. G. A. Shakespear and G. Barlow, with biographical and critical notices by Sir Oliver Lodge, Sir Joseph Larmor, Sir J. J. Thomson, and Dr. G. A. Shakespear; "An Introduction to the Study of Cytology: An Outline of the Main Facts of Cytology for Advanced Students," Prof. L. Doncaster; "The Foundations of Einstein's Theory of Gravitation," E. Freundlich, translated by H. L. Brose; "A History of English Philosophy," Dr. W. R. Sorley; "Discovery in Greek Lands," F. H. Marshall; and "Life and Labour in the 19th Century," C. R. Fay. *Messrs. Constable and Co., Ltd.*, announce "Montessori Experiments," Miss Blackburn. Prof. Patrick Geddes has written a volume, which *Messrs. Longmans and Co.* will issue shortly, on the life and work of Sir Jagadis Chandra Bose, the founder of the Bose Research Institute in Calcutta.

OUR ASTRONOMICAL COLUMN.

FIREBALL ON DECEMBER 25.—A brilliant fireball was visible on Christmas night at 10h. 21m. at Bristol. It must have very much exceeded Venus in lustre, for it gave a flash which illumined the whole sky, and in that section of its flight where the greatest outburst occurred it left a streak about 3° long for 40 seconds. The apparent path was from 115°+34° to 105½°+1°. The motion was rather swift, the course of about 35° being traversed in 2 seconds. The radiant point is doubtful; it may have been at 165°+73°, 219°+75°, 245°+72°, or 261°+62°. If the second is the correct position, the meteor may quite possibly be considered to have been a fragment of Mechain-Tuttle's comet, which has a period of about 13½ years. Further observations of the object would be valuable, and should be sent to Mr. W. F. Denning, 44 Egerton Road, Bristol.

COMETS.—The following continuation of the ephemeris of Finlay's comet is for Greenwich midnight, from the elements in Lick Bull. 325:—

	R.A. h. m. s.	N. Decl. ° ′	Log r	Log Δ
Jan. 2 ...	3 3 35	21 47	0·1703	9·8160
6 ...	3 12 57	22 24	0·1806	9·8510
10 ...	3 22 24	22 58	0·1911	9·8849
14 ...	3 31 21	23 27	0·2013	9·9173
18 ...	3 40 9	23 55	0·2114	9·9485

The comet will traverse the Pleiades on January 18.

It is calculated that Holmes's comet passed perihelion about November 30, and a search ephemeris was published. The comet is probably too faint to give much hope of its recovery. It has not been seen for two revolutions.

RADIATION PRESSURE.—The *Astrophysical Journal* for October last contains an article by Mr. Megh Nad Saha in which the opinion is expressed that the quantum theory of light will explain the repulsion of particles much more minute than those the dimensions of which are of the order of a wave-length. In the undulatory theory the repulsion is a maximum for particles of that order of magnitude, and becomes practically zero for those of the dimensions of molecules. Mr. Saha quotes the results of spectrum analysis of comets' tails, and some laboratory experiments by Lebedew (*Ann. der Physik*, 1910), for the fact that gaseous molecules actually do suffer repulsion by radiation pressure, which he considers an argument in favour of the quantum theory.

Assuming that a pulse of light gives all its momentum to a hydrogen atom, the velocity imparted to the latter by each "kick" would be 60 cm./sec. Some calculations are given, from which the author deduces that by repeated "kicks" the atom might acquire a velocity of 6×10^7 cm./sec., which has sometimes been observed in the solar prominences.

THE ORION NEBULA.—We lately noted Dr. Bergstrand's estimate of the parallax of this object, 0·0078″. Prof. W. H. Pickering (Pubns. Ast. Soc. Pac., April, 1919) contends for the value 0·0020″. This is deduced from assumptions of the absolute magnitudes of a number of faint stars which appear to be associated with the nebula. By comparing their photographic with their visual magnitudes, he concludes that their spectral type is A or B, whence their absolute magnitude is unlikely to be very low. But this involves the conclusion that the brighter stars in Orion are super-giants. Rigel in particular would have 87,000 times the luminosity of the sun. But perhaps it is nearly as easy to accept this as the value 5000 times the sun, which results from Dr. Bergstrand's parallax. Prof. Pickering estimates for the masses of the faint B7 stars in the nebula only four times that of Jupiter, using his parallax. With Kapteyn's parallax 0·0054″, the mass would be one-twentieth of this. Either value seems far too small for a body to attain the temperature necessary to shine as a B star.

SPHERICAL SHELL CRYSTALS IN ALLOYS.

AT the autumn meeting of the Institute of Metals recently held in Sheffield, Dr. J. E. Stead presented an account of his investigations on some ternary alloys of tin, antimony, and arsenic, one of which was noticed by him to crystallise in a most unusual and remarkable way.

Having found that the alloys of antimony and tin crystallise in what appear to be cubic crystals, and those of tin and arsenic in rhombohedral flat plates, he made trials with the object of finding how the metals would arrange themselves when the three elements were fused together and the melt allowed to cool. The results obtained were astonishing, for the crystals found in the matrix had the form of incomplete spherical shells, the radii of which were small or great, according to the time allowed for development. With rapid freezing the radii were less than half a millimetre; when it was protracted for one hour they were 5 mm. or more. The most perfect structural arrangement of the crystals was obtained in an alloy containing from 70–85 per cent. of tin, 25–15 per cent. of antimony, and 4–5 per cent. of arsenic. Whether cooled slowly or quickly, the polished surface of the alloys, after dissolving away the matrix, is very suitable for printing blocks, since the hard crystals stand out in bold relief (see Fig. 1). The alloys are very brittle, and the fracture was found to travel midway along the shell walls. An alloy containing tin 70 per cent., antimony 25 per cent., and arsenic 5 per cent. gave the following arrests on cooling:—

(1) First separation of crystals ... 440° C.
(2) Retardation in cooling between 325° and 320° C.
(3) Solidification of the eutectic ... 244·9° C.

The last-named temperature agrees closely with that of the eutectic of the tin-antimony alloys. The conclusion is, therefore, warranted that the eutectic cannot contain more than a trace of arsenic, an inference confirmed by experiment. It was afterwards shown by analysis that the primary crystals contain a maximum amount of arsenic, and that, as crystallisation proceeds, the deposits contain less and less of this metal.

A large number of ternary alloys were prepared. It was found that, while it required 2·5 per cent. of arsenic in the presence of 25 per cent. of antimony to produce slightly curved crystals, 0·5 per cent. of arsenic in the presence of 3·75 per cent. of antimony yielded curved segments in the upper layers. In an alloy containing 1·65 per cent. of arsenic, 14·35 per cent. of antimony, and 85 per cent. of tin, spherical crystals were found in the top layers, below these smaller segments, under the latter cuboidal crystals, while the lowest stratum consisted of the eutectic. It was evident that the compound richest in arsenic was the first to freeze and floated upwards to the surface. As yet the analyses have given no decisive results as to the composition of these shells. Further details have been promised by Dr. Stead, and will be published in due course.

FIG. 1 (Nature-prin).

In the instance just quoted, four distinct stages of crystal growth can be observed. When, however, the proportion of antimony is between 20 and 25 per cent. and that of arsenic about 5 per cent., the primary crystals are distributed evenly through the whole alloy and there is no stratification.

That the primary crystals which form in such alloys are spherical shell crystals was shown by chilling

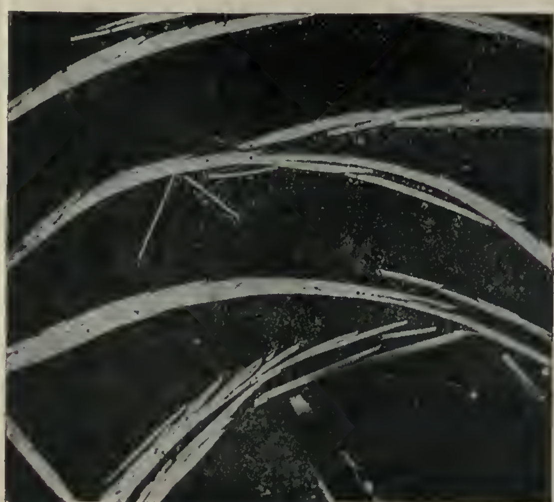

FIG. 2 (Photograph).

them just below the first thermal arrest. Fig. 2 depicts the structure after this operation. Sections of the shells are visible which are smooth on the concave, but slightly broken on the convex, side, due possibly to the stresses set up during quenching. With somewhat slower cooling, as shown in Fig. 3, both surfaces of the shells are seen to be smooth. That these are composite and contain a hard primary core was shown by grinding and polishing experiments.

In the latter part of his paper Dr. Stead quotes the opinion of Mr. L. J. Spencer, to whom specimens of the alloy containing spherical shells were submitted for his opinion, and who furnished Dr. Stead with important data regarding the curvature of crystals in minerals. Mr. Spencer's complete notes on the subject have been communicated to the Mineralogical Society. In them he refers to various instances of apparent curvature classified under these headings:—

(1) Curved crystallites; (2) capillary habit; (3) aggregations of crystals; (4) interfacial oscillations; (5) vicinal faces; (6) bent crystals; (7) twisted crystals; and (8) cylindrical and spherical crystals.

It would appear that, according to his view, the last-named constitutes the closest analogy to the alloy in question. "The mineral kylindrite is a sulphur salt of tin, lead, antimony, and iron. . . . It has the appearance of consisting of tightly wound rolls of foil with a smooth surface and a brilliant metallic lustre. The ore consists of large numbers of these rolls, with a more or less radial grouping. . . . The rolls have a diameter of a few millimetres up to one centimetre,

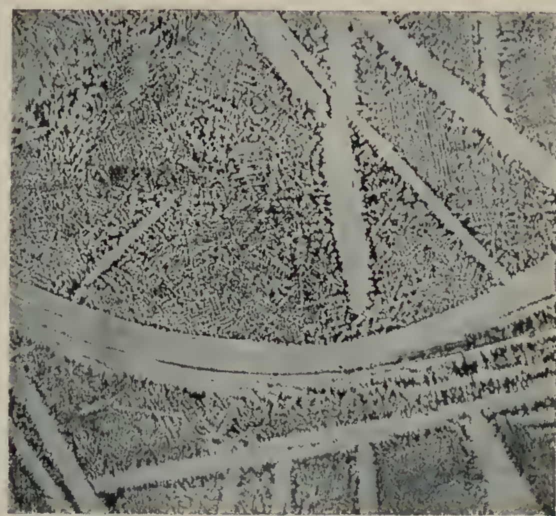

FIG. 3 (Photograph).

and reach a length of three to four centimetres. They flake off in concentric cylindrical shells with all the appearance of a perfect cleavage, very similar to that of the allied minerals, franckeite and teallite. These cylindrically curved cleavage flakes are perfectly bright and smooth and show no visible signs of being built up of smaller elements. Spherical aggregates of crystals possessing a perfect cleavage are, however, met with, but here a radial grouping is much more common than a concentric arrangement. Examples of radiating spherical aggregates of lamellar crystals with platy cleavages are pyrophyllite, zeophyllite, gyrolite, faröelite, tyrolite, etc."

With reference to the cases of curvature in mineral crystals thus referred to, Dr. Stead contends that none approach in character or form the spherical shell crystals obtained in his ternary alloys; that radial crystallisation round a nucleus is common in minerals, but the spherical form finally produced is an aggregation of many crystals, and not a single crystal; and that kylindrite consists of a number of cylindrical crystals which have formed round a central axis and are not independent cylinders. He states that no case is known to him in which the idiomorphic forms of the crystals are segments of spherical shells which have crystallised out of a liquid except in the ternary alloys referred to. The reason why idiomorphic shell crystals develop under such conditions and the laws which govern their formation await further research. Meantime, Prof. Bragg, to whom some of the separated crystals have been sent, has kindly promised to study them. H. C. H. C.

FORECASTING FROSTS.

In most countries during the spring, and to a lesser extent in the autumn, there are periods in which the meteorological conditions result in a frost. Leaving out of the question spells of cold weather, the prediction of which is the concern of a Meteorological Service, there remains the possibility of local frosts in isolated districts, occurring on clear, windless nights and lasting for a portion of the night and early morning. These frosts are capable of doing great damage to fruit-trees, etc., and the possibility of forecasting them in time for the fruit-growers to take precautions is of interest and importance.

It has long been recognised that local cooling of the soil can be largely prevented by a smoke pall produced by the burning of damp materials such as straw. Boussingault ("Economie Rurale," Paris, 1844) discusses this, and records an observation on the point by Pliny. In America definite systems of frost prediction have been in operation for some years, and practical methods have been evolved by which the grower can economically combat the danger to his crops. A study of these preventive measures is instructive in showing that several causes are concerned in producing a frost. The methods are varied. Leaving out those which attempt to delay the flowering-time until the danger period is past, they fall into four main classes:—(1) Increasing the water-content of the area (spraying or flooding); (2) "smudge" burning (damp smoke from wet straw, etc.); (3) temporary roofing; and (4) dry heating. The last method supplies additional heat mainly; the other three are largely indirect, and aim at reducing the rate of temperature fall either by increasing the heat capacity of the soil by the added water or by restricting the radiation from the soil.

Up to the present no complete correlation has been made of frost in any particular locality and its causes. For this purpose an examination by statistical methods of a series of continuous observations (of the automatic recording type) of meteorological factors is needed. The published papers deal usually with one factor, such as dew-point or air temperature, and the number of daily observations made is small. This is, no doubt, due to the necessity of keeping the cost of apparatus and working as low as possible for the sake of the growers. However, a general idea of the factors concerned can be obtained from a broad survey of the various papers.

The effect of an overcast sky on air temperatures near the ground has been studied by Hellman (*Preuss. Akad. Wiss.*, Berlin, 38, 1918, p. 806), who on clear nights found an exponential decrease of temperature with height, the average difference from ground-level to a height of 50 cm. being 3·7° C. An increase of cloudiness by 1° of scale (0=clear, 10=overcast) diminished this difference by at least ⅓° C. There was no temperature gradient when the sky was overcast, while windy and rainy weather resulted in a slight reversal of the gradient. Schubert (*Met. Ztsch.*, 32, 1915, p. 343) considers that during the last half of the night the fall of temperature is relatively greater with dry than with moist air, owing to the formation of dew, and frost from the latter resulting in latent heat being set free by the condensation. The presence of water-vapour in the atmosphere also retards the radiation cooling of the soil.

J. Warren Smith (*U.S. Monthly Weather Review*, 42, 1914, p. 573; 45, 1917, p. 402) has examined the accuracy of various methods of temperature prediction. The first, and simplest, is to subtract from the maximum temperature of the day the known average fall in temperature on clear, still afternoons and evenings for the appropriate period of the year. This temperature range varies in different months, but is remarkably uniform under similar topographical conditions and at similar seasons of the year. It has been used by Church (Nevada Station Report, 1915, p. 46).

The second method is due to Smith, and involves two temperature readings daily. Smith discovered that the daily temperature curves showed marked similarity in periods of calm, clear weather when a high-pressure system was centred over the district and conditions were favourable for strong insolation during the day and free radiation at night. For these curves the half-way point in the temperature fall from the maximum of one day to the minimum of the next morning (the "median") occurred at very nearly the same time. Hence a forecast of the probable minimum can be made by subtracting from the maximum the temperature shown at the time previously ascertained to be that of the median, and then subtracting this difference in turn from the observed median temperature. The values thus obtained agreed much more closely with the observed minima than those given by the original dew-point method, which is mentioned immediately below.

The third method, as developed by Smith, is an elaboration of the dew-point determination. This, as used by Hazen (Minn. Expt. Sta. Bull. 12, 1890), and by O'Gara (U.S. Farmers' Bull. No. 401, 1915), consists simply in determining the dew-point in the early evening (6–10 p.m.), and assumes the dew-point temperature will be the probable minimum temperature reached. Smith found that the prediction could be made much more accurately if the relative humidity of the atmosphere was also determined, and he used the correlation method to show that with high relative humidity the minimum temperature falls below the determined dew-point, while with low relative humidity the reverse is true. A satisfactory equation expressing this relation was obtained,

$$Y = 18{\cdot}314 - 0{\cdot}39R,$$

where R = relative humidity in the evening, and Y is departure of minimum temperature of the following morning from evening dew-point. A determination of R gives the value of Y, which added to (or subtracted from) the dew-point gives the probable minimum temperature to be expected. The numerical terms in the equation differ for different localities.

Recently T. B. Franklin (Proc. Roy. Soc. Edin., 39, 1919, p. 120) has published some observations on the cooling of the soil at night, with special reference to late spring frosts, and has arrived at a number of important conclusions, which will help considerably in developing methods for forecasting the minimum surface-soil temperature in this country. As a result of observations of temperatures in the air, on the soil, and at a depth of 4 in., Franklin concludes that a prediction of frost depends on assessing the value of:—(1) Average relative humidity during the night; (2) the temperature of a given depth (4 in.) at the time of surface minimum temperature; (3) the conductivity of the layer between the assigned depth and the surface; and (4) the difference between the surface-soil minimum and that of the air above it. These determinations are necessary because:—(i) The radiation from the soil on calm, clear nights is a function of the relative humidity (A. Angström, Smithsonian Misc. Coll., 65 No. 3); (ii) the radiation from the soil can be accounted for in balancing the upward conduction and the latent heat of freezing, the residue only cooling the soil; and (iii) the temperature of the surface soil rapidly falls sufficiently below the temperature of the 4-in. depth to make the conduction from this depth balance the radiation; after this the surface temperature falls no faster than that of the 4-in. depth.

Franklin has also noted rapid changes in underground temperature (6-in. depth) after heavy rain. This he attributes to the receding water drawing hot or cold air into the soil, but it is scarcely possible that the volume of air thus drawn in could supply or abstract sufficient heat to account for the observed differences. These latter are in the direction which would be expected from the time of the day when the readings were taken; and while the re-aëration of the soil may have slightly increased the temperature changes, it is unlikely that it had a predominating influence.

B. A. KEEN.

LUBRICATION AND LUBRICANTS.

THE meeting of the Physical Society held on November 28 was devoted to a discussion on the subject of lubrication, suggested by a paper on "Oiliness and Lubrication" by Mr. R. M. Deeley, sent by the Committee on Lubrication. Other contributors included Dr. Stanton, Principal Skinner, Messrs. W. B. Hardy, Dorman, Southcombe, Martin, Archbutt, Edser, and Dr. H. S. Allen.

In the consideration of lubrication problems a clear distinction must be made between two prevailing conditions, viz.: (1) Those in which the solid surfaces are completely separated by a film of oil, as occurs in the lubrication of cylindrical journals and their bearings working under moderate pressures, revolving at high speed, and supplied with abundance of oil; and (2) those in which, owing to the shape or condition of the surfaces, the kind of motion, high bearing pressure, low speed, or an inadequate supply of oil, the oil-film cannot form completely, or becomes broken, and the solid surfaces come into contact. In (1) the friction is entirely due to the viscosity of the oil, as proved by Beauchamp Tower and Osborne Reynolds. Engineers have Reynolds's theory to guide them in the design of bearings so as to secure fluid friction, and it is possible by determining the viscosity and chemical characteristics of an oil to form a sound opinion as to its suitability to meet the required conditions. In (2) the circumstances are quite different. Lubricating value is then found to depend upon some property which is quite distinct from viscosity, and has been called "oiliness."

In opening the discussion Dr. Stanton referred to experiments recently made at the National Physical Laboratory for the Lubrication Committee with the Lanchester worm-gear testing machine, in which working pressures of several tons per square inch are developed, showing that in the case of all the mineral oils tested the lubrication at a certain temperature suddenly became imperfect, the friction irregular, and the efficiency of the gear fell off. With fixed oils no such "breaking-down" point was observed under the conditions of the tests, and it was found that by adding quite a small percentage of fatty oil to a mineral oil the breaking-down point, though not obliterated, occurred at a higher temperature.

Mr. Deeley described and exhibited a small hand-driven machine which he had invented for the purpose of measuring the oiliness of lubricants under conditions of metallic contact. Three flat-ended metal studs, each 5/32" in diameter, secured concentrically as feet to a metal disc, rested upon another metal disc which could be slowly rotated. The upper disc could be weighted as desired, and actuated a spindle to which a spiral spring and a recording finger were attached. The lower disc, when rotated, carried the studs and upper disc with it by friction until the stress in the spring caused the surfaces to slip, when the pointer gave the frictional resistance, oscillations being damped by gearing the spring and pointer to a train of wheels. Experiments made with this machine showed that the static friction depended upon the nature of the metal surfaces in contact as well as upon the oil, and the fatty oils which in practice are found to be the best lubricants gave lower static coefficients than the mineral oils. Mr. Deeley's view is that the oil, or some constituent of it, enters into physico-chemical union with the comparatively rigid metallic surface, forming a composite film having the yielding nature of velvet-pile, and that the best lubricants are those which produce the most easily sheared contact films.

Dr. Allen directed attention to the important work of Irving Langmuir on surface films, and suggested that the property of "oiliness" depends upon the chemical forces called into play between the active part of the oil molecule and the solid surface of the bearing, and not only on the nature of the lubricant, but also on that of the solid surfaces with which the liquid is brought into contact.

Mr. W. B. Hardy referred to the work carried on by his son and himself, and discussed by them in the *Philosophical Magazine* of July last. In the apparatus they used there was only one point of contact between the solid surfaces, which consisted at first of a curved watch-glass on a flat glass plate, and latterly of similarly shaped surfaces of bismuth. The force measured was that necessary to cause the curved surface to slide over the plate when lubricated by the films formed by individual chemical substances representative of various groups of chemical compounds. The authors concluded that the true function of a lubricant was to reduce the energy of the surface, and thereby to reduce the capacity for cohesion and the resistance to slip when two composite surfaces are applied one to the other. This, in the opinion of the present writer, is the conclusion to which all recent work leads, and the problem before the chemist is to determine in what manner the molecular structure of the chemical compounds in lubricants determines their "oiliness."

The practical side of the problem cannot, however, be neglected, and it is necessary to experiment with commercial lubricants acting between such dissimilar metal surfaces as are used in the construction of machines, in order to obtain the information which engineers require to guide them in the lubrication of machinery. Mr. Southcombe's observation that the interfacial tension between oil and water and oil and mercury is much higher with mineral oils than with fatty oils, and that the addition of a very little free oleic acid to a mineral oil greatly lowers the surface tension, is of great importance. It appears that by adding 1 per cent. of free fatty acid to a mineral oil the lubricating power is increased as much as by adding a very much larger percentage of fatty oil. The emulsifying properties can also be materially modified by the addition of fatty acids.

L. A.

ADULT EDUCATION.

THE Final Report of the Adult Education Committee of the Ministry of Reconstruction (Cd. 321, 1s. 9d.), appointed in July, 1917, as a Sub-Committee of the Reconstruction Committee, over which the Prime Minister presided, but afterwards, on the establishment of the Ministry of Reconstruction, as a Committee of the Department, has been issued and presented to the Prime Minister, in the absence of a Minister of Reconstruction to succeed Sir Auckland Geddes. It is a most informing and suggestive document, and has been preceded by three interim reports dealing respectively with industrial and social conditions in relation to adult education, and suggesting drastic reforms, both industrial and social; education in the Army; and libraries and museums, in which it is insisted that a much closer relationship and co-operation should be arranged with other branches of educational work, even to the extent of the transfer of their administration to the local education authorities.

The Committee was presided over by the Master of Balliol, who has prefaced the Report by a most illuminating covering letter addressed to the Prime Minister. The Committee comprised scholars, employers, trade unionists, and representatives of the Workers' Educational Association, and included men and women fully conversant with the needs of working people and others, and familiar with the work of the various educational organisations, both public and private. Its terms of reference were:—"To consider the provision for, and possibilities of, adult education (other than technical or vocational) in Great Britain, and to make recommendations." The scope of the inquiry necessarily covers a wide field, but it has been fully considered in its various aspects, and comprises a history and general review of adult education since 1800; standards and methods in adult education and its weaknesses and possibilities; the relation of the State and local authorities and of the higher institutions of learning to adult education; the supply of teachers; the development of adult education in rural areas; the relation of technical to humane studies; the organisation and finance of adult education; and concludes with certain valuable recommendations for its effective establishment.

The Report covers 178 pages, and, as is the case with the interim reports, is unanimous. It is followed by four important appendices, the first of which reviews respectively and at great length the present provision of the means and facilities of adult education; the part played therein by the local authorities; the universities in respect of lecture extension courses, and especially of tutorial classes; voluntary agencies such as the Workers' Educational Association; the colleges for working people, including the London Working Men's College and the Ruskin and Labour Colleges at Oxford; the educational work of residential settlements like Toynbee Hall and the Passmore Edwards Settlements, and of non-residential such as Swarthmore, Leeds; the Gilchrist Trust, the National Home Reading Union, the co-operative movement, and other activities of literary and scientific societies; war-time developments; and, finally, adult education abroad. The further appendices deal with university education in London and in Wales, the report of the Committee on the position of natural science and that of modern languages in our educational system. The appendices, which are replete with statistics and fertile in suggestion, cover 200 pages of the Final Report.

The Report lays down as an absolute condition of future civilised progress that education, taken in its true sense, is the basis and postulate of all urgent problems of reform, whether they refer to domestic questions such as those of nationalisation, the claims of Labour to better conditions of life, the position of woman, the subject of a Second Chamber, and social matters such as those of drink and prostitution, or to political questions dealing with the Imperial position in relation to the self-governing Dominions or to India and Egypt, or to the international problems involved in the redrawing of the map of Europe on sound lines of nationality with due regard to the claims of racial and religious minorities.

These serious and urgent problems will not find a speedy and wise solution until we have an educated and enlightened public. There is abundant evidence, in the opinion of the Committee, of the demand of the adult members of the public for the means of a humane and liberal education, which shall include literature, modern languages, local and general history, economics, art, and the natural sciences. There is latent in the mass of the people a capacity, far from being recognised as it should be, to rise to the fundamental conceptions of great issues and to face the difficulties incident to their realisation.

The Committee has based its main conclusions on the following propositions:—The main purpose of education is to fit a man or woman for life as a member of a civilised community, and so the education of the adult must proceed on the lines of successive periods in his education: the family, the school, the trade union or the profession, and the locality, which are all successive stages, and reach their fullness in the life of the community; and whilst each part of the process must be related to its appropriate stage, the goal of all education must be citizenship, viewed in relation to both rights and duties on the part of the individual as a member of the community. This is the *raison d'être* of the need for facilities for education and training

Adult education must not be regarded as a luxury for a few exceptional persons, or as a thing which concerns a short span of early manhood, but as an object of permanent national necessity, as an inseparable aspect of citizenship, and be therefore universal and lifelong, spread systematically and uniformly over the whole community in its own interest and as a duty to its members. All possible encouragement should be given to voluntary organisation, so that there may be freedom of experiment and that their work may find its appropriate place and opportunity of development in the national educational system.

The tutorial class methods of instruction are unreservedly praised in the Report, and, in order that the higher institutions of learning shall be enabled to take their full share in their development, the demand is made that the State and the local authorities shall place more abundant resources at their disposal, so that their staffs of teachers may be largely increased. In the present crisis of the nation's affairs is found the chief and abiding reason for the speedy adoption of the Committee's recommendations.

AN OBSCURE DISEASE, ENCEPHALITIS LETHARGICA.[1]

ABOUT two years ago reports began to appear concerning a "new" acute general disease associated with a condition of apathy and drowsiness which passed into lethargy. Other striking features were progressive muscular weakness and paralysis of various cranial nerves, leading especially to squint. The prevailing abnormal conditions of life and living

[1] Report of an Inquiry into an Obscure Disease, *Encephalitis lethargica*. Local Government Board Reports (New Series, No. 121), 1918.

caused suspicion at first to fall on articles of diet. Thus some observers were struck by a similarity to cases of botulism, a disease due to the poisons of a bacillus which can flourish in foodstuffs kept out of contact with air, as when meat or vegetables are immersed in a weak pickle. Others suggested that some essential accessory factor had been lacking in the diet, so leading to a "deficiency" disease, perhaps analogous to beri-beri, in which nervous symptoms are prominent from affection of the peripheral nerves. But the wide area over which cases were distributed, and the rarity with which more than a single member was attacked in any one family, almost excluded such theories of causation.

Further clinical investigation, and especially pathological examination, established the close resemblance between the new disease and the well-known condition, acute poliomyelitis or infantile paralysis. In both diseases the essential pathological feature consists in microscopic areas of inflammation, with cellular infiltration, consisting largely of round cells, in the perivascular lymphatic sheaths and in the grey matter. In *Encephalitis lethargica* these changes were most noticeable in the upper part of the pons and in the basal nuclei. In the affected areas the nerve-cells showed the usual changes indicative of degeneration. In addition, Marinesco found degeneration of the Purkinje cells of the cerebellum in the two cases examined by him; such changes are similar to those observed by Mott in shell-shock, and previously studied by Crile, who considered them an expression of cellular exhaustion.

Thus the nervous lesions did not at all resemble those originally investigated by Marinesco in botulism. On the other hand, there are certain well-marked differences from infantile paralysis as regards the localisation of paralysis, which in the new disease mainly affects the cranial centres, while the spinal cord is commonly the site of lesions in infantile paralysis; also there is a practically equal incidence of the disease at all ages, whereas infantile paralysis affects mainly children and young adults. But such differences are possibly within the limit of variations which may occur in a clinical "entity" or "syndrome," since modern investigation of infective diseases in general has taught that the number of "typical" cases of any condition may constitute a variable, and sometimes relatively small, proportion of the total number.

The experimental results are of greatest importance, however, as tending to show that the two diseases are distinct in their causation. It has been well established by various observers in different parts of the world that in cases of infantile paralysis the central nervous system especially harbours the virus, and that the disease can be transmitted to monkeys by intracerebral inoculation with glycerinated emulsions of brain or spinal cord. On the other hand, McIntosh consistently failed to transmit the new disease to monkeys by injecting emulsions of nervous tissue from cases under similar conditions to those which are successful in poliomyelitis.

The disease, after obtruding itself in the spring and early summer of 1918, has again relapsed into obscurity for the time being. The valuable work in this report has outlined the natural history of the manifestations, but the failure to reproduce the disease experimentally or to identify any micro-organism as constantly associated with it has prevented the elaboration of a basis for dealing with a future outbreak. It may be presumed that, like infantile paralysis, it is a disease to which the majority of individuals are relatively resistant, and that healthy carriers, who harbour the virus in the nose and pharynx without themselves suffering from ill-effects, probably play a large part in dissemination. The practically simultaneous occurrence of *Encephalitis lethargica* in this country, France, and Austria is another of the unaccountable manifestations of the disease.

C. H. B.

EXPLORATION OF NORTHERN GREENLAND.

THE second Thule Expedition to northern Greenland in 1916 to 1918, under the leadership of Mr. Knud Rasmussen, is the subject of articles in the *Geographical Review* for August and September (vol. viii., Nos. 2 and 3). With Thule on Melville Bay as a base, the main party of the expedition left on a long sledge journey to explore the northern coast of Greenland between Robson Channel and Peary Land. This coast had been only roughly sketched by Peary on one of his northern journeys. Mr. Rasmussen's party charted it in detail between St. George's Fjord and De Long Fjord. It was found that Nordenskjöld Inlet, at one time supposed to be the end of the so-called Peary Channel, but disproved in 1907 by Mylius Erichsen, is a short fjord ending in a glacier. The distribution of ice-free land was found to be the opposite of what was before believed to be the case, the land round St. George's Fjord being ice-free, and that round Nordenskjöld Inlet ice-covered. Mr. Rasmussen failed to find any ruins of Eskimo houses in that district, or any signs that Eskimo had ever migrated round the north coast of Greenland. This was previously supposed to be the route by which Eskimo at one time reached the east coast, where traces of camps and villages are numerous. Musk-oxen may have migrated in small herds round the north, but the general conditions of hunting are so poor that Eskimo are unlikely to have been attracted to the route. The ice-free areas are not large enough to furnish sufficient game for a wandering tribe, and the conditions of the pack-ice along the north-west coast make hunting on the sea impossible. Mr. Rasmussen believes that the east coast natives travelled from the west by Cape Farewell, and that reconnoitring parties of hunters went so far north as Independence Fjord. The botanical work of Dr. Thorild Wulff, who died from starvation, was important, and Mr. Lauge Koch obtained valuable geological results. The new map of the coast, of which a sketch is added to the article, was carefully prepared, forty observations of latitude and forty determinations of longitude being taken.

AQUATIC FAUNA OF SEISTAN.

UNDER the auspices of the Indian Medical Research Fund, Dr. N. Annandale and Mr. S. W. Kemp undertook in November, December, and January, 1918–19, an expedition to Seistan and Baluchistan with the object of discovering whether the disease Bilharziasis (or Schistosomiasis) occurred in Seistan, and, in particular, whether any of the known molluscan hosts of the parasite were to be found in that region. So far as the medical part of the inquiry was concerned the results were negative, but the opportunity was taken to make a collection of the limited aquatic fauna of the country. The zoological results of the expedition are now in course of publication as a special volume of the "Records of the Indian Museum" under the title of "Report on the Aquatic Fauna of Seistan." In an introductory essay Dr. Annandale describes the physiographical conditions of the Hamun-i-Helmand, the basin into which the

Helmand River flows, and which is occupied, according to season, by a large lake or by a series of lakes of variable area. Owing to the fact that in flood-time the Hamun overflows, by the Shelagh River, into the Gaud-i-Zirreh, "the Dead Sea of the Helmand system," its waters do not reach a high degree of salinity, and it sustains a fauna, impoverished indeed, but rich in comparison with that of true salt lakes. Dr. Annandale points out that although the Hamun occupies part of an ancient lake-bed, "there has been no biological continuity between the old lake and the recent one." The present lake may even have originated within historic times by a shifting of the course of the Helmand River. Dr. Annandale describes the Cyprinid fishes of the genus Discognathus found in the region and, in collaboration with Dr. B. Prashad, the Mollusca. In the case of the latter it is pointed out that the fauna shows a mingling of Palæarctic and Oriental types and a noteworthy absence of Western Asiatic elements. The fauna, however, "is a starved one, in which only species of great adaptability can survive."

PHYSICS AT THE BRITISH ASSOCIATION.

ONE day of Section A was devoted almost entirely to matters relating to wireless telegraphy. Prof. Eccles opened a discussion on thermionic valves, giving a general description of the history and development of the three-electrode valve, explaining its rectifying property, the method of heterodyne reception, and the arrangements necessary to produce continuous waves. Experiments were shown illustrating these uses of the valve, and the way was thus prepared for the discussion of special points by subsequent speakers. Prof. Fortescue directed attention to the functions and properties of the various parts of the valve in some detail. The hot filament is the source of the electrons upon which the action of the valve fundamentally depends; with tungsten filaments as at present used only 4½ per cent. of the energy heating the filament is usefully employed as electron emission. This efficiency might be improved by using oxide-coated filaments or higher temperatures, but at present neither of these methods has been entirely successful in practice. The construction of the grid and the question of freeing the anode and containing vessel from occluded gas during pumping were also discussed, and the importance of investigating the methods of removing the last traces of gas and examining their nature was emphasised. Dr. Whiddington directed attention to the possibility of using valves and oscillating circuits for making many standard physical measurements. Thus, for example, the coefficient of mutual induction can be determined by observing the degree of coupling at which oscillations are just started and maintained. He also alluded to Prof. Eccles's example of the extreme sensitiveness of heterodyne reception as illustrated by the effect of passing coal-gas between the plates of a condenser in an oscillating circuit. The temperature coefficient of resistance, the conductivity of flames, the permeability of liquids, and other quantities could also be measured by this delicate method.

In a paper entitled "A Wireless Method of Measuring e/m" Dr. Whiddington showed how oscillations may be set up in valve-circuits, not including capacities and inductances. The oscillations are produced by bursts of electrons from hot spots on the filament of a soft valve and the periodic return of positive ions from the space between the grid and anode. In the special experiments described it was shown from the value of e/m obtained that the ions consisted of mercury.

The report of the committee on wireless telegraphy was of special interest on account of the observations made on the strength of signals during the recent solar eclipse. It was, however, too early to give any very definite conclusions, although it was stated that Malta and Paris had received signals of increased intensity during the eclipse. Bearing on the same point, Prof. G. N. Watson gave a *résumé* of his recent work on the diffraction of electric waves, in which, starting from the Heaviside-Eccles hypothesis of conduction in the upper regions of the atmosphere, Austin's formula can be obtained as a result of certain simple assumptions.

Papers were read by Prof. Horton and Miss A. G. Davies and by Prof. Horton and Miss D. Bailey respectively on the ionisation by electron collisions in argon and helium and on the luminosity produced in the latter gas. It appears that there are two critical velocities of the electrons at which radiation from the atoms and ionisation occur respectively. In argon these two phenomena occur at 11·5 and 15·1 volts, and in helium at 20·4 and 25·6 volts. The results are of great interest, but, as Dr. Goucher pointed out, their interpretation seems still open to question.

The phenomena of novæ were dealt with in two papers by Mr. Stratton and Father Cortie. In the former paper the types of spectra occurring in the course of the history of Nova Geminorum were described. The observed displacements of the spectral lines correspond with velocities reaching 2×10^8 cm./sec., which are so large that electrical causes are suggested to explain them. Similar velocities were deduced from the observations on Nova Aquilæ, and, after sketching the sequence of progressive changes occurring in the star, Father Cortie concluded that a solar eruption in a giant star situated in a dark nebula would square with the observed spectral changes.

In an interesting communication on the theory of vision Sir Oliver Lodge put forward the suggestion that the retina may be found to contain atoms in such a condition of instability that impulses of the correct luminous frequency can excite them and cause the expulsion of electrons. A difficult but highly interesting experiment was suggested of trying to find in the retina chemical substances capable of emitting high-speed electrons when subjected to light.

Prof. Eddington gave an account of the observations which had been made at Principe during the solar eclipse. The main object in view was to observe the displacement (if any) of stars the light from which passed through the gravitational field of the sun. To establish the existence of such an effect and the determination of its magnitude gives, as is well known, a crucial test of the theory of gravitation enunciated by Einstein. Prof. Eddington explained that the observations had been partially vitiated by the presence of clouds, but the plates already measured indicated the existence of a deflection intermediate between the two theoretically possible values 0·87″ and 1·75″. He hoped that when the measurements were completed the latter figure would prove to be verified. Incidentally, Prof. Eddington pointed out that the presence of clouds had resulted in a solar prominence being photographed and its history followed in some detail. Some very striking photographs were shown.

Following on this account Prof. Eddington opened the discussion on relativity, and referred again to the bending of the wave-front of light to be expected from Einstein's new law when the light passes near a heavy body. It should be possible to test experimentally this law, which demands that the speed of light varies as $1-2\Omega$, where Ω is the gravitational potential. He showed that, whether Einstein's solution of the problem be correct or not, it has, at any rate, given a new orientation to our ideas of space and time. Sir Oliver Lodge regarded the relativity theory of 1905 as a supplement to Newtonian dynamics by the adoption of the factor $(1-v^2/c^2)$ and its powers necessitated by experimental results; but he did not consider this dependence of mass and length on velocity as entailing any revolutionary changes of our ideas of space and time, or as rendering necessary the further complexities of 1915. He compared the difficulties involved with the case of measuring temperature, defined in terms of a perfect gas, and made with gases which only approximate to this ideal state. Dr. Silberstein pointed out that Einstein's theory of gravitation predicts three verifiable phenomena, *i.e.* a shift of spectral lines, the bending of light round the sun, and the secular motion of the perihelion of a planet. In the neighbourhood of a radially symmetric mass such as our sun, the line-element ds is given by

$$ds^2=(1-2M/c^2r)c^2dt^2-(1-2M/c^2r)(dx^2+dy^2+dz^2).$$

The coefficient c^2dt^2 gives by itself a lengthening of the period of oscillation for a terrestrial observer in the ratio $(1+M/c^2r):1$, demanding a shift of spectral lines of about 0·01 Å.U. Secondly, the path of rays of light is obtained by putting $ds=0$, and the first and second coefficients give jointly a bending which for rays almost grazing the sun is 1·75″. Thirdly, Keplerian motion is predicted with a progressively moving perihelion, which in the case of Mercury turns out to be 43″ per century. He directed attention to the fact that St. John's results in 1917 showed no shift of the spectral lines, which in itself would overthrow the theory in question. Father Cortie pointed out that Campbell's photographs taken in 1918 and measured by Curtis gave no trace of any displacement of the images of forty-three stars distributed irregularly round the sun.

Amongst other papers read at the meeting may be mentioned an account by Sir Frederick Stupart of weather conditions in Alberta and a paper by Prof. Forsyth on Gauss's theorem.

CHEMISTRY AT THE BRITISH ASSOCIATION.

IT was perhaps only to be expected that the programme of the Chemical Section should be coloured by the four years of war through which we had just passed, but, though war chemistry took a prominent place, more academic subjects were not entirely relegated to the background.

Some excellent summaries of work in different branches of chemistry during the war were given by various speakers.

Sir William Pope spoke on the general subject of the position of chemistry in Germany and this country as a result of the war, and pointed out that while German chemical industries emerged from the war in a strengthened position, ours remained much as they were, and that we were faced with a great, immediate danger in a strong propagandist movement to rehabilitate the German chemist in the eyes of the world.

Brig.-Gen. Hartley described the development of chemical warfare and the measures taken to counteract its destructive effects by means of gas-masks, etc. This particular form of warfare is, perhaps, not so inhuman as it is often regarded to be; for if it be granted that human lives must be sacrificed and suffering endured to achieve military objectives, then such objectives can often be attained by the use of gas attacks, lachrymatory shells, etc., with less loss of life and permanent injury than by the employment of high explosives.

Col. C. D. Crozier reviewed the output and methods of manufacture of high explosives during the war, directing attention to the improvements in method and quality which took place as the exigencies of the military situation called for an ever-increasing output, and claimed that this result was due in no small part to the activities of the Inspection Department.

Prof. Desch gave an excellent *résumé* of the metallurgical position in this country and the Central Empires, and showed how metallurgical considerations entered into the Franco-German Peace of 1871, and largely influenced the war and the territorial readjustments of the Peace Treaties. The necessities of war, if without any striking metallurgical developments, have at any rate, so far as this Empire is concerned, done much to stimulate the working within the Empire of locally produced ores, while fresh industries have arisen to smelt ores of metals hitherto imported from enemy countries. In Germany, as might have been expected, the study and use of substitutes for such metals as copper, nickel, and manganese have received close attention.

A paper by Dr. M. W. Travers described the position of the glass trade after the war. Though much has been done to supply the demand for various kinds of glass in this country, Dr. Travers must undoubtedly be written down as an optimist when he declares we can now supply from home-made stock all requirements of laboratory glass and glass for scientific purposes. We fancy few universities and schools would endorse his view, as most of them have great difficulty in supplying the requirements of their students.

Prof. Boswell contributed a paper on some recent problems in geo-chemistry. The border-line of chemistry and geology presents problems of the greatest interest and value as regards the sources and supply of raw materials for chemical manufactures, and the necessity of finding fresh material or substitutes during the war has greatly stimulated geochemical research. Prof. Boswell reviewed the different problems created by war demands, and showed how geo-chemistry has developed our home supplies of materials formerly obtained from enemy countries.

A short but interesting paper by Major E. R. Thomas on the work of an ammunition chemist in the field concluded the papers directly dealing with the war. Major Thomas, with improvised appliances and some Chinese coolies for labour, recovered upwards of a ton daily of KNO_3 and pitch from condemned ammunition. Major Thomas deserves the warmest praise for setting an example of economy and showing that so-called waste is really valuable material.

Though not directly dealing with war chemistry, a paper by Drs. Lowry and Perman on the equilibrium in the system ammonium nitrate—sodium chloride—sodium nitrate—ammonium chloride gave the results of much work conducted for war purposes.

Several papers were contributed from H.M. Naval Cordite Factory at Holton Heath, dealing mainly with industrial bacteriological problems such as the preparation of acetone and industrial alcohol, though a few of them dealt with pure organic chemistry. Special mention must be made of the paper by Dr. A. C. Thaysen, which gave a capital review of different aspects of bacteriology outside medicine, and showed how large a field of investigation is open to bacteriologists in a technical rather than a microscopical sense.

A discussion took place on the report of the Fuel Economy Committee. At nearly every recent meeting of the association a somewhat similar discussion has taken place, and though fuel economy is far more imperative now than it has ever been, and is most unpleasantly brought home to all of us by our local Coal Controllers, it cannot be said that the discussions have been very constructive. They range over a wide field, they are disjointed, and while each speaker's communication is of value in itself, the discussion as a whole somehow seems unreal and almost futile. One wishes that the committee round the report of which the discussion centres were able to present definite propositions which, if approved after due discussion, could be sent through the council of the association to the Government Department, or whomever else they concerned. They would be received with more of the importance due to them if they came from the British Association as a whole. Fuel economy, however, is so vast a subject that probably the committee has scarcely had time yet to distil the essence from the great quantity of valuable material it is collecting.

Prof. E. C. C. Baly, Prof. A. Lapworth, and Prof. R. Robinson wound up the meeting with three papers on pure chemistry of great interest, since they all dealt with the mechanism of chemical reaction. In these papers the writers discussed the molecular and other aspects of chemical reactivity. It is refreshing to find that the great demands of war on the genius of chemists has not smothered the efforts of those who seek to probe deep into the very fundamentals of the science.

Mention must be made of a very enjoyable and interesting excursion to the Naval Cordite Factory at Holton Heath. By kind invitation of the superintendent, Capt. Desborough, eighty members of the Section were shown all over the factory, which in its completeness is second to none.

In conclusion, it should be stated that the meetings of the Section were very well attended, and more enthusiasm was shown than for many years past.

ZOOLOGY AT THE BRITISH ASSOCIATION.

SECTION D attracted a representative gathering of zoologists, and the papers were the subject of much interesting discussion. The following is a summary of the proceedings of the Section :—

Mr. E. S. Goodrich, in a paper on phagocytosis and protozoa, stated that phagocytosis of living protozoa had rarely been observed in vertebrates. Invertebrates deal more successfully with protozoal parasites; the leucocytes cling together, surround and finally smother a parasite. This power of aggregation appears to be due to the fact that the floating leucocytes are provided, not with outstanding pseudopodia, but with delicate films of protoplasm ready to spread over any foreign substance. It is the optical sections of these folded films which are usually figured as pseudopodia.

Mr. E. Heron-Allen, for Mr. Earland and himself, directed attention at a joint meeting of Sections D and K (Botany) to some hitherto unemphasised modifications of growth in the life-history of Foraminifera. He exhibited slides showing the modifications brought about by the cultivation of Foraminifera in hypertonic sea-water, the affinity of certain genera for gems as building material, and the power of selection of material exercised by certain species.

Dr. A. C. Coles exhibited photomicrographs of *Leptospira icterohaemorrhagiae*—the organism of infective jaundice in man—from the kidney of local rats.

Mr. A. T. Watson gave further details on the tube-building operations of the Polychæte worm, *Pectinaria koreni*.

Prof. E. W. MacBride described some further experiments on the artificial production of Echinus larvæ with a double hydrocœle. He stated that the optimum result was obtained when larvæ three days old were transferred from normal to hypertonic sea-water for a week or ten days and then put back into normal sea-water, and he offered a tentative explanation.

Prof. G. H. F. Nuttall gave a lecture on "Lice and their Relation to Disease." Commencing with the biology of *Pediculus humanus*, of which there are two races—*capitis*, the head-louse, and *corporis*, the body-louse—Prof. Nuttall described the mode of oviposition, the development, hatching, moulting, feeding, etc. The female lays 150 to 300 eggs, and under favourable conditions the life-cycle from egg to egg is completed in sixteen to seventeen days. Under experimental conditions dark or pale lice can be reared at will according as they are raised on dark or light backgrounds respectively. Hermaphrodites in large number have been obtained by crossing the two races *capitis* and *corporis*. After pointing out that lice transmit relapsing, typhus, and trench fevers, Prof. Nuttall described some of the methods of control on a large scale, *e.g.* hot-air disinfestors (Orr's huts) and railway vans into which steam from a locomotive was introduced under pressure.

Dr. E. Hindle traced the history of isolated pairs of body-lice and of their offspring raised through five generations. Out of sixty families, twenty-four were mixed (composed of males and females), nineteen were female, thirteen male, and four crosses were sterile. The lice were all fed on the same individual and under similar conditions, and no explanation of the occurrence of the three sorts of families could be discovered. The proportion of females to males in the total number of adults raised to maturity agreed almost exactly with that occurring in Nature—60 per cent. females and 40 per cent. males.

Dr. M. C. Grabham gave an account of the Argentine ant (*Iridomermyx humilis*) in Madeira. The ant was introduced twenty-seven years ago, but was only identified three years later, when it had become firmly established. Coffee cultivation has been ruined and every sort of fruit-tree—citrus especially—which would support coccus or aphis has been almost entirely destroyed. Sugar-cane and bananas still exist, though badly attacked, but sweet potatoes have disappeared in many districts. Attention was directed to the methods of the ant in searching for food, and to the harmony in working, there being a singular absence of fighting when separate communities meet. The ant has few enemies, *e.g.* spiders and Pholcus. A covering of powdered chalk on the basal part of the trunk of a tree is a deterrent to the ant, and banding the trees with rags soaked in corrosive sublimate has also been found effective. Dr. Grabham suggested that our Colonies should be warned as to the importance of this pest.

Prof. Dendy delivered a lecture on "Grain-pests and the Storage of Wheat," for the main points of which the reader is referred to NATURE for March 20 last, p. 55.

Before a joint meeting of Sections C (Geology) and D, Mr. C. Tate Regan spoke on the distribution of fresh-water fishes, with special reference to the past history of continents. He dealt particularly with the Ostariophysi—the dominant group of fresh-water fishes—and took the view that they originated in Gondwana Land in Cretaceous times, and that Australia and Madagascar became isolated before these fishes could reach them. The severance of Africa from South America and from southern Asia probably left Characiformes and Pimelodidæ in South America, Characiformes and Bagridæ in Africa, and Cypriniformes and Bagridæ in southern Asia. At the end of the Cretaceous new land connections may have enabled the ancestors of the Catostomidæ and Amiuridæ to reach North America through eastern Asia. Isolation of the continents during the Eocene helped the development of endemic types, and the union that followed in the Oligocene or Miocene probably gave Cyprinidæ to North America and a few Nearctic fishes to eastern Asia.

Prof. MacBride and Mr. Goodrich expressed some doubts as to the value of the evidence, on the zoological side, for the existence of Gondwana Land, but Dr. D. H. Scott regarded the evidence afforded by the Glossopteris flora as strongly in favour of the former existence of such a land area. Mr. D. M. S. Watson considered that the evidence from fossil plants, Pelecypoda, and vertebrates indicated a connection between Africa and America in Permian times, but whether this continued to the Cretaceous was doubtful.

Dr. J. W. Evans did not agree with those who dwelt on the incompleteness of the evidence for the existence of Gondwana Land. He was inclined to look with favour on the view that the land-masses had not always held their present relative positions, *e.g.* Africa and South America may have been nearer together. The Falkland Islands show closer geological relationship to Africa than to America.

Mr. Tate Regan, in replying, reaffirmed his belief in the former existence of Gondwana Land.

Before the same joint meeting Mr. D. M. S. Watson gave a paper on "Palæontology and the Evolution Theory," an account of which will be given in the article upon the proceedings of the Geological Section.

Dr. Marie Lebour summarised the results of her investigations, extending over three seasons at Plymouth, on the food of larval and post-larval fishes. Most of the fish examined were from 0·5 mm. to 15 mm. in length. The greater portion of their food consists of Entomostraca; diatoms seem to be little eaten by young fish except at a very early stage. Other unicellular organisms are rarely found in young fish, but the flounder up to about 10 mm. in length was found to be feeding exclusively on the flagellate Phæocystis, but at about 11 mm. it changes to a diet of copepods. Larval molluscs, though often abundant in the plankton, are much more seldom found than Crustacea in young fishes. The young fishes thus select their food to a great extent, but that which is selected is generally common, and there is no indication of any special migration on the part of the pelagic young in search of food.

Mr. L. P. W. Renouf gave an account of the development of the Bute Laboratory and Museum.

J. H. Ashworth.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

The helpful paper, "On Lecturing with the Lantern," by Prof. G. A. J. Cole, which appeared in the *Journal of the Department of Agriculture and Technical Instruction for Ireland* (vol. xix., No. 1), has been reprinted with the permission of the Department, and is now published as a pamphlet by Mr. T. H. Mason, Dame Street, Dublin.

Applications for the Tyndall Mining Research Fund studentship are invited by the Royal Society. The studentship is for study and research on subjects relating to mining and the safety of miners, is of about 35*l*. in value, and open to any British subject. Applications must reach the Assistant Secretary of the Royal Society not later than January 15, give particulars of the kind of research it is proposed to carry out, and where, and be accompanied by not more than two testimonials or references.

Yale University is offering two Theresa Seessel research fellowships for the promotion of original research in biological studies. Each fellowship will be of the value of 200*l*., and preference will be given to candidates who have obtained their doctorate and demonstrated their fitness to carry out successfully original research work of a high order. Applications, accompanied by reprints of scientific publications, letters of recommendation, and particulars of the problem proposed by the candidate for investigation, must be made before May 1 next to the Dean of the Graduate School, New Haven, Conn., U.S.A.

The Association of Science Teachers has issued a list of science books which are suitable for use in schools. That a compilation of this sort is a matter of some difficulty is doubtless the reason for its being so rarely attempted. The association has done well to risk imperfection so as to supply an obvious need. The list, which contains the names both of text-books for the use of pupils and of books of reference for the library shelf, is attractively printed and reasonably classified. It is to be regretted that biology (as distinct from botany) and astronomy find no place in the main divisions, despite the fact that Dr. Sophie Bryant, in her excellent foreword, directs attention to the desirability of these subjects in the early stages of a child's training. The "Book List (1919)," which we hope will become a periodical publication, may be obtained for 1*s*. 1*d*. from Miss F. Storr, hon. secretary of the association, 12 Angell Park Gardens, S.W.9.

We are used to large private benefactions for education and science in the United States, but the announcement made in the *Times* of December 27 of a gift of 25,000,000*l*. for these purposes from Mr. John D. Rockefeller is really marvellous to those of us who know how little private generosity can be depended upon for like needs in our own country. The gift is divided into two equal parts of 12,500,000*l*. each to the General Education Board and to the Rockefeller Foundation. It is the largest sum of money ever given at one time to philanthropy, and it brings the total amount of Mr. Rockefeller's donations to 100,000,000*l*. The donation now announced is to be devoted to two purposes:—(1) To some plan of increasing the salaries of the teaching staffs of the colleges and universities of the United States; and (2) to the promotion of the objects of the Rockefeller Foundation, which are defined as the well-being of mankind throughout the world. The General Education Board was founded by Mr. Rockefeller in 1903, and the general purpose of the corporation is "the promotion of education within the United States of America, without distinction of race, sex, or creed." The principal funds of the board have been about 0,000,000*l*., and grants amounting to about 400,000*l*. have been made annually to various institutions. It was only a couple of months ago that Mr. Rockefeller added 2,500,000*l*. to his previous endowment of the Rockefeller Institute for Medical Research. This gift was to meet rapidly growing needs in the institute's many lines of research and also to make new knowledge available in the protection of the public health and in the improved treatment of disease and injury.

One of the notable features of the great struggle in which the nation has been engaged, and for which recruits were drawn from all classes of the United

Kingdom, was the effort made, in camps both at home and abroad, to continue, however imperfectly as to means and methods, the education already gained, having regard to the fact that sooner or later large numbers of men would return to civil occupations and duties, and that it would be desirable, so far as time and circumstances permitted, that military service should offer opportunities of continued study. It is gratifying to observe that the Army of Occupation on the Rhine, which numbers 250,000 men, is animated by the same spirit. The 222nd number of the *Cologne Post*, a daily paper printed and published at Cologne in English for the Army of Occupation, and the Christmas souvenir number of the same journal (price 9*d*., or 7 marks), both contain articles urging the vital importance of education, not only in its general and scientific aspects, but also as applied to the promotion of special phases of industry, of commerce, and of agriculture, with the view of fitting men for these several pursuits, and describes the means taken at Cologne and other Rhine towns for effective instruction and training in the various subjects by the institution of laboratories, workshops, and field allotments. At Siegfried there was held recently an exhibition in which was displayed a great deal of good work, the results of training men who had previously learned no trade to become wage-earners of the best possible type. The courses of study include educational facilities extending from the absolutely illiterate to the university graduate, but these articles are also remarkable for the point of view they express, namely, that the soldiers are urged on returning home to civilian life to insist that their children shall receive their due, and be trained to think and to appreciate the beauties of life.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Meteorological Society, December 17.—Sir Napier Shaw, president, in the chair.—F. J. W. **Whipple**: The laws of approach to the geostrophic wind. The mode of transition from the winds near the surface of the earth to the general current at moderate heights has been discussed by various authors. In the present paper stress is laid on the geometrical aspect of the question. The term "relative wind velocity" being used for the velocity which must be combined with the geostrophic wind velocity by vector addition to give the actual wind velocity at any level, the laws of approach to the geostrophic wind are:—(1) The relative wind turns uniformly with increasing height; (2) the relative wind decreases with increasing height according to the exponential law; and (3) the actual wind at the surface and the relative wind there are inclined at 135°.—G. M. B. **Dobson**: Winds and temperature-gradients in the stratosphere. From the results of temperature observations by *ballon-sondes*, it can be shown that the horizontal pressure-gradient, and therefore the wind velocity, should decrease rapidly on passing from the troposphere to the stratosphere. Previously there had been little confirmation of this by actual observations. Seventy ascents recorded by the International Commission gave data for temperature, wind velocity, and wind direction to great heights. These showed that, almost without exception, winds of moderate or great velocity in the troposphere fall off very rapidly on entering the stratosphere, while the wind direction remained constant. On days with small pressure-gradients this effect was not usually found—a result which was to be expected, since the slope of the tropopause would then not necessarily be towards the low pressure. Horizontal pressure and temperature-gradients calculated for the observed winds on typical days with moderate or large pressure-gradients show that the pressure-gradient is suddenly reduced, and the temperature-gradient suddenly reversed, on entering the stratosphere. The temperature-gradients calculated from the observed wind velocities are in good agreement with those deduced by Mr. W. H. Dines from temperature and pressure observations.—Capt. C. J. P. **Cave**: Quotations from the Diary of Samuel Pepys on the weather. In this the author has collected together all references to the weather from the "Diary," using for this purpose Wheatley's edition. These amount to as many as 557 entries, and are arranged in chronological order. They form a brief comment on the general weather conditions prevailing from January, 1660, to May, 1669. In a preliminary essay the author summarises the principal weather events for each year. He points out that Pepys cannot claim to be considered as a meteorologist, and that his references to the weather are such as anyone might make in writing a diary or in correspondence. He also states that Pepys's memory for meteorological events was not always good, and his remarks on the worst or best weather he remembers must be taken with caution.

EDINBURGH.

Royal Society, November 3.—Prof. F. O. Bower, president, in the chair.—Capt. T. B. **Franklin**: The cooling of the soil at night, with special reference to late spring frosts. The aim of this investigation was to obtain data on which predictions might be formed as to the coming night temperature. Continuing a course of investigation, the author gives a formula whereby the minimum temperature on any calm, clear night may be known by about 5 p.m. on the previous afternoon. A comparison of his results with the observed minimum soil temperatures on twenty favourable nights between April and October, 1919, shows an average error of 0·3° C. only; it would thus appear that, under the weather conditions favourable to spring frosts, it is possible to forecast the occurrence of a frost with great exactness.—Sir Thomas **Muir**: Note on the determinant the matrix of which is the sum of two circulant matrices.—G. F. **Quilter**: Note on and exhibition of photographs of appearances of mirage at Ingatestone. These photographs showed apparent pools of water in the street in which pillars appeared reflected at a distance of about a hundred yards. The photographs were interesting as following up a previous paper by Mr. Alex. G. Ramage communicated to the society in 1918.

December 1.—Prof. F. O. Bower, president, in the chair.—Dr. R. **Kidston** and Prof. W. H. **Lang**: Old Red Sandstone plants showing structure from the Rhynie Chert bed, Aberdeenshire. Part iii.: *Asteroxylon Mackiei*, Kidston and Lang. The fourth vascular Cryptogam found in the silicified peat-bed at Rhynie, the age of which is not younger than the middle Old Red Sandstone of Scotland, was a larger and more complex plant than *Rhynia Gwynne-Vaughani*, *R. major*, and *Hornea Lignieri*, described in the earlier papers of this series. It has been named *Asteroxylon Mackiei* after Dr. Mackie, the original discoverer of the chert-bed. The remains of Asteroxylon are abundant, though fragmentary, and give, with more or less certainty, a fairly complete knowledge of the plant.

December 8 and 9.—Prof. W. Peddie, vice-president, in the chair.—Prof. R. A. **Sampson**: (1) Newton's views on gravitation and their subsequent history. (2) The theory of Einstein and its observational tests. In the second address, by the kindness of Sir Frank Dyson, the Greenwich photographs taken at the expedition to

Sobral, Brazil, were exhibited, and the method of measurement and agreement obtained were explained. It was pointed out that the first success of Einstein's theory was to explain completely a long-outstanding discrepancy in connection with the orbit of Mercury. Of the two other tests, which were in the form of predictions, one, that gravity would modify the solar spectrum, had not been verified, while the second, that light from a star passing near the sun would be deviated, had been verified. The general processes by which Einstein derived this formula carried no assurance that the results would describe Nature, and the theory must rest upon such tests as he himself has proposed for it. From this point of view, though it shows its changes only in minute remote phenomena, its claims are too vast to be settled in a short time.

PARIS.

Academy of Sciences, December 1, 1919.—M. Léon Guignard in the chair.—P. A. **Dangeard**: The distinction of the chondriome into vacuome, plastidome, and spherome.—The **Prince of Monaco**: The oceanographic study of the Mediterranean. An account of an international conference held at Madrid on November 17 last, at which France, Italy, Spain, Greece, Monaco, Egypt, and Tunis were represented.—G. A. **Boulenger**: The distribution in Africa of the barbel, sub-genus Labeobarbus.—G. **Bouligand**: The problem of Dirichlet for an infinite domain.—R. **Soreau**: Experimental laws of the variations of barometric pressure and of the specific gravity of air with altitude. From forty series of observations with sounding balloons, carried out in 1912 at Trappes, Uccle, Strasburg, Hamburg, Munich, Pavia, and Vienna at heights up to 23 km., formulæ are deduced giving the pressure and density as functions of the altitude.—H. **Godard**: Observation of Finlay's periodic comet (1919*e*) made at the Bordeaux Observatory with the 38-cm. equatorial. Position of comet and comparison star given for November 25.—M. **Auric**: The cycle of eclipses. The ratio l/d is expressed in continued fractions, the fifth of which, $\frac{242}{223}$, was known to the Chaldeans as the Saros cycle; its error is 0·036 day in 18 years. The fraction $\frac{4904}{4519}$ is in error by only 0·0003 day in 365·4 years.—G. **Sagnac**: The direct comparison of the two simultaneous mechanical systems of radiation. Method of showing the translation of the earth.—S. **Procopiu**: Layers of metal, of minimum thickness, measured by their electromotive force.—H. **Abraham**, E. **Bloch**, and L. **Bloch**: The ultra-rapid kinematograph. The film is moved continuously and the object illuminated by electric sparks. With the arrangement described and figured, upwards of twenty thousand photographs per second can be taken on the film.—G. A. **Hemsalech**: The spectra emitted by the red fringe and luminous vapour in the neighbourhood of a plate of incandescent graphite.—C. **Staehling**: The radio-activity of uranium. An account of some experiments undertaken in an attempt to split up uranium into uranium I. and uranium II. The attempt at separation was unsuccessful, but some of the phenomena described do not appear to be simply explained by the current theories of radio-activity.—G. **Claude**: The synthesis of ammonia at very high pressures. The results of a series of experiments on the formation of ammonia from its elements in presence of a catalyst at pressures varying between 200 and 1000 atmospheres and at temperatures between 536° C. and 740° C. are given graphically. At 1000 atmospheres and 536° C. the percentage of ammonia in the mixture amounts to 41 per cent. Having regard to the reaction velocity as well as yield, the zone of utilisable temperature is between 500° C. and 700° C. The yield per gram of catalyst per hour is much higher than that obtained in German works.—L. **Guillet**: The transformation undergone by certain aluminium alloys. It was shown about twenty years ago that certain alloys of aluminium with iron, manganese, and nickel rapidly fell to powder on exposure to air. This phenomenon has been further investigated, and it is found that the change in the aluminium-manganese alloy is due to an allotropic modification, whilst the aluminium-antimony alloy oxidises in moist air. The iron and nickel alloys did not change, and it is probable that some unknown impurity was the cause of the falling to powder observed in the earlier experiments.—P. **Dejean**: The critical points of self-tempering steels.—A. **Kling**, D. **Florentin**, A. **Lassieur**, and R. **Schmutz**: The preparation of chloromethylchloroformates. The existence of monochloromethyl- and dichloromethyl-chloroformates is proved and methods for their preparation are described.—L. **Moret**: The discovery of lacustral Eocene beds at the Roc de Chère (Lake of Annecy).—L. **Mercier** and C. **Lebailly**: Primitive cancer of the pancreas and giant cells in mice.—P. **Bugnon**: The use of commercial inks in plant histology. Some commercial inks of French manufacture can be employed with advantage as histological stains. Two formulæ for triple stains are given in which ink is one of the constituent dyes.—J. **Offner**: Phytogeographical remarks on the massifs of Vercors and Dévoluy.—M. **Baudouin**: The fibula of a newly born infant of the Polished Stone period, and consequences in anatomical philosophy. The faces of the bone are smooth and free from the grooving found in the Neolithic adult. The grooves are therefore acquired, being due to special muscular actions depending on the mode of walking of these prehistoric men.—MM. G. **Bertrand**, **Brocq-Rousseu**, and **Dassonville**: The influence of temperature and other physical agents on the insecticidal power of chloropicrin. When using chloropicrin against insects the intensity of the light and the hygrometric state of the air need not be taken into account; the temperature, however, is of importance; the higher the temperature, the more rapid is the destruction of the insects.—T. **Kabéshima**: Experimental researches on preventive vaccination against the dysentery bacillus of Shiga.

CALCUTTA.

Asiatic Society of Bengal, December 3, 1919.—Dr. N. **Annandale**: A loom used by the Gaodar herdsmen of Seistan. The loom, though of very simple structure, seems to be degenerate rather than primitive, its peculiarities depending not so much on lack of skill in its makers as on lack of proper materials, notably wood.—V. H. **Jackson** and A. T. **Mukerjee**: Improvements in measurements with quadrant electrometers. Part ii. Simplified arrangements for accurate and continuous work. During most months in the year accurate measurements with sensitive quadrant electrometers cannot be made in India without special precautions, owing to the high temperature and humidity. In continuation of earlier work the authors have now considerably simplified the arrangements for accurate and continuous work.—V. H. **Jackson** and A. T. **Mukerjee**: The utility of desiccants in electrostatic measurements. The authors have tested the relative efficiency of the various desiccants used in electrostatic measurements under strictly uniform conditions, using Dolezalek electrometers with the arrangements described in the previous paper. Calcium chloride has been found quite unsatisfactory, metallic sodium (extensively used in Germany) and phosphorus pentoxide worse than useless, and quicklime only temporary in its effect. Strong sulphuric acid is the only satisfactory desiccant for this purpose.

DIARY OF SOCIETIES.

THURSDAY, JANUARY 1.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. W. H. Bragg: The World of Sound: Sound and Music (Christmas Lectures).

FRIDAY, JANUARY 2.

ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 3.30.—Miss Hilda Bowser: A Visit to the Diamond Mountain in Korea (Christmas Lecture to Young People).

ROYAL SOCIETY OF ARTS (Indian Section), at 4.30.—A. P. Morris: Burmese Village Industries: Their Present State and Possible Development.

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—A. V. Sims: Automatic Electric Weighing Machines, as used with Machine Packers.

SATURDAY, JANUARY 3.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. W. H. Bragg: The World of Sound: Sounds of the Country (Christmas Lectures).

MONDAY, JANUARY 5.

BRITISH PSYCHOLOGICAL SOCIETY (Education Section) (in Mathematics Theatre, University College), at 2.30.—Dr. P. B. Ballard: The Development of Mental Tests.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.

SOCIETY OF CHEMICAL INDUSTRY (at Chemical Society), at 8.—E. V. Evans: The Natural and Acquired Facilities Existing in the Occupied Area of Germany for the Manufacture of Chemical Products—the Outstanding Impressions resulting from an Inspection of Chemical Works in that Area, and a Consideration of the General Position in the Light of more Recent Developments in this Country.—Dr. G. S. Walpole: The Collective Effort of German Chemistry Industry.

ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 8.30.—Prof. J. W. Gregory: The African Rift Valleys.

TUESDAY, JANUARY 6.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. W. H. Bragg The World of Sound: Sounds of the Town (Christmas Lectures).

ROYAL PHOTOGRAPHIC SOCIETY (Technical Meeting), at 7.—Dr. G. H. Rodman: The X-Rays approached from the Popular Standpoint.

RÖNTGEN SOCIETY (at Medical Society of London), at 8.15.

WEDNESDAY, JANUARY 7.

ROYAL SOCIETY OF ARTS, at 3.—L. Pendred: Railways and Engines (Juvenile Lecture).

PHYSICAL SOCIETY OF LONDON (at Exhibition of Apparatus, in conjunction with the Optical Society, at the Imperial College of Science), at 4.—Prof. Rankine: The Use of Light in the Transmission and Reproduction of Speech; at 8.—Prof. F. J. Cheshire: Some Polarisation Experiments.

GEOLOGICAL SOCIETY OF LONDON, at 5.30.—S. S. Buckman: Jurassic Chronology: I. Lias. Supplement I. West England Strata.—F. J. North: Syringothyris, Winchell, and Certain Carboniferous Brachiopoda referred to Spiriferina.

ROYAL SOCIETY OF MEDICINE (Surgery, Subsection of Proctology), at 5.30.—Dr. W. M. Telling and Others: Diverticulitis.

WATER-POWER AND DARTMOOR.

THE proposal to develop electrical energy from water-power on Dartmoor has led to a strong protest against interference with the amenity of the moor as appreciated by the lovers of solitary places. Mr. Eden Phillpotts first directed attention to the matter by a letter in the *Times* of December 10, in which he called on the Duchy of Cornwall, the landlords of Dartmoor, to act quickly "and help to create a body of Parliamentary opinion; otherwise the destructive and ill-considered enterprise may receive sanction from an indifferent House of Commons next session." A Plymouth correspondent supplied to the *Times* of December 23 an account of the scope of the proposed scheme, and on later days other writers expressed their strong disapproval of the project from local, engineering, or æsthetic points of view. Unfortunately for a journal which desires to review the situation justly, the supporters of the scheme have not taken part in the newspaper discussion, and as we have not seen the Bill in question we can judge of its provisions only from the statements of its opponents, and must accordingly assume an attitude which may appear more critical of the upholders of the *status quo* than our sympathies would have dictated had we access to both sides of the question.

To many lovers of Nature, Dartmoor has already suffered disenchantment by the grim associations of the prison which has been established there for a century, and there may be some who object to the system of leats which for a still longer period has supplied water to the towns on its fringes. The correspondence referred to does touch unfavourably on the modern waterworks which supply Plymouth, Torquay, and Paignton, but these are accomplished facts, and serve merely to strengthen the opposition to new interference with the moor and its rivers.

The scheme of the Dartmoor and District Hydro-electric Supply Company is briefly to utilise the great rainfall and high altitude of Dartmoor in the generation of electricity at several power stations situated on different streams, to convey the current to the neighbouring towns and villages for ordinary municipal purposes, and possibly to erect industrial establishments where current might be used for electrolytic or power purposes. It is claimed that this work will furnish needed employment for the population of the district, provide a continuous and economical supply of electricity for lighting, traction, and heating, reduce the congestion of railway traffic by diminishing the demand for coal, and generally increase prosperity and confer public benefits more than sufficient to counterbalance any interference with agriculture, fishing rights, or the pleasure of visitors to the Moor.

The general, and especially the local, public is not qualified to weigh the rival claims, and as things now stand Parliament must proceed by the old, cumbrous, and very costly method of hearing eloquent advocates and technical experts on all the points raised.

No one is now likely to deny the general applicability of the rule that private convenience must give way to public advantage; but there is still a great deal of confusion as to the criteria by which the conflicting claims should be judged. It is in our opinion essential that all matters connected with the use of natural resources should be investigated by experts whose personal interests are not involved in the case. It is of equal importance that full and impartial information should be available before a decision is arrived at. In the present instance no one knows what the available rainfall on Dartmoor really is, but this can be ascertained if an average rainfall map is constructed from the data which are accessible and according to methods which have been established. The available fall between reservoirs and power-houses can be found by direct surveys guided by the existing Ordnance Survey maps.

The cost of the necessary engineering works is a more difficult and practically a more important question, as no one can foresee the price of materials or the value of the pound note during the years which must elapse before the works can be completed. The size of the dams required in forming reservoirs and the depth of their foundations, on which any estimate of cost must be based, can be ascertained only by detailed surveys and numerous borings, which experience of private Bill legislation has taught us are not always carried out before the Bill is deposited. The danger of underestimating the cost is less likely to be incurred by a company which depends on the scheme showing a profit when carried out than by a public authority which does not labour under that wholesome disability. In other aspects, however, the exploitation of natural resources by public authorities is more likely to be to the public interest, and certainly more likely to secure general confidence.

At present the whole question of the water resources, and especially of the water-power, of the British Isles is being investigated by a Committee of the Board of Trade, and on this account Parliament may be inclined to postpone the consideration of private Bills dealing with water, if not of special urgency, until the Committee has reported. There are few areas in England where an unused gathering-ground exists at an altitude allowing of the development of water-power, and it may well be considered inexpedient to allocate them finally before a hydrometric survey has been carried out to enable the available power and its cost to be calculated on a sure basis before work is commenced.

RADIO-COMMUNICATION AND THE THERMIONIC VALVE.

(1) *The Thermionic Valve and its Developments in Radiotelegraphy and Telephony.* By Prof. J. A. Fleming. Pp. xv+279. (London: The Wireless Press, Ltd., 1919.) Price 15*s*. net.

(2) *Text-book on Wireless Telegraphy.* By Prof. Rupert Stanley. New edition in two volumes. Vol. i.: *General Theory and Practice.* Pp. xiii+471. Vol. ii.: *Valves and Valve Apparatus.* Pp. ix+357. (London: Longmans, Green, and Co., 1919.) Price 15*s*. net per vol.

(1) SCIENTIFIC workers who desire to learn something about the latest developments in radio-communication generally find that books on the subject are either scientific but too technical, or not sufficiently scientific and so useless for their purpose. It is little use to have illustrations of the kenotron, the pliodynatron, the ultra-audion, and the tungar, with diagrams of their connections, unless we have also some reasoned account of their mode of action. The reader soon tires also of vague accounts of the electron theory, which is regarded by some authors as a kind of fetish which must never be criticised and the mere mention of which is supposed to explain everything.

In the first chapter Prof. Fleming gives an interesting and instructive historical introduction. So far back as 1883 he read a paper to the Physical Society describing the molecular radiation in incandescent lamps with horse-shoe filaments. He proved that the blackening of the bulb was due to the scattering in straight lines of carbon particles from the filaments, one leg of the horse-shoe filament protecting a long strip of the bulb from being blackened.

Later in the same year Edison discovered that a current would flow between the positive terminal of the filament and a metal plate sealed in the bulb. In those pre-electron days the phenomenon was considered by electricians hopelessly puzzling. In 1897 Sir J. J. Thomson first published an account of his demonstration that negative electricity is always associated with certain masses about 1800 times smaller than the mass of an atom of hydrogen, and that under certain conditions these electric corpuscles are emitted from hot bodies. It then became possible to give a scientific explanation of the Edison effect. It was not, however, until 1904 that Prof. Fleming published his master patent, which proved the utility of the Edison effect in radio-telegraphy.

The Fleming valve, which is the parent of all the thermionic valves, allows electricity to flow from a heated filament to a cylinder, both being enclosed in a vacuum bulb, provided the cylinder be at a higher potential than the filament. If the potential be lower than that of the filament, then practically no current flows. The device thus acts as a true valve, allowing current to flow in one direction, but not in the other. The high-frequency currents in the aerial can thus be rectified, and the consequent gushes of electricity in one direction can magnetise the electromagnet of the telephone and thus produce a sound.

In chap. iii. a description is given of several types of three-electrode valve and of the various ways they can be connected up. Special stress is laid on the historical side of the development of this valve. In chap. iv. we are told of the discovery that the three-electrode thermionic valve could in certain circumstances act as a generator of oscillations. It would be of interest to know who suggested to Meissner that he should try whether it was possible to make the thermionic relay into a generator. Whoever it was deserves great credit for his suggestion.

Prof. Fleming points out how analogous the action of the generator valve is to that of the "humming telephone," which has been known to electricians for the last twenty-five years, and also, but not so obviously, to that of the Duddell arc.

The great advantage of the thermionic valve as a detector in practical work is that it is not liable to be damaged by electric atmospheric discharges, which often cause endless trouble when coherers or crystal detectors are employed. In chap. v. the uses of the thermionic detector in radio-telephony are described, the complicated diagrams being quite easy to follow, partly because of the use of the excellent system of symbols standardised by radio-engineers. In chap. vi. descriptions are given of the methods of using thermionic devices in radio-telephony. We are pleased to note that due credit is given to H. J. Round, of the Marconi Co., for his numerous inventions.

In the concluding chapter an account is given of some recent improvements in thermionic devices mainly developed during the war. There are several suggestive methods of testing the efficiency of radio-apparatus described in the book, some of which are due to the author. There is also, perhaps naturally, a great deal about the law case between the Marconi Co. and the De Forest Radio Co., which ended so triumphantly for Prof. Fleming. We can heartily recommend the book to all scientific readers.

(2) The development of the art of radio-communication during the war has forced the author to expand his text-book into two volumes, the second volume being mainly devoted to vacuum valves and valve circuits. In writing the first volume Prof. Stanley had in view the needs of wireless operators and amateurs. He was impressed by the lack of a text-book on electricity and magnetism suitable for radio-students. We are told that the existing text-books do not discuss sufficiently fully induction, oscillatory currents, and the true significance of "magnetic or electric lines of strain in the all-pervading ether." In the author's opinion the electron theory will present fewer difficulties to the student than the "vague fluid theories which it has replaced." The reviewer read, therefore, his introductory chapters, giving an elementary *résumé* of the latest theories, with an open mind and with considerable interest.

The impression produced on him, however, was very disappointing. The student is at once introduced to electrons. He is told that there are 10^{23} free electrons in a centimetre cube of metal, that electricity is a constituent of all forms of matter, and that "a unit of negative charge is an electron, and a unit of positive charge, etc." He is told this before negative or positive charges are defined. On p. 13 he has to answer the question, "If the electron theory is taken as the correct one, what is electricity?" Potential (p. 23) is defined as follows: "The electric strain in the ether available for making an electric current flow through the medium is called the electric pressure, or potential, and is measured in units called 'Volts.'" This is certainly not the academic definition of potential, but it is getting perilously near the "vague fluid theories." We are told that "if two bodies of the same size are charged equally with 'positive or negative electrification' there is no difference of potential between them." This is misleading. It is true in free space, but if there are any other bodies in the neighbourhood it is probably not true.

Some of the definitions are carelessly given. The joule, for instance, is defined to be the work done by one ampere of current in flowing between two points, A and B, when the difference of potential between A and B is one volt. Similarly, in the definition of the erg (p. 42), the "per second" is left out. The dielectric constant is defined (p. 55) as "its effect when used as a dielectric as compared with an air dielectric." This is unintelligible. The formula for measuring the mutual inductance between two coils (p. 78) is wrong; it should be $M=(L_1-L_2)/4$. There is a misprint also in the formula for the time given on p. 82. The rest of the first volume is mainly concerned with ordinary radio-practice and is readable. Some of the diagrams are admirably clear.

In the second volume the author begins, very properly, with a recapitulatory chapter on "electrons." The theory of the thermionic valve is mainly concerned with the passage of electricity through gases, and the electron theory explains this admirably. As the author was chief wireless instructor with the B.E.F. in France he is thoroughly at home when describing the systems and apparatus used by the Allies in their wireless services. Radio-engineers will find the chapters on continuous wave (c.w.) transmission and on radio-telephony useful.

A. R.

CATALYSIS.

Catalysis in Theory and Practice. By Dr. Eric K. Rideal and Prof. Hugh S. Taylor. Pp. xv+496. (London: Macmillan and Co., Ltd., 1919.) Price 17*s*. net.

THE whole subject of catalysis stands in a peculiar position. For many years it has attracted investigators on the purely scientific side, who have added greatly to its scope in respect both of new material and of theoretical speculation. It is being actively pursued along both lines at the present time. There are also its vast technical applications, many of them already well known, to which addition is being constantly made, and wherein new fields are rapidly opening up, of which the modern chemist must take cognisance. Yet, in spite of all this, we should be hard put to it to distinguish clearly between a catalytic and a non-catalytic process. The so-called catalytic criteria are not really very helpful. Ultimately the term "catalysis" will probably vanish from chemical literature as our knowledge of the mechanism of chemical processes advances, though the term may remain for long as a convenient, though arbitrary, term of classification. But we are very far from this state of affairs at present, and there is the greatest possible need that the importance of the subject should be emphasised and its immense possibilities clearly indicated. We find this well brought out in the book before us. A brief enumeration of the contents will give an idea of what the authors have attempted.

After a short historical outline and a consideration of catalytic criteria, we are brought to the subject of promoters. There is a brief discussion of the possible mechanism of promoters, and it is pointed out that the beneficial effect of several promoters present simultaneously "may be due to the greater range of temperature over which at least one of the oxides is unstable or labile." In connection with induced or mutual effects, Liveing's views are given their just prominence.

Chap. iii. contains valuable information of a kind not usually met with in a text-book—*i.e.* such points as space-velocity and space-time yield—together with a short description of the authors' apparatus for the quantitative measurement of heterogeneous catalytic processes.

In the succeeding chapter oxidation processes are considered, viz. the manufacture of sulphuric acid, salt cake, the oxidation of ammonia to nitric acid, the manufacture of chlorine, the oxidation of sulphuretted hydrogen, the purification of illuminating gas and gaseous fuels, surface combustion, catalytic oxidation in the dye industry, the drying of oils, and other processes. Incidentally, the necessity of a sound knowledge of the thermodynamics of physico-chemical processes is made evident.

Chaps. v. and vi. deal with the manufacture of hydrogen and with processes of hydrogenation and dehydrogenation. These include some of the most recent and important developments of applied chemistry. The authors in these chapters, as elsewhere in the book, have added greatly to the interest and value of their work by useful suggestions regarding the directions along which further advances are likely to be made or are most urgently required. (As a minor point one might query the meaning of the data attributed to Rittman on p. 217.)

In chap. vii. we pass to a consideration of the all-important problem of the fixation of nitrogen, especially by the Haber process, which has attracted so much attention recently in the Allied countries, and upon which the authors write from first-hand knowledge, though too briefly.

After dealing with hydration and hydrolysis in chap. viii., in which such subjects as synthetic alcohol, the manufacture of glucose, and the Twitchell process are dealt with, the authors return in chap. ix. to reactions of the "Sabatier" type in their account of dehydration processes, consideration being given at the same time to dehydrations in homogeneous systems.

To a very large extent the preceding chapters are devoted to catalytic processes of technical importance—actual or potential. In chap. x. our attention is directed to a different aspect of the field, namely, the *rôle* of catalysis in organic synthesis, in which such topics as the Grignard reagent, the Friedel-Crafts reaction, halogenation, the aldol and benzoin condensations, dynamic isomerism, racemisation, and muta-rotation are discussed, on the whole, rather too briefly perhaps.

In chap. xi. ferment and enzyme action is taken up. Here we find catalysis the dominant characteristic, serving as the link between chemistry on one hand, and physiology and bacteriology on the other. This chapter is particularly good. The authors acknowledge their indebtedness to Prof. Bayliss for his criticism of the treatment given.

In the next chapter we are brought to the consideration of yet another field—namely, catalysis in electrochemistry, a subject in which catalysis plays an important but, on the whole, little recognised part. It is of the greatest value to have this aspect emphasised. The problems dealt with are: cathodic reduction, anodic oxidation, and passivity.

The concluding chapter is entitled "Catalysis in Analytical Chemistry." It is a familiar subject considered from a somewhat novel point of view. The treatment is comprehensive and sufficiently detailed to give the reader a true impression of the *rôle* of catalysis in this fundamental branch of chemical training and practice.

The book is excellent. It is indispensable, in fact, to everyone interested in chemical science whether on the academic or on the applied side.

W. C. McC. L.

THE NEGLECTED STUDY OF PROBABILITIES.

Calcolo delle Probabilità. By Prof. Guido Castelnuovo. Pp. xxiii + 373. (Milano-Roma-Napoli: Società Editrice Dante Alighieri di Albrighi, Segati e C., 1919.) Price 20 lire.

AMONG the sins of omission for which mathematicians and teachers of mathematics might be charged, there is probably none which has so vitally affected our national welfare as the neglect of the study of probabilities. Into every event of ordinary life considerations of probability enter in a greater or less degree, and for this reason every boy or girl who has learnt to use vulgar fractions ought to be taught to apply them to simple games of chance, and in this way to illustrate the rules for fractional addition, multiplication, and so forth. In default of this knowledge, millions of pounds are spent on postal orders in response to attractive offers of hundred-pound prizes the expectation value of which is not one-tenth of the price paid. Yet it was only recently that the Central Welsh Board excluded probabilities from an examination syllabus in algebra which was simply loaded up with questions on collections of letters and symbols that could convey no meaning to the victims of the examination system.

Other applications are to such problems as life assurance and statistics. In the former the calculations must, of course, be largely left to experts, but the public ought to acquire an intimate familiarity with the nature and meaning of probability and expectation and their numerical representation in order properly to appreciate the transactions. This elementary knowledge should come under arithmetic, not algebra. As for statistical applications, the systematic way in which parliamentary electors are misled for lack of understanding these things is evident. They have not realised that when wages go up prices also go up.

Now Prof. Castelnuovo's treatise strikes the reviewer as just the kind of book of which it would be worth while to publish an English translation. It is a long time since we had a standard work on the subject on similar lines, and in the interval our notions on teaching mathematics have certainly moved in a practical direction. Prof. Castelnuovo's book well meets the situation. Of course, the treatment is mathematical and the calculus is freely used, but the formulæ are introduced as statements of principles rather than as purely algebraic relations, and the whole treatment centres largely round practical applications. Any B.Sc. candidate would find the book quite easy reading, and the subject very useful in connection with physics, biology, philosophy, or, indeed, any branch of science, even including that all-embracing subject, aeronautics. A special feature on the more advanced side is the account given at the end of the discoveries of Tchebychef, who is quoted as having made the greatest contributions to the subject after Laplace.

Of course, the initial difficulty lies in the definition of probability, regarding which Prof. Castelnuovo's treatment both in the preface and at the beginning of the text is probably as good as the circumstances permit. There is no unique definition of probability, and in most cases no unique measure of its value. The old definition by an event which may happen in m ways and fail in n ways postulates a preconceived condition of "equal probability" for the m and n ways. There are, as Prof. Castelnuovo points out, many cases, in particular in games of chance, in which this postulate is admissible and the measure of probability has something like a unique value. But in most cases the estimated probability of an event depends on the extent of knowledge possessed by the person making the estimate, and, indeed, is a continually varying quantity depending on the progress of previous events. No two people would assign the same measure to the probability of a certain candidate passing an examination, and, indeed, the estimated chance varies continuously until the appearance of the list (sometimes even afterwards!). All that we can do in place of a definition is to substitute numerous examples in which the measure of probability is free from ambiguity. The nearest approach to a definition is given by the rules for compounding probabilities, of which the above-mentioned old definition is a particular case, with the additional convention that the probability always lies between 0 and 1, and that after an event has happened we must substitute 1 for the probability of its happening and 0 for the probability of its failing in our future estimates of the probabilities of dependent events. In fact, the theory of probability owes its existence to ignorance of future, and partial ignorance of past, events.

Attention has been frequently directed by the reviewer to energy running to waste among our mathematicians which could be utilised in connection with aeroplanes. In our universities a great deal of waste energy in the departments of pure mathematics could also be utilised by turning out graduates with a knowledge of probabilities and statistics which would filter down through the teachers to the elementary schools and thus to the citizens of the future. And for a start at the top of the ladder, Prof. Castelnuovo's book seems excellent.

G. H. BRYAN.

THE STUDY OF THE FAMILIAR.

A Source Book of Biological Nature-Study. By Elliot Rowland Downing. (The University of Chicago Nature-Study Series.) Pp. xxi+503. (Chicago, Illinois: The University of Chicago Press; London: The Cambridge University Press, 1919.) Price 3 dollars net.

IT is encouraging to read that never before has there been in America "so insistent a demand for a more thorough and more comprehensive system of instruction in practical science." To direct this demand, Mr. Downing is editing a Nature-study series, and has written a source book for the biological side. It aims at showing students in schools of education and teachers at work what materials are readily available and how these may be effectively used. "It undertakes to make significant some of the commonplace environment and to suggest ways in which living material may serve educational ends." Great prominence is given to material which has social and practical interest, but the danger of fostering a one-sided utilitarian outlook is guarded against. "The great contributions of science to the life of mankind are: its emphasis on the scientific mode of thinking or the problem-seeing, problem-solving attitude of mind; a mass of scientific knowledge that serves as the basis for desirable skills; and an interpretation of Nature productive of an inspiring appreciation, both intellectual and æsthetic, of her phenomena. Science instruction needs to assure these things to the individual pupil." These are clearly defined aims, and the book appears to us to be highly successful in all the three directions indicated—in setting problems and cultivating the curious spirit; in showing that Nature-study makes for efficiency as well as for understanding; and in cultivating a reasonable love of Nature. A note with fine resonance is struck when the author declares his ambition to treat his material so that "the everyday things may stand revealed as the wonders they really are."

The book deals with animals of pond and stream, insects and their allies, birds, gregarious animals, wayside flowers, common trees, seeds and seedlings, the garden, and spore-bearing plants. Each chapter has its list of references; there are practical hints as to material; the illustrations are abundant and interesting. They include some pupils' drawings. There is a genuine attempt throughout to get at the child's point of view and to use its judgment of values. "The teacher needs to take much of the foolishness of childhood along with her, and needs also to be persuaded that it is not altogether foolish." But there is no namby-pamby nonsense. We wonder a little, however, at some of the phrases which are unfamiliar to us, such as the chick's egg or the chicken's egg. Why not the hen's egg, and be done with it?

Of the many features which are admirable, we may give a few illustrations: (*a*) There is an embarrassment of living creatures in many country places. The author's plan is to make sure of the commonest—let us say, a score of the butterflies, birds, or trees. (*b*) There are many subjects which are so little understood that the cautious teacher is often inclined to leave them alone. The author's advice is rather to tackle them, to confess them as unsolved problems, and to leave them as seeds in the mind. We refer to such subjects as the migration of birds. (*c*) The author is not afraid of sounding the note of wonder. "To watch the germination of an inert seed, the development therefrom of the tiny plant, the growth of bursting bud and flower, is to cross the threshold of Nature's impenetrable mysteries." He quotes the sentence: "The love of a flower in the heart of a child is the highest thing that Nature-study can hope to develop." But the suggestion of this mood is not inconsistent with learning quite precisely how to graft or with understanding the work of Mendel or of Pasteur. We are sure that teachers of Nature-study will find Mr. Downing's book very profitable, and they ought also to know his almost perfect introduction to heredity, "The Third and Fourth Generation."

VACCINE-THERAPY.

Practical Vaccine Treatment for the General Practitioner. By Dr. R. W. Allen. Pp. xii+308. (London: H. K. Lewis and Co., Ltd., 1919.) Price 7*s*. 6*d*. net.

THE author of this little work is well known as an enthusiastic advocate of vaccine-therapy, on which subject he has already written widely. In the present volume he addresses himself more particularly to the general practitioner, for whose benefit and guidance he explains in lucid and forcible terms his methods and practice. The one theme which runs through the whole volume, and colours his frequent comments on the experience and teaching of other vaccinists, is his insistence on the necessity for adequate dosage capable of exciting focal or general reactions and its control by the closest observation of the patient's responses and clinical symptoms. He asks his readers to follow his methods and thereby assist vaccine-therapy "to take its rightful position as the most truly scientific therapeutic agent in the doctor's armamentarium." Unfortunately, however, the book contains scarcely one pessimistic note, and, again, the unbiassed reader, who otherwise wishes vaccine-therapy well, is left with the reflection that, so long as the results of vaccine-therapy continue to be assessed by the unscientifically accumulated personal impressions of vaccinists, so long will vaccine-therapy continue to hold no higher position than that of an empirical remedy, in spite of its undoubted scientific basis.

On this point the author, referring to vaccine treatment in respiratory diseases, remarks: "No physician has the right to play about with cases of pneumonia to satisfy statisticians or opponents of vaccine treatment. It thus becomes necessary to rely on the clinical impressions of reliable observers." Such impressions, we believe, carry less and less weight when we come to evaluate the results of specific therapy in its widest sense, and it is not unlikely that, as our knowledge of the non-specific as well as the specific therapeutic effects arising from the introduction into the animal body of a bacterial protein accumulates, many of the deductions so glibly drawn by ardent vaccinists may go by the board. None the less, as an exposition of the faith of an enthusiastic and somewhat over-confident vaccinist, the book is well worthy of perusal, and contains what, on the whole, appears to be sound advice.

The early chapters are devoted to general questions connected with the nature, preparation, and administration of vaccines, and are excellently written. For the chapter dealing with the best methods for securing material from various sources for culture and preparation of vaccine, the reviewer has nothing but praise, the laudable object being to secure "the right kind of material in the right kind of way." Chapters follow on the use of vaccines in prophylaxis and in the treatment of the carrier-state, but the greater part of the book is devoted to vaccines as therapeutic agents in practically every microbic disease. There would appear to be no microbic disease, whether of acute or chronic character, which is not amenable to vaccine-therapy when employed in the manner indicated by the author.

OUR BOOKSHELF.

The Stars Night by Night: Being the Journal of a Star Gazer. By J. H. Elgie. (First published as "Night Skies of a Year," 1910.) Pp. xiv+247. (London: C. Arthur Pearson, Ltd., 1919.) Price 1*s.* 6*d.* net.

There are many ways of being an astronomer, of which perhaps the easiest is to learn the stars and know them by position and name—and there are grades even in that. We do not imply that this defines Mr. Elgie's limitations, but he has written a very pleasant and useful book to help others to attain this degree of astronomical knowledge. Of such books there are many, but this is somewhat unusual. Written in a chatty manner on the model of White's "Selborne," it describes the author's experiences as a star-gazer or naked-eye observer throughout a year, with much quotation, anecdote, and general astronomical information intermingled. There are more than a hundred diagrams, showing the constellations as they appear with reference to the horizon at different dates. Naturally, the diagrams apply to any and all years, so the year when the observations were made is not given, except incidentally in the index, but the fact that the author saw Mira Ceti at maximum early in January, and that it was then as bright as γ Cygni, is fairly conclusive evidence that it was 1907.

The book is a cheap reprint of an earlier one published in 1910, "The Night Skies of the Year," which still remains as the page-heading, and it is not surprising that this reprint should have been considered advisable. It should command a large sale, for both the general reader and the astronomer of any category will find something of interest in its pages.

The Examination of Milk for Public Health Purposes. By Joseph Race. Pp. vi+224. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1918.) Price 8*s.* 6*d.* net.

This book gives a very useful summary of the chemistry and bacteriology of milk. The chemical portion includes the composition of milk and the chemistry of the various constituents, enzymes, immune bodies, mineral salts, etc., with details for their detection and estimation. Milk standards are considered, as well as preservatives. In the bacteriological portion a general account is given of the bacteria of milk and of methods for their enumeration. Chapters are devoted to excremental organisms and to streptococci, to the tubercle bacillus and other pathogenic organisms which may occur in milk, to cells, dirt, débris, etc. Chap. ix. deals with pasteurised milk and aciduric bacilli; and directions for the preparation of culture media and tables of specific gravity, for the conversion of cuprous oxide and copper to lactose, etc., are given in an appendix. The descriptions throughout are clear and concise, and the analytical methods are clearly set out. The book, which contains within its compass an extraordinary amount of information, is most useful, and can be strongly recommended as a laboratory handbook for the teacher and student.

R. T. H.

Insect Pests and Plant Diseases in the Vegetable and Fruit Garden. By F. Martin Duncan. Pp. 95+12 plates. (London: Constable and Co., Ltd., 1919.) Price 3*s.* 6*d.* net.

The object of this little volume is to provide gardeners and allotment-holders with a simple account of the commoner insect and fungoid pests. The descriptions of the various harmful species appear to be on the whole trustworthy, and some approved methods for eradicating them are recommended. But the book's value is diminished by want of revision in the light of modern work. For example, the author is content with Curtis's determination of the potato aphid, and states that the larva of *Anthomyia radicum* is a common pest on cabbage roots, which, despite the name of the fly, is not the case. The account of the infection of potato by Phytophthora and the denial of sexual reproduction in this fungus also require modification. The seven orders (including the comprehensive "Neuroptera" of old-time entomology) into which insects are said in the introduction to be "generally grouped" would not be accepted as an adequate systematic arrangement by any student of to-day. The illustrations include some good photographs and some indifferently executed drawings.

The Deflection of Light during a Solar Eclipse.

IN discussing the effects of atmospheric refraction during solar eclipses Prof. Anderson disregards the shallowness of the effective layer of air as compared with the diameter of the moon's shadow. Unless the sun be very near the horizon, a line of sight drawn from the centre of the umbra to a point in the corona will remain within the umbra right through this layer. This consideration vitiates the method of solution adopted by Prof. Anderson, and consequently its results. On reading his first letter (NATURE, December 4, 1919) I was struck by the ingenuity of his explanation, more especially as I believe he undervalued the amount of the angular deviation arrived at on his theory through taking the sun's radius to be half, instead of a quarter of, a degree. In view of the importance of the subject, a fuller investigation seemed to be required. I hope soon to publish a note giving the complete solution of the problem, and may therefore confine myself here to a statement of the result, which is quite fatal to Prof. Anderson's explanation. I take the altitude of the sun to be 45° and the maximum fall of temperature 4°; the figures given may easily be modified to suit other conditions. I further assume the most favourable distribution of temperature, which is that adopted by Prof. Anderson, when the line of maximum fall of temperature is parallel to the edges of the moon's shadow and independent of altitude. Two stars at a distance of three solar diameters from each other might then show an increase in apparent distance owing to refraction amounting to the 240,000th part of a second of arc. If the diminution of the temperature effect with altitude be taken into account, this figure should be divided by 4.

ARTHUR SCHUSTER.

The Magnetic Storm of August 11–12, 1919.

THE principal question raised by Mr. Evershed in NATURE of January 1, viz. the simultaneity of S.C.s (sudden commencements of magnetic storms) at different parts of the globe, has already a considerable literature. It has been discussed by Prof. S. Chapman and myself in the Proceedings of the Physical Society (vol. xxx., p. 205; vol. xxvi., p. 137; and vol. xxiii., p. 49). It scarcely admits, perhaps, of a precise answer. S.C.s vary from one part of the earth to another, not merely in size, but also in type. In India, for instance, they are normally unidirectional, and much larger in H (horizontal force) than in the other elements. At Kew, and still more at Eskdalemuir, they are often oscillatory, the main movement, a rise in H, being preceded by a shorter and smaller fall. In the Antarctic (Scott's stations) they seem to be always oscillatory and of similar magnitude in the different elements. The time when a movement becomes visible depends on its size and the sensitiveness of the magnetograph. Magnetographs differ widely in sensitiveness and vary in type. An oscillatory movement that is very small or of very short period cannot be recorded by an ordinary magnetograph.

Whether the time of the S.C. is affected by the meridian position of the sun, *i.e.* by the local time, has been discussed by Prof. Chapman. Whether the results he got implied any real difference is a matter of opinion, but if any difference existed it was a question, not of minutes, but of seconds. If any difference existed in the times, one would expect it to be at least as conspicuous in the amplitudes. As I have lately shown, the *type* of the S.C. recorded in the Antarctic does seem to depend on the local time. Eleven S.C.s which occurred between 11h. 59m. and 17h. 20m. G.M.T. agreed in type; while six which occurred between 21h. 3m. and 23h. 25m. also agreed in type; but the two types were fundamentally different. The first class represent noon and the earlier afternoon at Eskdalemuir, but midnight or early morning in the Antarctic; while the second class represent hours near noon in the Antarctic. Complete measurements of the horizontal amplitudes of the S.C. movements exist for eight of the first and three of the second class. Dividing the sum of the Eskdalemuir movements by the corresponding Antarctic sum, we get 0·43 for the first class and 0·42 for the second, the mean from all the S.C.s of which I have complete records at both stations during 1911–12 being 0·42. The values of the ratio vary greatly for individual S.C.s, so that the coincidence in the above figures must be largely accidental. But, at all events, it seems incompatible with any conspicuous influence of local time on the amplitude.

As to the particular S.C. of August 11–12, 1919, when first measuring the Kew curves I made the time slightly before 7h. G.M.T., whether one or two minutes before I now forget. Remeasuring it now, with as little prejudice as possible, I make the time 6h. 58m., agreeing with the value got by Dr. Crichton Mitchell for Eskdalemuir. The time-breaks at Eskdalemuir occur on the curve itself, so the estimate there is free from the uncertainty to which, I presume, Mr. Evershed refers, which is usually known as "parallax" between the curve and time lines. This source of uncertainty is also practically non-existent at Kew, but the train and tram disturbances now experienced there make all measurements less certain than they used to be. The S.C. on August 11 was, however, so large, and the discontinuity in the H curve so conspicuous, that I think the uncertainty might fairly be put at ±0·5 minute. The uncertainty of the ordinary measurement at the average observatory, even for S.C.s, is certainly not less than this, and is probably a good deal larger.

C. CHREE.

Relativity and Radio-activity.

WITH regard to some of the postulates of relativity, it seems interesting to ask if radio-active instability might not be capable of providing a timekeeper which would retain its uniformity independently of motion relative to the æther.

As to how such a clock might be made practical or whether it must remain theoretical is beside the present question. So also is the degree of accuracy which might be attainable. Primarily, we might suppose the radio-active clocks rated one with another by a simple count of the α-rays emitted over a certain solid angle and during a certain time interval, the clocks being in the one locality. Thereafter these clocks would serve to define simultaneity in widely separated localities, the diminishing quantity of the radio-active substance notwithstanding.

As I say, the primary question is not so much one of practical application, but as to whether it would be theoretically possible in this way to observe motion relative to the æther.

Or is radio-activity also "in the conspiracy"?

J. JOLY.

British Botanic Gardens and Stations.

In the article on British botanic gardens and stations in the jubilee number of NATURE (p. 263) the statement is made that by the middle of the eighteenth century, when Kew and the Botanic Garden at St. Vincent were founded, "the purpose of botanical collections had become largely limited to the assemblage of plants interesting because of their rarity. Presently a healthy reaction against this rather narrow outlook arose . . .," and the example is quoted of the Calcutta Garden, founded in 1786 for the purpose, not of collecting rare plants as articles of curiosity, etc., "but for establishing a stock for disseminating such articles as may prove beneficial to the inhabitants, as well as to the natives of Great Britain, and which ultimately may tend to the extension of the national commerce and riches." Your contributor appears to have overlooked the fact that a very similar purpose underlay the founding of the St. Vincent Garden, as shown by the advertisement which appeared in the Transactions of the Society of Arts for 1762, offering a reward "to anyone who would cutivate a spot in the West Indies in which plants useful as medicine and profitable as articles of commerce might be propagated, and where nurseries of the valuable productions of Asia and other distant parts might be formed for the benefit of his Majesty's Colonies."

I am glad to add that the Royal Botanic Gardens, Trinidad, attained its centenary this year.

W. E. FREEMAN,
Director of Agriculture.
St. Clair Experiment Station, Port-of-Spain,
December 6.

I AM very grateful to Dr. Freeman for having directed attention to the existence of this interesting documentary evidence that West Indian public opinion in 1762 was a quarter of a century in advance of official opinion in the East Indies. This conclusion is pointed to by the circumstance that there was a demand in the West Indies for such sumptuous works as "The Natural History of Barbados," by Griffith Hughes, published in 1750; "The Natural History of Carolina, Florida, and the Bahamas," written by Mark Catesby, revised after Catesby's death by G. Edwards, and published in 1754; and "The Natural History of Jamaica," by Patrick Browne, published in 1756, of which a second edition was called for in 1780. It is important to have this conclusion definitely confirmed.

THE WRITER OF THE ARTICLE.

NATURAL HISTORY OF SOUTH AFRICA.[1]

MR. FITZSIMONS'S volumes are not strictly zoological treatises. They are intended to supply information about the ways and habits of the creatures of veld, forest, mountain, and stream. It sounds somewhat strange to hear mammals referred to as belonging to the "lower animal kingdom." The author speaks sometimes of "animals and birds"; in other places he alludes to "birds and mammals," while the bats are spoken of as "flying mammals." Since this work is addressed to school teachers, senior pupils, and the general public, it would have been better to explain what is meant by "mammals" and retain the term throughout. Mr. Fitzsimons holds the view that the leopards in wild countries uninhabited by man "are still fulfilling the mission for which the Creator evolved them" (i., p. 120), and that "it is essential that the old, decrepit, or malformed animals should not be allowed to live and breed, otherwise the great plan of the Creator in perfecting the various forms of life would be marred" (ii., p. 79).

[1] "The Natural History of South Africa." By F. W. Fitzsimons. "Mammals." In four volumes. Vol. i., pp xix+178; Vol. ii., pp. xi+195. (London: Longmans, Green, and Co., 1919.) Price 9s. each vol.

These and other views may not be acceptable to the modern zoologist, but there can be no doubt about the importance and interest of these two volumes to all lovers of natural history, and particularly to those who keep monkeys and other mammals as pets and to the guardians of our Zoological Gardens. A charm of style and a freedom from errors distinguish the volumes. The vivid descriptions of the habits of the blue ape and the Chacma baboon, as well as of those of

FIG. 1.—A baby Vervet monkey, born at the Port Elizabeth Museum. From "The Natural History of South Africa."

many other species, are fascinating to read. The author gives us further particulars of the wonderful story we heard long ago of "Jack," the Chacma which acted as signalman on a South African railway line. When his master, to whom he was devotedly attached, became incapacitated, owing to an injury, "Jack" took over his duties. He worked even the levers on the line by himself (i., pp. 61–67), and finally pushed his master home every night on a little railway truck. This marvellous story is fully substantiated by creditable witnesses.

Mr. Fitzsimons had a serval which was as tame as any domestic cat, and even when fullgrown it did not lose any of its playfulness, and nothing gave it keener joy than to be romped and played with. It had, however, to be kept in partial confinement on account of its fondness for poultry. The author makes some appropriate remarks on the subject of keeping animals in confinement.

Some people consider it distinctly cruel to deprive animals of their liberty, although they may be confined in large, roomy, comfortable cages and all their physical needs provided for. Such folk know little or nothing of the hardships which most animals in their native haunts are called upon to undergo in the shape of scarcity of food, inclement weather, and the necessity to be at all times on their guard against the many enemies by which they are surrounded. The feelings of the lower animals cannot be gauged by those of us who have the mental, moral, and spiritual faculties and an advanced condition of development. If the physical needs of the lower animals, and even the primitive races of man, are provided for, they are then in a condition of perfect happiness.

No one would imagine that lions could live on vegetables, and yet the late Dr. Livingstone pointed out that the lion of Central Africa frequently feeds on the desert water-melon. Mr. Fitzsimons is wrong in his statement that the lioness produces no more than five young at a birth (i., p. 123). On several occasions a lioness in the Dublin Zoological Gardens had a litter of six cubs.

There seems to be evidence to show that the African wild cat breeds freely with the domestic cat, and this would strengthen the view that the former is the ancestor of the European domestic cat.

The two volumes which have been issued contain a most valuable store of information on the habits of wild mammals. It is interesting to note that the aardwolf lives almost entirely on termites; that the Cape hunting dog will scour the country for days, doing perchance more than 100 miles a day, on a perfectly empty stomach; and that the Cape otter seems to be slowly abandoning its aquatic habits. Some mammals, like the ratel, exhibit an unusual amount of intelligence, if the reports can be credited that it follows the movements of a little bird known as the honey guide in its search for honey. "Of all the animals known to me," says the author, "the ratel has the most energy, endurance, and perseverance."

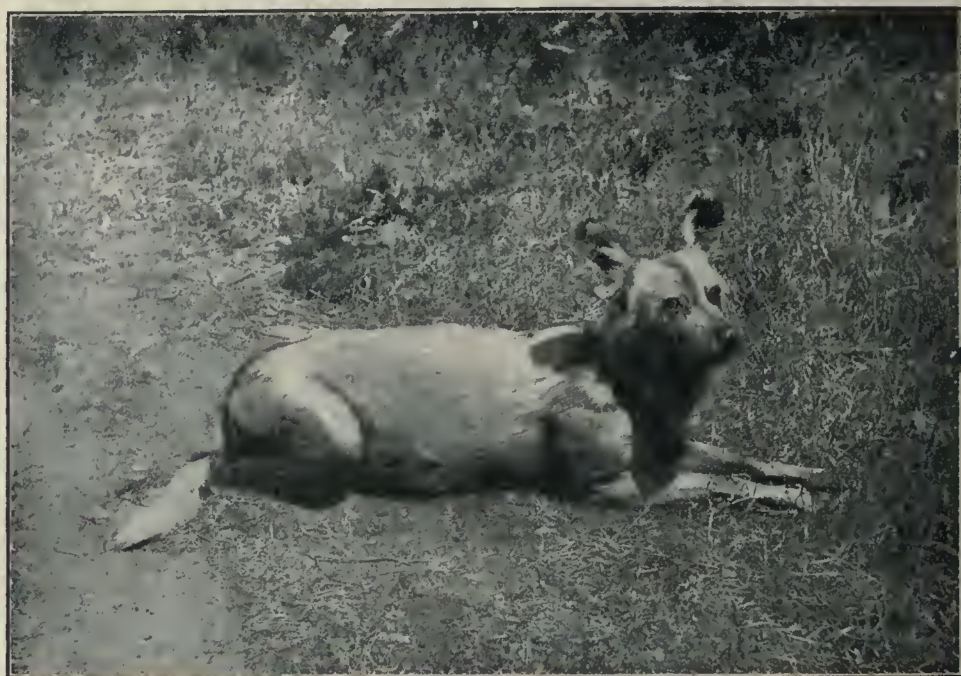

FIG. 2.—The Cape Hunting Dog, which is as big as a mastiff. From "The Natural History of South Africa."

Many of the illustrations are of a high standard, and add to the value of this welcome work.

INDUSTRIAL RESEARCH.[1]

DURING the past few years manufacturers have tended to lift the veil of secrecy behind which they were wont to hide their works processes and operations. Under the menace of war, and with the partial removal of ordinary intercompetitive conditions, rival manufacturers who were faced with problems incident to the fabrication of new war products turned to each other for mutual guidance and assistance, and a very considerable interchange of knowledge and experience resulted, to the benefit of all concerned. The tendency to secrecy, which prevented manufacturers from sharing their knowledge for the common benefit of the industry and for the better combating of foreign competition, was one of the

[1] Report of the Committee of the Privy Council for Scientific and Industrial Research for the Year 1918–19. Pp. 94. (London: His Majesty's Stationery Office, 1919.) Price 6d. net.

greatest obstacles in the way of organising industrial research on a scale and of a character requisite for the needs of industry as a whole. It is therefore most interesting to note, from the recently published report of the Department of Scientific and Industrial Research, what success has attended the efforts to establish research associations. These associations are organised and supported by manufacturers in specific industries, and some financial aid is granted by the Department for a limited period of time, of an amount about equal to that contributed annually by the firms comprising the associations.

Through such means research bearing on problems of common interest in the several industries may effectively be carried out, and those channels for the interchange of knowledge and experience with which we have become familiar during the war, and which are so essential if the greatest benefits are to be obtained, will be maintained.

Already a number of the most important industries have established research associations, and most of the remainder are giving this matter earnest consideration. Some question might be raised on the soundness of the policy of conducting research in this manner, whereby each industry is more or less self-contained, so that difficulties arise in the ready interchange of special knowledge which, though acquired in the first instance by and for one special industry, would be, if readily available, of the very greatest interest and value in others. One might anticipate, however, that the present type of organisation will be only a step towards an ultimate goal, possibly a centralised scheme which will effectively provide for that interchange of thought and knowledge between research workers without which the whole benefit of their knowledge and discoveries cannot be secured.

The widespread variety of researches coming under the survey of the Department is worthy of note; of these, none is of greater importance than that relating to medical work. Jointly with the Medical Research Committee, the Industrial Fatigue Research Board has been established, in order to carry out investigations in industry concerned with output, timekeeping, labour, wastage, and such data as will serve as indices of fatigue. The enormous waste of human effort arising from inefficient application in almost every kind of mental and manual operation has long been recognised. Much of this inefficiency has been due to a lack of knowledge of the fundamental conditions governing fatigue, and at this time there is no investigation of greater importance than that which concerns the conservation of human effort, especially having regard to the far-reaching effects of fatigue, manifested in ill-health, increased risk of accidents, and loss of production. The results of researches falling within the scope of the Industrial Research Board may prove of outstanding value, not only as affording a scientific basis for the determination of the real working capacity of individuals, but also as indicating the laws underlying the most economical application of human effort, the observance of which will reduce to a minimum all the physiological and psychological reactions arising from fatigue, which are such potent factors in the cause of industrial discord and unrest.

It is gratifying to note the increased attention given by the Department to the financial assistance of those students who desire to qualify for research work. The lack of sufficient numbers of really sound research workers is acutely felt in industry, and money expended in bringing to maturity the powers of young men who exhibit an inherent capacity for scientific investigation will be wisely spent.

A further interesting feature of the report is the organisation of means for co-operating with the extensive scientific investigation that is being conducted by research organisations in the overseas Dominions. It is not sufficiently realised by consumers in this country that it is just as important for research to be conducted towards the efficient production of raw material as towards cheapening the more advanced processes of manufacture. In this connection every encouragement should be given to maintaining the closest possible relation with research in the Colonies.

A matter to which one would like to see greater attention given is a means for developing and maintaining an acute interest in scientific research on the part of the manual workers in industry and by the general public. As the report truly points out, a marked change is taking place in the attitude in industry towards scientific research, but this attitude has largely been the result of scientific achievement during the war, and unless efforts are made to stimulate and maintain it this interest is likely to suffer eclipse as other problems arise. Probably no better means could be devised for achieving this purpose than such displays as the admirably conducted British Scientific Products Exhibitions of the last two years, coupled with systematic propaganda in the daily and technical Press.

A. P. M. FLEMING.

SERICULTURE IN INDIA.[1]

FOR long past, the decline of the Indian silk industry has given rise to considerable anxiety. The main feature of the situation has been a serious falling off in the production of raw silk in Bengal (hitherto the principal silk-producing province of India) involving a restricted use of Bengal silk in India itself and a great decline in the overseas exports of raw silk. The place of these exports has in part been taken by the excellent silk now produced in Kashmir, but the quantity is small compared with the Bengal exports of former years. The unfortunate result has been a great advance in the import into India

[1] Report on an Inquiry into the Silk Industry in India. By H. Maxwell-Lefroy and E. C. Ansorge. Vol. i., "The Silk Industry." By H. Maxwell-Lefroy. (1916.) Pp. ii+211. Price Rs. 2, or 3*s*. Vol. ii., "Present Condition of the Silk Trade of India." By E. C. Ansorge. (1916.) Pp. vi+115. Price Rs. 1 As. 6, or 2*s*. Vol. iii., Appendices to Vol. i. By H. Maxwell-Lefroy. (1916.) Pp. 227. (Calcutta: Superintendent Government Printing, India, 1917.) Price Rs. 2 As. 12, or 4*s*. 2*d*.

of raw silk from foreign countries (especially Japan), and, more unfortunate still, a startling increase in the import of manufactured silk piece goods, also from Japan. When it is added that, with notable exceptions, the Indian raw silk is so defective as regards reeling and other characters as to hold but a low place in the estimation of manufacturers, it will be evident that the position of the Indian silk industry is indeed serious.

With the view of ascertaining whether, and by what methods, the revival of the industry is possible, the Government of India in 1915 decided upon a comprehensive survey of the whole question in both its sericultural and industrial aspects. Prof. Maxwell-Lefroy and Mr. C. E. Ansorge were appointed to conduct this inquiry, and their exhaustive reports are now available. Prof. Lefroy's inquiry was mainly concerned with sericultural and technical questions, while Mr. Ansorge's investigations have provided an admirable account of the industrial aspect of the industry.

India possesses great advantages as a silk-producing country. The enormous areas suited to the worms and their food-plants (in addition to the cultivated mulberry silk she has at least one promising "wild" silk), the abundance of cheap labour, the local market, and, not least, an experience extending over many centuries, should place India in the forefront of the silk countries of the world. Her present unfortunate position (resulting mainly from the decline in the Bengal production) is ascribed by Prof. Lefroy to four main causes, viz., (1) the increased production of silk in Japan, (2) disease among the worms, (3) increased value of other crops, (4) the inferiority of the Bengal worm. We suspect that (2) and (4) are the fundamental causes of the existing state of affairs. With expert organisation, the compulsory and exclusive use of disease-free seed and the improvement or replacement of inferior races of worm would unquestionably result in the relative rise in value of silk as a crop, and enable the competition of Japan to be more successfully met. Unmistakable object-lessons are afforded by the results of the scientific management of the industry in the native States of Kashmir and Patiala, both of which now produce an excellent mulberry silk.

These facts are recognised by Prof. Lefroy in making his recommendations. His principal suggestion is for the establishment of a central silk institute to investigate all branches of sericulture with a view to improvement; to study processes of weaving, dyeing, and finishing; and to afford expert advice on all phases of the industry, including the questions of trade and possible new markets.

It is possible that the results of Prof. Lefroy's investigations may not be regarded officially as indicating a clear case for a strong forward silk policy in India. The fact that the decline in silk is in part attributed to the increased value of the other crops will naturally result in hesitation to embark on a large development of sericulture absorbing an amount of energy which conceivably might be more profitably utilised in other directions. It must not be overlooked, however, that silk-raising can be successfully carried on only as a cottage industry, and that without deflecting a single worker from any other crop scientific organisation and control of the present sericultural industry would add enormously to the quantity and quality of the output of raw silk. The question is, however, admittedly difficult. Unfortunately, the fact is that for a large part of India's requirements the quality of the local silk is "good enough," and there may be a disposition to leave it at that. In doing so, exceptional opportunities —commercial, industrial, imperial—will be ignored. With the measures suggested by Prof. Lefroy (notably the establishment of a silk institute), India should be able to replace with locally-produced silk much of the raw material imported from Japan, and enable the growing import of silk fabrics to be reduced. As regards the overseas export of raw silk, India would find markets ready to take all the silk she could spare so long as it conformed to accepted standards of quality, reeling, and cleanliness. Within the last few years there has been a remarkable development in the world's consumption of silk (especially in America), and manufacturers would welcome with open arms new sources of supply of the raw material. The situation offers unique opportunities for India to establish her position as an Imperial source of merchantable raw silk; and before finally deciding as to the future silk policy of the country the authorities would be well advised to consider the changes that are taking place in the economic conditions of the world's silk trade.

SIR WILLIAM OSLER, BART., F.R.S.

ACLAND, Burdon Sanderson, Osler; and if to these we add—in a chair closely allied to theirs—George Rolleston, we look upon a procession of men of rare distinction of character and accomplishments; and each in his very distinction different from the others. Of such children Oxford may well be proud. For if Osler by birth was a Canadian, and in much of his life American, yet his temper and culture were also of the best Oxford could give; Oxford whose gifts are lavished abroad far beyond the narrow limits of her own walls. Thus Osler, "after a sleep and a forgetting," and "trailing clouds of glory" from the old West Country of his fathers, came to Oxford as to a spiritual home. And Oxford took him to her heart as her own; there, as one of her own, he rested; but bringing with him, as gifts from the New World, an openness and simplicity of mind and conversation, a frankness and generosity of temper, a freedom from the frost and weight of custom, and a pioneer's command of affairs which made him as delightful a fellow-worker as he was clear-sighted and effectual. Children loved him, for in him they found the best part of themselves. Osler happened to be visiting in Oxford with the present writer when Sanderson intimated his intention to retire from his chair; a few hours later, after some hints from his friends, Osler felt the call of the bounteous mother; and not the least of the warrants of his qualities was in this, that his friends in Oxford almost sprang upon him, as they realised that before them they had a man worthy to succeed his honoured predecessors.

And if Osler had not also to capture Great Britain, as he captured Oxford, it was because Great Britain was already his mistress. Indeed, there was not a school of medicine in the Old World where his presence was not almost as well known, and his friendship as precious, as in the New. It was characteristic of him that a few years later he obtained leave from Oxford to spend some months in Paris, during which period he regularly attended the clinics of the great hospitals, at 7.30 a.m., like an ordinary student.

Of Osler's contributions to knowledge it is as hard to make a list as it would be for Socrates. They were many, no doubt, but consisted even more in his insemination of other minds, in personal teaching and influence upon his disciples. His great text-book, for many years, and still, the guide of every English-speaking student, had many and almost singular merits. Although within its compass no particular subject could be dealt with at large—for every subject had to be kept in subordination to the whole—yet in the successive editions it was always helpful in any quest to turn to "Osler," because, if it were but in a word, or the turn of a sentence, one perceived that the latest and best researches, if not presented in detail, were known to the author. Thus the work was not a provider only, but also to the wise an indicator. The reader feels as he reads that both whole and parts were being continually re-adapted to the developing phases of knowledge. Perhaps the author's most original and valuable researches were in the field of the diseases of the spleen and blood; but he made eminent contributions also to the study of infections of the heart, of angina pectoris, of malaria, and of many minor maladies. But, the most modest of men, his conversation was always of the good work of others, silent on his own. It is to be hoped that some one of his pupils will prepare a bibliographical list of his essays and papers, and, furthermore, of his literary essays, such as are contained in the delightful volume entitled "Æquanimitas." It is said that a great part of the revision of the text-book for the new edition, on which he was at work, is written.

Osler's work for others was so incessant, and his hospitality so unbounded, that one always wondered when and where he amassed and made use of his learning; learning which, in particular, would discover itself, as it were, by accident, unless, indeed, his companions were expert enough to see it under the surface of his talk. Somehow or other he was not only in sympathy with various subjects of study other than medicine, especially with literary pursuits, but was able also to converse on something like equal terms with the masters of them. When in Cambridge, he found himself thus quite at home with Aldis Wright in the literature of the seventeenth century; and his proficiency in the history of medicine, well known to all students of the subject, gave breadth and living interest to all his teaching. His apprehension must have been as quick as his memory was tenacious and orderly and his power of expression felicitous. His address last year to the Classical Association was as sparkling as it was profoundly humane; eminent for the depth of its sympathies and for the compass of its understanding, it was no *tour de force*; the speaker made no pretence to technical scholarship, his discourse had a more free air, was more of the world, more comprehensive than is common with such addresses, but yet on its own ground was a brilliant oration.

A quality that made Osler so fascinating a companion, his teaching so vivid and telling, and his parts in debate often so lively, was his wit and humour; the sharpness of the wit tempered by the sweetness of the humour. Indeed, much of his playfulness and whimsical mystifications were, in naturalist's phrase, a protective colouring to cover deep sensibilities. In its *finesse* his conversation resembled that of Henry Sidgwick; not a more or less laboured deliverance of epigrams, but a light, nimble play of insight and fun. Much of its piquancy lay in the half-concealment of the treasures of the mind.

It is a touching thought that with all these attainments, all these accomplishments, we are mourning at this moment, not, or not merely, the skilful doctor, the great scholar, the research student, or even the wise and tactful reformer, but far more the sympathetic friend of all and of a few; one in whom this expansion of his friendship made him none the less a dear brother to those who were nearest to him.

The loss of his one child, an undergraduate of Oxford who was killed in action, smote Osler to the heart. His son had inherited his father's abilities and character, and shared his literary tastes and his pride in the fine library which had been always the library *Gulielmi Osler et amicorum*. This blow to him and Lady Osler was beyond healing; but last summer, during some fine weeks in Guernsey, he regained much bodily health. A fine swimmer, he drew life from the sea. Unhappily, a little later he was caught by the ruthlessly sudden strike of the railwaymen, and had to travel in an open motor-car from Newcastle to Oxford. He reached home chilled and weary, and was attacked by a broncho-pneumonia, which, after many phases and some transient signs of amendment, ended rather unexpectedly in death on December 29. Two days before had arrived in Oxford the "Festschrift," compiled by his friends for his seventieth birthday. This volume, which had been presented in form but delayed in completion, he was never to see; it is now a monument, one among many, to his memory.

C. A.

NOTES.

THE list of New Year Honours includes one earl, three barons, seven Privy Councillors and three in Ireland, nineteen baronets, and a number of appointments to orders of knighthood. Sir Bertrand Dawson, Physician in Ordinary to the King, and Dean of the medical faculty of the University of London, is one of the new peers. Among the new knights are Prof. Arthur Schuster; Dr. E. A. Wallis Budge, Keeper of Egyptian and Assyrian Antiquities, British Museum; Col. W. A. Churchman, Ministry of Munitions Explosives Department; Dr. J. Court, known by his researches on diseases of miners; Mr. F. C. Danson, chairman of the Liverpool School of Tropical Medicine; Mr. D. E. Hutchins, for his services to forestry; Mr. James Kemnal, for public services in connection with the manufacture of munitions; Mr. F. S. Lister, research bacteriologist, South African Institute for Medical Research; Mr. H. J. Mackinder, M.P.; and Dr. F. G. Ogilvie, Director of the Science Museum, South Kensington. Prof. S. J. Chapman, Joint Permanent Secretary, Board of Trade, and Sir Richard Glazebrook have been promoted from C.B. to K.C.B. Dr. G. R. Parkin has been promoted to the rank of K.C.M.G., and Mr. H. N. Thompson, Chief Conservator of Forests, Nigeria, has received the honour of C.M.G.

WE regret to announce the death on January 4, at seventy-eight years of age, of Sir Thomas R. Fraser, F.R.S., emeritus professor of materia medica, University of Edinburgh, and Honorary Physician-in-Ordinary to H.M. the King in Scotland.

THE PRINCE OF WALES, who has recently become vice-patron of the Royal Geographical Society, will be present at the meeting of the society on Monday, February 2, at the Central Hall, Westminster, at 8.30 p.m., when a paper will be read by Major-Gen. Sir Frederick Sykes on "Air Routes of the Empire."

THE *Times* correspondent at New York reports that violent earthquake shocks were felt over the greater part of the Mexican Republic on Saturday night and Sunday, January 3–4. The State of Véra Cruz seems to have suffered most. The Mexican Government Observatory places the centre of the disturbance near the volcano of Orizaba. A shock was recorded by the seismograph at Kew Observatory at 5.25 a.m. on January 4.

ON Tuesday next, January 13, at 3 o'clock, Sir John Cadman will deliver the first of two lectures at the Royal Institution on (1) "Modern Development of the Miner's Safety Lamp," and (2) "Petroleum and the War." The Friday evening discourse on January 16, at 9 o'clock, will be delivered by Sir James Dewar on "Low-temperature Studies," and on January 23 by the Hon. Sir Charles Parsons on "Researches at High Pressures and Temperatures."

THE Ramsay Memorial Fund has received from Prof. H. Kamerlingh Onnes a very substantial contribution of 1571*l*. 9*s*. 5*d*., which has been given or promised by donors in Holland. These generous contributions are evidence of the sympathy felt in Holland for British science and scientific workers, and the respect so widely felt in that country for the memory of the late Sir William Ramsay. Among the subscriptions are:—Philips Gloeslampenfabriek, 500*l*.; Fransch Hollandsche Oliefabrieken, Delft, 300*l*.; Nederlandsche Gist & Spiritusfabriek, Delft, 300*l*.; Van den Bergh's Fabrieken, Rotterdam, 300*l*.; and Lym & Gelatinefabriek, Delft, 100*l*.

ANNOUNCEMENT is made in the *British Medical Journal* that the eighty-eighth annual meeting of the British Medical Association will be held at Cambridge next summer, under the presidency of Sir Clifford Allbutt, Regius professor of physic in the University, who will deliver his address on the evening of Tuesday, June 29. The sectional meetings for scientific and clinical work will be held on June 30, July 1, and July 2, the mornings being given up to discussions, and the afternoons to clinical and laboratory demonstrations. There will be twelve sessions, of which five will meet on each of the three days, and the remainder each on one day. The annual representative meeting will begin on June 25. The annual dinner has been fixed for July 1, and on the evening of July 2 Dr. G. S. Graham-Smith will give the popular lecture. Saturday, July 3, the last day of the meeting, has been set apart for excursions to places of interest in the neighbourhood.

FURTHER excavations at the well-known Anglo-Saxon site of Ravensbury Manor, Mitcham, have brought to light numerous remains of the period. The old gravel-pit is being extended, and further relics will no doubt be found. Six graves have so far been opened up, with the bones of two giant chieftains and a cripple with a diseased thigh-bone. Two swords, a bronze buckle, and an earthenware jar have been found. At earlier excavations no fewer than a hundred skeletons were exhumed. The first discovery was made in 1848, and in 1895 the opening-up of a new gravel-pit by Mr. G. P. Bidder brought to light a quantity of objects. Later digging by Col. H. F. Bidder produced knives, spear-heads, a few swords, pottery, shield-bosses, saucer-shaped brooches, and some beads, whilst a number of female skeletons were found to have been thrown carelessly into the graves of the men. One grave contained a coin of Constantius II., and Mr. Reginald Smith was of opinion that the date of the cemetery was the first half of the fifth century. Great care will, it is understood, be taken to preserve anything of value that comes to light, but at present nothing new has been found.

THE annual meeting of the Iron and Steel Institute will be held on Thursday and Friday, May 6 and 7, at the Institution of Civil Engineers, Great George Street, London, S.W.1. The retiring president, Mr. Eugene Schneider, will induct into the chair Dr. J. E. Stead, the new president-elect. The council is prepared to consider applications for grants from the Carnegie Fund in aid of research work, of such value as may appear expedient, but usually of the value of 100*l*. in any one year. The awards are made irrespective of sex or nationality. Special forms, on which candidates should apply before the end of

February, can be obtained from the secretary of the institute. The research work must be on some subject of practical importance relating to the metallurgy of iron and steel and allied subjects. The results of research work must be communicated to the institute in the form of a report. By the invitation of the retiring president, Mr. Eugene Schneider, arrangements are in progress for holding the autumn meeting in France next September, provided no unforeseen contingency occurs. Early notice will be given of the precise date and place of meeting and the localities which will be visited.

WE note with much satisfaction that the Government of New Zealand has extended the absolute protection of seals in the area under its control for a period of three years, and that the Prime Minister of Tasmania has decided not to renew the lease of Macquarie Island to the company which so mercilessly exploited the wild life over which it had obtained control. Quite apart from the hideousness of the methods of slaughter, this protection has barely come in time to save these creatures from extermination. Although this danger has, time and again, been pointed out, the authorities allowed commercial interests to prevail. Yet the penguins, seals, sea-lions, and sea-elephants which contrived to maintain a hold on life in those inhospitable regions represent types of animal life which it was our bounden duty to preserve. A hope has been expressed that Macquarie Island may be set apart as an inviolable sanctuary for Antarctic life, and we trust not only that this will be done, but also that steps will be taken to guard against marauders who may be tempted to make occasional raids for the sake of the profits to be gained. To this end the island might be used for the purposes of a biological and meteorological station. Before it is too late we hope that the matter of protection for the whales in the Antarctic seas will also speedily find a place on the Statute-book. The subject has been long under consideration, but as yet nothing has been done on account of the opposition of commercial interests.

DURING 1919 many meteorological features of special interest occurred, and some of these introduced problems well worth discussing. In July and October the weather was exceptionally cold and dry over the British Isles, and the rainfall in both months for the whole country was only 55 per cent. of the normal for the thirty-five years ended 1909. The cold in the autumn was quite remarkable. The Greenwich observations show that the mean temperature for the year was 48·8° F., which is 1·3° colder than the normal for the thirty-five years ended 1915; the mean maximum temperature was 56·7°, and the mean minimum 40·9°. May, June, August, and December were the only months with an excess of temperature. The warmest month was August and the coldest February. There were four months, February, July, October, and November, with a deficiency of temperature amounting to 4° or more. December was 2·4° warmer than the normal, and 3·4° warmer than November, when there were only five days with 50° or above, whilst December had thirteen such days. The total rainfall for the year was 23·4 in., which is 0·1 in. less than the normal. December was the wettest month of the year, and the other months with an excess of rain were January, February, March, and April. The driest month was May with 0·36 in. March and December both registered precipitation on twenty-two days; during the year precipitation was measured on 175 days. Bright sunshine was registered for 1489 hours, which is eleven hours more than the normal for the year. May had the greatest duration of sunshine, 268 hours, and December the least, 21 hours.

THE Report of the Director-General of Public Health, New South Wales, for the year ended December 31, 1917, has recently reached us. It contains the usual full statistical data of the health of the State, and reports on the work of the microbiological laboratory. The latter is chiefly devoted (pp. 150–280) to an exhaustive inquiry on an epidemic of acute polio-encephalo-myelitis. Some 134 cases occurred, mostly in children, of whom 94 died. The chief features were fever in all cases, convulsions in many, and paralysis in a few, with rigidity and mental lethargy, confusion, and drowsiness as a rule. The disease was proved to be the meningitic or cerebral form of acute poliomyelitis (infantile paralysis, Heine-Medin disease).

IN the Journal of the Royal Society of Antiquaries of Ireland (vol. xlix., part 3, June, 1919) Mr. H. S. Crawford publishes a well-illustrated article on the mural paintings and inscriptions at Knockmoy Abbey, which are now partially destroyed, but once covered the entire northern wall of the chancel of the abbey church. The writer adduces arguments to show that they probably date from the sixteenth century. "At an earlier period pictures would hardly have been allowed in a Cistercian church, and at a later the costumes of the figures and the forms of the inscriptions would probably have been different."

IN the Journal of the Royal Anthropological Institute (vol. xlix., 1919, January–June) Prof. F. G. Parsons presents the results of his anthropological examination of a number of German prisoners of war interned in England. He thus states his conclusions: "The more one thinks of it, the more one is convinced that since the sixth century the broad-headed Alpine race has been slowly and steadily supplanting the long-headed Nordic type, not only in Prussia, but in every part of Germany, and the prisoners at our disposal give no reason for thinking that there is any part of Germany in which the Alpine or Slav characteristics have not dominated the Teutonic or Nordic." This view is based on head and face shape and coloration, and, so far as the evidence goes, it is supported by that of stature. The tall provinces are in the north and west of Germany, while the shorter men inhabit the south and east. Curiously enough, after what we have heard of the Pomeranians, they are a short race, the average height being 5 ft. 6·4 in. Of course, it is possible that the exceptionally tall men were drafted into special corps, such as the Guards and Marine Artillery, and that these were not fully represented in the material at the Prisoners' Bureau.

SIR E. BRABROOK has reprinted from the *Anglo-French Review* for October an interesting article entitled "The Anthropological Institutes of France and the United Kingdom." The Société d'Ethnologie de Paris was founded in 1839, and the Ethnological Society of London in 1844. In 1859 the Société d'Anthropologie de Paris was founded by Pierre Paul Broca, and the Anthropological Society of London by James Hunt in 1863. The London society had at first a chequered career; the question of the plurality of races had a political bearing, and some communications made to the society on the characteristics of the negro race were thought to overstep the line which restricts scientific societies in their choice and treatment of subjects for discussion. The question was finally solved by the foundation of the Anthropological (now Royal Anthropological) Institute of Great Britain and Ireland in 1870, which has since enjoyed a useful and prosperous career, though it has never received a State grant such as is enjoyed by its French sister, and has not obtained adequate support from those interested in the problems of our Indian and Colonial Empires. A project has recently been initiated for the establishment among the anthropologists of the Allied nations of a permanent central office of the International Institute of Anthropology, a scheme which, if framed on satisfactory lines, will do much to co-ordinate the work now carried on in Great Britain and on the Continent. Whether Germany will ultimately be invited to share in this organisation depends on the future conduct of that country.

PROF. A. KEITH's important twenty-first Robert Boyle lecture, entitled "Nationality and Race from an Anthropologist's Point of View," has been published by the Oxford University Press (price 2s. net). Prof. Keith begins by classifying the progress of human culture into two stages: that of natural and artificial subsistence. "Man's great bowel, including the cæcum, appendix, and colon, which answered his needs well when his dietary was coarse and uncooked, is ill-contrived to deal with foods which are artificially prepared and highly concentrated." The thesis which he proposes is that "in our modern racial strifes and national agitations we see man's inherited tribal instincts at war with his present-day conditions of life." This he illustrates by a survey of racial and national problems in the United States, Canada, Spanish America, Australia and New Zealand, South Africa—where "the problems of race and of nationality appear in a more acute and tangled form than anywhere else in the world"—and Europe, and by a reference to the Jewish question. As regards the Irish problem, Prof. Keith remarks that, "except for a trick of speech or a local mannerism, the most expert anthropologist cannot tell Celt from Saxon, or an Irishman from a Scotsman. There are, to be sure, certain physical types which prevail in one country more than in another; but I do not know of any feature of the body or any trait of the mind, or of any combination of features or traits, which will permit an expert, on surveying groups of university students, to say this group is from Scotland, that from Wales, the third from Ireland, and the fourth from England." Prof. Keith ends by a strong plea that a knowledge of tribal and racial spirit is essential for statesmen.

PROF. W. TRELEASE discusses the bearing of the distribution of some elements of the existing flora of Central America and the Antilles on former land connections in this area (Bull. Geol. Soc. Amer., No. 29, pp. 649–56). The most important evidence is supplied by the genus Agave, which includes the familiar century plant. Its chief centre is Mexico, but it ranges from Arizona to the Isthmus of Panama, and occurs also in tropical Florida and northern equatorial America. It is represented in the West Indies by about fifty endemic species comprising six distinct types, and from their distribution in the islands the author concludes that the genus was derived from the mainland of Central America at some late Tertiary or early Quaternary time when islands and continents were continuous. Later they spread through the chain over continuous land; the continuity was broken by subsidence or faults when the very deep Anegada Passage, which separates the islands of St. Thomas and St. Croix, was formed, and later subsidences have caused in succession the deeper and lesser water gaps by which the Antilles are divided into groups successively more or less distinct in their Agave flora. These conclusions harmonise with the fact indicated by Eggers: that the greatest break between the northern and southern elements in the Antillean flora coincides with the deepest, and presumably the oldest, break in the Antillean bridge, now represented by the Anegada Passage.

THE geological work on the Western Front forms the subject of an interesting paper by Mr. W. B. R. King in the *Geographical Journal* for October (vol. liv., No. 4). Mr. King was Geologist at General Headquarters in France for more than three years. His problems were mainly concerned with water-supply, which at times presented much difficulty in view of the amount required. The advice of the geologist was also of great importance in mining and tunnelling operations and in the construction of dug-outs.

WE have received a copy of the Rain Map of Australia for the year 1918, published by the Commonwealth Government. It gives the total rainfall for the year and separate maps for each month. Some small inset maps show the areas with rainfall above the average in recent years. The year 1918 was in marked contrast to the two preceding years, both of which had an unusual amount of precipitation. In some respects it resembled 1915, when there was severe drought in the interior of New South Wales and Queensland. Rainfall was good until the end of February, when drought set in over the central and eastern parts of Australia. The westerly, or, as this chart names it, the Antarctic, rainfall in the south seems to have been fairly normal, but its influence was restricted to the coasts in the south-west and south-east. South Australia suffered from drought, and throughout the wheat-belt there was a serious deficiency in spring rains. A cool spring, however, minimised this want, and cereal crops were fairly good in Western Australia, South Australia, and Victoria, but largely a failure in New South Wales and Queensland.

THE shortage of potassium salts and nitrates during the war has directed attention to many possible sources of supply previously neglected. In Memoir 14 of the Geological Survey of South Africa Messrs. Frood and Hall discuss the deposits of saltpetre found as an interstitial filling along the bedding planes at the base of the valleys in a region of hard ferruginous shale near Prieska and Hay, Cape Province. No satisfactory estimate is available of the average composition and depth of the deposits. Nitrification of the animal excreta accumulating near the sheltered portions of the cliffs is believed to be the source of the nitrate, which then passed in solution along the joint planes, producing irregular encrustations and pockets. If this be the correct explanation of their origin, it is improbable that the deposits could be of any great depth.

THE Summary of Progress of the Geological Survey of Great Britain for 1918 (issued in 1919) is of special interest through its description of the bauxitic nature of certain Carboniferous strata in Ayrshire. A clay of Millstone Grit age has been found to be a good refractory, with 26–50 per cent. of alumina, 28–50 per cent. of silica, and combined water 7·5–15 per cent. Most of the alumina is combined with silica, probably as kaolin, but there remains an excess, as in bauxitic clays. This excess is, however, not easily soluble in hydrochloric acid, unlike that in bauxite. Oolitic varieties of the bed contain most free alumina. Basaltic lavas underlie the clay, and the conditions that produce laterite and bauxite seem to have prevailed in southern Scotland in Upper Carboniferous times. The discovery and value of this material will stimulate observation in other localities of Carboniferous rocks. It is pointed out that the quality of the material may vary considerably, and that the presence of titanium dioxide, which occurs as rutile, in a greater proportion than 5 per cent. reduces the refractory property considerably. In the same Summary of Progress a record is given of the personal and official services rendered by the staff of the Geological Survey during the five years of war. Among others, our congratulations go out to Capts. E. B. Bailey and J. E. Richey.

IN a valuable paper read before the Royal Society of Edinburgh (Proceedings, vol. xxxix., 1919, pp. 157–208), Prof. C. G. Knott continues his investigations on the propagation of earthquake-waves through the body of the earth. In his new analysis Prof. Knott does not assume any relation between the velocity of propagation and the distance from the earth's centre. His work, which must have been most laborious, leads him to the following conclusions. He finds that the seismic rays of both the condensational and the distortional waves are concave outwards until they reach a depth of about three-tenths of the earth's radius. To this depth, then, the velocity of propagation must increase with the depth. It then becomes nearly constant, but at still greater depths it decreases a little, so that the rays there are slightly convex outwards. The data furnished by seismological observatories enable him to trace the rays to a depth of six-tenths of the earth's radius, but not beyond. At or near this depth the distortional wave seems to die out, for at arcual distances of more than 120° from the epicentre their characteristic appearance in our seismograms is lost. Dr. Knott thus arrives at a conception of the earth's interior which is practically the same as that advanced by Mr. Oldham thirteen years earlier: that the earth consists of an elastic solid shell down to a depth of about half the earth's radius, that here the rigidity breaks down, and that at a depth of about six-tenths of the earth's radius the elastic solid shell gives place to a non-rigid nucleus of measurable compressibility.

SOUTHPORT, by its report of the meteorological observations made at the Fernley Observatory during the year 1918 and discussed by Mr. Joseph Baxendell, the meteorologist to the Borough Corporation, adds much to our knowledge of the weather at one of the principal English health resorts. The report contains more than detailed observations of the weather, and now that the observatory has continued for forty-seven years the results yield values of much importance. Two local atmospheric pollution stations were started during the year, one to be representative of urban and the other of rural Southport. Hourly wind-direction-frequency normals are given numerically, as well as in diagram form as a frontispiece; they show a preponderance of southerly winds in the winter and of westerly and north-westerly winds from off the sea during the day-hours in the summer months. Mr. Baxendell hopes definitely to establish a marked and persistent meteorological periodicity of nearly 5·1 years, which, he states, is especially noticeable in wind direction. The year 1918 was marked by general warmth and wetness, resulting from a very abnormal predominance of winds from the warmer and more humid half of the compass (south-east through south to west). The table giving the rainfall with different wind directions shows that 78 per cent. of the total amount of rain was with winds from these directions.

THE Fifth and Sixth Reports of the Director of Veterinary Research of the Union of South Africa contain an account by Mr. H. H. Green of an improved method for the estimation of small quantities of arsenic by micro-titration with iodine. It was used for determining the fate of ingested and injected arsenic in sheep. Bacteria capable of oxidising sodium arsenite and reducing sodium arsenate have been isolated from arsenical cattle-dipping tanks. Examination of maize-milling products by dietetic experiments upon pigeons shows a close parallelism between the distribution of vitamine and phosphorus in individual maize-kernels, but not in different samples of maize. In the absence of information about the original grain and the extent of milling, microscopic examination would provide a safer test than the estimation of phosphoric acid. An extensive study of diets containing varying amounts of vitamine shows that the daily demand of pigeons for vitamine is not constant, but depends upon the extent of exogenous metabolism.

TECHNOLOGIC Paper No. 139 of the Bureau of Standards, Washington, U.S.A., contains an account of tests of light aluminium casting alloys. Among other tests, a number were carried out to determine to what extent the mechanical properties of cast alloys could be improved by heat treatment as follows:—Heating for two hours at 500° C., following by cooling in air, the specimens then being left to age several days before testing. Some thirty specimens were so treated, and in all but five or six cases there was a resulting increase in tensile strength of from 5 to 50 per cent. In cases where the heat treatment showed a decrease in strength, the whole group of bars of the heat was of inferior quality, cast and heat-treated ones alike. The hardness was increased by the heat treatment. The effect on elongation was more erratic, but in general a decreased elongation was found in the heat-treated specimens. It would appear that the treatment of light aluminium castings has commercial possibilities. Copies of the paper may be obtained by addressing a request to the Bureau of Standards.

THE *Technical Book Review Index* issued by the Carnegie Library at Pittsburgh, U.S.A., appears quarterly, and is a useful guide to new books on pure and applied science. The compilers have not had the actual books before them while preparing the index, but have obtained their information entirely from reviews that have appeared in scientific and technical journals. The accuracy of the information given depends therefore, in each case, upon the care taken in the review consulted. Books are arranged in the alphabetical order of the authors' names. The title of each book is followed by full reference to journals where reviews of the book may be found, and a short quotation from each review, giving, where possible, some idea of the scope and object of the work. The compilers have wisely refrained from expressing any opinion of their own as to the value of each book, although it appears that an attempt in this direction is made upon the index-cards of the library at Pittsburgh from which this review index has been prepared. It will, however, be found that the extracts quoted from reviews give, in most cases, adequate assistance in forming an opinion as to the merits of each work.

PHOTO-ELECTRIC activity seems destined to play an important part in technical photometry. In No. 349 of the Scientific Papers of the U.S. Bureau of Standards Mr. K. S. Gibson gives an account of experiments on photo-electric spectrophotometry by the null method, using potassium hydride cells now on the market. Such cells give a maximum response, usually near 460$\mu\mu$; consequently, the method admirably supplements the visual and photographic methods, being best in the blue and violet parts of the spectrum, where they become poor, and becoming poor only after they have become trustworthy. By employing the null method, first brought out by Richtmyer, errors due to want of direct proportionality between photo-electric current and exciting radiant power, and to the current through the cell when not irradiated, are eliminated. Experiments have also been carried out on diffuse spectral reflection, and the method is applicable to the measurement of the relative radiant power of two sources and to the measurement of fluorescence. In another publication of the same series (No. 344) Messrs. W. W. Coblentz and H. Kahler give data as to the change in the electrical resistance of the sulphide of silver and of bismuth when exposed to radiations of wave-lengths extending from 0·6μ to 3μ. Galena, cylindrite, pyrites, and jamesonite did not show any noticeable sensitivity. At very low temperatures the intrinsic sensitivity of silver sulphide was greatly increased—a result of interest in connection with the fact that some substances exhibit luminescence only at low temperatures.

PART ii. of a paper on the cutting power of lathe-turning tools was read at the Institution of Mechanical Engineers on December 19 by Mr. George W. Burley, of Sheffield University. Part i. was read in 1913 by Prof. W. Ripper, and a number of points raised in the discussion are dealt with in the present paper, which gives an account of the continuation of the series of experiments. Among the conclusions arrived at is the fact that there is no practical cutting speed below which it is impossible to obtain a satisfactory finished surface on plain-carbon steels by the use of tools of plain-carbon tool-steel, ordinary (non-vanadium) high-speed steel, or superior (vanadium) high-speed steel, but there are upper limits as follows:—For finishing mild steel, 48 ft. to 58 ft. per minute for each of the three varieties of tool-steel; for finishing hard steel, 23 ft. to 28 ft., 17 ft. to 21 ft., and 28 ft. to 34 ft. per minute respectively for the three varieties of tool-steel mentioned above. The cutting power of a high-speed lathe tool is influenced by both the cross-sectional area of the shank of the tool and the nose-radius, but the influence of the latter factor predominates. Thus, with a number of different sections of tool-steel, an increase of 100 per cent. in nose-radius produced an average increase of cutting power of 45 per cent.; whereas an increase of the shank cross-section of the tool of 500 per cent. with a constant nose-radius produced an average increase in the cutting power of only 8·5 per cent. There is no marked difference in the net amounts of energy required per cubic inch of material removed from mild-steel and hard-steel bars at high and low cutting speeds.

Messrs. Longmans and Co. expect to publish in January "Applied Aero-Dynamics," L. Bairstow; "The Design of Screw Propellers, with Special Reference to their Adaptation for Aircraft," H. C. Watts; "Telephonic Transmission, Theoretical and Applied," J. G. Hill; and vol. i. (The Extremities) of "A Manual of Practical Anatomy," Prof. T. Walmsley. Others books, in the press or in preparation, by the same house are:—"An Introduction to the Study of Terra Sigillata, Treated from a Chronological Standpoint," Dr. F. Oswald and T. D. Pryce; "Structural Steelwork," E. G. Beck; "Tuberculosis and Public Health," Dr. H. H. Thomson; "Food Supplies in Peace and War," Sir R. H. Rew; vols. ii. and iii. of "A Manual of Practical Anatomy," Prof. T. Walmsley; and, as already announced, "The Life and Work of Sir Jagadis Chandra Bose," Prof. P. Geddes.

OUR ASTRONOMICAL COLUMN.

THE BIRTH OF THE MOON.—Prof. W. H. Pickering in *Popular Astronomy* (October, 1919) endeavours to reconcile Sir George Darwin's estimate of the moon's age (less than 60,000,000 years) with recent geological opinion, which demands a period of 1,200,000,000 years since the formation of the earth's crust. He suggests that the matter of the moon left the earth at that remote epoch, but remained for ages circulating round the earth as a cloud of fragments. In this form its tidal influence would be small, and the earth would for long retain its assumed primitive rotation period of some four hours. Gravity in the tropics would be much reduced by centrifugal force. Prof. Pickering seeks thus to explain the existence of the huge reptiles like the Atlantosaurus and the Diplodocus, also the fact that heavy reptiles like the Pterodactyls had the power of flight. He suggests that the moon was consolidated from the cloud of fragments in the middle of the Cretaceous period, and quotes geological authorities for a great invasion of land areas by the sea and tremendous volcanic activity at that epoch, which he ascribes to the great tides which the moon would have raised when so near the earth. That epoch would agree well enough with Sir George Darwin's estimate of the moon's age, supposing it to date from its consolidation, not from its leaving the earth.

DISTANCES OF THE STARS OF TYPE F.—Mr. C. F. Lundahl discusses the distances of these stars in *Meddel. Lunds Astr. Obs.* (series ii., No. 21). He works on the same lines as Prof. Charlier in his recent memoir of the B stars; that is, he assumes a constant absolute magnitude, and deduces the distance of each star from its apparent magnitude. The F stars have a wider range of absolute magnitude than those of type B, but the great majority of them are included in a range of about 2 mag.; hence tolerable results for the distances may be expected. In fact, he states that 60 per cent. of the stars the parallax of which has been measured agree with his values within the limits of probable error. He quotes Prof. Plummer's research on the same stars, which was based on the assumption that they were moving parallel to the galactic plane. As that method showed an agreement with measured values for only 40 per cent. of the stars, Mr. Lundahl concludes that his own assumption is nearer the truth. He notes from his results that ζ Tucanæ and η Cassiopeiæ are evidently dwarf stars, while Polaris and still more Canopus are notable giants. The density of distribution of F stars is estimated by two independent methods, which give respectively 8 and 4 cubic siriometers for one star of this type (a sir. = 1,000,000 astr. units).

ABSOLUTE MAGNITUDE AS A FUNCTION OF COLOUR.—Mr. F. H. Seares indicates a relation between colour and absolute magnitude in stars of the same spectral type (Proc. Nat. Acad. Sci., July, 1919). The colour is determined photographically by taking graduated exposures of the star on an isochromatic plate with and without a yellow filter. The ratio of exposure times that give images of equal intensity in the two cases is a measure of the colour. The method has been tested on about 150 stars the absolute magnitude of which has been otherwise determined. The following are the results deduced:—Giant stars of types G and K are decidedly redder than dwarfs; also in type B the brighter stars are redder, but the difference is less marked. On the other hand, in type A the fainter stars are redder, while in types F and M the curve is too flat to permit of the absolute magnitude being found from the colour. Thus the method can be applied only if the spectral type is known, but it promises to be a useful supplement to the spectroscopic method. Experiments are being made to examine whether the necessity of knowledge of the spectral type can be evaded by taking three series of exposures with screens of different colours; if this were possible, the method could be applied to much fainter stars.

CROSS-CIRCULATION AS A PHYSIOLOGICAL METHOD.

IN the mutual co-ordination and integration of the physiological processes in a complex organism, in which actions exerted by the environment on a particular part affect the whole and the functional activity of one organ has its influence on numerous others, there are two chief methods adopted. One is by means of the central nervous system, in which messages received from the periphery along certain nerve-fibres are reflected back, as it were, to outgoing nerve-fibres, setting into play the appropriate muscular or other response, it may be in a distant part of the organism. This method has been compared to a telephone exchange. The other is by means of the blood. Owing to the continual circulation of the same mass of liquid through all parts of the body, it will readily be seen that a chemical substance, produced in any one part and passing into the blood-vessels supplying this part, must be carried, sooner or later, to all other parts, and give rise to effects in any tissue or organ sensitive to it. We have here an actual transport of material, the materials carried, when they result in changes in distant organs, being known as "chemical messengers" or "hormones."

In many cases there is difficulty in discovering to which of these modes of communication a particular reaction is due. Thus when muscular exercise is taken, the depth and rate of breathing increase. We know that carbon dioxide is produced in the combustion process that affords the energy for the muscular work. This passes into the blood, and may be in itself sufficient to set into greater activity the nerve-centre controlling the muscles of respiration. On the other hand, it might be that sensory nerves in the muscle are stimulated by the movements, and that the appropriate message is conveyed by nervous channels, or both chemical and nervous factors may be involved. Perhaps a clearer case is that of the pancreas, which pours its powerful digestive juice into the small intestine as the food arrives there from the stomach. We know now that the chief, if not the only, way by which this co-ordination is effected is that the acid of the gastric contents causes the formation of a chemical messenger in the walls of the intestine. This, passing into the blood, ultimately reaches the pancreas and excites it to activity, but it was for a long time believed to be a nervous reflex. Again, the origin of wound-shock has recently been shown to lie mainly in the production in the injured tissues of poisonous compounds, which are carried by the blood to the rest of the body and cause widespread damage to the capillary blood-vessels, resulting in a failure of blood-supply throughout the body. At the same time the co-operation of nervous factors has not been altogether excluded.

The analysis of many problems of this kind has been greatly assisted by the various methods known as "cross-circulation." It is obvious that if we can make a connection between the blood-vessels of one animal (A) and those of another (B), any chemical messenger produced in A must affect B also, whereas a process in A brought about entirely by the nervous system will have no effect on B. In this mode of experiment the blood of A may either be allowed to circulate through the whole of B, and *vice versa*, or some particular organ only of B may be supplied from A, this organ being cut off from the circulation of B. The details of the procedure cannot be described here, but some recent improvements in the technique may be referred to. The chief difficulty lies in the fact that when the blood comes into contact with any foreign surface that is wetted by it, such as the glass or india-rubber tubes connecting the two animals, clotting occurs. This may be obviated by making the blood incapable of clotting. A substance extracted from the heads of leeches will do this, but it is at the present time almost impossible to obtain it. Other substances having the same effect are too poisonous. Since the blood does not clot in the uninjured blood-vessels themselves, Hédon in France and Dale and Laidlaw in this country have made use of pieces of vein to connect the blood-vessels required. The latter workers desired only to divert the blood from one vein of an animal into another of the same animal, so that no great internal pressure was present, and it was sufficient to pass a short metallic tube (Crile's canula) over each end of the piece of vein, reflecting the ends over the tube and tying them. When this is done, and the tube is introduced into a blood-vessel, the blood comes into contact only with the lining of a normal blood-vessel. Hédon, wishing to connect the artery of one animal with that of another, took a metallic tube long enough to enclose nearly the whole length of the piece of vein and reflected the ends over this. The vein was thus adequately supported against the pressure of the blood in the arteries.

Bazett and Quinby, in the current issue of the *Quarterly Journal of Experimental Physiology* (vol. xii., No. 3), describe a method in which the fact is made use of that if blood is in contact only with a foreign surface not wetted by it, clotting is absent for a long time. They coated the interior of the glass and rubber tubes used with a mixture of paraffin and vaseline, and by interposing a specially constructed stopcock were able to connect the circulation of the two animals or return to normal at will.

These improvements in the technique of cross-circulation should render it possible to investigate problems hitherto difficult to solve. There is one disadvantage in it which must not be overlooked. This is the fact that a fall in the blood-pressure in one animal causes an inflow from the other when there is complete intercommunication between the two. Thus one of the animals may be seriously depleted if the low pressure lasts for any length of time. For this reason the production of wound-shock in one animal by the products of tissue-injury of another seems impossible, because the fall of blood-pressure, which is the most marked symptom of the state, would in itself drain blood from the normal animal and produce a similar state merely by loss of blood, apart from the action of a chemical substance. W. M. BAYLISS.

NICKEL-CHROMIUM STEEL FORGINGS.

DURING the war there was a considerable development of the use of alloy steels, in particular of those containing nickel and chromium. These uses were of the most varied kinds, not the least important being in the construction of internal-combustion engines used in aircraft, where service conditions are very severe. It is not surprising, therefore, that difficulty in complying with the specifications was encountered in manufacture, and much novel experience has been accumulated by technical workers in this field of steel metallurgy.

At the autumn meeting of the Iron and Steel Institute two important papers relating to this class of steel were presented: one was by Messrs. Andrew, Greenwood, and Green, of the metallurgical research department of Sir W. G. Armstrong, Whitworth, and Co.; the other by Mr. R. H. Greaves, of the research department, Woolwich Arsenal. It is interesting and significant to note that the latter paper is entitled "Metallurgical Communication No. 1, from the Research Department, Woolwich."

Messrs. Andrew, Greenwood, and Green, who took up the investigation of defects in the final tests of nickel-chromium forgings, have carried out their work in a most thorough and exhaustive way, following up the manufacture of these from the original casting to the finished article. It needs considerable courage for the investigators in a works to publish evidence showing manifest defects in the products of the firm's work, and the authors are to be commended for their honesty in taking this step. It is but rarely that such cases are met with.

The manufacture of a hollow forging may be divided broadly into three distinct sets of operations: casting, forging, and heat treatment. The authors emphasise the operation of casting as the most important of all, because any defects present in the ingot, generally speaking, persist throughout up to the final treatment. It is essential that not only the metal but also the mould-walls should be clean, and that all loose sand must be prevented from getting into the mould. As a method of assisting in the achievement of these results, the authors suggest the use of a tundish with sloping walls lined with basic material. They say that if the metal were run directly into this from the iron ladle, the sloping walls of basic material would act as a cleanser, since the slag would adhere to the sides of the dish. The cleansing action would be similar to that brought about with mercury when poured through a paper cone with a fine orifice at the bottom. They recommend that ingots should be cast wide-end up, and that the smallest size consistent with requirements should be used. They recommend further a high-ladle, but a low-casting, temperature, since this is found to be advantageous in cleansing the metal. The macrostructure of the ingot is determined by the temperature and method of casting. High-casting temperatures are to be avoided because they give rise to excessive segregation, ghost lines, etc., and coarse crystallisation.

The authors advise that, after casting, the ingot should not be allowed to cool more than is unavoidable, but should be solid forged as soon as possible. This breaks up the crystals, thus refining them. It also assists in the diffusion of the carbon and thus renders the mass more homogeneous. The effect is to produce a much stronger material the thermal treatment of which can be undertaken with greater safety. In carrying this out with large forgings, very slow heating up to the temperature range, 730–760° C., must be adopted. Above this the rate of heating may be quicker. The authors suggest further that they have obtained evidence that mechanical work can be overdone, and that the greater the amount the more prone is the tendency to a laminated fracture. A somewhat similar point was made by M. Charpy in a recent paper published on "The Hot Deformation of Iron and Steel." With regard to the final heat treatment the authors say that the temperature of oil-hardening appears to make little or no difference to the mechanical properties; *the* important factor is the time at the temperature in question. This should be as short as possible, since a prolonged heating even at 850° C. coarsens the grain-size and causes a deterioration in properties.

The paper by Mr. Greaves deals with the "temper brittleness" of a nickel-chromium steel containing 3·5 per cent. of nickel, 0·6 per cent. of chromium, 0·5 per cent. of manganese, and 0·25 per cent. of carbon. This term is applied to the condition induced in such a steel by slow cooling from the tempering temperature, and is revealed by a low absorption of energy in the single-blow impact test on notched bars. The author has found that wide differences in the impact figure with almost identical tensile test results can be produced by suitable heat treatment. He has also found that whereas, after hardening, every tempering treatment involving a final rapid cooling from 600° C. or above produced good impact figures, a final slow cooling produced a considerably lower, and often a bad, impact figure; further, that in any given steel the degree of brittleness which can be produced by a given condition of tempering depends on the original hardening temperature. The higher this is, the lower is the impact figure. He has also found that reheating to about 520° C. produces brittleness, whatever the subsequent rate of cooling, and that this can be removed by reheating to between 600° C. and 670° C. and cooling rapidly.

These results can be explained on the assumption that a critical temperature or temperature range exists in the neighbourhood of 550° C., above which the tough, and below which the brittle, condition is stable. Quick cooling through this temperature retards this change, and the unstable tough condition is retained. Slow cooling results in the production of the stable brittle condition. If the tough material is heated to a temperature rather below the change point, the rate of change to the brittle condition is at a maximum, and brittleness results. The rate diminishes rapidly with fall of the temperature, and below 450° is negligible. Provided, therefore, the critical temperature is not exceeded, the rate of cooling after this reheating is immaterial. Mr. Greaves does not show any cooling or heating curves of his steel. Those published by Messrs. Andrew, Greenwood, and Green on a steel of approximately the same composition indicate that the carbon-change point on cooling occurs between about 490° and 465° C. The character of the curve obtained depends upon the initial temperature from which the steel is cooled.

CEPHALODISCUS AND THE ARCHICHORDATES.[1]

THE history of Cephalodiscus, dredged at 245 fathoms in the Strait of Magellan by the *Challenger*, and at first taken for an Alga, and then for a compound Ascidian, goes back only three dozen years. Moreover, the sole species (*C. dodecalophus*) held the field for twenty-one years before the other species made their appearance; but now, with Dr. Ridewood's memoir before us, the total number of species reaches from twelve to sixteen, though further research may reduce that number. It is noteworthy that whilst the majority group themselves around the South Pole, four occur in the Indian and Pacific Oceans.

In the present memoir Dr. Ridewood, already known as an authority on the subject, keeps to the classification adopted previously, the group Pterobranchia (Aspidophora of Allman) having three subgenera of Cephalodiscus, viz. Demothecia, colony branched, with a continuous cavity throughout the cœnœcium; Idiothecia, colony branched, but each aperture leading into a tube occupied by one zooid and its buds; and Orthothecus, in which the colony is cake- or cone-like, each aperture entering a tube holding a zooid and its buds. The author first treats of the structure of the zooids, the similarity of which throughout the whole series is noteworthy; only in the reduced male zooids of *C. sibogae*, Harmer, is there a divergence. This fact alone would give differences due to variations in the cœnœcium less weight.

Amongst other features of interest are the enlargements at the ends of the tentacles, for instance, in the original species, which the author terms "end-swellings with refractive beads," and it is curious that no special function has been assigned to them. Similar enlargements at the tips of the branchial filaments are prominent features in Filograna and the so-called Salmacina, and great weight has been placed on them specifically, and even generically, by certain observers. In all probability they are sense-organs in both groups, since they are not connected with secretion, nor do they perform the function of opercula in Filograna (a Serpulid), in which form they are present or absent with puzzling indifference, for the plasticity of the species is phenomenal. The changes in the character of the epithelium on the dorsal and neural surfaces of the arms, and on the two surfaces of the post-oral lamellæ, are probably due, as in other forms (*e.g.* the Serpulids), to differences in function. The length of the testis is thought by the author to be a specific character, but that of the ovary is not.

Details are given of a new species, *C. evansi*, a branched form, in which each ostium leads into a tube ending blindly in the middle of the branch. The other three species procured in the expedition were formerly known, viz. *C. nigrescens*, Lankester, *C. densus*, Andersson (which the author considers to be a variety of the next), and *C. hodgsoni*, Ridewood. Thereafter a discussion on the Demothecia occurs, the species being extremely difficult to distinguish either by cœnœcium or zooids, and it is possible that future observers may reduce the number of species, since the variations of both cœnœcium and zooids in a single species are considerable.

No new feature is given in connection with reproduction and development further than that the author thinks there is no certain relation between the number of arms and the sex, as Andersson did, and that in *C. hodgsoni* the short stalk of the egg spreads over the egg-shell. Males, females, and hermaphrodites are found in *C. hodgsoni*, *C. aequatus*, *C. nigrescens*, *C. solidus*, and *C. densus*, whilst no males have yet been found in *C. dodecalophus*, *C. levinseni*, and *C. gracilis*. In *C. sibogae* and *C. agglutinans* only males are known, and in *C. gilchristi* and *C. evansi* both sexes frequent the same colony.

The author makes no allusion to the systematic position of Cephalodiscus in zoological classification, or to the homologies of the organs which have received the attention of many zoologists in connection with that classification. Dr. Masterman's Archichordata (Trimetamera), therefore, stands as before, with its two classes (1) Hemichordata (*e.g.* Balanoglossus) and (2) Diplochordata (*e.g.* Phoronis, Cephalodiscus, and Rhabdopleura), though not without dubiety in certain aspects, which even the labours of Spengel, Weldon, Cori, Fowler, De Selys-Longchamps, Lankester, Harmer, Gilchrist, Ridewood, Schepotieff, Davidoff, Hill, Gravier, Pixell, and Roule have not quite elucidated. Much of the dubiety is connected with the notochord and the gill-slits. Dr. Harmer thought that the proboscis-vesicle and "heart," with the notochord, essentially agreed with the condition in Balanoglossus, as described by Mr. Bateson; but Dr. Masterman, keenly working at Actinotrocha, Tornaria, Phoronis, and the young forms of Cephalodiscus, held that the primitive types had a double notochord, and his beautiful and accurate drawings speak for themselves whatever interpretation may be put

[1] "British Antarctic (*Terra Nova*) Expedition, 1910. Cephalodiscus. By Dr. W. G. Ridewood. With 12 text-figures, 5 plates, and a map (Published by the Trustees of the British Museum (Natural History), 1918.) Price 12*s*.

on them. Dr. Harmer's notochord, proboscis-vesicle, and heart are Dr. Masterman's subneural gland, subneural sinus, and preoral sac respectively, and Masterman has demonstrated that the subneural gland of Cephalodiscus and the "Eicheldarm" of Balanoglossus occupy entirely different relationships from the surrounding organs in each case, and therefore cannot be homologous. In both Balanoglossus and Actinotrocha there is a large subneural sinus. The presence of pleurochords in Cephalodiscus, of lateral grooves in Tornaria, and of pharyngeal pleurochords in Rhabdopleura, terminating (as in Tornaria) in oral grooves, which Morgan has shown grow outward into serial pouches, are points of interest in connection with Dr. Masterman's view. Besides, in Balanoglossus there are other chordoid parts in addition to the notochord of Bateson and Harmer. Larval Enteropneusta, again, have a pharynx with simple, paired pleurochords terminating in lateral grooves. It has to be borne in mind that Davidoff describes the notochords and nervous system in certain Tunicates as arising from paired rudiments, and the same observation has been made by Brooks in Salpa. In any case, as Masterman shows, Roule's view that Actinotrocha is a trochophore cannot be held, since the cavity of the latter is a hæmocele, whereas the hæmocele of Actinotrocha is restricted to a small space between the cœlomic sacs. The whole subject is a complex one, yet it may be that further research will weld these diverse views into harmony. Meanwhile, Masterman's opinions have much in their favour.

The memoir concludes with a useful synopsis of the species of Cephalodiscus, and the five plates are excellently drawn and lithographed, the map at the end showing at a glance the distribution of the various species, the whole forming a worthy tribute to the methodical and patient industry of the author, who, along with Dr. Harmer, of the same great museum, has done so much to extend our knowledge of this very remarkable group.

W. C. M.

THE ITHACA AGRICULTURAL EXPERIMENTAL STATION.[1]

AGRICULTURAL experts visiting the United States always include the Ithaca Experimental Station in their programme if they can possibly manage to do so, for it is one of the finest and largest in that country of large institutions. Incidentally also, it appeals to all who read and loved Fenimore Cooper in their younger days, for it is situated in the lake country, and still preserves some of the waterfalls and woods associated with his heroic, if somewhat mythical, warriors.

The reports before us are bulky volumes, each of a thousand or twelve hundred pages; they are in keeping in point of size with the whole institution. The list of the staff occupies four closely printed pages, and includes nearly two hundred names. The number of printed copies of bulletins, reports, etc., sent out during one year only was 3,014,000. The State grant was 450,000 dollars in 1913; it rose during the war to 779,401 dollars for the year 1917–18. An Englishman reading these figures, and realising how greatly the income of this one institution exceeds that of all English agricultural colleges and experimental stations put together, begins to gasp when he finds the acting Dean declaring:—"The greatest single need of the college at the present time is more funds for research"; and again, "In common with other colleges in the University, the College of Agriculture is suffering because of the inadequate salaries which members of the staff are receiving."

The investigations cover the whole field of agriculture, but as no summaries are given it is not easy to find one's way through them.

A large number of the bulletins deal with diseases and pests of farm and garden crops, devoting special attention to practical methods of coping with them. In this type of work the American investigator excels; we have scarcely begun to make provision for field-work in plant pathology in Great Britain, although a promising start has been made with the more fundamental investigations. An extended series of observations on the nodule organism (*Bacillus radicicola*) of soybean is given in Bull. 386; the general result is that nodule formation can be considerably checked or stimulated by the presence or absence of certain salts and by variations in the amount of soil-moisture. Chlorides, phosphates, calcium salts, and certain organic compounds such as sugars, starch, oxalic, lactic, and citric acids, increase the amount of nodule formation; increases in moisture-content had a notable effect also. On the other hand, nitrates, ammonia compounds, and sulphates reduce it, though they do not kill the organism.

The direct assimilation of certain carbohydrates by green plants is discussed in Memoir 9 (1916). Saccharose, glucose, maltose, and fructose are directly absorbed and utilised by plants (green maize, Canada field pea, timothy, radish, vetch, etc.); moreover, they produce a characteristic branched-root system. It is suggested that the absorbed sugar is largely utilised in the root itself, but little migrating to the stems and leaves; this diminishes the downward migration of the sugar produced by photosynthesis and leads to increased top growth. Certain plants, such as radishes, vetch, and Canada field pea, are able to utilise lactose, although this sugar has not been found in the vegetable kingdom. Curiously enough, however, galactose is toxic to green plants, although it is utilised by various fungi. The bearing of the results on the old question of the source of carbon for plants is obvious, and the author concludes, as Laurent did in 1904, that the organic matter of soil plays a direct part in the nutrition of green plants, and in certain circumstances, notably in glass-house work, this part may be very important.

The soil surveys of Oneida County (Bull. 362) and of Orange County (Bull. 351) are typical of this kind of work as done in America. They form interesting reading, and would be helpful to a young man wishing to settle on the land but uncertain to which part of the country to turn.

Costs of production of farm crops form the subject of an important investigation (Bull. 377, 1916). In 1912 and 1913 the average costs of producing oats per acre in New York State were respectively 23·51 dollars and 22·34 dollars per acre, *i.e.* 4*l.* 18*s.* and 4*l.* 13*s.* respectively. It is interesting to compare these figures with the Rothamsted data, where the cost in 1913 was 6*l.* 4*s.* per acre. In both cases one of the largest single items is labour; in New York State it was 3·60 dollars per acre (15*s.*), at Rothamsted 21*s.* 4*d.* per acre, although the rate of wages paid in New York was double that paid in this country. The New York yield was 33·5 bushels per acre, that at Rothamsted 48 bushels.

Bull. 338 contains an interesting study of fertile and infertile soil otherwise similar in character; it was found that the former more readily accumulated nitrates than the latter. The most obvious cause was the difference in compactness of the soil, the fertile being less compact and having a smaller volume-weight than the less fertile one. An extensive bacteriological

[1] Reports of the Agricultural Experimental Station, Ithaca, New York, for the Years 1914–17.

examination was made by H. J. Conn, but it led to no result, indicating the weakness of present-day methods. The bacterial numbers fluctuated with the moisture-content, as at other centres. Some interesting soil-moisture relationships are brought to light in Bull. 352 (1914).

E. J. RUSSELL.

THE RAINFALL OF THE UNITED STATES.

PROF. ROBERT DE C. WARD, of Harvard University, contributes an article on "Some Characteristics of the Rainfall of the United States" to the *Scientific Monthly* for September. The article is essentially of a popular character, but it is dealt with in a strictly scientific manner, and references to the several works from which the information is selected are given throughout, so that a closer and more minute study can be made where thought desirable. Many of the characteristics dealt with are among the most important, and certainly the most interesting, associated with rainfall. There is an endeavour to explain the cause of the special characteristics, a feature in many discussions of the present day. It has often been said in the past, with respect to meteorology, that there are bricks enough, but that we now require builders. Those who have been familiar with meteorology for the last half-century note with satisfaction its practical development.

Referring to the annual and monthly rainfall, Prof. Ward associates the varying amounts with the tracks of cyclones and the general pressure distribution which constitute the rain-producing conditions. The ratio of wettest and driest years to the mean fall is given for the United States generally. Where the annual rainfall ranges from 5 in. to 30 in. the fall in the wettest years may be expected to amount to about 180 per cent. of the average, whilst in the driest years the total is not likely to be less than about 55 per cent. of the average. Years with precipitation above the mean are less frequent than years with precipitation below the mean. It is emphasised that it is always instructive to investigate the weather-map conditions in all cases of unusually wet or dry periods, and to follow especially the tracks of low-pressure systems.

Dealing with periods with or without precipitation, the article states that "over most of the country the number of consecutive rainy days has been between 10 and 20. . . . On the north-western coast (Western Oregon), where the rainfall is heavy and the cyclonic activity is marked, more than 30 days in succession (30 to 40) have been rainy. . . ."

It is said that droughts may occur anywhere in the United States, especially where cyclonic controls of precipitation are weak. There is a distinct relation between droughts and forest fires—"a pre-requisite of a forest fire is a drought."

The Government meteorological reports, such as the Annual Report of the Chief of the Weather Bureau and the Monthly Weather Review, give much valuable material with respect to rainfall. As a rough-and-ready classification of excessive rainfalls, mention is made of 10 in. or more in a month; 2·50 in. or more in twenty-four hours; and 1 in. or more in an hour. Referring to secular variation of rainfall, it is pointed out that trustworthy conclusions cannot be drawn, as few observations go back to 1850, and most observations date from later than 1870. A period of observations for twenty-five years, 1887–1911, for all districts of the United States "lends no colour to the theory of a cycle in precipitation," and curves for New England, the Western Gulf, and North Carolina for 1879–1911 "show no approach to uniformity of distribution in time or space." For non-instrumental evidence a study has been made of the "rings" of trees in Arizona and California, "it being assumed that the thickness of the annual layers of tree-growth gives an approximate measure of the annual amount of precipitation. . . . The fact that the 'big trees' have continued to thrive for three thousand years has been taken to indicate a remarkable uniformity of climatic conditions rather than a series of oscillations."

C. H.

RETIREMENT OF SIR OLIVER LODGE.

ON January 1 the City of Birmingham gave expression to its high appreciation of the work of Sir Oliver Lodge as Principal of the University. At a meeting in the Council House, at which the Lord Mayor (Alderman William Cadbury) presided over a representative gathering of the leading citizens, an illuminated address was presented to Sir Oliver and Lady Lodge. The address, which was read by Sir Gilbert Barling (Vice-Chancellor of the University), was as follows:—"To Sir Oliver Lodge, F.R.S., LL.D., and Lady Lodge: On the eve of your departure from Birmingham we desire to express to you our deep sense of loss, our sincere appreciation of your great services, and our warmest wishes for your happiness and well-being in your new home. To you, Sir Oliver, we owe much as a physicist. Your distinction has added lustre to our city. As academic leader you have started our University on its career with lofty ideals. You have done much to form public opinion as to the meaning of true education in all its forms and among all classes, and your ethical teaching has ever been directed towards social amelioration. You may be satisfied that your labours of nearly twenty years have left a deep and lasting mark on the community which you have so long adorned. To both of you we wish good-bye with the deepest regret, and our most kindly feelings accompany you."

Sir Gilbert added that it was the intention of the subscribers to present also more substantial evidence of their kind feelings in the form of a motor-car, and a jewel for Lady Lodge. He reminded his audience of the greatness of the task which Mr. Joseph Chamberlain had set before the first Principal of the University, and he bore eloquent testimony to the admirable way in which Sir Oliver had realised the ideals of that statesman and justified his choice.

Sir Oliver Lodge in his reply emphasised the debt which the city owed to those public-spirited men who had gone before. He hoped the city had become proud of the University which it had brought into being. It took a little time always to know what an institution was worth, but the University was the crown of the city. He referred to the difficulties under which the University had laboured through lack of funds, but he believed that a better day was dawning. The State and the city were co-operating to a greater extent than before. One of the first uses he proposed to make of his freedom was to visit America. He had often been asked to go, but had never before been free to do so.

THE CHIPPAWA-QUEENSTON HYDRO-ELECTRIC DEVELOPMENT SCHEME.

AMONG the whole of the world's sources of water-power the Niagara Falls stand in a position of unique importance. Not only is the gross capacity of 5,000,000 h.p. a magnificent industrial asset of unrivalled proportions, but the actual development of the Falls at the present time has enabled the Hydro-Electric Power Commission of Ontario to create the largest system of electric transmission in the world. There are altogether ten plants belonging to the commission in various parts of the province, aggregating 248,000 h.p., and supplying nearly 200 municipalities, to which Niagara contributes the supply for 118. The transmission lines comprise 455 miles of 110,000 voltage, double circuit, and 2100 miles of low tension. Such has been the achievement of the commission up to the end of last year.

There is now in hand a most important extension of this remarkable system. The Chippawa-Queenston project, as it is designated, will within a few years' time increase the serviceable capacity by from 200,000 h.p. to 300,000 h.p., and, ultimately, by 1,000,000 h.p. The first instalment of the work is expected to be ready by the spring of 1921, at an estimated cost of 5,000,000*l*. We gather the following interesting particulars of the project from a recent series of articles in the *Engineer*:—

Instead of the relatively small head (between 135 ft. and 165 ft.) of the actual Falls, it is proposed to utilise nearly the full difference in level, amounting to 330 ft., between the surfaces of Lakes Erie and Ontario. In order to effect this, a canal nine miles in length will be excavated so as to connect the Welland River with the Niagara River at Queenston, and the Welland River itself will be widened and deepened for $4\frac{1}{2}$ miles from its mouth. The channel thus formed will deliver water to a power-house below the Falls under a head of 305 ft., which will enable 30 h.p. to be developed for each cusec of flow instead of the 14 h.p. per cusec which is all that is available from the existing installation. The mean velocity of flow will be 2 ft. per sec. in the Welland River and 6 ft. to 7 ft. per sec. in the canal, resulting in a discharge of 10,000 cusecs at low-water level.

The canal route lies mainly in the solid rock of the Niagara Limestone formation, with the remainder ($1\frac{1}{2}$ miles) in earth and loose material. In rock the cross-section will be rectangular, 48 ft. in width; in earth it will be prismatic, with a bottom width of 70 ft. and side-slopes of 1 in $1\frac{3}{8}$, pitched with stone facing.

At the delivery end of the canal a forebay will be formed in solid rock 1000 ft. long, widening to 300 ft. at the extremity. Penstocks of riveted steel plates, 14 ft. in diameter and about 450 ft. in length, will extend down to the power-house at the foot of the river-bank.

The initial generating plant will consist of 4 to 6 units of 50,000 h.p. each. On each turbine-shaft there will be a 3-phase, 25-cycle, 12,000-volt internal revolving field generator of 43,900 kilovolt-amperes at a power factor of 85 per cent.

BRYSSON CUNNINGHAM.

THE ORGANISATION OF CHEMICAL INDUSTRIES.

AT the meeting of the London Section of the Society of Chemical Industry, held at Burlington House on Monday, January 5, two interesting papers were read by Mr. E. V. Evans and Dr. G. S. Walpole on the present position of the chemical industry of Germany. The authors of these papers were deputed to visit a number of important chemical factories in the Rhine Valley in the early part of last year. They are well-known chemists with considerable experience of chemical plant on a large scale. The information which they were able to disclose was valuable and suggestive. Mr. Evans and Dr. Walpole described the German chemical factories as being maintained in a state of perfection, but paralysed at the moment through lack of labour and raw materials. They contrasted the huge and well-staffed factories in Germany with the smaller equipments in this country, and dealt in particular with the manufacture of dyestuffs and intermediate products which has been developed in this country since the outbreak of war.

During the war the demand of the country for raw materials for war purposes was so great as to make it impossible to organise this new industry on a scale adequate to compete with the German chemical industry. The authors of the papers were satisfied that the ability and knowledge of British chemists were at least equal to those of their German competitors, but they directed attention to the fact that it was not possible in the long run for a number of firms in this country, each producing a limited number of products in comparatively small quantities, to compete successfully with the huge German factories, all amalgamated into one organisation and capable of turning out in a relatively small number of places the huge quantities of dyes required by the world.

To enable this country to retain the trade in dyestuffs and intermediates which were now being manufactured here, and to enable it to do a certain amount of export trade in these commodities, there must be an organisation comparable with that of Germany, and time would be required to build up such an organisation. Meanwhile, some protection against the importation of German dyestuffs and intermediate products was necessary, and the trade could not flourish until some of the existing Government restrictions were removed.

The action of the Government in licensing the importations of German dyestuffs was a useful measure and had been of great value. It is to be hoped that these important papers will stimulate the chemical trade of this country and the Government Departments concerned to study the better organisation of chemical industries here and to put forward some carefully considered scheme.

GEOLOGY AT THE BRITISH ASSOCIATION.

THE break in the continuity of sectional proceedings due to war conditions had, to a great extent, prevented those interested in geology throughout the country from keeping in touch with one another, and full advantage was taken of the opportunity for reunion offered by the Bournemouth meeting. Although arranged at short notice, the standard of former years was well maintained in the communications presented, and every moment of the week was full of interest.

The district has long been famous for its geological features, and consequently much interest has been taken locally in this branch of science. As a result, the papers by Dr. W. T. Ord on the Tertiary rocks of the Hampshire basin and the erosion of Bournemouth Bay, coupled with Mr. H. Bury's contribution on the history of the Chines, gave rise to considerable discussion. Important records of the rate of marine erosion at the present time and in recent years were contributed by many of those taking part in the discussion, and the Borough Engineer's measurements taken a short time ago were confirmed by collateral evidence.

Mr. Reginald Smith's paper on the Post-Tertiary geology of the area round Bournemouth, with special reference to the worked flints collected from many of the beds, was introductory to a joint discussion with Section H, and produced a very animated controversy. An admirable exhibit of such flint implements was arranged specially for this meeting by Mr. Scott, and added point to many of the remarks.

A second joint meeting, namely, with Section D

(Zoology), on subjects of less local interest, stimulated the most important discussions held during the proceedings of the Section. Mr. C. Tate Regan initiated one of these on the past history of continents as indicated by the distribution of fresh-water fishes; and Mr. D. M. S. Watson, a second, on palæontology and the evolution theory. Mr. Watson submitted that the data of palæontology cannot suggest the mechanism of evolution in the way that experimental biology and genetics can, but any evolutionary scheme must be consistent with these palæontological facts. The fossil record shows that intermediate groups rarely occur between two types; that innovations in any form, once initiated, tend to persist; and that innovations only arise from the more primitive members of a stock, *i.e.* from those which have retained their evolutionary plasticity.

The suggestion offered from the palæontological argument is that evolution is due to the operation of a variety of non-correlated factors, and that the initiation of a great group may be brought about by a set of nearly contemporaneous saltations.

Most of the speakers who followed commented on conditions seen in the groups they were specially interested in, and cases of convergence, divergence, homoplasy, rejuvenation, and extinction were instanced from the biological and palæontological records, all of which had to be taken into consideration in formulating any scheme of evolution. As showing the difficulties to be overcome, the case of the great auk was mentioned. Here a well-known bird had become extinct, yet no reason could be assigned save by postulating that a racial senility had set in, with a consequent loss of plasticity. The difficulties confronting the explanation of extinction in former ages were correspondingly greater in that we could not know accurately the conditions prevailing at those times.

The consensus of opinion was, however, that a restatement of the palæontological record in the light of present biological experimental results had become necessary, and the hope was expressed that this discussion might stimulate some such work.

Two exceedingly valuable contributions on aspects of geological research in our Colonies were presented by Dr. Miller on the pre-Cambrian rocks of Central Canada, and by Mr. A. E. Kitson on the discovery of diamonds in the Gold Coast. The former paper records a reasoned attempt to place the correlation of the pre-Cambrian rocks of Canada on a sound basis. This is very important in view of the fact that many minerals of economic value are associated with that series. The author directed attention to certain points where he had altered former correlations of these rocks, and especially to the discarding of the term "Huronian." The reason justifying the changed nomenclature is that Logan's name "Huronian" included two series of rocks, and later writers have applied it sometimes to one set and sometimes to the other, thus leading to confusion. New names have, therefore, been adopted for each set.

Mr. Kitson's discovery of diamonds in the Gold Coast was made so recently that no estimate can be made of its ultimate importance. Unfortunately, the paper was read at the end of the sectional proceedings, and there was not sufficient opportunity for discussion of the many interesting points raised. The whole question of the conditions of production of diamond in Nature is again opened up by the fact that no important basic igneous rocks, like the kimberlite of South Africa, occur in the whole surveyed area of the Gold Coast. The specimens so far obtained were exhibited, and all were small, but exploitation of the diamantiferous gravels may lead to the discovery of larger and more valuable specimens.

Other interesting communications on British geology were presented by Prof. S. H. Reynolds on the Lower Carboniferous rocks of the Avon section, Clifton; by Dr. Evans on the correlation of the marine Devonian rocks of North Devon and Somerset; and by Prof. Kendall and Dr. Gilligan on types of faults in the Coal Measures.

Two important papers have been left for consideration until the end, though they were read at an early part of the proceedings. In such an interesting district from a geological point of view it was felt that the Sectional Excursions ought to bulk largely, and consequently the general arrangement of the programme was correlated with the excursions to be held during the meeting. The first day's programme, therefore, included a description of the Tertiary rocks of the Hampshire basin by Dr. W. T. Ord, and was followed by an excursion under his leadership to the Bournemouth cliffs, where the Lower Tertiary rocks were examined. This examination was continued, three days afterwards, by a visit to Barton and Hordle led by Mr. H. W. Monckton, when the Upper Eocene beds, long famous for their marine fossils, were searched by many of the party with considerable success.

The lecture by Sir Aubrey Strahan on the geology of the Mesozoic rocks of the Bournemouth area was introductory to visits to Swanage, Lulworth, and Kimmeridge, the first two led by the author and the last by Dr. J. W. Evans. On these various excursions the structures which dominate the whole trend of the southern coastline were demonstrated, as was the manner in which the effect of these structures had been modified by subsequent denudation. Several of the curious natural phenomena, such as Lulworth Cove, Stair Cove, Durdle Door, etc., familiar to most geological students through the activity of the Committee for the Collection of Geological Photographs, were fully explained in the field.

The classic section at Kimmeridge was visited on the day following the official termination of the meeting, but, none the less, a large party was led by Dr. Evans along a most interesting coast section.

ECONOMICS AT THE BRITISH ASSOCIATION.

At the meeting of the British Association held in Bournemouth last September, Sir Hugh Bell presided over Section F (Economics), and in his presidential address emphasised the need for increased production, holding that by thus serving the common weal each one would at the same time be serving his own best interests.

In the discussion of problems of labour and capital a paper was read by the Right Hon. F. Huth Jackson on "The National Alliance of Employers and Employed." Comparison was made between the objects of the alliance and those of the Whitley Committees. While the latter stood for improvement in the commercial and working conditions in single industries, the former was also intended to bring together the employers and employed in all industries in a particular area with the object of improving not only the industrial, but also the housing, educational, and recreational conditions of the district.

Problems arising out of the war conditions were dealt with from three sides. The Hon. Sir Charles G. Wade approached the question of prices from the side of Government control, making special reference to the experience of Australia. The degree of success attained by the method of price-fixing during the war must not, he held, be taken as a guide for peace conditions. Apart from complete State control of industry, the effect of price-fixing had always been, and inevitably would be, the creation of a scarcity of the article the price of which was fixed; and moreover, the regulation of the price of any one commodity would necessitate the application of similar control to every link in the chain of production of that article. The only way to maintain an adequate supply of capital and sufficient production under a system of fixed prices was to institute complete State control of all production and distribution, but this was impracticable. His remedy, therefore, was, while refraining from any control of prices, to apply publicity to costs and profits by means of profiteering tribunals.

Dr. J. C. Stamp was also on the track of the profiteer, but rather with the aim of making up the deficit in the national revenue. For this purpose he believed a substantial increase in the income- and super-taxes would result either in a hindrance to the accumulation of capital or in a great addition to working-class burdens, and was therefore inadvisable. Nor did he argue for the levy on capital, which would fail, he believed, to bring about distributive justice. His solution of the problem lay in the taxation of the profits of all businesses in excess, not of their own pre-war profits, but of a normal rate of interest on capital. He believed that in this way it would be possible to reach those businesses which, through good fortune, received abnormal profits, and therefore had a high capacity for bearing taxation without ill-effects to the community.

The elimination of the gold standard during the war destroyed the system under which gold and credit were interchangeable, and wrecked the stability of the system of debts based on the gold unit. The gold standard, Mr. R. G. Hawtrey maintained, must be restored, but this must be done with judgment. The business community was hostile to deflation through fear of contraction of trade; the sudden re-introduction of the gold unit and the reduction of the value of paper below its face value involved an increase in the burden of debts, which would bring serious difficulties; and the reduction of the gold value of the monetary unit below its former nominal value was open to the imputation that public faith had been broken. His argument was that to make possible an unvarying gold currency unit, without which the stability of debts was impossible, it was necessary that the demand for gold currency should be kept as steady as possible. For this purpose, international co-operation was required, with the object of stabilising the general level of prices as measured by index numbers, and of regulating the actual amount of note issue in each country. Such international co-operation need not be universal; the inclusion of the financially strong countries would be sufficient; and this could be begun so soon as the Anglo-American exchange could be brought to par.

ENGINEERING AT THE BRITISH ASSOCIATION.

At none of the meetings of the British Association in recent years have such large numbers been attracted to the Engineering Section as at Bournemouth during the meeting in September last. Not only was the hall in which the meetings were held uncomfortably crowded almost throughout the whole of the proceedings, but on the last day many members were unable to gain admission. This was probably due to the fact that many of the papers were of a popular and descriptive nature, and dealt with matters of great interest in connection with the war. The authors in all cases were leading authorities who had been mainly responsible for the development of the special branches with which their papers dealt. The British Association, being for the purpose of the advancement of science among the general public, should encourage this type of paper rather than the highly specialised technical type which is better suited for the various learned and technical societies.

Prof. Petavel's presidential address was followed by the report of the Committee on Complex Stress. This report embodied six important papers by members of the committee, viz. the strength of tubular struts; stresses in aeroplane wing frameworks; the soap-film method of stress estimation; eccentric loading; effect of low-frequency alternations of tensile strength; and the strain energy function and the elastic limit. A summary of the work was given by Prof. Coker and Dr. Haigh.

Of the three papers read on the Wednesday, the first was "An Account of the British Tanks Used in the War" by Sir E. H. Tennyson-d'Eyncourt, the Director of Naval Construction, who traced the history of these devices from the war chariots of the ancients, through the one horse-power one-man "tank" of the Battle of Hastings, viz. the knight in armour, down to the highly developed vehicle which proved such a valuable ally to our infantry during the great war. The author dealt frankly with the thorny questions concerning the development of the Tanks from the time that they were first proposed to Mr. Churchill until they appeared on the Somme in September, 1916. The various types were explained and the reasons given for the successive modifications.

Prof. Inglis read a paper on portable military bridges, describing in detail the type of bridge with which his name is associated, and which proved so valuable in the final advance of our armies on the Western front. In connection with this paper a demonstration was given at the Christchurch bridging centre on the same Wednesday afternoon, when Inglis bridges of various types were constructed and used to convey Tanks across the river. The final paper on that day was by Mr. R. J. Walker, entitled "The Development of Geared Turbines for the Propulsion of Ships," in which the great advantages obtained by the substitution of turbines for reciprocating engines were clearly shown.

Thursday morning (September 11) was devoted to aeronautics, and opened with a paper on airships by Wing-Comdr. Cave-Browne-Cave, who discussed the questions of rigid and non-rigid types, fabric materials, gases, fire risk, etc. Mr. Bairstow, of the National Physical Laboratory, traced the progress of the scientific development of aviation during the war, and explained the various instruments devised for the investigation of the stresses on the aeroplane structure during various evolutions, and also of the inherent stability of aeroplanes when uncontrolled by the pilot. It would appear that although the factor of safety is ample for normal flight, it is reduced to a very small margin by unskilful handling in the air, and no aeroplane has yet been devised which could not be crumpled in the air by suitable mishandling. Col. Tizard dealt with the problem of the reduction of engine performance at a great height to a standard pressure, density, and temperature; at present this reduction involves a great deal of uncertainty. Prof. Bryan gave a summary of investigations which he has carried out on the sound emitted by air-screws when running with tip speeds exceeding the velocity of sound. Under such conditions the sounds emitted at various parts of the revolution reach the ear simultaneously and give rise to unpleasant sensations. Capt. Rolleston West read an interesting paper on the application of air-brakes to aeroplanes so as to enable them to make steep landings and short runs when alighting in a restricted space.

The morning of Friday (September 12) was devoted to electrical papers, and opened with a paper by Capt. J. Robinson on directive wireless telegraphy as applied to aircraft, in which, after explaining the principles involved, he described the various improvements developed mainly by himself during the war. This will undoubtedly find an extensive application, not only for aerial, but also for marine navigation. Prof. Fortescue explained the application of the three-electrode thermionic valve as a generator of high-frequency alternating current, and described, with the aid of numerous lantern-slides, the various arrangements adopted by the Navy embodying this device for the purposes of radio-telegraphy and telephony. Dr. Eccles followed with two papers describing special arrangements of three electrode valves, one being an improvement on the ordinary method of connection as explained in the previous paper, and the other a relay device whereby a snap of the finger and thumb several feet from a telephone receiver is caused to upset the stability of the device and operate a relay. A paper on the ignition of gases by hot wires was read by Dr. Thornton, who reported briefly on some unexpected results obtained, and indicated the lines along which the probable explanation might be found.

The final day opened with a paper by Comdr. Gwynne on submarine mining; our pre-war mining policy was referred to and compared with that of other countries, as was also our position at the outbreak of war. The author discussed the development of the various types of mines during the war in so far as was permissible. This was very aptly followed by a paper on the paravane or otter, which was devised by Comdr. Burney, and proved a very effective weapon against both mines and submarines. Mr. R. F. McKay, the author of the paper, also showed a number of kinematograph films illustrating the various stages in their manufacture and application. Prof. Thornton read a very interesting and suggestive paper on the relation between the thermal conductivity and the velocity of sound in insulating materials. The meetings concluded with a short note by Prof. Bryan on the improvement of the efficiency of radiators in the heating of rooms.

ANTHROPOLOGY AT THE BRITISH ASSOCIATION.

IN Section H (Anthropology), which met under the presidency of Prof. Arthur Keith, communications were fewer in number than usual, as one afternoon's session was given up to an excursion to the museum at Dorchester. In quality, however, they were quite up to the average. The meetings were well attended, and, as a rule, a high level of discussion was maintained.

Several papers dealt with physical anthropology and questions relating to racial distribution. Prof. F. G. Parsons, in his paper on "Racial Characters of the Modern Briton," raised the question of the relative value and practicability in use of the various methods of estimating race. In discussing the value of the cranial index he insisted on the contrast between the typical German population and that of the British Isles; the modern Briton had, on the average, the lowest cranial index in Europe, while a methodical examination of German prisoners of war had revealed that the Germans, even in Schleswig-Holstein, were round-headed. The Germans, in association with their Pan-Germanic views, had refused to collect or publish the evidence which showed the facts.

Prof. H. J. Fleure, in a comparison of an ancient and a surviving type of man, recorded the survival in remote parts of Wales of a primitive type which, in common with those found in similar "nests" in Europe and North Africa, resembled in many ways pre-Neolithic types such as that of Combe Capelle. This type, it was suggested, may have contributed to a considerable degree towards the evolution of the Mediterranean and the Nordic types. Mr. L. H. Dudley Buxton submitted the results of measurements, both of the living and of ancient skulls, made in Cyprus. Both series of measurements showed a common differentiation into two distinct types.

An important communication on the Finnic problem by Mr. H. Peake dealt with the origin and relation of the Nordic and Mongoloid elements in the Finnic population in the light of a fresh examination of the archæological evidence. The first wave of these Mongoloid people would appear to have arrived in the Baltic region on the retreat of the Ice Sheet; towards the close of the Neolithic age they were driven northward by the arrival of the Nordic people in Scania and West Gothland. In the middle of the Bronze age further Mongoloid peoples were occupying the margins of the Finnish lakes. The present Nordic element in the population was traceable to an immigration of Nordic people from Sweden which took place about A.D. 1000.

Miss M. A. Czaplicka discussed the relation of history and ethnology with special reference to North Central Asia. The present classification for Eastern Europe and North and Central Asia was historical rather than ethnological, and an uncritical adoption of the history of the Jinghis Khan period had led to the use of such terms as "Mongolic type," although such an original type did not exist in the sense in which there was a "Tungusic" or a "Turkic" type.

In prehistoric archæology a communication by Dr. R. R. Marett described recent excavations in Jersey on the site of La Cotte de St. Brelade, and also in a recently discovered cave on the north coast of the island. In the latter, shells of various species, including *Astralium rugosum*, which is at present confined to southern waters, and pieces of antler, which Dr. Andrews is disposed to bring into close relation with Pliocene deer from Auvergne, have been found in hard breccia, associated with small stalactites of unique occurrence in the island. A communication from Mr. T. W. M. de Guérin described a sculptured human figure recently discovered on the dolmen of Déhus, Guernsey. There is evidence that the worship of the divinity represented existed for a very long period in the island, extending probably from the Æneolithic until well into the Iron age. In a joint meeting with Section C (Geology) Dr. Reginald Smith opened a discussion on the age of the flint implements of the Bournemouth district.

In Mediterranean archæology Prof. J. L. Myres described excavations on sites in Cyprus in 1913, among them being the necropolis at Lapathos on the north coast, in which a sequence of tombs was obtained covering the "early" and "middle" periods of the Bronze age. The date-marks showed that the "middle" period began not earlier than the twelfth dynasty of Egypt. Mr. Stanley Casson ably summarised the results of discoveries (mostly in Macedonia) made in the Balkans during the war. It is interesting to note that the evidence thus obtained goes to show that the early culture of Macedonia pertains to the north rather than to the south.

A number of papers dealt with primitive religious cults, amongst them being a detailed study of the death ritual of Eddystone Island of the Solomons by Mr. A. M. Hocart, and an examination of the mother-cults of India by Dr. W. Crooke. Mr. Peake's communication on "Santiago: The Evolution of a Patron Saint" dealt with the survival of a menhir cult in the Iberian peninsula and its association and confusion with the cult of St. James.

In a joint meeting with the Psychology sub-section, Prof. Carveth Read read a paper on "Magic and Science," and the Rev. H. J. D. Astley a paper on the relation of primitive art and magic.

Papers of a general ethnographic character were few in number. Mr. F. J. Richards's paper on the Badaga clans of Southern India was a valuable and comprehensive study, which included a detailed account of an interesting and important harvest festival. Mr. E. W. Pearson Chinnery in his paper on "Stonework and Goldfields in New Guinea" described a number of stone objects, including pestles and mortars, which showed that the country was visited at some time, presumably in search of gold, by a stone-using people, differing in many respects from the present inhabitants. In a second paper Mr. Chinnery described the people of the hilly country of the interior, and maintained that there was in these regions an extensive Negrito element similar to the Mafulu described by Williamson.

An afternoon session was devoted to a visit to the Dorchester Museum, where the party was hospitably entertained by the Curator and Mrs. Acland. A visit was also paid to the Maumbury Rings, where the results of the excavations were explained by Mr. C. Prideaux.

REWARDS FOR MEDICAL DISCOVERY.[1]

I. DEFINITIONS.—Medical discovery may here be defined as being: (1) The ascertainment of new facts or theorems bearing on the human body in health, and the nature, prevention, cure, or mitigation of injuries and diseases of human beings. (2) The invention of new methods or instruments for the improvement of sanitary, medical, and surgical practice, or of scientific and pathological work.

II. REASONS FOR REWARDING MEDICAL DISCOVERY.—These are: (1) To encourage medical investigation. (2) To discharge a moral obligation incurred by the public for its use of private effort.

III. VARIOUS POSSIBLE TYPES OF REWARDS.—(1) Titles and honours given by the State, by universities, and by other public bodies. (2) Prizes and medals. (3) Patents. (4) Promotions and appointments. (5) Pecuniary awards by the State.

IV. GENERAL PRINCIPLES OF ASSESSMENT.—It will probably be agreed that in the interests of the public all medical discoveries should, if possible, receive some kind of acknowledgment or recompense. But in view of the very variable conditions, nature, and effects of particular investigations, it will often be difficult to assess the kind of recompense most suitable for each.

In the first place, a distinction should be drawn between *compensation* and *reward*. By compensation is meant an act of justice done for the purpose of reimbursement of losses; by reward, an act of grace in appreciation of services rendered.

The following different cases should next be considered:—

A. Discoveries involving pecuniary or other loss to an investigator, either by direct monetary sacrifice, or by expenditure of time, or by diminution of professional practice, without corresponding pecuniary gains. A great example is that of Edward Jenner, who occupied himself so closely with the investigation of vaccination against smallpox that he lost most of his medical practice, and also considerable sums in expenses. The plea for compensation in such cases is unanswerable; and in 1802 and 1807 Parliament fully acknowledged its obligations under this head by giving Jenner compensation in two sums of 10,000*l.* and 20,000*l.*

B. Discoveries which have increased the professional emoluments of the investigator by enhanced practice or other means. Such are, frequently, improvements in surgical operations or medical treatment, which lead to increased practice. Another case is that of serums, etc., which may have been protected and put on the market. Here compensation cannot be demanded, and pecuniary awards may be generally held to be unnecessary. On the other hand, honours are often, and justly, bestowed upon such work.

C. Discoveries which involve neither gain nor loss to the investigator. This class includes most of the good, and sometimes great, clinical, pathological, and sanitary discoveries achieved in the world. Here also compensation can scarcely be demanded, and honours are already often given; but pecuniary awards should be sometimes bestowed as an act of grace when the value of a discovery to the public (or to a Government) greatly exceeds the emoluments of the investigator; and this principle should hold even in the case of men who were directly paid for undertaking the researches which led to their discoveries, especially when such payment was (as usual) small and the resulting discovery great.

The following particular cases, which sometimes occur, should be specifically noted:—(1) Men who have refused lucrative posts in order to complete their researches. (2) Men who have refused to protect their work for fear of limiting its application. (3) Men who have carried out investigations for Governments for little or no payment on patriotic grounds.

The following considerations must generally be borne in mind:—

(*a*) Honours (which are always much esteemed) are usually given as much (or more) for clinical success as for medical discoveries, though the latter possess a far wider influence and application than do the former.

(*b*) When given for clinical work or for discoveries under class B, honours often confer distinct pecuniary advantages by enhancement of practice, but for discoveries under classes A and C they have no such effect, and cases are on record where they tend to reduce emoluments by unfitting recipients for certain posts.

(*c*) Most people enter the medical profession (at considerable expense) not only from altruistic motives, but also to make a living, and it is usually only at a later period that they take up scientific investigation—either from a sense of duty, or from predilection, or merely because a good opportunity offers. When, therefore, a man finds that his scientific work, however successful and important it may have been, has actually yielded him less emolument than he might have obtained from ordinary clinical work, he feels naturally discouraged, and his experience prevents young men of ability from following his example, and therefore tends to check the prosecution of studies which are of the highest value to humanity.

(*d*) In the public interest, then, this committee begs to insist upon the principles:—(1) That no medical discovery should be allowed to entail financial loss upon him who has made it. (2) That the compensation or reward which he deserves should be assessed

[1] Report presented by the Joint Committee of the British Medical Association and the British Science Guild on Awards for Medical Discovery. The members of the joint committee are:—*Representing the B.M.A.*: Sir T. Clifford Allbutt, K.C.B., F.R.S.; Dr. R. T. Leiper; Prof. Benjamin Moore, F.R.S.; Mr. E. B. Turner; and Prof. J. S. Haldane, F.R.S. *Representing the B.S.G.*: Lt.-Gen. Sir Alfred Keogh, G.C.B.; Col. Sir Ronald Ross, K.C.B., K.C.M.G., F.R.S.; Prof. W. Bayliss, F.R.S.; Dr. D. Sommerville; Sir Richard Gregory; and Lt.-Col. O'Meara, C.M.G.

as being equal to the difference between the emoluments which he has actually received and those which a successful clinician might have received in the same time.

This is obviously the principle which was accepted by Parliament in the case of Jenner in 1802 and 1807.

Additional reasons for insisting upon this principle are :—(1) That few medical discoveries are patentable. (2) That such discoveries seldom give good grounds for promotion or for administrative appointments in the public services.

V. PARTICULAR ASSESSMENTS.—Whether a particular discovery should receive a large or small assessment will depend not only on the considerations given above, but also on the following :—

(1) *Width of Application.*—For example, the work of many of the older anatomists, physiologists, and parasitologists, of Pasteur, and of investigators of immunity has affected most recent discovery. Discoveries on widespread diseases, such as the work of Lister, of Laveran, and of Koch, are often, though not always, more important than those on more limited maladies.

(2) *Difficulty of the Work Done.*—For example, the solution of a difficult problem requires more study and also more time and cost, and therefore deserves more recompense, than a lucky chance observation.

(3) *Immediate Practical Utility.*—A strong plea for State remuneration can be made on behalf of cases of this kind, unless they come under class B. It is strange that at present they never receive it, while academical recognition is also often not forthcoming for them.

(4) *Scientific Importance.*—Discoveries which are not of present practical utility may become so at any moment, and should obviously be included in the scheme if they are sound and of wide application.

Medical discoveries made by persons who do not themselves belong to the medical profession should be included in all schemes of reward.

Of course, each case must be judged on its merits, and the assessment will not always be easy.

VI. STATE AWARDS FOR MEDICAL DISCOVERY.—Honours, prizes, and medals, being bestowed by H.M. the King or by public bodies and learned societies, are acts of grace which are generally given after much consideration, and the committee does not purpose to consider them. But the subject of *pecuniary awards* lies entirely within its province.

During the last few years the British Government has disbursed an annual grant of about 60,000*l.*, under the Medical Research Committee, for subsidising *investigations in progress* authorised by the committee and carried on by workers selected by it. This grant does not remunerate discoveries *already made*, but proceeds upon the principle of payment for benefits *already received*, deserves close attention, and has been recognised in other countries.

We think that both principles are sound, but they apply to two different classes of research, and are, indeed, complementary of each other. Payment for prospective benefits is "good business" only when some return is almost certain; and for this reason subsidised researches must frequently deal with simple and straightforward questions, admitting of immediate experimental reply. But, as a matter of fact, most of the greatest medical discoveries were built upon a much more speculative and uncertain basis, and were achieved by men who neither sought nor received subsidies for those investigations—as, for instance, Küchenmeister, Jenner, Simpson, Lister, Koch, Laveran, Bancroft, Manson, Bruce, Mackenzie, and a score of others who have so greatly improved medical practice. Surely the State should encourage this class of investigation also, partly because it costs the State nothing in so doing, and partly because it seems to achieve the greatest results. And there is only one way to encourage it: by paying for discoveries when made. Payment for benefits received is always not only "good business," but also a moral obligation. There are at present hundreds of medical men and others in this country who possess the knowledge, the brains, and the opportunity for private independent discovery without subsidies, but do not attempt it because medical research work does not pay even when brilliantly successful. Let these men also be brought into the fold of research by offering them reward when they succeed.

We therefore suggest that, in addition to assisting investigations in progress, it is proper for the State to remunerate those of its citizens who have already conferred the benefits of medical discovery upon it, just as it is proper for a patient to pay his doctor. And this policy will be not only an act of justice, but also an act of wisdom.

Our proposals are in detail :—(1) That Parliament should follow the precedent of Jenner by paying *compensation* when due for losses incurred in achieving medical discoveries. (2) That Parliament should provide an annual sum, say of not less than 20,000*l.*, for life-pensions to be given as rewards to such of his Majesty's subjects as have made worthy medical discoveries, such pensions amounting to between 500*l.* and 1000*l.* a year.

Such pensions would be preferable to donations in capital, and the sums suggested would be sufficient, because men of science seek only such independence as will enable them to employ their talents in the manner they think best.

The procedure of allotment should be similar to that used for the Nobel prizes, and for the honours and medals of learned societies—that is, full particulars of the work of all applicants should be kept and considered.

Parliament grants large subsidies to soldiers and sailors, has appointed a Commission to consider awards to inventors, and allows patents. It should not, therefore, complain if, the medical profession, which has done so much for the nation during the war, now asks for some similar consideration.

(This committee is concerned only with medical research, but recognises that similar awards should be given to workers in other fields.)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BIRMINGHAM.—At the beginning of the coming term Prof. R. H. Yapp will take up his duties as successor to the late Prof. G. S. West in the Mason chair of botany, and Dr. William Cramp will succeed Prof. Gisbert Kapp in the chair of electrical engineering.

LONDON.—The following courses of advanced lectures in physiology are now commencing :—"The Regulation of Respiration" (Guy's Hospital, Borough, S.E.), by Dr. M. S. Pembrey and Mr. J. H. Ryffel, at 4.30 p.m. on Thursdays, January 8, 15, 22, and 29, and February 5, 12, 19, and 26; "The Reaction of the Blood and Acidosis" (St. Bartholomew's Hospital), by Mr. J. W. Trevan, at 4.30 p.m. on Wednesdays, January 28, February 4, 11, 18, and 25, and March 3, 10, and 17; and "Physiologically Balanced Solutions" (Physiological Laboratory of the University, South Kensington, S.W.7), by Mr. W. L. Symes, at 5 p.m. on Tuesdays, January 27, February 3, 10, 17, and 24, and March 2, 9, and 16. The lectures are addressed to advanced students of the University and to others interested in the subject. Admission is free, without ticket.

Other advanced courses to be delivered are:—Six lectures on "The Physical Properties of Soil" (Imperial College of Science and Technology), by Mr. Bernard A. Keen, on Tuesdays at 4.30 p.m., beginning on February 3; and a course on "A General Survey of the Globe and its Atmosphere," with practical work (Meteorological Office, South Kensington), by Sir Napier Shaw, on Fridays at 3 p.m. during the second term, beginning on January 23.

DR. D. W. CARMALT JONES has been appointed to the chair of systematic medicine in the University of Otago, New Zealand.

MISS F. M. G. MICKLETHWAIT has been appointed principal of the Horticultural College, Swanley. Miss Micklethwait holds the diploma of the college, and was a Beit research fellow; she has published a number of papers on her researches upon chemical subjects.

IN connection with the London County Council's lectures for teachers on recent developments in science, a lecture on "Aviation" will be given by Lord Montagu of Beaulieu at King's College, Strand, W.C.2, on Tuesday, January 13, at 6 p.m. The chair will be taken by Major-Gen. Sir Frederick H. Sykes.

THE Civil Service Commissioners announce that an examination will begin on May 4 next for the purpose of filling ten vacancies for assistant examiners in the Patent Office. The examination will be confined in the main to candidates who have served in his Majesty's Forces, and will consist of a qualifying examination followed by interview by a selection board. The subjects of the qualifying examination are English composition, *précis*-writing, general knowledge, and *one* of the following: General chemistry, electricity and magnetism, mechanics and mechanism. The limits of age are twenty to thirty. Initial salary 150*l*. a year, together with a war bonus. Copies of the regulations and forms of application may be obtained by writing to the Secretary, Civil Service Commission, Burlington Gardens, London, W.1. The last day for making application is March 4.

IN a pamphlet on college studies, published by the Stanford University of California, Prof. H. W. Stuart, professor of philosophy in the University, points out that the old discussion on the relative merits of literary and scientific studies in the training of a well-educated man has now become the problem whether citizenship in the modern world can be based on the contemplation, criticism, and enjoyment of life, or whether it requires a capacity for constructive participation in the activities of life in addition. It is remarked that while a literary education supplies a direct acquaintance with the characteristic interests and experiences of life, and a scientific education a knowledge of the means and machinery of life, neither recognises adequately those interests which find expression in the family, amongst friends, in play, or in the responsibilities of citizenship. Culture, in Prof. Stuart's opinion, expresses a personal capacity for conduct, not the body of knowledge of which the person makes use. It must comprise both literary and scientific discipline and study and experience of social science. The evidence of culture in an individual is the proper fulfilment of his functions in the society in which he lives, and each age must have its own standard of culture.

SOCIETIES AND ACADEMIES.

LONDON.

Aristotelian Society, December 15, 1919.—Prof. A. N. Whitehead in the chair.—Dr. G. E. **Moore**: External and internal relations. The most important part of what is meant by those who say that no relations are purely external seems to be the proposition that *every* relational property belongs *necessarily* to every term to which it belongs *in part*. This proposition is false, the truth being that *some* only among relational properties belong necessarily to those terms which possess them. To say that the property P belongs necessarily to the subject S is to say that from the proposition, with regard to any term, A, that it has not got P, it *follows* that A is numerically different from S. And this has been falsely taken to be true of every P and every S, because it is, in fact, true that from the proposition "S is P" it *follows* that any term, A, which has not got P is, *in fact*, other than S. The proposition that if p is true, then the conjunction "q is true and r false" *must* be false, has been compared with the proposition that if p is true, then "q is true and r false" is *necessarily* false in the sense that r *follows* from q. From the proposition "from 'p is true' it *follows* that 'q is true and r false' is false," it does not follow that, if p is true, then r *follows* from q.

Geological Society, December 17, 1919.—Mr. G. W. Lamplugh, president, in the chair.—Prof. S. J. **Shand**: A rift-valley in Western Persia. Asmari Mountain, near the oilfields of Maidan-i-Naftun, in the Bakhtiari country of Western Persia, is an inlier of Oligocene limestone among the beds of the Fars system (Miocene), the latter consisting, in the lower part, of bedded gypsum with intercalated shales and a few thin limestones. The mountain is a whale-back, formed by a simple symmetrical anticline plunging at both ends. The north-western end plunges rather steeply, and shows no abnormal structures; but at the south-eastern end the fold has collapsed along its length for a distance of three miles, letting the gypsum-beds down into a trough in the limestone. This trough is bounded by two main faults hading north-eastwards and south-westwards respectively, with an average hade of 20°, and marked by steep escarpments. The gypsiferous beds which once completely filled the trough have been partly removed by erosion, clearly revealing the fault-walls in the lower part of the valley.

MANCHESTER.

Literary and Philosophical Society, December 16, 1919.—Sir Henry A. Miers, president, in the chair.—C. E. **Stromeyer**: The study of nationalities. Although structural peculiarities are very useful for differentiating non-related species, they are of little use for the purpose of classifying branches of one species, and it is necessary to study their characteristics. There are very marked differences amongst the characteristics of different nationalities, *i.e.* the Semitic and Slavonic races have wonderful memory gifts, and the Scandinavians are pre-eminently inventive. The author dealt with the vague words employed in defining various characteristics and with the reagents which might be employed for revealing fundamental characteristics of different nationalities.—W. J. **Perry**: The historical process. The study of the geographical distribution of peoples in various stages of culture, and of the migrations of peoples, suggests that the degree of civilisation possessed by any community that has advanced beyond the pure hunting stage is the result, direct or indirect, of cultural influences propagated from some original centre. It seems as though the fundamental arts and crafts of civilisation were invented in one place, and that the knowledge of them was carried to the outlying parts of the earth, thus producing the various degrees of culture possessed by different communities. The study of archæological remains supports this contention. If this conclusion be accepted, it becomes possible to regard the study of human society from a point of view different from that commonly adopted. We can examine the effects of various social institutions on behaviour. The hunting tribes, the most primitive men of whom we have direct knowledge, display a uniform type of behaviour: they are peaceful, truthful, monogamous, honest, kind to children and animals, and thus, presumably, represent the normal type of human behaviour. The people above them in culture have adopted the institutions of civilised peoples to varying degrees, and their modes of behaviour appear to correspond to their historical experience. The wide range of culture which exists in the world makes it possible to examine in detail the effects upon human beings of various social institutions, and thus to pave the way for the foundation of a science of society, the ultimate aim of which will be to determine which institutions are fitted to develop men to the greatest possible extent.—Prof. F. E. **Weiss**: Green jade work by natives of New Zealand.

PARIS.

Academy of Sciences, December 8, 1919.—M. Léon Guignard in the chair.—A. **Laveran**: Obituary notice of Prof. R. Lépine, correspondant of the Academy of Sciences.—C. **Moureu**, C. **Dufraisse**, and P. **Robin**: The stabilisation of acrolein. Part 4. Compounds hindering the formation of disacryl.—C. **Richet**: Injections of gum or of plasma after bleeding. A criticism of a recent communication by M. Barthélemy. The animal must have lost more than 70 per cent. of its blood before the injection of solution or plasma, or its survival cannot be regarded as decisive.—V. **Grignard**, G. **Rivat**, and Ed. **Urbain**: Researches on the chlorination of methyl formate and methyl chloroformate. Details of a semi-industrial method for the preparation of the ultimate chlorination product, CCl_3CO_2Cl.—M. Paul Janet was elected a free Academician in succession to the late M. Landouzy.—G. **Valiron**: Regular ensembles of zero measure.—M. **Mesnager**: Elementary solution of the rectangular plate fixed at the edges, carrying a load uniformly distributed or concentrated at its centre.—E. **Belot**: Possible causes of the light curve and the pulsation of Cepheus.—I. **Tarazona**: Observation of the solar eclipse of November 22, 1919, at the astronomical observatory of the University of Valencia, Spain. The first contact was found to be 8·4 seconds earlier than calculated.—J. **Guillaume**: Observations of the sun made at the Lyons Observatory during the second quarter of 1919. Observations were made on eighty-one days, and the results summarised in three tables showing the number of spots, their distribution in latitude, and the distribution of the faculæ in latitude.—Ed. **Fouché**: Search for a characteristic equation applicable to atmospheric air. The equation is of the Clausius form,

$$\left[p+\frac{\psi}{(v+n)^2}\right](v-b)=RT,$$

in which ψ is a function of the temperature only. The constants n, b, R are determined from experiments by Witkowski, pressures ranging from 1 to 130 atmospheres and temperatures from −145° C. to +100° C.—G. A. **Hemsalech**: The origin of luminous radiations emitted by vapours in an electrical resistance tube furnace. The spectrum results from two independent emissions, one of which is of thermal and the other of electrical origin.—P. **Jolibois**: An apparatus for rapidly mixing homogeneous liquids.—E. **Mesnard**: Cyclonic formations of the atmosphere.—Ph. **Flajolet**: Perturbations of the magnetic declination at the Lyons Observatory (Saint-Genis-Laval) during the first and second quarters of 1919.—L. **Blaringhem**: Floral anomalies observed in hybrid plants from *Linaria vulgaris* × *L. striata*.—P. **Descombes**: The use of trees in extracting water from the atmosphere. Evidence from various sources of the increased deposit of moisture, as dew, caused by trees.—A. **Piédallu**: The *rôle* of iron in the blue *casse* of wines.—Mlle. Lucienne **Dehorne**: Hermaphroditism and scissiparity.—H. **Bierry**: Inanition, temperature, and glycemea.—A. **Richaud**: The action of ouabaine and of strophantine on the salivary secretion, and the mechanism of this action.—A. **Clerc** and C. **Pezzi**: The antagonism of adrenalin and quinine.—C. **Oberthür**: The symbiosis of ants and the caterpillars of Lycæna.—A. **Paillot**: Natural immunity in insects. Study of a case of humoral immunity.—C. **Nicolle**, A. **Cuénod**, and G. **Blanc**: Experimental demonstration of the *rôle* of flies in the propagation of trachoma (granular conjunctivitis).

CAPE TOWN.

Royal Society of South Africa, October 15.—Dr. J. D. F. Gilchrist, president, in the chair.—Sir Thomas **Muir**: Additional note on the resolvability of the minors of a compound determinant.—J. **Moir**: Colour and chemical constitution. Part ix. An empirical law of change of colour. The wave-lengths of the absorption spectra of all the halogen derivatives, and many other derivatives of phenolphthalein and fluorescein, can be calculated from the formula

$$\frac{n}{n_0}=\frac{\lambda_0}{\lambda}=1-0{\cdot}0115m-0{\cdot}000037m\,N,$$

in which n=frequency, λ=wave-length, m=number of halogens, etc., and N=atomic number of halogen in question. All the groups investigated have very similar effects on the colour, a most remarkable fact.—J. S. **Thomson**: South African Alcyonacea.

DIARY OF SOCIETIES.

THURSDAY, JANUARY 8.

ROYAL AERONAUTICAL SOCIETY (at the Royal Society of Arts), at 3.—Major H. E. Wimperis: How Airmen Find Their Way (Juvenile Lecture).
ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. W. H. Bragg: The World of Sound: Sounds of the Sea (Christmas Lectures).
PHYSICAL SOCIETY OF LONDON (at Exhibition of Apparatus, in conjunction with the Optical Society, at the Imperial College of Science), at 4.—Prof. F. J. Cheshire: Some Polarisation Experiments; at 8.—Prof. Rankine: The Use of Light in the Transmission and Reproduction of Speech.
INSTITUTION OF ELECTRICAL ENGINEERS (at Institution of Civil Engineers), at 6.—J. Shepherd: Failures of Turbo-Generators and Suggestions for Improvements.
OPTICAL SOCIETY, at 7.30.
INSTITUTION OF AUTOMOBILE ENGINEERS (at 28 Victoria Street), at 8.—T. Clarkson: Steam Vehicles.
ROYAL SOCIETY OF MEDICINE (Neurology Section), at 8.30.—Dr. F. M. R. Walshe: Forms of Peripheral Neuritis among Troops Serving with the Egyptian Expeditionary Force, 1915–1919.

FRIDAY, JANUARY 9.

GEOGRAPHICAL ASSOCIATION (at the London Day Training College), at 2.—Prof. R. N. Rudmose Brown: Spitsbergen.—At 6.—Sir Charles P. Lucas: Islands, Peninsulas, and Empires (Presidential Address).
ROYAL ASTRONOMICAL SOCIETY, at 5.—J. K. Fotheringham: The Longitude of the Moon from 1627 to 1918.—Prof. H. H. Turner: The Suggested Decrease of Period of Stars in Phillips's Group II., with particular notes on R Hydræ, S Tauri, U Herculis, R Aquilæ, χ Cygni, S Cygni, and S Coronæ Borealis.—Dr. J. L. E. Dreyer: The Original Form of the Alfonsine Tables.—C. Davidson and W. V. Woodman: An Equatorial Mounting for Eclipse Observations.
ROYAL SOCIETY OF MEDICINE (Clinical Section), at 5.30.—Sir Anthony Bowlby: The Application of War Methods to Civil Practice.
MALACOLOGICAL SOCIETY OF LONDON (at the Linnean Society), at 6.—Dr. S. S. Berry: A New Species of Mitra from California.—Dr. A. E. Boycott: Local Variation in Size of *Clausilia bidentata* and *Ena obscura*.—H. C. Fulton: Molluscan Notes, IV.
PHILOLOGICAL SOCIETY (at University College), at 8.—Dr. W. Perrett: The Perception of Sound.

SATURDAY, JANUARY 10.

GEOGRAPHICAL ASSOCIATION (at Regent Street Polytechnic), at 10.30 a.m.—Capt. C. E. Hodges: Demonstration of the Value of the Cinematograph in Geographical Teaching.
GEOGRAPHICAL ASSOCIATION (at the London Day Training College), at 3.—M. de Carle S. Salter: Rainfall as a Geographic Function.
ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. W. H. Bragg: The World of Sound: Sound in War (Christmas Lectures).

MONDAY, JANUARY 12.

ROYAL GEOGRAPHICAL SOCIETY (at Lowther Lodge), at 5.—Capt. H. Thomas: Geographical Reconnaissance by Aeroplane Photography.
INSTITUTION OF MECHANICAL ENGINEERS (Graduates' Association), at 8.—A. R. Munro: Right-angle Belt Drives.
SURVEYORS' INSTITUTION, at 8.—E. M. Konstam and C. H. J. Clayton: Land Drainage from the Administrative and Engineering Points of View.

TUESDAY, JANUARY 13.

ROYAL HORTICULTURAL SOCIETY (at Vincent Square), at 3.
ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir John Cadman: Modern Development of the Miner's Safety Lamp.
INSTITUTION OF CIVIL ENGINEERS, at 5.30.—J. Mitchell: Whitby Harbour Improvement.—R. F. Hindmarsh: The Design of Harbours and Breakwaters with a View to the Reduction of Wave-action Within Them.—J. W. Sandeman: Wave-action in Harbour Areas; with Special Reference to Works for Reducing it at Blyth and Whitby Harbours.—W. Simpson: The Improvement of the Entrance to Sunderland Harbour, with Reference to the Reduction of Wave-action.
ROYAL PHOTOGRAPHIC SOCIETY and THE RÖNTGEN SOCIETY (at the Royal Photographic Society), at 7.—Major G. W. C. Kaye and Others: Discussion on Some Aspects of Radiology and Radiometallography.
ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—Dr. A. C. Haddon: The Outrigger of Indonesian Canoes (illustrated by Lantern Slides).

WEDNESDAY, JANUARY 14.

ROYAL SOCIETY OF ARTS, at 3.—L. Pendred: Railways and Engines (Juvenile Lecture).
ROYAL UNITED SERVICE INSTITUTION, at 3.—Major A. Corbett Smith: The Traditions of the British Navy.
FARADAY SOCIETY, ROYAL MICROSCOPICAL SOCIETY, OPTICAL SOCIETY, and PHOTOMICROGRAPHIC SOCIETY, in co-operation with the Optical Committee of the British Science Guild (at the Royal Society), at 4.30 and 8.—Sir Robert Hadfield, J. E. Barnard, Sir Herbert Jackson, Prof. F. J. Cheshire, Prof. A. W. Porter, and Others: Symposium and General Discussion on the Microscope: Its Design, Construction, and Applications.
ROYAL SOCIETY OF MEDICINE (History of Medicine Section), at 5.—Mr. Vivian: Thomas Campion: His Works.—Canon Westlake: The Gild of Our Lady of Rouncyval.
INSTITUTION OF ELECTRICAL ENGINEERS (Wireless Section) (at the Institution of Civil Engineers), at 6.—Capt. H. J. Round: Wireless Direction and Position Finding.

THURSDAY, JANUARY 15.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. R. R. Terry: Renaissance Music in Italy and England (with Musical Illustrations).
ROYAL SOCIETY OF ARTS (Indian Section), at 4.30.
LINNEAN SOCIETY, at 5.—Dr. B. Daydon Jackson: Methods of Botanic Illustration during Four Centuries (Lantern Lecture).
CHEMICAL SOCIETY, at 8.—L. E. Hinkel and H. W. Cremer: The Condensation of Acetoacetic Ester with *p*-Dimethylaminobenzaldehyde and Ammonia.—G. S. Butler and H. B. Dunnicliff: The Action of Alcohol on the Sulphates of Sodium.—M. Nierenstein, C. W. Spiers, and in part the late K. C. R. Daniel: Guarana Tannin.—R. Lessing: Studies in the Composition of Coal: (1) The Behaviour of the Constituents of Banded Bituminous Coal on Coking; (2) The Mineral Constituents of Banded Bituminous Coal.—P. Ray and P. V. Sarkar: The Hydrazino-thiocyanates of certain Divalent Metals.

FRIDAY, JANUARY 16.

INSTITUTION OF ELECTRICAL ENGINEERS (Students' Meeting) (at the City and Guilds (Engineering) College), at 7.—J. H. Reyner: The Development of Automatic Telephony.
ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Sir James Dewar: Low Temperature Studies.

SATURDAY, JANUARY 17.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—A. Noyes: The Anglo-American Bond of Literature.

SURGERY OF DEFORMITIES.

Menders of the Maimed: The Anatomical and Physiological Principles Underlying the Treatment of Injuries to Muscles, Nerves, Bones, and Joints. By Prof. A. Keith. (Oxford Medical Publications.) Pp. xii + 335. (London: Henry Frowde; Hodder and Stoughton, 1919.) Price 16*s*. net.

PROF. KEITH'S book is undoubtedly one of the most interesting and instructive which have yet been written on this important branch of surgical work. The author treats the subject from an entirely new point of view; instead of following up each forward step and discussing the influence which the various workers in this field had on that progress, he gives us a *résumé* of the career of the workers who made this advance possible.

Nothing could be clearer or more concise than the way in which Prof. Keith has selected from the career of the men who are chiefly responsible for this progress the various points of importance in making us understand the influence which these men had on the progress of the surgery of deformities.

The book enables us to understand how great was the handicap under which these pioneers had to conduct their studies. It shows us how two men such as John Hunter and Hugh Owen Thomas, whilst working in widely different fields, the one finding most of his data in the dissecting room and the other gathering all his observations from clinical studies at the bedside, each arrived at practically the same conclusions in regard to the healing of wounds and the cure of disease.

These are two men who in their practice had found that the proper treatment for inflamed or injured bones or soft tissues was not the method of movements and massage which was the popular one in their time, but fixation, which promotes rest of the tissues and allows Nature's reparative changes to come unhindered into action.

Hunter perhaps better than any other clearly defined the relationship between fixation and massage in an injured or diseased joint in the principle which is enunciated in his book on "Diseased and Wounded Joints respecting their Motion," in which he states that "nothing can promote contraction of a joint so much as motion before the disease is removed."

The subject with which Prof. Keith deals is one that has always interested surgeons, and although of late years the great advances which have been made in abdominal surgery have tended to overshadow this important branch of surgery, yet no more opportune moment could have been selected for the publication of this work.

The hundreds, or rather thousands, of soldiers and ex-soldiers who are to-day walking about in our cities with deformities of joints, with mal-united fractures, or with paralysis of one or more limbs are a constant reminder of the importance of a clear grasp of the principles for the treatment of these injuries.

The great disadvantage under which a medical man labours at the present time is that he can find in no library a trustworthy history of the work of those who have gone before him in any special field. The result is that careful and capable workers in some special branch of surgery or medicine are often found struggling with the solution of a problem which has already been solved, or proved by the work of a forerunner to be of little importance.

This is where Prof. Keith's book is of such great value. He forces us to realise the work which has been accomplished by the men who were the pioneers in the art, and in a few all too short chapters follows up that progress through the careers of those who followed.

No part of the book is better conceived than the chapters which Prof. Keith has devoted to the growth of bone and the practice of bone grafting. Here we follow down through the years the gradual increase of knowledge from the work of Goodsir and Syme to that of Albu and Hey Groves. We see how each succeeding investigator added in some way to what was known of the subject, and built up our present knowledge, which is daily increasing and changing.

At no time in the history of the subject has there been such an immense number of cases on which this problem of bone regeneration and bone transplantation can be studied, and in many cases fractures have occurred of a bone graft soon after its implantation, with a subsequent union of the parts of the graft.

The book is intended primarily as a *résumé* of the history of the subject, and does not enter into a discussion of treatment except in the broadest sense of the term, and perhaps its one weak spot is the short discussion on the relative values to be placed on different lines of treatment.

This is seen in the remarks on the relative advantages of the treatment of fractures by means of plating as compared with non-operative methods. Here Prof. Keith follows entirely the report of a commission, and from the purely theoretical point of view decides that the results of the treatment of fractures by plating is superior to those obtained by splints, etc., and does not realise that we are comparing the work of the best surgeons on the staff of a hospital, who alone would perform the operation, with, in many cases, the work of a newly qualified house-surgeon.

In many respects the book fills a gap in medical literature, and will be of great help not only to the general body of medical workers, but also more particularly to those who are specially engaged in this line of work.

THE OIL-HARDENING INDUSTRY.

The Hydrogenation of Oils: Catalysers and Catalysis and the Generation of Hydrogen and Oxygen. By Carleton Ellis. Second edition, thoroughly revised and enlarged. Pp. xvii+767. (London: Constable and Co., Ltd., 1919.) Price 36s. net.

"FAT hardening" and "hydrogenation" are the trade terms for the chemical process of saturating liquid oils with hydrogen in presence of finely divided nickel. These operations, which a few years ago were conducted with great secrecy, are now regarded as more or less normal in every soap factory, and the usual extensive literature has grown up to describe them. Much of this is naturally diffuse, and much again inaccurate, so that there was ample room for an authoritative book on the subject. This was provided by Carleton Ellis in 1914, but since its publication the strides made in the oil-hardening industry have been very great, making a second edition, which endeavours to bring the subject up to date and offers suggestions of future possibilities, more than welcome.

The book has now swollen to 700 pages, and is replete with information; it is essentially a work of reference for the expert, and necessarily filled with far too much detail to be easily readable by chemists in general.

The first edition, reviewed in NATURE of May 20, 1915, deservedly established a very high reputation for the author, which will be enhanced by the new volume. Doubtless this contains the inevitable printer's errors and minor inaccuracies, but we are less concerned to seek for these than to thank the author for his unselfish labours on behalf of his future readers.

The plan followed is first to discuss the methods of hydrogenation in detail, much of the plant being illustrated and full account taken of the patent literature. The next section, occupying more than 150 pages, is devoted to the many aspects of the subject of the activity of the base metals as catalysers. The vexed question as to whether metallic nickel or nickel oxide is the active agent is fully discussed in so far that the opinions and experiments of the protagonists are given at length, but the author refrains here, as elsewhere in the book, from giving the reader any lead as to which theory is the more probable. There follows an important chapter on the analytical constants of hydrogenated oils.

Although first introduced for providing hard fats for soap-making, hydrogenation has proved equally applicable to edible oils. As fats naturally fetch a higher price as foodstuffs than as soap-making materials, their technical production in the edible form has been extensively studied. Reference is made to other uses and properties of hardened oils.

The hardening process has also been extended to petroleum, where many new problems arise, which are now described. Not only does crude petroleum contain unsaturated constituents, but these are also formed in some quantity during the cracking processes.

The first stage in any hardening process is the production of hydrogen of the necessary purity and cheapness. A variety of methods for making hydrogen are in practical operation, and still more have been suggested, so that it is not surprising that fully a quarter of the book is devoted to the description of these. In the future the cheap production of hydrogen will play a great part in the formation of ammonia from the air, and through ammonia of nitrates, and so influence increased soil fertility.

The fat-hardening industry has had more than its share of patent litigation, famous cases having been fought both in this country and more recently in America. The report of the English case is given, substantially as published in the British official journal, in an appendix, whilst the case of The Procter and Gamble Co. *v.* The Berlin Mills Co. is reprinted in such detail as to occupy eighty pages.

E. F. A.

POLITICAL SCIENCE.

A New Chapter in the Science of Government. By Benchara Branford. Pp. xlviii+190. (London: Chatto and Windus, 1919.) Price 5s. net.

THIS book is not perhaps likely to become popular. It is defective both in shape and in style; nor is the language of the author free from eccentricity and even ambiguity. It is possible that some reason may be urged for such phrases as "Britamerindian Commonweal" or "Britamerindian re-orientation of politics," in which the author seems to take an especial pleasure. But phrases like "a spiritual instrument of exploration on the rough politico-economic *terra incognita,*" or "feeling of communitary responsibility," or "an extension of our synoptical categories," or "a synoptical survey of the grand human bi-directional spiral," are disturbing, and may well be forbidding, to general readers.

Still, Mr. Branford takes a clear and strong view upon certain points which vitally concern the theory of government. Nothing can be better than the passage in which he defines the guiding spirit of the new era (p. 143). It is almost too late to advocate now the rights of women; for womanhood has already entered upon its political heritage; but he rightly bases the enfranchisement of women upon their interest, which is at least equal to men's, in the good order of the State (p. 28). Mr. Branford will carry the assent of all wise thinkers in proposing "to drop the rootedly false distinction between manual work and brain work," a distinction which "has worked so fatally and so long against the humanisation of all labour, against its higher productivity, and against the social solidarity and happiness of mankind" (p. 100). All that he says about Labour is worthy of serious regard. It is only right, too, to express an acknowledgment of the passages (for example, on pp. 79 and 80) in which he defines the successive relations between the family and the city, the region, the nation, the State, and humanity as a whole.

But when the book is judged in the light of its title, as "a new chapter in the science of government," it cannot be said that Mr. Branford's positive reforms are altogether convincing. The most original of them seems to be an inference which he draws from the "warp and weft," as he calls them, of society, *i.e.* the geographical or regional and the occupational or industrial divisions of mankind. He sees clearly that, so long as mankind is distributed geographically into countries or nations, and into these alone, patriotism itself must be exposed, as it was in Germany, to the danger of assuming a selfish, violent, and aggressive character. He finds, or hopes to find, a counter-balancing force in the various occupations of mankind. Thus if all Englishmen are naturally united in the cause of England, the miners or the railwaymen, not in England alone, but all the world over, may be united in support of their own industry. There will then be an international or cosmopolitan sense balancing the local patriotic sense of particular countries. This is, or was in the days before the war, the idea of the Labour Party; but when the war broke out, even the Socialists in Germany suffered their vocational or occupational feeling to be merged in their patriotism; and so it remained, at least until the scales of victory began to incline against the German Empire.

Mr. Branford looks forward to a "Grand Council of Humanity," which he conceives as "a world-bicameral legislature," containing, after the manner of the British Constitution, two Chambers, the Lower being geographical and the Upper occupational; and it is through this Grand Council that he hopes to attain the solution of the political, social, and industrial problems which are now dislocating the civilised world. Upon the whole, if Mr. Branford cannot be said to have made a solid contribution to political science, he has thrown out a good many suggestive ideas which may well bear fruit in the political history of the new-born age. J. E. C. WELLDON.

AMERICAN BOOKS ON AGRICULTURE.

(1) *Productive Agriculture.* By Prof. John H. Gehrs. Pp. xii+436. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1917.) Price 5*s.* 6*d.* net.

(2) *Farm Concrete.* By K. J. T. Ekblaw. Pp. xi+295. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1917.) Price 8*s.* 6*d.* net.

(3) *Peach-growing.* By H. P. Gould. (The Rural Science Series.) Pp. xxi+426+xxxii plates. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1918.) Price 10*s.* 6*d.* net.

(1) FROM the house of the Macmillan Co., of New York, there issues a constant flow of good agricultural books, and it is gratifying to find that the three now to hand are fully equal to some of their predecessors.

The first book, by Prof. J. H. Gehrs, of the Warrensburg State Normal School of Montana, is written for school children of the upper classes who propose to take up farming as the business of their life. It is frankly vocational: "this is not primarily a book *about* agriculture, but one *on* 'Productive Agriculture.' . . . Unless this book helps to increase the average yields, improve stock, make for better and more fruit, and promote better farm management, it will have failed of the purpose for which it was written."

It may at once be stated that the book deserves to achieve success. The subject-matter is very interesting; the book is full of bits of old country-lore that always make a strong appeal to the country child and the countryman, and the information so far as we can see is sound. Under the heading "Wheat," for instance, the author gives a chart showing the production in bushels of the more important wheat countries of the world with the percentage that each contributes to the world's total. This brings out in striking manner the fact that Europe normally contributes 51·4 per cent. of the world's wheat—a sufficient explanation of the present scarcity. North America contributes only 27·6 per cent.—little more than European Russia. A chart is then given to show the production in certain of the States. North Dakota and Kansas easily come first, followed by Nebraska, Minnesota, Washington, etc. In yield per acre it is gratifying to note that Great Britain stands first with 33·4 bushels, followed by Germany with 30·7, France with 20·1, and the United States with 15 bushels. The cost of production per bushel is stated to be lower in Great Britain than elsewhere; but to this English farmers might not agree. The low position of the United States is not to the author's liking: "Why European countries produce larger yields an acre than the United States is an important question for study. Our natural resources are ordinarily as great as those of European countries."

America scores, however, in the efficiency of the farm labourers and the use of machinery. The portrait of Cyrus H. McCormick, who devised the modern reaper and thus revolutionised the growth of wheat, occupies a prominent place in the book, and much space is rightly devoted to machinery. A table is introduced showing how the time required of man labour to produce and thresh a bushel of wheat has fallen since 1832 from $3\frac{1}{2}$ hours to 10 minutes only, and the cost of the labour has fallen from $17\frac{3}{4}$ cents to $3\frac{1}{3}$ cents. Maize naturally claims a good deal of attention as the most important farm crop in the States in respect both of money value and of food value. The United States contributes no less than 78 per cent. of the world's supply; Iowa and Illinois are the largest producers, but Indiana, Nebraska, Missouri, and Ohio grow large amounts; these and Kansas constitute the famous "corn belt" of the States. Of oats, as of wheat, Europe is the chief producer, growing no less than 61·2 per cent. of the world's total; but in point of yield Germany comes first with 57·4 bushels, followed by the United Kingdom with 44·7, France with 30, and the United States with 29·4 bushels. Later chapters deal with animals; the style is equally good, and the matter equally interesting; a brief history of the principal breeds of live stock is given, with descriptions of their characteristics, valuable features, and methods of treatment. Next come sections on the soil, laying special stress on physical properties, then sections on fertilisers, and finally chapters on choosing a farm.

Altogether the book is one of the most successful for its purpose we have yet seen, and we imagine it will make a vivid appeal to the American students for whom it is written.

(2) The other two books are more specialised. Mr. Ekblaw writes about farm concrete, a subject of which we are likely to hear much more in this country in the future, for the making of concrete requires only sand, cement, and gravel (or similar substances); it can be moulded to almost any shape and adapted to almost any farm building purpose. The author deals with natural cement, made by calcining and then pulverising natural argillaceous limestone without preliminary mixing and grinding; and Portland cement or artificial cement, made by mixing finely ground argillaceous and calcareous materials in proportions approximately of three parts of calcium carbonate to one of silica, alumina, and iron oxide, then calcining and finely pulverising. Portland cement, it is interesting to note, was invented by an Englishman, Joseph Aspdin, in 1824, and for many years we led the way in its manufacture; but now the United States leads, surpassing all other countries both in manufacture and in use. Several varieties of concrete are made, but the constituents are always cement, a fine aggregate (usually sand) and a coarse aggregate (usually pebbles or broken stones), the purpose of the fine material being to save cement by filling up more closely the pore spaces; an apparatus called the voidmeter is described for estimating the amount of pore spaces of different materials. Reinforced concrete as used for buildings is concrete in which steel or other material is embedded to increase its strength. It was invented by a French gardener, Jean Monier, in 1876, and has proved very successful. Its use is still somewhat empirical, the underlying principles not being quite understood, but sufficient useful knowledge has been gained to reveal its great promise for the future.

Great stress is laid on the fire-resistant properties of concrete for building purposes. The building regulations in New York are severe; a building to be considered fireproof must withstand when fully loaded a temperature of 1700° for four hours, and then be subjected to a stream of water discharged from a $1\frac{1}{8}$-in. nozzle under a pressure of 60 lb. without failure. A number of systems of reinforced concrete have successfully passed the test.

The rest of the book is devoted to the special purposes for which concrete can be used on the farm. For building purposes it takes the place of both brick and wood; it can be used for buildings, posts, mangers, floors, yards, and the farmhouse itself. The book will be of great interest to country builders and estate agents who wish to build as cheaply and quickly as possible.

(3) The last book on the list, "Peach-growing,"

by Mr. H. P. Gould, follows the same lines as the other special crop-books of the Rural Science Series, of which Dr. L. H. Bailey is the editor. It is a worthy member of the series. Opening with an account of the history and economic position of the crop, the author proceeds to discuss the details of laying out and managing a peach orchard, the pests, and other details which the intelligent grower ought to know. References are given to bulletins of colleges and agricultural experiment stations, where further information can be gained.

HANDBOOKS OF CHEMISTRY.

(1) *Senior Practical Chemistry.* By H. W. Bausor. Pp. viii+217. (London: W. B. Clive. University Tutorial Press, Ltd., 1919.) Price 3*s.* 6*d.*

(2) *Volumetric Analysis for Students of Pharmaceutical and General Chemistry.* By Charles H. Hampshire. Second edition. Pp. 127. (London: J. and A. Churchill, 1919.) Price 5*s.* net.

(3) *The Preparation of Substances Important in Agriculture: A Laboratory Manual of Synthetic Agricultural Chemistry.* Third edition. By Prof. Charles A. Peters. Pp. vii+81. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1919.) Price 4*s.* net.

(4) *Salt and the Salt Industry.* By Albert F. Calvert. (Pitman's Common Commodities and Industries.) Pp. vii+151. (London: Sir Isaac Pitman and Sons, Ltd., n.d.) Price 2*s.* 6*d.* net.

(5) *Industrial Chemistry.* By Dr. Clerk Ranken. (The People's Books.) Pp. 126. (London and Edinburgh: T. C. and E. C. Jack, Ltd.; T. Nelson and Sons, Ltd., 1919.) Price 1*s.* 3*d.*

(1) THESE small books differ from each other perhaps as widely as it is possible for five chemical books to differ, except in one matter, namely, that each author seems to be fully competent to deal with his subject. Mr. Bausor disclaims responsibility for the character of the course of work given in his "Senior Practical Chemistry," as it is designed to meet the requirements of the Senior Cambridge Local Examination in Practical Chemistry. We may be old-fashioned, but we still think that the qualitative character of things should be studied before an attempt is made to estimate their quantity. To say the least of it, it appears strange to us that a student, after having made preparations and done experiments some of which demand considerable manipulative skill, should then be instructed how to bend and cut glass tubing, and how to take small quantities of materials out of bottles by means of a spatula. But we suppose that this is a matter of the syllabus. The final section deals with qualitative analysis, but only so far as the detection of the acid and the base of a single salt.

(2) The title of Mr. Hampshire's manual sufficiently indicates its scope. This author also works to a syllabus, but one that is much more definite and restricted than in the preceding case. In order to make the volume more generally useful, the applications of methods to substances that may be of little importance to those who are not students of pharmacy are printed in smaller type. But the majority of these will be found of interest to any earnest student of analytical chemistry, and those who have to direct their work will find in these small-print examples an excellent help towards getting out of the ruts that "laboratory work" is so apt to suffer from.

(3) The three other volumes differ from the first two in that the authors are not guided by syllabuses prepared by others. Prof. Peters gives within his few pages of large type a really surprising amount of information. The substances of which the preparation on a laboratory scale is described are superphosphate, ammonium sulphate, four potassium salts, lead nitrate, lead arsenate, lime-sulphur (the product of boiling lime and sulphur together in water), copper sulphate, Paris green, Bordeaux mixture, and paraffin oil emulsions. But the book will prove far more interesting than if it consisted merely of these practical directions. The use and manner of action of each substance are referred to, or of each constituent of a mixture, and the reason for employing the mixture rather than the single active substance. The last line of the preface informs us that "a few simplified spellings have been used." We have failed entirely to find consistency in these simplifications. *Ph* is replaced by *f* in *sulphate*, but not in *phosphate*. Final *e's* are sometimes omitted, but by no means always, and the same may be said of the *e* in the final syllable *ed*. *Coold, cald, lims, eg, brot, floc, thot, enuf, thru, volum* are examples of the simplifications, while, on the other hand, the author uses *feldspar*, although in this country the *d* has been omitted for more than a generation. These peculiarities mar the book, for they cannot fail to distract attention from the main subject. A students' manual of chemistry is not the place to introduce spelling reforms.

(4) Mr. Calvert, in his monograph on "Salt," restricts himself almost entirely to the history of the Cheshire salt district and its industry. The scant treatment of this subject at the hands of authors in general is ascribed to the comparatively

small group of men engaged in the industry, and their jealousies of one another and especially of outsiders. They have endeavoured to keep their secrets as well as their profits. The author says that the story is, for the most part, a chronicle of bitter struggles to maintain a monopoly, even at the cost of ruinous losses, and the stubborn persistence in "obsolete methods." But the chapter on the "latest methods of salt-making" leads us to hope that these times are now of little more than historic interest. The book is well illustrated, showing ancient works from old prints, salt-mine interiors, subsidences of land consequent on salt mining, and the most modern apparatus.

(5) "Industrial Chemistry" is, of course, a much more extensive subject than any of the preceding. Though the price of this volume is less than half that of any of the others, it is not the smallest book, and, bound in a very presentable green cloth, it shows what is possible in book production even in these times. It is difficult to see how anyone could have got more information into the same space than Dr. Ranken has, or to find any section of this wide subject that he has passed over, and yet the volume is a true "people's book," and does not leave any impression of undue condensation. The first chapter, being headed "Catalysis and Catalysts," may tend to repel the non-technical reader, but he has only to pass over the title and all will be well. The honesty of the author is highly commendable when he says that "there are fashions in chemistry as in other lines, and the views concerning catalysis held to-day may be absolutely unfashionable to-morrow." This is true of other matters than catalysis. C. J.

FRESH-WATER BIOLOGY.

(1) *Fresh-water Biology.* By Prof. H. B. Ward and Prof. G. C. Whipple. With the collaboration of a Staff of Specialists. Pp. ix + 1111. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1918.) Price 28*s.* net.

(2) *Aquatic Microscopy for Beginners; or, Common Objects from the Ponds and Ditches.* By Dr. A. C. Stokes. Fourth edition, revised and enlarged. Pp. ix + 324. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1918.) Price 10*s.* 6*d.* net.

(1) PROFS. WARD AND WHIPPLE and their twenty-five collaborators have produced a volume to which students may refer for precise information upon the organisms met with in fresh water in North America. Introductory chapters deal with general biological factors and methods of collecting. Succeeding chapters, devoted respectively to single orders or classes, give a general account of the occurrence, a brief description of the anatomy (including reference to the features used in classification) and of the life-history and biological relations, and, finally, a key to the genera, and in several cases also to the principal species of the group. The information in the key about any given genus includes not only the diagnostic characters, but also in most cases an illustration and some reference to the frequency, the range, or other data; thus the whole information "forms a solid panel and appeals promptly and as a whole to the eye and mind of the student."

Much good work has been put into this book, and especial mention may be made of the excellent chapters on Turbellaria, Trematodes and Cestodes, and free-living Nematodes, the last-named noteworthy for the detailed figures. The chapters on Cladocera, Copepoda, Ostracoda, and Mollusca are provided with numerous original illustrations. In the chapter on Rotifers, Prof. H. S. Jennings has given a very useful account of the biology and structure of these animals, and a survey of the families, pointing out the various modifications from the Notommatoid type from which the author (with Wesenberg-Lund) considers the other families to have been derived.

In addition to the notes on habitat given throughout the book, here and there are short notes on points of special importance connected with the distribution. Two of these may be cited as examples. Reference is made to the finding by Prof. Garman, in September, 1916, of large numbers of the fresh-water medusa *Craspedacusta* (*Limnocodium*) *sowerbii* in a creek near Frankfort, Kentucky. This medusa, first found in 1880 in the Victoria Regia tank in the Botanic Gardens in Regent's Park, and afterwards in tanks in other gardens in Europe and America, is now recorded for the first time from other than artificial surroundings. Dr. Ortmann, in a short note under *Mysis relicta,* states that, so far as the North American stock of this species is concerned, there is no reason to assume that it is a marine relic; it may be regarded as an immigrant into the Great Lakes in Glacial times.

This excellent treatise should greatly stimulate the study of the fresh-water fauna of North America, and will be very helpful for comparative purposes also to workers in this country.

(2) The author, who modestly styles himself "only a beginner" writing for beginners, has given his descriptions of the microscope and its parts and of aquatic organisms in language as

little technical as possible. The biology and some elementary points of structure of each group are briefly considered, and useful keys are provided to aid the reader in finding at least the generic name of the more common organisms which the author has collected from a single pond in New Jersey. Special attention has been devoted to certain groups—*e.g.* Gastrotricha, Rotifera, Polyzoa. Here and there the desire to be non-technical in terminology has been carried a little too far—*e.g.* the egg-masses of Cyclops should not be called "external ovaries," and the term "contractile vesicle" is not a good substitute for "contractile vacuole"—the latter term could have been quite easily defined. Helpful illustrations (198) as aids in diagnosis of the genera are given, but we would suggest that when the book reaches a fifth edition figures should be added of some of the commoner transparent animals, *e.g.* a rotifer, a polyzoon, Daphnia, in which the chief internal organs are clearly shown and labelled.

OUR BOOKSHELF.

The Elements of Astronomy for Surveyors. By Prof. R. W. Chapman. Pp. x+248. (London: C. Griffin and Co., Ltd., 1919.) Price 5s. net.

SIR JOHN HERSCHEL'S dictum in his well-known panegyric on star-catalogues, that "every well-determined star from the moment its place is registered is as effective for mapping down the intricacies of a petty barony as for adjusting the boundaries of transatlantic empires," may be taken as the *raison d'être* of this book. The author is professor of mathematics and mechanics in the University of Adelaide, and doubtless the southern continent gives scope for surveying on a large scale in which astronomical observation is a necessity.

The book is on conventional lines, the first six chapters dealing with the elements of geometrical astronomy, including one which explains at some length with examples the conversion of sidereal into mean time and similar arithmetical processes. The latter half of the book consists of chapters on the determination of true meridian, on azimuth of a mark, of latitude, time, and longitude. Most of the recognised methods are concisely explained, and illustrated in some cases by examples taken from actual experience. Use is made of the observation of circumpolar stars at elongation for determination of azimuth, and for time the observation of altitude of the sun or a star near the prime vertical is recommended and discussed in full detail. The inclusion of a few pages on the almucantar is a useful addition to the book, which will fulfil its intended purpose of providing an elementary exposition of the principles of the formulæ used by the surveyor.

Organic Chemistry for Students of Medicine. By Prof. James Walker. Second edition. Pp. xi+332. (London: Gurney and Jackson; Edinburgh: Oliver and Boyd, 1919.) Price 10s. 6d. net.

THIS second edition of Prof. Walker's book for medical students does not differ substantially from the first edition as issued in 1913. It may, however, be useful to direct the attention of medical students and their teachers to a volume which has been written specially to suit their requirements, and the value of which is shown by the publication of a further issue.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Promotion of a Plumage Bill.

ALL lovers of animals must sympathise with any efforts to prevent the ruthless destruction of bird-life for trade purposes, referred to by Mr. H. J. Massingham in his letter in NATURE of December 25. It is open to grave doubt, however, whether the measures announced are the best that can be devised or will meet with a sympathetic following. They are the formation of a "Plumage Bill group," designed to fight the plumage trade and to bring pressure upon the Government to introduce a Bill forbidding the importation of all birds' skins for millinery purposes, with a few exceptions.

From time immemorial plumage has been employed to satisfy the decorative and æsthetic instincts of mankind, though to-day public opinion is rightly determined that it must be procured under conditions conforming with our humane sentiments. We may well inquire, therefore, whether the æsthetic demands for plumage can be met without outraging these. The ostrich in South Africa supplies a forcible case in point. In times past the wild bird was hunted for its precious plumes, and would have become almost extinct ere this had not its domestication been undertaken. As it is, the wild bird is now preserved and is increasing in numbers, and hundreds of thousands of domesticated birds lead a pampered existence on the ostrich farms. A big industry has arisen of the highest importance to agricultural South Africa, representing in pre-war days an annual export value of about 3,000,000*l*.

It is submitted that what has been accomplished with the ostrich may be possible with other birds supplying ornamental plumage; that, like it, others may give rise to industries and yield their plumage in conformity with the highest humane demands. One ventures to suggest that, instead of pursuing a repressive policy, the efforts of Mr. Massingham and his associates would be better directed in instituting studies and investigations as to conditions under which plumage-birds could be reared on an industrial basis.

Mr. Massingham appears to have an unworthy view of the issues involved in his announcement, for in the plumage trade he sees "no other purpose than to feed the profits of a small band of East End traders and to satisfy the frivolity of some women." Though ostrich plumes are exempted from the operations of the proposed Bill, yet so sensitive is the inter-relationship between plumage of all kinds that when the Anti-Plumage Bill was introduced in 1913 the trade insecurity engendered was so far-reaching as to constitute one of the principal causes of the serious slump in the South African ostrich industry, involving the loss of millions of pounds—a slump from which, the war supervening, the Union is only slowly recovering. The introduction of another Bill would be viewed with alarm in South Africa, and would have a serious international bearing, particularly upon our Ally, France, involving thousands of workers and millions of capital. It surely were wise not to attempt it when other measures are possible which would afford a wide stimulus to industry and to the study of bird-life.

Musical Drums with Harmonic Overtones.

IT is well known that percussion instruments as a class give inharmonic overtones, and are thus musically defective. We find on investigation that a special type of musical drum which has long been known and used in India forms a very remarkable exception to the foregoing rule, as it gives harmonic overtones having the same relation of pitch to the fundamental tone as in stringed instruments. Five such harmonics (inclusive of the fundamental tone) can be elicited from the drumhead in this type of instrument, the first, second, and third harmonics being specially well sustained in intensity and giving a fine musical effect. The special method of construction of the drumhead which secures this result will be understood from the accompanying illustration (Fig. 1). It will

FIG. 1.—Drumhead giving harmonic overtones.

be noticed (1) that the drumhead carries a symmetrical distributed load, decreasing in superficial density from the centre outwards (this appears as a dark circle in the middle of the membrane, the load consisting of a firmly adherent but flexible composition, in which the principal constituent is finely divided metallic iron); and (2) that a second membrane in the form of a ring is superimposed on the circular membrane round its margin.

The character of the vibrations of this heterogeneous membrane which give rise to its remarkable acoustic properties have been investigated by us. It is found, as might have been expected, that the fundamental pitch and the octave are derived respectively from the modes of vibration of the membrane without any nodal lines and with one nodal diameter. The third harmonic, we find, owes its origin to the fact that the next two higher modes of vibration of the drumhead (those with two nodal diameters and with one nodal circle respectively) have identical pitch, this being a twelfth above the fundamental. There is reason to believe that the fourth and fifth harmonics similarly arise from some of the numerous more complex modes of vibration of the drumhead becoming unified in pitch in consequence of the distributed load at the centre and round the periphery of the membrane. The central load also improves the musical effect by increasing the energy of vibration, and thus prolonging the duration of the tones.

Power from the Sun.

MR. A. A. CAMPBELL SWINTON, in his letter on the above subject in NATURE of December 18, states that "it is hopeless to expect to be able to effect anything of this nature with the heat-engine, for with this we should scarcely reach the 2 per cent. efficiency nearly attained by vegetation."

For nearly four years immediately preceding the war I was engaged by the Sun Power Co. (Eastern Hemisphere), Ltd., and the Shuman Engine Syndicate, Ltd., on the problem of the utilisation of solar energy, upon which these companies spent a considerable sum of money, the experiments being conducted on a large scale in America and Egypt, while the trials of the necessary low-pressure engine (which made an easy record for such engines) were made in this country. The results of the whole of this work are recorded in my two papers both bearing the title "The Utilisation of Solar Energy," one being read before the Society of Engineers in April, 1914, and the other before the Royal Society of Arts in April, 1915.

At p. 540 of the Journal of the Royal Society of Arts of April 30, 1915, it was shown that the overall thermal efficiency of the sun power plant erected in Egypt was 4·32 per cent., which is to be compared with the performance of the best steam-engine and boiler of 11·5 per cent. At p. 560, *ibid.*, it was shown that the theoretical efficiency of an engine working between the same limits of temperature would be 5·9 per cent., and that, consequently, the relative efficiency of the sun power plant to this ideal engine was no less than 73·2 per cent. From this it will be seen that Mr. Campbell Swinton's estimate of the thermal efficiency of 2 per cent. for a sun-power steam plant is more than 100 per cent. too low.

It is well that any wrong impression which the lower figure might give should be corrected, for in these days of extremely expensive coal it is desirable that inventors, experimenters, and financiers should not be discouraged from attempting to utilise solar energy, which some of us think is bound to be realised in the future. In the Royal Society of Arts paper it was shown that the cost of solar energy was equivalent to coal at 3*l.* 10*s.* a ton, and from this it is obvious that had the companies had more time in which to develop and construct plants before the war, they would have been paying handsomely, with coal at its present prices, in Egypt, Chile, and other sun-bathed countries.

TRIODE VALVES AS ELECTRIC AMPLIFIERS.

AMONG the most exquisite tools that modern wireless telegraphy now proffers to investigators working in the fields of pure science, that known as the amplifier stands out as being of the most obvious promise in various directions. The amplifier offers the means of magnifying varying electro-motive forces and currents, otherwise imperceptible, so that they come within the range of ordinary laboratory measuring and recording instruments. It was developed during the war to a high pitch of excellence, not only for the improvement of wireless telegraph signals, but also for other kinds of signalling and for listening under water and under the ground—that is to say, it has been fully developed for the magnification of the high-frequency currents used in wireless telegraphy and for currents of telephonic frequency. Descriptions of the apparatus have now been published in many places, and the tool as thus developed will in due course take its place in the laboratory. For many purposes, however, an amplifier that will faithfully magnify slow variations of a current or electro-motive force is demanded, and since little has been published about such apparatus, the following notes of methods used in the writer's laboratory during the past few years are now presented.

As the term is usually understood nowadays, an amplifier consists of one or more of the three-electrode thermionic vacuum valves of wireless telegraphy associated with auxiliary transformers or analogous apparatus. This particular kind of valve may for brevity be called a triode valve, or even a triode. It comprises a hot filament for supplying electrons, which serves as cathode, a plate, or cylinder, which serves as anode, and an intervening grid, all contained in a highly evacuated bulb. The bulbs generally used in amplifiers are about the same size as the common incandescent filament lamp, but the filament cathode of the triode is proportioned so as to become white hot when a battery of about 5 volts is joined to its terminals to supply about three-quarters of an ampere of current. A battery of, say, 50 volts, connected with its positive pole to the anode and its negative pole to the cathode, causes a current of order one milliampere to flow when the grid is at the same electric potential as the mid-point of the filament, and of perhaps twice this value when the grid is given a potential one volt higher.

The reason for this influence of the grid may be briefly explained as follows: When, in obedience to the electro-motive force applied between anode and filament, an electron current flows from the filament, the distributed electric charge in the space creates an electric field that tends to repel electrons back to the filament, or, in other words, gives rise to a back electro-motive force acting against the battery. But making the grid positive relative to the filament partially neutralises the field of the space charge, and therefore reduces the back electro-motive force. This influence is greater the closer the mesh of the grid; in some commercial triodes one volt on the grid will cancel ten volts of the back electro-motive force, or, in other words, one volt applied to the grid is worth ten volts applied in the anode circuit. At the same time, the current flowing on to the grid when one volt is applied between grid and filament is, perhaps, only a microampere; the multiplication of current performed by the triode is thus a thousandfold. Moreover, since the energy input to the grid is, in the assumed circumstances, 1×10^{-6} watt, and the consequent additional energy output of the high-voltage battery in the anode circuit 50×10^{-3} watt, the energy ratio is 50,000. Not all this output is available for use, however; we may, in fact, scarcely hope to use half of it.

It is worth while emphasising here a difference between an electro-magnetic transformer and a triode regarded as a transformer. The transformer may be arranged to give in its secondary circuit a voltage many times that applied to the primary, but the current is correspondingly diminished to keep the output of the energy equal to the input (losses being neglected). But in the case of the triode valve the current, as well as the electro-motive force, is multiplied, and the consequently multiplied energy output takes place at the expense of the high-voltage battery.

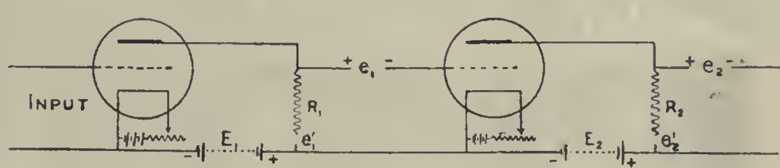

FIG. 1.

The most highly developed type of amplifier is that intended for the magnification of currents alternating more than 100 times per second, and consists of a number of triode valves linked in tandem by means of the mutual inductance of transformers. The earliest instruments were probably constructed by de Forest. Excellent instruments can now be made for any frequency between 100 and 1,000,000. It is stated that Mr. H. J. Round, of the Marconi Co., has used up to twenty-two triodes in tandem, and obtained magnifications of potential difference of about half-a-million-fold. As already stated, amplifiers for rapidly alternating current have been described elsewhere, and are not the subject of this article.

The type of amplifier described in Fig. 1 may be used for magnifying currents that vary slowly. It appears to have been conceived first in the French Military Radio-telegraphic Laboratory in Paris. In this apparatus the linkage between successive triode valves is accomplished by means of resistances and batteries. Considering the anode circuit of the first bulb, we see that it contains a resistance R_1 and a high-voltage battery E_1. Let $E_1=80$ volts, $R_1=30,000$ ohms, and the current be 1 milliampere. At present ignore the batteries marked e_1, e_1'; then the fall of potential along R_1 is $30,000 \times 10^{-3}=30$ volts. Such a potential difference applied between the grid and filament of the second triode would put this tube completely out of action. It is therefore necessary to introduce a neutralising battery of about 30 volts at the point marked e_1, or at the point marked e_1'. In the latter case the battery will, in fact, be a portion of the battery E. Suppose

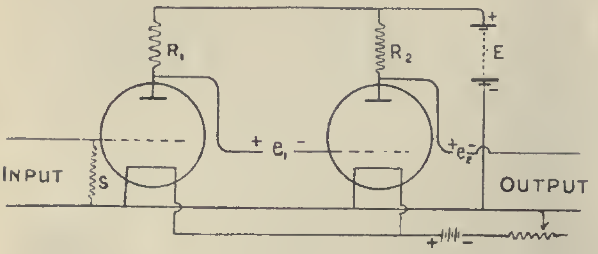

FIG. 2

this to be done, and imagine an electro-motive force e_g to be applied between the input terminals of the amplifier. Then it can be shown that the consequent increase of current in the anode circuit is

$$\frac{ge_g}{R_1+1/h_a},$$

where g is the triode's voltage factor, and h_a its differential conductance. These parameters are frequently of the order

$$g=10 \text{ and } h_a=10^{-4}.$$

The electro-motive force handed on to the second triode from the terminals of R_1 is clearly of magnitude

$$\frac{R_1 ge_g}{R_1+1/h_a}.$$

Using the value of R_1 suggested above, we find that the multiplier of e_g becomes

$$\frac{30 \times 10^3 \times 10}{40 \times 10^3}=7 \cdot 5.$$

The amplification approaches the limit 10 (that is, the value of g) the greater we take the value of R_1; but obvious practical reasons limit the magnitude of this resistance.

This type of amplifier, usually spoken of as a resistance cascade amplifier, has been much used by the Americans and the French for amplifying rapidly varying currents, but in that case a condenser is substituted for the battery at e_1; a "grid leak" of order a megohm must then be connected between grid and filament in each triode in order to avoid the accumulation of negative electricity on the now insulated grid. The complete instrument is then usually connected so as to utilise a common battery of 4 or 6 volts for all filaments, and a common battery of about 80 volts for all anodes. Adopting common battery connections, a finished two-stage amplifier is seen in Fig. 2. The grid leak S connected between the first grid and its filament might be about a megohm, and is necessary only when the circuits from which the input to the amplifier comes are such as would otherwise leave the grid insulated. According to the computations given above for one stage, the amplification with this two-stage instrument should be

$$7 \cdot 5 \times 7 \cdot 5=56\text{-fold}.$$

Finally, a mode of connection due to the present writer may be described. It is shown in Fig. 3, arranged to constitute a two-stage amplifier suitable for use with slowly varying currents. The first triode of the pair has resistances Q_1, R_1, S_1, connected so as to constitute with the bulb the four arms of a balanced Wheatstone bridge. The high-voltage battery E_1 is connected across two opposite corners of the bridge. An electrical stimulus applied to the grid causes the balance to be disturbed, and a corresponding potential difference arises between the filament lead and the junction of Q_1 and R_1. This difference of potential is conveyed to the next triode by direct connections. The magnification is the same as that obtained with the arrangement of Fig. 2 when resistances S_1, S_2 are taken of the same value as R_1 in that figure. A grid leak S is used when necessary, for the reason explained before.

In conclusion, it would be well to point out that in deciding upon the resistances and the voltages to be employed in constructing these amplifiers, the characteristics of the triodes should be kept in mind with the view of using them all at such adjustments that the relation between input and output potential differences is linear, and the magnification therefore free from distortion.

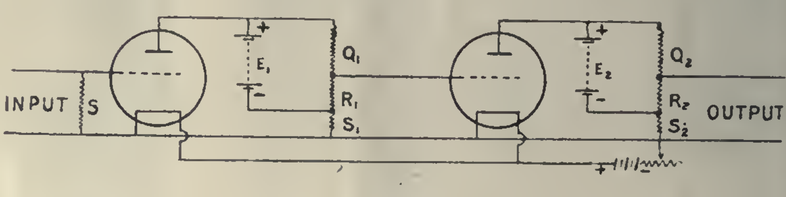

FIG. 3.

INDIAN GEOLOGY.[1]

THE appearance of a manual of Indian geology of so excellent a character as the present work, written by an Indian geologist, is an event of some importance, since it furnishes a fresh and convincing answer to the argument so often

[1] "Geology of India for Students. By D. N. Wadia. Pp. xx+398+xx plates. (London: Macmillan and Co. Ltd., 1919. Price 18s. net.

put forward that the Oriental mind, though it may assimilate the ideas of Western science with ease, is yet incapable of applying the principles of that science to original research. It is true that the author in his preface modestly admits that the book is in the main a compilation; yet the able manner in which he has marshalled the facts, and the clearness of his reasoning, especially when dealing with matters that are still open to controversy, show that he is by no means lacking in originality of thought and expression.

As a text-book for the use of the elementary student, perhaps, the work is not all that is required. There is still room for a book which would lead the student gradually to a knowledge of the science, by illustrations drawn from the rich field of observation that lies open to him in India itself. No systematic attempt is made to explain the meaning of geological terms, and the book presupposes a knowledge of the subject which the average student certainly would not possess. To the advanced student, in the sense that every scientific man is a student throughout his life, the book must prove extremely useful.

There are many pitfalls awaiting the student who fails to profit by the pertinent advice (p. 41) "not to commit the mistake of merely trying to memorise the dry summary of facts regarding the 'rocks' or 'fossils' of a system, or consider that the idea of a geological system is confined to these. These are the dry bones of the science; they must be clothed with flesh and blood by comparing the processes and actions which prevailed when they were formed with those which are taking place before our eyes in the world of to-day. A sand-grain or a pebble of the rocks is not a mere particle of inanimate matter, but is a *word* or *phrase* in the history of the earth, and has much to tell of a long chain of natural operations which were concerned in its formation. Similarly, a fossil shell is not a mere chance relic of an animal that once lived, but a valuable *document* whose preservation is to be reckoned an important event in the history of the earth. . . ." (The whole passage is too long to quote, but it furnishes a good example of the author's style.) In the making of tables of rock-sequence and correlation it is impossible to avoid what appear to be definite statements regarding a formation the position of which may be doubtful; and when the student merely learns these tables by heart for examination purposes (a practice which too often defines the limits of the candidate's knowledge of the subject), he is apt, having missed the qualifying explanation given in the text, to unload his modicum of knowledge with results disastrous to himself. Thus, in the general table of formations (p. 47), the rocks of the Simla area, from the Blaini boulder bed upwards, are boldly correlated with the Vindhyans of the peninsula,

FIG. 1.—Bellary Granite-Gneiss Country, Hampi. From "Geology of India for Students."

though it has not yet been proved that this boulder bed is not the equivalent in age of the Carboniferous Talchers. The Simla and Jaunsar slates, the Dalings of Sikkim, and the Shillong quartzites in Assam are all correlated with the Dharwars of Southern India, and, probable as these correlations may be, even as regards lithological resemblance there is little in common between these formations and the highly altered schists and jaspers of the typical Dharwars. Again, in the table giving the Cambrian succession of the Punjab Salt Range, the salt marl is placed at the base of that system, though it has recently been shown that there is good reason to believe this peculiar formation to be of Tertiary age.

FIG. 2.—"Marble Rocks" (Dolomite marble), Jabalpur. From "Geology of India for Students."

The arrangement of the book follows the usual lines. The physical features, mountains, glaciers, etc., are each briefly dealt with in the opening chapter. (Some of these are again described in a chapter on "Physiography" towards the end of the book (chap. xxv.), a somewhat peculiar arrangement, resulting in a good deal of repetition.) Then follow the various systems from Archæan to Pleistocene and Recent, the information with regard to each being carefully and clearly given in sufficient detail. Full advantage is taken of recent advances in our knowledge of Indian geology. Allusion is made to the revolutionary ideas of Dr. Smeeth and his band of workers in Mysore concerning the age of the Dharwars, which would make them the oldest rocks of the Peninsula (p. 69). Insistence is laid (pp. 135, 150) upon the importance of the stratigraphical break at the close of the Carboniferous period, which separates the Dravidian and Aryan groups of Sir T. Holland's classification of the Indian geological sequence. Full attention is also given to the recent discovery in Kashmir of beds containing the characteristic flora of the Talcher series, associated with marine strata, thus fixing a base limit for the Gondwana system, and closing a long-standing controversy.

A useful chapter on "Economic Geology" closes this part of the work, and then follows a special chapter on the geology of Kashmir, where, as the author remarks, "within a small geographical compass one of the finest developments of the stratified record seen in the Indian region and perhaps in the world" is revealed, in a situation more accessible to the student than any other in the whole length of the Himalaya. It may here be remarked that much remains to be done before the geology of this fascinating country is worked out in detail.

The book is written in clear and good English, and is well got up. Very few typographical errors have been noticed, but among them may be mentioned "Jena," presumably for "Jura" of Spiti (p. 165); "corrosion" for "corrasion" (p. 277); and twice (pp. 198, 200) "*Physa princepii*" for the typical fossil of the intertrappean beds of the Deccan, named in honour of the well-known secretary of the Asiatic Society of Bengal, James Prinsep. Numerous photographic views, diagrams, and maps add to the interest of the work, most of which are taken with due acknowledgment from the publications of the Geological Survey of India. Of the author's own views, two have been selected for reproduction, one showing a typical landscape in the crystalline area of the peninsula, and the other that unique feature in one of the great peninsular rivers—the falls on the Narbada, near Jabalpur. T. H. D. L.

METEOROLOGY IN THREE DIMENSIONS.[1]

IN 1916 Mr. W. H. Dines put together in a concise report the information then available about the pressure, temperature, and density of the atmosphere up to heights of 15–20 kilometres. His report is now published, and should prove extremely useful and informing both to the new generation of meteorologists and to the wider circle whose interest in the atmosphere is non-professional.

The first nine sections deal with the methods and places of observation, the averages and seasonal variations of pressure, temperature, and density, and the stratosphere and troposphere; short accounts of humidity and atmospheric motion are also included.

The tenth and eleventh sections are concerned with the results of the statistical treatment of the original data; the interpretation of these results will provoke much discussion. First, the correlation coefficient between (1) the mean temperature of a vertical column extending from a height of 1 km. to a height of 9 km. and (2) the pressure at the *top* of the column is 0·95. The hydrostatic equation connecting variations of pressure at 1 km. and 9 km. with variations of the mean temperature of the column of air is

$$\frac{\delta p_9}{p_9} = \frac{\delta p_1}{p_1} + \frac{k\delta T}{T^2}.$$

From this it follows that if $\frac{\delta p_1}{p_1}$ is (1) zero or (2) proportional to $\frac{\delta p_9}{p_9}$, then the correlation coefficient between p_9 and T is unity.

The first condition is not fulfilled in temperate latitudes; the second condition would be satisfied if the isobars at 9 km. were parallel to those at 1 km.—*i.e.* if the wind-directions at these levels were identical. But in the troposphere convection is always tending to make the direction of the wind the same at all levels, so that the magnitude of the correlation coefficient found by Mr. Dines may be due to the effectiveness of convection in regulating the wind. It would be interesting to know the differences from parallelism permitted by the 0·05 by which the actual coefficient falls short of unity.

Secondly, if T_0, P_0; T_1, P_1, etc., are the temperatures and pressures at heights of 0, 1, 2, . . 13 kilometres, then the correlation coefficients between corresponding T's and P's, beginning with T_0, P_0, are as follows: ·11, ·42, ·66, ·77, ·84, ·85, ·86, ·86, ·86, ·71, ·32, −·19, −·36, −·28. It follows that pressure and temperature go up and down together with great regularity at all heights between 3 km. and 9 km. Presumably the same would hold for the surface were it not for the effects of radiation and of the surface water of the ocean upon the surface temperature of the air.

Two outstanding deficiencies in the information available call for comment. There are no records from the United States, India, Australia, South Africa, South America, and Japan. This is no doubt partly due to the difficulties of recovering records in these countries if the ordinary European method of investigation is used; but it is also due to the defects of pre-war international meteorological organisation in which no place was found for an active permanent bureau. Further, the information about atmospheric motion is hopelessly inadequate. This arises less from lack of original records than from the absence of any proper arrangements for summarising the results of pilot-balloon ascents. A young meteorologist seeking a field of independent research might do worse than turn to the statistical treatment of vectors.

Before the war the investigation of the free atmosphere was, broadly speaking, pure research; the work had no direct application in forecasting or climatology, and the means of investigation were slight and relatively expensive. During the war a knowledge of the actual conditions of the atmosphere at least up to 20,000 ft. (6 km.) became essential for heavy artillery and for aviation, and their importance for actual daily forecasting began to be dimly recognised. Now that artillery operations are over and aviation is practically restricted to low levels, there is a great risk of the investigation at higher levels by aeroplanes and kite-balloons being neglected; and instead of information being available an hour or two after it was obtained, records would again creep in months or years out of date, with no possibility of immediate practical usefulness. E. GOLD.

SIR THOMAS R. FRASER, F.R.S.

WHEN, in 1877, and then in his thirty-sixth year, Thomas Richard Fraser was called to succeed Sir Robert Christison as professor of materia medica in Edinburgh University, it could scarcely have been anticipated how closely he was to rival his great master in his length of tenure of the chair and in the distinction with which he was to fill it. In his varied spheres of action Fraser attained a commanding position as a physician, as an investigator, and as a professor.

Gifted with acute senses and a fearlessly logical mind, and trained in the habits of accurate observation and experiment in the laboratory, Fraser brought to the hospital wards a rare combination of qualities. He had few equals as a diagnostician and therapeutist. As a teacher, his unswerving scientific attitude to the problems of clinical medicine had on the thousands of students who passed through his hands an influence scarcely to be overestimated. He taught not only accuracy of method, but also precision of language. His gifts as a physician were recognised by his holding, among other distinctions, the offices of physician to the King in Scotland, and of president of the College of Physicians of Edinburgh, of the Association of Physicians of Great Britain and Ireland, and of the Indian Plague Commission. He was knighted in 1902.

As an investigator, Fraser was one of the pioneers of experimental pharmacology. His greatest discoveries—from the point of view of their immediate practical application—were those which, in strophanthus and physostigmine, added to our Pharmacopœia remedies still in everyday use for the purposes for which he recommended them. For far-reaching scientific value they were even exceeded by the monograph which he wrote in collaboration with Prof. Crum Brown on the relation between chemical constitution and physiological action, embodying one of the most suggestive and fruitful researches in the history of pharmacology. For his researches he was made a laureate and Barbier prizeman of the French Academy of Sciences, and was awarded the Macdougall-Brisbane and Keith prizes of the Royal Society of Edinburgh.

Fraser combined an aptitude for both science and business. He took a keen interest in educational problems and an active part in introducing many university reforms. For twenty years he acted as dean of the faculty of medicine, and for ten years represented that faculty on the University court, and his University on the General Medical Council.

Endowed with a remarkably lucid and quick mind himself, Fraser was intolerant of mental slowness in others, sparing of praise, and at times not slow to censure. But he expected a man's best, and his standard was high. He carried himself—a keen, spare, scholarly figure—with a faint, indefinable hauteur, which may have been to many a barrier to close intimacy. But when this barrier was surmounted, and when he could lay aside the cares of too unremitting labour and of indifferent health, he would weave a grace and charm which few could resist or forget. Especially in later years he fought a continual battle with bronchitis and emphysema with a fortitude which is surely characteristic of sufferers from this condition. That he was so long permitted to lead an active life—for he retired only two years ago—was due in no small measure to the loving care and encouragement of Lady Fraser and the kindly supervision of his staunch friend and physician, Sir James Affleck.

Plummer, Gregory, Fowler, Withering, Lister, Simpson, Hughes Bennett, Christison, Brunton, Fraser—alumni or professors of the University of Edinburgh, a roll enviable and for one medical school possibly unequalled—file before us in retrospect. Their achievements in adding to our knowledge of remedies for disease and for pain stretch from the picturesque twilight of empiricism to the clear light of scientific method. With the passage of the last to that unknown bourn, we salute their memory.

J. A. G.

NOTES.

A SPECIAL general meeting of the Royal Society will be held on January 22, at 3.30, to admit H.R.H. the Prince of Wales as a fellow of the society.

THE meeting of February 5 has been set apart by the council of the Royal Society as a meeting for a discussion on "The Theory of Relativity," to be opened by Mr. Jeans and continued by Prof. Eddington, the Astronomer Royal, and others.

THE International Research Council has been constituted, by successive meetings in London, Paris, and Brussels, as a Federation of National Research Unions. Under its auspices unions are being formed for the organisation of international work and co-operation in different departments of science, the unions already instituted being for astronomy, geodesy and geophysics, mathematics, and (provisionally) chemistry and biology. The question of international organisation in science is raised, to a great extent, by Article 282 of the Peace Treaty, which states that "treaties, conventions, and agreements of an economic and technical character not included in a specified list cease to be operative." That this article was intended to cover conventions on scientific matters appears from the list of exceptions, in which the Metric Convention and the International Agricultural Institute at Rome are included.

WITH the view of obtaining the opinion of representatives of pure and applied science upon the subject of the co-ordination of international effort and action, a special meeting of the Conjoint Board of Scientific Societies was held at the Royal Society on January 8. After much discussion the following resolutions were passed:—"(1) That the executive committee be requested to appoint committees for the purpose of considering the desirability of forming in branches of science, as recommended by the Brussels Conference, international unions connected with the International Research Council, or of joining such Unions if formed independently. (2) That these committees be authorised to make recommendations with regard to the proposed statutes and the constitution of national research councils. (3) That the committees consist of representatives nominated by the principal societies concerned, together with additional members nominated by the executive committee."

WE regret to see the announcement of the death on January 11, at seventy-three years of age, of Father J. N. Strassmaier, the distinguished Assyriologist, whose work with Father Epping on Assyrian astronomy is well known.

THE Scientific Instrument, Glassware, and Potash Production Section of the Board of Trade has been transferred from 7 Seamore Place, W.1, to the main offices at Great George Street, S.W.1.

THE council of the Geological Society of London has this year made the following awards:—Wollaston medal, Prof. Baron Gerard Jakob de Geer (Stockholm); Murchison medal, Mrs. (Dr.) E. M. Shakespear; Lyell medal, Mr. E. Greenly; Wollaston fund, Mr. W. B. R. King; Murchison fund, Dr. D. Woolacott; and Lyell fund, Dr. J. D. Falconer and Mr. E. S. Pinfold.

THE Secretary of the Department of Scientific and Industrial Research announces that the Research Association for the British Launderers' Industry has been approved by the Department as complying with the conditions laid down in the Government scheme for the encouragement of industrial research. As the association is to be registered as a non-profit-sharing company, the promoters have applied to the Board of Trade for the issue of a licence under section 20 of the Companies (Consolidation) Act of 1908. The secretary of the committee engaged in the establishment of this association is Mr. J. J. Stark, 162–165 Bank Chambers, 329 High Holborn, W.C.2.

WITH the approach of a return to normal conditions, the Natural History Museum, we are glad to learn, is developing a policy of adding to the national collections by means of exploration. Thus Mr. Willoughby Lowe, who has already made several expeditions to Africa on behalf of the museum, has recently started on a mission to the West Coast of Africa for the purpose of collecting specimens for South Kensington, and Capt. Hubert Lynes, R.N., has just left England on an expedition to Darfur, where he intends to make a special survey of the avifauna of the Jeb-Maria Mountains, which should yield many forms new to science to the Bird Department. Other similar expeditions are, we believe, contemplated by the museum authorities.

A MEETING of surgeons, representing the surgical staffs of all the great teaching hospitals of Britain, assembled in the theatre of the Royal College of Surgeons of England on January 8, under the chairmanship of Sir Rickman J. Godlee, and resolved to form an "Association of Surgeons of Great Britain and Ireland." British surgeons have thus followed the precedent set by their colleagues the physicians, who formed a similar association a number of years ago. The object of the newly formed association is to permit surgeons on the staffs of the greater hospitals to meet together from time to time at various centres in order to exchange observations and compare results. The association will stand as the representative body for British surgeons, and in that capacity will represent British interests at international surgical congresses. Sir John Bland-Sutton was elected president of the new association.

ACTIVE steps are now being taken in the movement to establish a memorial to Lord Lister in Edinburgh. The movement had already begun to take shape in 1914, but its progress was arrested by the outbreak of war. The war, which has caused delay, has given at the same time an overwhelming demonstration of the value of Lord Lister's work. The University and Royal Colleges of Physicians and Surgeons in Edinburgh, under the control of which the memorial will be established, have determined to provide an institute for research and teaching in medicine. A site has been secured, and a committee is now being formed to make an appeal to the public for a sum of 250,000*l.* Mr. Balfour, Chancellor of the University, has consented to be president of the committee, with the Duke of Atholl, Lord Rosebery, Lord Beatty, Lord Glenconner, Lord Leverhulme, and Sir J. Lorne McLeod as vice-presidents.

THE Journal of the Washington Academy of Sciences for December 19 announces that Mr. E. C. McKelvy, of the Chemical Division of the Bureau of Standards, died on November 29, in his thirty-sixth year, as the result of burns caused by an explosion of ammonia-condensing apparatus containing petroleum-ether cooled by liquid air. Mr. McKelvy was born at Upper Sandusky, Ohio, on May 9, 1884. He joined the staff of the Bureau of Standards in July, 1907, and was chief of the physico-chemical section of the Chemistry Division at the time of his death. His work for several years past had been on the physical constants of ammonia and other substances used in commercial refrigeration. He was a member of the Washington Academy of Sciences and one of the associate editors of its Journal, and had been secretary of the American Chemical Society since 1915.

AN exhibition of radiographic prints has been arranged by the Röntgen Society, and is being shown at the Royal Photographic Society's house at 35 Russell Square, W.C.1. The exhibition is open free to the public until February 7, between 11 a.m. and 5 p.m. daily. The two hundred or so prints which are hung on the walls of the gallery well illustrate present-day practice in both medical and industrial radiology as developed by some of the leading X-ray workers in this country. We hope to make extended reference to the subject in a future issue. Incidentally, the growing custom of holding joint meetings of kindred societies is one much to be commended, and we are glad to note that the Röntgen Society, in addition to its recent joint meeting with the Faraday Society, has similarly co-operated during the present exhibition with the Royal Photographic Society. Furthermore, it has arranged, in the near future, joint meetings with the Institution of Electrical Engineers and the Electro-therapeutic Section of the Royal Society of Medicine. The officers of the Röntgen Society deserve every support for their energy and enterprise.

REFERENCE is made in the *Times* of January 12 to an exceptionally high velocity, at the rate of 180 miles an hour, attained by the north-west wind at 25,000 ft. over southern England on January 9 as a precursor to the recent rough and stormy weather. Deep cyclonic depressions had spread in from the Atlantic, the central area of one passing over the northern parts of Ireland and England on January 10, and a second disturbance skirted our north-western seaboard on January 11, when the barometer in the Hebrides fell to 28·3 in. The intensity of the storm was greatest in the English Channel. In the Scilly Isles the wind attained the velocity of 68 miles an hour in a gust during the evening of January 11. Inland the gusts attained an hourly velocity of 50 to 55 miles. Thunderstorms occurred in many parts of the country, and heavy rain was general, whilst in the Shetlands snow covered the ground to the depth of 6 in. On January 13 the Daily Weather Report of the Meteorological Office showed that the wind in the south of England was blowing at 12 miles an hour, whilst at 4000 ft. it had increased to a rate of 54 miles an hour. During the morning a storm area had its centre over Thorshavn, where the barometer stood at 29·05 in. There were indications of the approach of another disturbance from the Atlantic. The storms have occasioned several wrecks, resulting in serious loss of life.

THE death is announced of the well-known Argentine geographer and naturalist, Dr. Francisco P. Moreno. Dr. Moreno was born in Buenos Aires on May 31, 1852, and doubtless inherited his love of natural science from his mother, who was the daughter of an English botanist. He spent his early years in exploring Patagonia and various parts of the Andes, and devoted himself especially to the making of anthropological and ethnological collections. His first contribution to science, on the prehistoric cemeteries of Patagonia, appeared in the *Revue d'Anthropologie* so long ago as 1874. In 1877 Dr. Moreno gave his collection to the Argentine Government to form the beginning of the Anthropological and Archæological Museum of Buenos Aires. In 1880 Buenos Aires became the federal capital, and two years later the city of La Plata was founded to replace it as the provincial capital. Dr. Moreno then devoted his thoughts and energies to the planning and foundation of a great museum at La Plata which should illustrate the natural history of the Republic. His scheme was realised in 1889, and the well-known publications of the La Plata Museum under his direction began in the following year. In 1898 Dr. Moreno came to London as representative of Argentina in the dispute as to the Argentine-Chilean boundary, which had been referred for settlement to the British Sovereign; and in 1900 he produced his report in four handsome volumes well illustrated with photographs. At the same time he brought and exhibited to the Zoological Society the famous piece of the skin of an extinct ground-sloth which he had discovered in a Patagonian cave. Dr. Moreno was an honorary corresponding member of the Royal Geographical Society, and received the Founder's medal in 1907. He was also a foreign correspondent of the Geological Society and a corresponding member of the Zoological Society of London.

DISPATCHES published in the daily papers last week contain brief accounts of destructive earthquakes that were felt over the greater part of Mexico during the night of January 3–4. The first shock occurred at 9.45 p.m. on January 3; this was followed by a second of great intensity at 10.25, and by a slighter shock at 11 p.m. The epicentral area lies about fifty miles west of the city of Vera Cruz, near the southern end of the Gulf of Mexico, after-shocks being especially frequent to the south of Jalapa. The principal damage, so far as is yet known, is at Cordoba, Jalapa, Coscomatopec, Calcahualco, Teocelo, and Cosautlan. The area within which injury to property occurred is, however, considerable. The city of Vera Cruz is deprived of gas and water, owing to many breaks in the mains, and, even so far west as Mexico City (150 miles from the coast and nearly 200 miles from Vera Cruz), the walls of large buildings were cracked. As in all destructive shocks, the central area was completely isolated, but the unusual violence of the principal shock is also evident from the change in the course of the River San Francisco, the rupture of water-mains at Vera Cruz, and the uprooting of thousands of trees in a forest twenty-five miles from that city. The loss of life is still unknown, but is sure to be considerable. At Coscomatopec it was increased by the rush of people to the church when the first shocks were felt. According to the officials of the Mexican Government Observatory, the centre of disturbance was situated in the volcano of Orizaba, but the earthquake was clearly tectonic, possessing none of the characteristic features of volcanic earthquakes, though the opening of a new crater in the volcano may be connected with the same movement which caused the earthquake. One point of some interest is its occurrence near the north coast of Mexico, the principal seismic regions lying on the south or Pacific side.

IN "Memoirs of the Bernice Pauahi Bishop Museum, Honolulu," vol. v., part iii., for 1919, Mr. T. G. Thrum publishes a long series of native documents from the Fornander collection, giving the Hawaians' account of the formation of their islands, the origin of their race, and their migrations. The records now printed in the original language, with English translations, include fifteen mythical tales, twenty-five traditionary stories, and the legend of Kawelo, which extends to six chapters. The publication is of great importance from the points of view of ethnology, folklore, and linguistics.

IN the Journal of the Royal Anthropological Institute (vol. xlix., January–June, 1919) Mr. J. Reid Moir discusses the occurrence of humanly fashioned flints in the Middle Glacial Gravel at Ipswich. These implements and flakes do not exhibit marked signs of abrasion by water action, and the writer regards it as a possibility that the place where these Middle Glacial specimens are now found cannot be far removed from the deposits in which they rested in an unabraded state, and that the water which laid down the Middle Glacial deposit did not flow at a turbulent rate. The only dateable artefacts so far recovered from this gravel are some small platessiform flint implements, which, though small, otherwise resemble closely the well-known early Chellean implements. "The occurrence of flint implements of early Chellean form in a gravel presumably more ancient than the Glacial Chalky Boulder Clay will no doubt come as a surprise to many archæologists, but there does not seem to be in this case any escape from such a conclusion."

IN the *Public Health Journal* for November (vol. x., No. 11, Toronto) Prof. Fraser Harris discusses the medical and allied professions as a State service.

He considers that the advantages of such a service far outweigh the possible disadvantages. Among the advantages are mentioned the speedy exclusion of quacks and irregular practitioners, and of the struggles for existence and rivalries among the regular practitioners, while the public health would be maintained as never before; treatment would be prompt and of the highest quality; specialists of all sorts easily accessible; and all manner of special treatments readily available for the rich and poor alike.

THE weekly mortality statistics of the influenza epidemic beginning in the autumn of 1918 for thirty-nine large American cities have been subjected to a preliminary analysis by Prof. Raymond Pearl (Reprint No. 548 from the Public Health Reps., Treasury Dept., U.S. Public Health Service). There was considerable variation among the several cities in the relative degree of explosiveness of the outbreak. The analysis appears to demonstrate that an important factor causing this variation was the magnitude of the *normal* death-rates occurring at the same time as the influenza epidemic in respect of pulmonary tuberculosis and diseases of the heart and of the kidneys.

IN *Medical Science: Abstracts and Reviews* for December (vol. i., No. 3) the influenza epidemic of 1918–19 is reviewed in all its aspects. In the civilian population of the United States the total number of deaths attributable to the epidemic was estimated at not fewer than 450,000, a death-rate of more than 4 per thousand. In the County of London some 22,750 deaths were caused by it. The statistics of the Life Insurance Bank of Gotha show that, whereas in 1889–90 epidemic influenza caused no deaths in the age period 15–30, in 1918 the greater number of deaths occurred in this age period—an experience similar to that which obtained in this country.

WE have received a copy of the general report of the Survey of India for 1917–18. Shortage of officers necessitated the curtailment of field work. Several officers and survey parties were supplied for Persia, Mesopotamia, and East Africa. New maps published included 43 one-inch sheets, 65 half-inch sheets, 4 quarter-inch sheets, and 13 sheets of the million map. The report gives useful index maps of all the sheets published up to the present on various scales by the Indian Survey Department.

THE United States Geodetic Survey has published a report on the connection of the arcs of primary triangulation along the ninety-eighth meridian in the United States and in Mexico (Special Publication No. 54). Mr. W. Bowie, the writer of the report, points out that this connection not only makes it possible to compute with greater accuracy than hitherto the dimensions of the earth, but also enables Mexico to extend new areas from the ninety-eighth meridian arc, which can be based on the North American datum, as the United States standard datum is now called. It had been intended to carry out this work in 1913, but the unsettled conditions in Mexico made it necessary to postpone the observations until 1916. The arc of the ninety-eighth meridian was completed to the Canadian frontier in 1907.

THE value of large-scale maps in war is the subject of an unsigned article in *La Géographie* (vol. xxxii., No. 7) on the Service Géographique of the French Army. This Service was practically created by the war, when it was realised that the available maps of France were on too small a scale to be of use. Maps on scales of 1/80,000 and 1/200,000, although valuable for war in the open, were unsatisfactory for trench warfare. Large-scale plans were available only for the neighbourhood of Paris and certain fortified places. It was decided to make maps of the war area on a scale of 1/20,000, 1/10,000, and 1/5000 (*plans directeurs*). Of these the smallest scale was for artillery use, the second for Staff work in general, and the largest scale, confined to front-line areas, for infantry use. Generally speaking, the 1/20,000 proved to be the most useful. It is hoped that this will be extended to the whole of France and be periodically revised. The urgency of the demand in war-time did not allow of detailed resurvey for this work, so recourse was had to existing survey material, land valuation plans, and aerial photography. Specimen sheets of the maps accompany the article.

IN the Bulletin of the Central Meteorological Observatory of Japan (vol. iii., No. 1) Prof. T. Okada attempts to discover a forecasting formula, starting from the undoubted fact that in Japan a hot August means a good crop, and a cold August a bad one, resulting in famine in 1902, 1905, and 1913. Prof. Okada connects the temperature of northern Japan with the sun-spot cycle, but more definitely finds a correlation between the August temperature in that region, the March pressure difference between Zikawei and Miyazaki, and the South American pressure for March to May, using data from Santiago and Buenos Aires. The South American data give larger correlation coefficients (0·5 or 0·6 with $P.E. < 0{\cdot}1$) than the Zikawei-Miyazaki pressure differences (0·3 or 0·4 with $P.E. > 0{\cdot}1$). Treating the districts of Hokkaido and Tôhoku separately, he obtains the yearly variation in the rice crop for the former as $0{\cdot}53x + 0{\cdot}26y$, and for the latter as $0{\cdot}18x + 0{\cdot}10y$, where x is the yearly variation of South American pressure, March to May, and y the yearly variation of pressure gradient, Zikawei-Miyazaki. The table of comparative results shows a fair agreement in sign between calculated and actual yields, especially for Hokkaido, and the conclusion is drawn that, in general, abnormally low pressure in the southern part of South America from March to May and abnormally small pressure gradient in March between Zikawei and Miyazaki are followed by a failure of the rice crop in northern Japan.

DR. G. R. WIELAND, in his "Classification of the Cycadophyta" (*Am. Journ. Sci.*, vol. xlvii., p. 391, 1919), reviews "the gymnosperm phylum," and goes much further than this in providing a table in which the evolution of dominant and specialised land-plants is correlated with the climates of successive geological periods. In this suggestive diagram various types are shown as moving towards "ascendancy and extinction" or "simplification and reduction," sharply or gently from a previous parallel course of evolution.

"Basic or semi-immortal types" of vegetation are represented by a horizontal line running across the bottom of the diagram. Elsewhere Dr. Wieland has lamented the depletion of the already small group of palæobotanists. If he could give us a general treatise on the problems expressed so concisely in his diagram, he might win a keen body of adherents.

MR. GEORGE BARROW, in a paper on "Some Future Work for the Geologists' Association" (Proc. Geol. Assoc., vol. xxx., p. 1, 1919), revives in a remarkable degree the view that some of the features of the chalk surface round London are due to marine erosion, acting probably in Pliocene times. It is urged that the quartz-pebbles of the pre-Glacial high-level gravels were washed into the chalk basin by the waters of a shallow sea, which cut passages in the escarpments and thus originated many of the wind-gaps. The chalk escarpments, together with those of the Lower Greensand, were, in their first form, ridges left by the marine denudation of the softer Gault and Eocene strata. If the "beach deposits" (high-level gravels) are of Pliocene age, no serious post-Pliocene bending of the region can have occurred, since they lie at approximately the same levels. Mr. Barrow suggests that they are little later than the Lenham Beds, and the members of the Geologists' Association are now invited to prove their age by a diligent search for fossils.

DR. R. E. SLADE and Mr. G. I. Higson, of the British Photographic Research Association, communicate to the Journal of the Royal Photographic Society (December, 1919) the results of their investigations, which show that the shape of the characteristic curve of a photographic plate depends not only on the thickness and opacity of the film and the time and method of development, but also on the relation of the different sizes of grains in the film to each other and the quantity of each size present. This new factor they claim to be the most important. If the grains are all of the same size, the curve is the steepest possible. If the grains are of various sizes, the curve is the sum of the curves due to each group of particles of the same size. The larger grains are more sensitive than the smaller grains. Uniformity of grain-size is, therefore, desirable in plates for black-and-white work, and the authors find that the steepness of the curve can be foretold from photomicrographs of the grain. Photomicrographs and curves are given in illustration.

IN May, 1914, we mentioned in these columns two methods which had been devised for reducing the measurement of the horizontal component of the earth's magnetic field to that of an electric current. In the first—due to Prof. Hicks and tested in practice by Mr. W. A. Jenkins (*Phil. Mag.*, October, 1913)—the earth's field was reversed by the current in a coil, and the reversal determined by the time of oscillation of a small magnet. In the second—due to Sir A. Schuster and tested at the National Physical Laboratory by Mr. F. E. Smith (*Terrestrial Magnetism*, March, 1914)—the earth's field was annulled by that of the coil, and a small magnet set itself at right angles to the field. In *Terrestrial Magnetism* for September, 1919, Prof. W. Uljanin, formerly of the Kazan University (from which the staff had to flee on the capture of the town by the Bolsheviks in September, 1918), gives an abstract of a paper he published in Russian in 1915 describing a third method. It retains the sine principle of the Kew magnetometer, but substitutes for the deflecting magnet a pair of coils through which a standard current measured by the potentiometer method is sent. The method gives results at least as accurate as those given by the magnetometer, and takes only a tenth of the time.

TWO useful papers on three-electrode thermionic valves have been published recently by the Bureau of Standards, Washington. The first paper, by Mr. J. M. Miller, discusses the connection between the input impedance of the valve and the load in the plate circuit. Theoretical relations are obtained which enable us to calculate the input impedance when the impedance in the plate-circuit is known. It is shown that the results are in excellent accord with experiment. It is interesting to notice that when the load in the plate circuit is inductive, the impedance can be represented as a negative resistance, in which case the valve can act as a generator. The second paper, by Mr. L. M. Hull, gives a partially successful attempt to obtain a method of rating thermionic-valve generators. A clear theoretical statement of the problem is given, and important theoretical conclusions are deduced, but experimental work is still in progress. The problem is one of considerable commercial importance, as thermionic-valve generators are now the standard source of supply for radio-telephone and radio-telegraph systems, except in the few cases when very high power is necessary. The present empirical method used for rating these generators is of little value. All interested in the subjects discussed in these papers, the numbers of which are 351 and 355 respectively, can obtain a copy of them by sending a request to the Bureau.

IN the U.S. Bureau of Standards Scientific Paper No. 350, entitled "Equilibrium Conditions in the System Carbon, Iron Oxide, and Hydrogen in Relation to the Ledebur Method for Oxygen in Steel," it is shown that mixtures of iron oxide and Acheson graphite are not, and mixtures of iron oxide with "cemented" iron or white iron (annealed or unannealed) are, reduced at 900° C. by the carbon in them when hydrogen is passed over them at rates of two litres per hour, or faster. Because of these facts it is probably impossible to determine by the Ledebur method more than 75 per cent. of the oxygen present in steels as ferrous oxide. The effect of rate of passage of hydrogen on the Ledebur oxygen-content of certain steels is shown. The paper can be obtained on application to the Bureau.

SCIENTIFIC Paper No. 347 of the U.S. Bureau of Standards describes an investigation carried out at the Bureau on the heat-treatment of alloys of the duralumin type, and the effect on the mechanical properties observed of variations in the various heat-treatment conditions. Conclusions are also drawn as to the best conditions for the commercial heat-treatment of this alloy. A theory of the mechanism of hardening during the ageing of duralumin is proposed, based on the decreasing solubility with decrease of temperature of $CuAl_2$ in aluminium. The precipitation of this compound, suppressed during quenching, proceeds during ageing, and takes place in a highly dispersed form. To the presence of this highly dispersed constituent is due the hardness of the aged alloy. Those interested may obtain a copy of the paper on application to the Bureau.

A SHORT list of books dealing with entomology, containing 165 titles, has just been issued by *Mr. F. Edwards*, 83 High Street, Marylebone, W.1. Many of the books listed are much reduced in price.

THE latest scientific catalogue (New Series, No. 89) of *Messrs. J. Wheldon and Co.*, 38 Great Queen Street, W.C.2, contains upwards of 1500 items relating to pure and applied chemistry, astronomy, electricity, mathematics, meteorology, physics, etc. In addition, particulars are given of many sets and long runs of scientific serials and transactions of scientific societies which Messrs. Wheldon have for disposal. The price of the catalogue is 2*d*.

THE following are among the announcements of books to be published by *Messrs. Macmillan and Co., Ltd.*, between now and Easter:—"Cytology: With Special Reference to the Metazoan Nucleus," Prof. W. E. Agar, illustrated; "The Principles of the Phase Theory: Heterogeneous Equilibria between Salts and their Aqueous Solutions," D. Clibbens, illustrated; "The Theory of Determinants in the Historical Order of Development," Sir Thomas Muir (vol. iii.: The Period 1861 to 1880); "A Manual of the Timbers of the World: Their Characteristics and Uses," A. L. Howard, to which is appended an account of the Artificial Seasoning of Timber by S. Fitzgerald, illustrated; "Essays on the Surgery of the Temporal Bone," Sir Charles A. Ballance, with the assistance of Dr. C. D. Green, 2 vols., illustrated; "Space, Time, and Deity" (Gifford Lectures at Glasgow, 1916–18), Prof. S. Alexander, 2 vols.; "Implication and Linear Inference," Dr. B. Bosanquet; "Mind-Energy," Prof. H. Bergson, translated by Prof. H. Wildon Carr, in collaboration with the author; "The Idea of Progress: An Inquiry into its Origin and Growth," Prof. J. B. Bury; "Essays in Critical Realism: A Co-operative Study of the Problem of Knowledge," Profs. D. Drake, A. O. Lovejoy, J. B. Pratt, A. K. Rogers, G. Santayana, R. W. Sellars, and C. A. Strong; "A Critical History of Greek Philosophy," W. T. Stace; "Through Deserts and Oases of Central Asia," Miss Ella Sykes and Brig.-Gen. Sir Percy Sykes, illustrated; "The Handbook to Cyprus," H. C. Luke and D. J. Jardine, new edition; "The Ila-speaking Peoples of Northern Rhodesia," Rev. E. W. Smith and the late Capt. A. M. Dale, 2 vols., illustrated; "Among the Natives of the Loyalty Group," Mrs. E. Hadfield, illustrated; "England," edited by F. Muirhead (The Blue Guides); and "Highways and Byways in Northumbria," P. A. Graham, illustrated by Hugh Thomson. *The Open Court Co.* (Chicago and London) will publish shortly "A History of the Conceptions of Limits and Fluxions in Great Britain from Newton to Woodhouse," Prof. F. Cajori. It will form No. 5 of the Open Court Classics.

OUR ASTRONOMICAL COLUMN.

SPECTROSCOPIC DETERMINATION OF STELLAR PARALLAX.—Since this method of parallax determination was devised the number of stars of which the parallax has been measured trigonometrically has increased considerably. With the view of testing the accuracy of the curves used for deducing absolute magnitude from the relative strength of certain spectral lines, Messrs. W. S. Adams and G. Strömberg have made an exhaustive comparison between their spectroscopic parallaxes, which now number some 1500, and the parallaxes deduced from direct measures and proper motions; the results are given in Proc. Nat. Acad. Sci., July, 1919. The stars are divided into five spectral groups, A7 to F8, F9 to G8, G9 to K3, K4 to K9, and Ma to Md. The spectroscopic method has not yet been applied to types B_0 to A_6, as suitable spectral lines have not been found. The graphs show very satisfactory accordance, the weakest point being the fainter absolute magnitudes in the first group, where the spectroscopic determinations of distance are smaller than those measured directly. The last two groups indicate very clearly the division into giant and dwarf stars; this is also faintly indicated in the second and third groups, but not at all in the first.

The authors draw the satisfactory conclusion that "in this large amount of observational material hardly a single serious contradiction has been found between the spectroscopic and trigonometric results."

MINOR PLANETS.—Dr. F. Cohn gives his annual report on the orbits of recently discovered planets in *Astr. Nach.*, 5030. There are now 914 planets to which permanent numbers have been assigned, besides several hundreds which have been observed insufficiently; approximate orbits have been computed for about eighty of the latter. Two of the freshly numbered planets are of special interest—No. 898 for its high eccentricity, amounting nearly to 0·4, and No. 911, since it is a sixth member of the Trojan group, the mean motions of which are the same as that of Jupiter. Two others, Nos. 895 and 914, are notable for large inclinations, more than 25° in each case.

LUNAR PHOTOGRAPHY WITH THE 100-IN. REFLECTOR.—*Popular Astronomy* and Pubs. Astr. Soc. Pacific for December contain reproductions of some beautiful photographs taken with the new reflector at Mount Wilson by Mr. F. G. Pease. Silver prints have also been presented to the Royal Astronomical Society. The equivalent focus is 134 ft.; the scale is, therefore, very large, and a wonderful amount of fine detail is shown. Prof. Hale notes that the instrument is to be called the Hooker telescope, in memory of the donor of the optical parts. It is welcome news that its performance comes up to the highest expectations, and that the Mount Wilson conditions of seeing prove equal to standing this most severe test upon them. "The (radial) motions of faint stars in the heart of globular clusters and in the star-clouds of the Milky Way can be measured." Nebulium has been found in the variable star R Aquarii, and luminous clouds of calcium vapour are found to surround the star in Hind's variable nebula in Taurus. It is also possible to study the spectra of the faint companions of close double stars.

PRIZE AWARDS OF THE PARIS ACADEMY OF SCIENCES.

AT the annual public meeting on December 22, M. Léon Guignard in the chair, the prizes awarded in 1919 were announced as follows:—

Mathematics.—The Bordin prize to Salomon Lefschetz; the Francœur prize to Georges Giraud, for his work on automorph functions.

Mechanics.—The Montyon prize to Albert Herdner, for his work on the construction and working of locomotives; the Poncelet prize to Gen. Prosper Charbonnier, for the whole of his work on ballistics.

Astronomy.—The Lalande prize to Vesto Melvin Slipher, for his work at the Lowell Observatory, especially his researches on nebulæ and star clusters; the Benjamin Valz prize to Félix Boquet, for his work at the Paris Observatory; the G. de Pontécoulant prize to Arthur Stanley Eddington, for his studies of stellar movements.

Geography.—The Gay prize to René Chudeau, for his explorations in Western Africa; the Tchihatchef prize to E. C. Abendanon, for his book entitled "Expédition de la Célèbes centrale."

Navigation.—The prize of 6000 francs between Yves Le Prieur and Georges Sugot; the Plumey prize between Georges Raclot (1500 francs), for his experimental researches on the longitudinal flexure of ships, Maurice Poincet (1500 francs), for his theoretical and experimental researches on the blades of steam turbines, and Alfred Schwartz (1000 francs), for his work as a whole.

Physics.—The Kastner-Boursault prize to Marius Latour, for his researches on electric motors; the Gaston Planté prize to Emile Brylinski, for his work in applied electricity; the Hébert prize to Raymond Jouaust, for his work on magnetism, electrical standards, photometry, and wireless telegraphy; the De Parville prize to Louis Décombe, for his work in various branches of physics; the Hughes prize to Henri Chaumat, for his work on the industrial production of ozone, the electrolytic reduction of indigo and other dyes, and other work in electrotechnics; the Pierson-Perrin prize to Georges Sagnac, for his work on the secondary X-rays, interference, and other optical phenomena; the Clément Félix foundation to Charles Féry, to enable him to continue his experiments on the production of a small dry accumulator.

Chemistry.—The Montyon prize (Unhealthy Trades) to Georges Rivat (2500 francs), for his work on the analysis and absorption of asphyxiating gases; an honourable mention to Arnold Lassieur (1500 francs), for his contribution to the identification of the substances contained in the German poison shells; an honourable mention (1000 francs) to Cyrille Toussaint, for his chemical studies connected with the war; the Jecker prize between Ernest Fourneau (5000 francs), for his services relating to the synthetical preparation of medicinal organic compounds, Louis Maillard (2500 francs), for the whole of his work in organic chemistry, and Marcel Sommelet (2500 francs), for his researches on the ether oxides, the homologues of benzyl chloride, alcohols, and aldehydes; the Cahours foundation divided equally between Georges Mignonac and Marcel Murat, for their work in organic chemistry; the Houzeau prize to René Locquin, for similar researches.

Mineralogy and Geology.—The Delesse prize to Frédéric Roman, for his geological and palæontological work; the Victor Roulin prize to Léonce Joleaud, for the whole of his work; the Joseph Labbé prize to Pierre Pruvost, for his studies on the Coal Measures of Northern France.

Botany.—The Montagne prize between Fernand Moreau (1000 francs) and Gabriel Arnaud (500 francs); the Jean Thore prize to Auguste Sartory, for his publications on cryptogamic botany; the De Coincy prize to C. Houard, for his work on the cecidology of European Phanerogams; the Jean de Rufz de Lavison prize to Raoul Combes, for his researches on the absorption of glucosides by plants and on plant pigments.

Anatomy and Zoology.—The Cuvier prize to J. Jolly, for his work in histology; the Savigny prize to Louis Boutan, for his botanical and zoological studies in the Red Sea and Indo-China.

Medicine and Surgery.—Montyon prizes to Michel Weinberg and Pierre Seguin (2500 francs), for their memoir on gas gangrene; Louis Martin and Auguste Pettit (2500 francs), for their memoir on ictero-hæmorrhagic spirochætosis; Henri Rouvillois, Guillaume Louis, Albert Pédeprade, and Antoine Basset (2500 francs), for their studies on war surgery. Honourable mentions (1500 francs) to Jean Fiolle and Jean Delmas, for their book on the discovery of the deeper vessels; to Alfred Boquet and L. Nègre, for their work on epizootic lymphangitis; and to H. Gougerot, for his work relating to venereal diseases. The Barbier prize to Albert Goris, for his work on the localisation of glucosides in plants and on the preparation of catgut for surgical purposes; the Bréant prize (arrears) to Paul Ravaut (3000 francs), for his researches on malaria, and to Lucien Camus (2000 francs), for his researches on infection and vaccinal immunity; the Godard prize to Albert Pézard, for his researches on the genital glands; the Chaussier prize between Albert Dustin (3000 francs), for his studies relating to neurology, embryology, and histology, Marcel Frois and Barthélemy Caubet (3000 francs), for a memoir on fatigue in industrial work, Adrien Grigaut (3000 francs), for his memoir on new chemical methods in pathology and their results, and Hector Marichelle (1000 francs), for his researches on the mode of production of speech sounds; the Mège prize (encouragement of 300 francs) to Jules Glover; the Bellion prize to the late Georges Demenÿ, for the whole of his work, and a very honourable mention to Humbert Boucher; the Baron Larrey prize to Camille Lian, for his memoir on the cardiac troubles of soldiers; the Argut prize to Robert Pierret, and a citation to Victor Raymond and Jacques Parisot, for their memoir on trench-foot.

Physiology.—The Montyon prize to Robert Lévy, for his work on the toxins of genital products of certain animals; the Lallemand prize to Léon Binet, for his monograph on trembling, and a very honourable citation to E. Couvreur and E. Duroux, for their work on nerve-lesions, and to André Léri, for his memoir on war-shock and emotions; the Philipeaux prize to Mme. Lucie Randoin-Fandard, for her researches on blood-sugar; the Fanny Emden prize to Léon Chevreuil, for his memoir on existence after death.

Statistics.—The Montyon prize to Arthur Chervin, for his book on Germany of to-morrow.

History and Philosophy of the Sciences.—The Binoux prize to the late René Larger, for his publications on the extinction of species by degenerescence and the theory of counter-evolution or degenerescence by pathological heredity.

Medals.—The Berthelot medal to Georges Rivat, Louis Maillard, Marcel Sommelet, and René Locquin.

General Prizes.—Grand prize of the physical sciences to Louis Roule, for his researches on the migrations of fishes; Petit d'Ormoy prize to Henri Lebesgue, for his mathematical works; the Estrade Delcros prize to H. Perrier de la Bathie, for his scientific work in Madagascar; the J. J. Berger prize between Paul Juillerat and Emile Gérards; the Saintour prize to Eugène Pagézy, for his anti-aircraft work; the H. de

Parville prize between Héloïs Ollivier (1500 francs), for his course of general physics, and Adrien Loir and H. Legangneux (1500 francs), for their work entitled "The Products of the Sea"; the Lonchampt prize to Camille Delezenne, for his work on the presence and *rôle* of zinc in animals; the Henry Wilde prize between Jean Rey (1000 francs), for his researches on projectors, and Adrien Bochet (1000 francs), for his mechanical and optical inventions; the Thorlet prize to Adolphe Richard, for his catalogue of scientific books in the libraries of Paris.

Special Foundations.—The Lannelongue foundation to Mme. Cusco and Mme. Ruck.

The Laplace prize to Robert Henri Le Besnerais, Maurice Victor Duruy, and the late Charles Marie Carcopino-Tusoli; the L. E. Rivot prize to Robert Le Besnerais and Maurice Duruy (each 750 francs), Louis Delmas and Henri Pagezy (each 500 francs), Joseph Fontaine and Albert Masselin (each 750 francs), Robert Besse and Henri Lang (each 500 francs).

Foundations for Scientific Researches.—The Gegner foundation to René Baire, for his work on the general theory of functions; the Charles Bouchard foundation to Jean Camus, for the continuation of his work on nerve reactions, the regeneration of nerves, and the effect of various poisons on the nerve-centres.

[*Note.*—As in former years, the Bonaparte and Loutreuil foundations have been omitted, and will be dealt with in a separate article.]

EDUCATIONAL CONFERENCES.

THE eighth annual Conference of Educational Associations was held at University College, London, on December 31–January 10. Three tendencies could be observed in the lengthy list of lectures and discussions arranged for this well-attended conference: the preparation of the citizen, testing for capacity, and care for the artistic side of life. The Master of Balliol took "The Education of the Citizen" as his topic before the Training College Association, while to the Assistant Mistresses' Association Mr. Evan Hughes lectured on "The Importance of a Wider Knowledge of Economic Principles." Under this head, too, came a discussion of continuation schools and their possibilities. Sir William Ashley, in presiding at a joint conference on this topic, emphasised the difficulty of forecasting the labour demand of different occupations, and of anticipating the place that skill would occupy within any one industry. Mr. Spurley Hey, Director of Education, Manchester, found his difficulties in the provision of buildings and teachers, and was critical of works schools; whilst Mr. Beresford Ingram was more distressed by the problem presented by the small employer. The Civic Education League also took up this question in a discussion on education and industry, which largely turned upon the problem of the works school, and, in conjunction with the Infant Welfare Association, arranged a course of twelve lectures dealing very thoroughly with the whole question of infant care and child nurture.

Eugenics entered into this course, but was more specifically treated by Dr. R. Douglas Laurie, who lectured on "Eugenics Education in the Training College," and at a later session on "Eugenics Education in the School," before the Eugenics Education Society. He would not allow the feeble-minded criminal to hand down his qualities, or the aggravated pauper to pass on his inherent pauperism; and the question of deaf-mutes and epileptics should be considered. The eugenic point of view should be part of the mental constitution of every normal citizen, and to this end he would have some measure of biological training given to every boy or girl. This should begin with Nature-study, develop into physiology, and then into hygiene, which should lead on to eugenics.

A correlative of such teaching was to be found in a brilliant lecture by Dr. Olive Wheeler to the Assistant Mistresses' Association on "New Views of Human Personality." Dr. Wheeler contrasted the mechanistic tendencies of the nineteenth century with those of a more idealistic character which were becoming current in the twentieth. This change she traced largely to the development of modern biology and psychology. The child was born with certain dynamic forces: the instincts as described by McDougall, the appetites as outlined by Drever. These powerful impulses needed expression; if repressed, they still existed in the realm of the unconscious, and continued to influence conduct. Attention was directed to Bergson's view that the essential difference between a living organism and a machine was the power of creation and the importance he attached to that modification in the "urge," or dynamic flux, which caused an organism to move in a specific direction.

The problem of testing capacity was first raised by Mr. G. F. Daniell, of the Kent Education Department, in opening the discussion on "The Selection of Elementary Children for Higher Forms of Education." Mr. Daniell favoured a preliminary examination in the elementary schools of pupils between ten and twelve years of age, by which some would be selected for a final examination, to consist of written tests in English and arithmetic. The teacher's report and the school record should be considered, and an interview arranged in at least all doubtful cases. Psychological tests he held to be useful and valuable in this connection, and he thought that careful inquiry did not support the view that the largely written character of the examination excluded from the secondary schools all who were gifted in artistic work and craftsmanship, though it would be well to include in the examination a test of such ability, could one be devised that was both satisfactory and easily applied.

The question of psychological tests was dealt with by Dr. P. B. Ballard in his lecture on "The Measurement of Practical Ability" before the Educational Handwork Association. Dr. Ballard's incidental exhibition of the well-known tapping machine for testing innate motor ability was largely reported in the Press, and equally misunderstood. The whole subject was treated more fully in his lecture on the following Monday to the British Psychological Society on "The Development of Mental Tests," one of the most successful and largely attended meetings of the conference. He pointed out that the history of mental testing was, in the main, an attempt to introduce mathematics into the solution of the problem of the selection of ability. The earliest attempts were in the direction of finding some physical correlate of mind, as in the phrenology of Gall, the physiognomy of Lavater, and the criminology of Lombroso. But neither such static measurements, nor the later applied dynamic measurements of motor response to stimulus, gave results that were valid beyond their own sphere. They had passed from the physical to the psycho-physical, and were now reaching out to the psychical tests. But success in securing standardised tests and measurements depended upon three mathematical conceptions: that of a definite scale for the measurement of intelligence first devised by Binet, much abused but much used; that of the law of normal distribution enunciated by Quetelet, but first applied to mental traits by Galton; and that of the doctrine of correlation, suggested also by Galton, but elaborated by Prof. Karl Pearson and by Prof. Spearman. The same subject received further treatment by Prof. John Adams in a lecture on "Tests of Intelligence" before the Association of University Women Teachers, wherein he pointed out the dependence of efficiency of intelligence upon its environment, and the well-marked distinction that tests had revealed between knowledge and capacity; educational attainments did not hide lack of intellectual ability.

Within the artistic sphere of the conference were embraced play, music, dancing, and the drama, all popular and suggestive topics. Prof. James Shelley gave a thoughtful lecture on "The Seriousness of Play" before the Froebel Society; Dr. Somervell treated of "The Place of Music in Education" before the Girls' School Music Union, as did Mr. Stewart Macpherson before the Association of Head Mistresses, before which also Mr. Burret Carpenter lectured on "The Place of Art in Education." Very popular, too, were the lecture, with demonstration, on "Folk Dancing" by Mr. Cecil Sharp before the English Folk Dance Society, and that on "Eurhythmics" by M. Jaques-Dalcroze, and held at the Lyceum Theatre; whilst the British Drama League drew a crowded house to hear Mr. Ben Greet's account of the great work being done in London in introducing the acted Shakespeare play to children from the elementary and secondary schools in school-time.

Altogether it was a very full conference, but those who attempted the whole course could only save themselves from "mental indigestion" by applying to the lectures Mr. Fisher's dictum about books given in his opening address. "Some books live to be skimmed; others claim to be studied minutely in whole or in part. The true reader discerns his proper food by intuition."

GEOGRAPHICAL ASSOCIATION.

The annual meetings of the Geographical Association were held in London on January 9–10. Sir C. P. Lucas, in his presidential address, opened out fresh lines of thought concerning islands as centres of preservation of human diversities and their relations to peninsulas, all in connection with the development and fate of empires and commonwealths. He suggested that the giving of self-government to British Colonies and Dominions might be due to home experience of diversities within the British Isles and of the need for giving each group opportunities of development in its own way.

Dr. R. N. Rudmose Brown emphasised the development of the coal export trade from Spitsbergen, and estimated that next year 250,000 tons of coal would be shipped. He referred to the extra-territorial rights of British, Swedish, and Russian estates within the new Norwegian dominion of Spitsbergen created by the Paris Conference.

The educational side was dealt with by Mr. T. W. F. Parkinson, who urged that the Board of Education should do more to encourage geography in the higher forms of secondary schools, and that more scholarships should be opened to students of geography. The discussion brought out references to the creation of a Geographical Tripos at Cambridge and to the full recognition of geography in the faculties both of arts and of science by the University of Wales, as well as to the new creation of an arts degree (Pass and Honours) at Leeds and London.

An important demonstration of the value of the kinema in geographical teaching was given to a large audience by Capt. C. E. Hodges. Mr. M. de Carle S. Salter, Superintendent of the British Rainfall Organisation, gave a very valuable original paper on rainfall as a geographic function.

SCIENCE MASTERS' ASSOCIATION.

The annual general meeting of the Science Masters' Association was held at the London Day Training College on January 6 and 7. The president (Mr. W. W. Vaughan, Master of Wellington College), in his address, directed attention to the importance of science as part of a liberal education. But the aim of scientific education must not be commercial prosperity. History taught that utilitarian science always degenerated. The object of education is the liberating of man's soul.

The following subjects were then discussed:—(1) The teaching of organic chemistry (Mr. W. J. Gale, King's College School, Wimbledon). (2) Biology in the school syllabus. Mr. F. W. Hodges (Cooper's School, Bow) urged the necessity of making biology an integral part of school science. Prof. Hickson (Manchester) supported this view, and contended that it was impossible to teach the science of life from plants only. (3) Laboratory management (Mr. H. Preston, Caistor Grammar School). (*a*) *The Training of Assistants.*—In order to obtain suitable boys, the occupation of laboratory assistant must not be allowed to remain such a blind-alley occupation as it is at present. Proper provision should be made to fit these boys for a career, and to provide suitable education for them. (*b*) *Cost of Apparatus.*—The high cost of apparatus is detrimental to the necessary expansion of science teaching at the present time. Mr. Preston considered that the cost was unnecessarily high in many cases, and indicated that science teachers were being exploited or else that British manufacturers were incapable of producing apparatus at a reasonable cost. As the result of this discussion a committee was appointed to inquire into the matter.

In the evening an interesting lecture was delivered by Dr. Crommelin on the British observations during the solar eclipse of May last. After giving a brief, but clear, outline of Einstein's theory and the experimental work which led up to it, Dr. Crommelin described the measurements of the deflection of light-rays passing close to the sun, as shown by the positions of star images on the photographic plates.

On January 7 the subjects discussed were as follows:—(1) Science teaching in the early stages. Major V. S. Bryant considered that science in preparatory schools should be part of the whole teaching, and not segregated. In the discussion the conclusions arrived at were:—To avoid so-called "practical measurement"; to stimulate the boys' interest, and that not less on the biological than on the mechanical side; to avoid restricting natural history to biology; and to give adequate attention to the teaching of English. (2) The divorce of laboratory and class-room courses (Sir Richard Gregory, and Mr. G. D. Dunkerley, Watford Grammar School). Sir Richard Gregory's paper was mainly a reaction against the idea that the only science teaching of value is that given in the laboratory. This view has led to the neglect of those sciences which do not lend themselves to experimental treatment, and hence the undue prominence given to physics and chemistry. The "science for all" courses of the S.M.A. are conceived in the new spirit of science teaching. Laboratory work should not merely be exercises in measurement, but also deal with subjects which cannot be treated in any other way. Laboratory work is intended to give an idea of scientific method; class-room courses should give a broad survey of scientific facts, principles, and achievement.

THE PHYSICAL AND OPTICAL SOCIETIES' EXHIBITION.

THE tenth annual exhibition of electrical, optical, and other physical apparatus, arranged by the Physical Society of London and the Optical Society, was held on January 7 and 8 at the Imperial College of Science, South Kensington. For the first time, we believe, the exhibition extended over two days. The extent of the exhibits was also greater, two floors of the physics department of the Imperial College being occupied in place of one, as in previous years, the last being 1913. To some extent this expansion was due to a special reason, namely, the inclusion of a supply of German instruments captured during the war, shown by permission of the Admiralty, the Air Ministry, and the War Office. The attendance was very satisfactory. The fact that the annual Conference of Educational Associations was meeting in London during the week allowed many teachers the opportunity to pay a visit, and we believe this was taken full advantage of.

There are two sides to an exhibition of this kind, the educational and the commercial, and the two react. The visitor is anxious to buy as well as to learn; the exhibiting firms are ready to learn as well as to sell. There is much intercourse and interchange of ideas, which may fructify later in the improvement of old instruments and in the devising of new.

Although business affairs are by no means stabilised as yet, the standard reached by the exhibits shows that a keen, progressive, and enterprising spirit is alive amongst makers of scientific appliances. It is not surprising to learn that a great exhibition of products of the British Empire, to be held in London in 1921, is already in hand.

Two discourses which attracted good attendances were given daily; one on "The Use of Light in the Transmission and Reproduction of Sound," by Prof. A. O. Rankine; the second on "Some Polarisation Experiments," by Prof. F. J. Cheshire. In the former was given an exposition of an application of the selenium cell, which suggests the possible supersession of the purely mechanical method of reproduction of speech and music by the gramophone.

A marked feature of the exhibition was the large number of demonstrations of apparatus in action. There is no doubt that this is widely appreciated, and that the effects in stimulating interest and inquiry are fully commensurate with the pains taken by the firms concerned. Amongst these may be mentioned the production of electrical oscillations by the triode thermionic tube, the indirect compensated illumination known as "Sheringham daylight," and Mr. Darling's simple device for indicating the quenching temperature in the hardening of steel. The model aeroplane cabin with its array of instruments *in situ* (shown by Hughes and Son) was also most instructive.

It is impossible in a brief survey to do justice to all the items of apparatus displayed, or to the firms who participated; only a few can be referred to. First, we would mention thermionic tubes. Few are unaware of the great use that was made of these instruments in the course of the war, and of the many purposes for which they can be employed; and one was naturally prepared to find, though not less grateful on finding, a fairly complete exhibition of various stages in the evolution of the diode, and especially of the triode, forms of tube. These were shown by the Marconi-Osram Co., the Edison-Swan Co., and H. W. Sullivan, the production of electrical oscillations by use of the triode tube being demonstrated.

The electrical CO_2 recorder (the Cambridge and Paul Instrument Co.) for the testing of flue-gases furnishes an interesting example of the application of physical principles in combination. The percentage of carbon dioxide in the flue-gases determines the thermal conductivity of the gas; this determines the rate of cooling of an immersed heated platinum wire; and this in turn determines the current in the galvanometer of an unbalanced Wheatstone bridge, of which the platinum wire constitutes one arm. This example recalls another instance of the application of indirect measurement, namely, the dionic (?) water-tester (Messrs. Evershed and Vignoles), where the electrical conductivity serves to indicate the extent of inorganic impurity present.

A collection of glasses by Chance Bros., though on a modest scale, was of great interest. It included the Crookes spectacle glasses, which protect the eye by cutting out the ultra-violet rays, and an ultra-violet glass, opaque to the visible spectrum, but transmissive of the ultra-violet. Demonstrations of their properties were made by the aid of a nichrome arc and a fluorescent screen of barium platinocyanide.

Amongst Hilger's instruments for refined optical measurement we may single out the vacuum spectrograph (shown by courtesy of Prof. Fowler), which permits of photographing the spectrum in the Schumann region.

Optical instruments of high quality were displayed by many firms, including Charles Baker, Hughes and Son, Bellingham and Stanley, Davidson and Co., Watts and Son, W. Ottway and Co., Penrose and Co., Watson and Sons, Newton and Co., and Rheinberg and Co. Exhibits of books by the Cambridge University Press, Macmillan and Co., and several other firms were much appreciated.

There is room, we think, for one criticism of the quality of the exhibits. We refer to the comparative absence of simple forms of apparatus. There is a great need, for teaching purposes in schools and colleges, of apparatus, made without elaboration, of an open type that will proclaim its principle at a glance. Dr. Searle's apparatus occurs to one as a good example of the type desired. Collaboration between teachers and manufacturers would serve to hasten a development that is urgently required, and we commend this field to the attention of both. D. O.

THE CHARTERS TOWERS GOLDFIELD.

THE Geological Survey of Queensland has published a very complete description of the Charters Towers goldfield by Mr. J. H. Reid (Publication No. 256). Although this was for long the most important goldfield in Queensland, and had, in fact, for many years the largest gold output of any of the individual goldfields in the whole of Australia, no full account of the geology of the field or of the nature of the ore deposits has yet been published, so that the issue of the present monograph is fully justified. Furthermore, had the issue of such a work been delayed much longer, it could never have been carried out effectually, as many of the mines are now closing down. The goldfield was discovered in 1871, and ten years later the gold production was close upon 75,000 oz. of gold bullion; in 1887 this output had doubled, reaching 151,500 oz.; and in 1899 the highest output, namely, 319,572 oz. of fine gold, was attained. From that time the production has been a steadily declining one, the drop since 1912 having been particularly rapid, until in 1916 the output was only 33,107 oz.

Unfortunately, it is only too clear from the report that this falling off is not a temporary phase, but is due to the very nature of the gold deposits themselves, and that the field is rapidly approaching exhaustion. It is shown that the principal country rock is a granodiorite of Lower Devonian or pre-Devonian age, traversed by numerous dioritic dykes and by well-marked systems of fault-fissures, the throw of the latter being generally inconsiderable. Within the zones of shattered rock accompanying these fissures veinlets of auriferous quartz have been deposited, undoubtedly, according to the author, by hydro-thermal agencies. The veins are, for the most part, narrow, ranging as a rule from a few inches to 5 ft. in thickness, anything more than 5 ft. being considered exceptionally large.

There are two main auriferous belts, both running north-east to south-west; the more northerly one, containing all the more famous lodes, such as the Day Dawn and the Brilliant, is about three miles long and three-quarters of a mile wide; the less important southerly belt is of about the same length, but never exceeds 200 yards in width. A small number of scattered mines have been worked outside these belts, but most of these are now closed down. The noteworthy feature of all the lodes is that, whilst the fissures persist in depth, the gold values do not, the mines as a whole showing progressive impoverishment in depth. To quote the author:—"It can be affirmed that pay shoots between the surface and the 1000-ft. level were richer than those between 1000-ft. and 2000-ft. levels, and that these were correspondingly richer than those found below 2000 ft."

THE NEW ZEALAND SCIENCE CONGRESS, 1919.

NEW ZEALAND occupies a unique and advantageous position for scientific work. Situated in the midst of the vast Pacific, she has splendid opportunities for the pursuit of the fascinating studies of oceanography and the meteorology and astronomy of the southern hemisphere. Innumerable problems in geography, geology, and physiography, of an entirely novel and supremely interesting kind, present themselves, not only in New Zealand itself, but also in the surrounding Pacific and further south in the mysteries of the Antarctic. In her flora and fauna and native races, in her varied mineral wealth, in her large reserves of water-power, both fluvial and tidal, there are endless opportunities for the man of science. In her political, social, and economic institutions she is bound to make valuable contributions to experimental sociology; and it is the experimental side that chiefly matters and stands most in need of encouragement in these days of nebulous theories and unsubstantial visions.

It is perhaps only natural that, in her present stage of development and in view of the smallness of her population, New Zealand should appear to limit her research outlook chiefly to matters of a practical and utilitarian nature. In such a purely agricultural community it is only to be expected that the biological sciences—applied botany and zoology—should occupy a predominant position, as is clearly evidenced by the election of a distinguished botanist as president of the New Zealand Institute and Science Congress, and also by an analysis of the contents of the first fifty volumes of the institute's Transactions. Such analysis discloses that, of the papers contributed, zoology claims 1143; botany, 654; geology, 503; anthropology, 204; physics (including astronomy and meteorology), 152; chemistry, 135; engineering, 76; mathematics, 40; economics, 37; history, 34; metaphysics, 22; medicine, 20; literature, 15; education and statistics, 12 each. It must be remembered, however, that many valuable contributions do not appear in the Transactions; some are published in scientific journals in Great Britain; the Geological Bulletins and the Palæontological Bulletins of the New Zealand Government absorb others. The *Polynesian Journal* takes most of the papers on anthropology.

In commenting on the predominance of the natural history papers, the president, Dr. Cockayne, pointed out that this is only to be expected in a new land with both flora and fauna so little investigated and containing so much that is endemic. Most of the papers are devoted to classification. "This must have been so; it is the natural evolutionary process in the history of biological research the world over. . . . As for chemistry and physics, which make but a poor showing in the work of the New Zealand Institute, little progress can be made in these sciences without well-equipped chemical and physical laboratories and men specially trained in such. Laboratories of this class are now attached to the various university colleges, and chemical and physical contributions—the work of trained students—are slowly but surely finding a place in the Transactions."

When it is remembered that the institute only receives the small sum of 500*l*. per annum as Government grant it is a matter for amazement that so much work has been accomplished. A levy of 200*l*. was made on the affiliated societies, which could ill afford it, but yet there are scarcely funds sufficient to publish the Transactions. Many papers of great value await publication, and much work of national interest awaits initiation. Government financial support and public sympathy are both badly needed, and it is hoped that the Science Congress, the first of its kind in New Zealand, will go far to supply these needs. The Government has, as a matter of fact, promised to do its utmost to place the institute on a firm financial footing, and has already made special grants for economic science.

The New Zealand Institute consists of a number of incorporated societies, namely, the Auckland Institute, the Wellington Philosophical Society, the Philosophical Institute of Canterbury, the Otago Institute, the Hawke's Bay Philosophical Institute, the Poverty Bay Institute, the Manawatu Philosophical Society, the Wanganui Philosophical Society, and the Nelson Institute. The management of the New Zealand Institute is vested in a board of governors representative of the incorporated societies and of the Government, and this board meets annually in Wellington in January.

The Science Congress, organised by the institute this year and held in Canterbury, was the first of its kind in the Dominion, and owed its inception largely to proposals for the reform of the institute made by Dr. J. Allan Thomson in 1917. Dr. Thomson said: "In its relation to the public the New Zealand Institute should, but does not, hold a position analogous to that of the British Association for the Advancement of Science, the body which most keeps the public in touch with science, and from which most of the improvements in the State attitude to science have had their origin. The Australasian Institute for the Advancement of Science meets too seldom in New Zealand to be effective in this direction." The Congress was opened by the Governor-General of the Dominion, who, in his address, enumerated four important matters for investigation and study, namely, (1) public health and pandemic disease; (2) afforestation; (3) the mineral oil industry; and (4) fisheries. The Hon. G. W. Russell, Minister of Internal Affairs, urged the development of natural resources, especially hydro-electric power, and promised the institute adequate financial support. "The State must be prepared to foot the bill. I therefore urge the Science Congress to press upon the Government that without Governmental expenditure science cannot grow and expand; that scientists cannot live on air or on the hope of posthumous fame; and that therefore, if the Dominion is to develop by means of science, adequate funds must be provided for research, for the training of teachers and professors, for the equipment of laboratories and staffs, and for the creation of the scientific atmosphere of which I have spoken."

The president of the Congress (and of the New Zealand Institute), Dr. L. Cockayne, gave a brief historical account of the institute and described its immediate aims and aspirations. These are mostly agricultural at present, and in such a farming community nothing demands years of close study more than the soil itself. The world over, soil science, notwithstanding many books on the subject, is in its infancy. Chemical analysis of a soil, even with far better methods than those now available, is only one part of the question. The extremely difficult problems of soil-physics at once confront the investigator. Then there is the rich soil-flora and the rich soil-fauna. When more of a fundamental character is known as to the relation of soil-physics, soil-chemistry, and soil-biology to one another, then, said the president, undoubtedly new methods of soil-utilisation will be in sight. In the domain of anthropology Dr. Cockayne made the interesting suggestion that there is no need to confine one's investigations to primitive races, for amongst the settlers in a new land evolution in certain directions goes on apace. The question of dialect, for instance, among the white people of New Zealand would form a valuable study.

Although the presidential address was mostly biological, it is sufficiently evident, from an examination of the numerous and varied papers read, that other important branches of science are not to be overlooked by the institute. *Section* 1, *Biology and Agriculture*, had several papers of value and interest to the agriculturist, concluding with one by Sir James Wilson on "Agriculture's Debt to Science." *Section* 2, *Geology*, had papers on "The Older Gravels of North Canterbury," by R. Speight; "The Significant Features of Reef-bordered Coasts," by W. M. Davis; "Rough Ridge, Otago, and its Splintered Fault-scarp," by C. A. Cotton; "Natural Features of the Arthur's Pass Tunnel," by F. W. Hilgendorf and others; and "Geology of the Middle Clarence and Ure Valleys," by J. Allan Thomson. These and other papers will ultimately appear in the Transactions. Dr. Thomson also gave some interesting notes on the geology and palæontology of the Palliser Bay district, and a quantitative study of the silica-saturation of igneous rocks, suggesting a valuable means of comparing rock analyses. About a thousand such analyses have been calculated and plotted, and it is hoped to continue the work with the aid of a Government research grant.

Mr. E. K. Lomas dealt with some of the educational aspects of geography, and his opening remarks are well worth quoting: "Education, from one point of view, consists in bringing a mind into close touch with its environment through the senses. The more often the mind is roused to activity by excitations from the outside the more it develops. The special section of the environment in which we are particularly interested—I speak to a meeting of geologists—is that included under the term 'geology'; and the only means we have of introducing our subject into the schools is through the medium of geography, so that this subject should be an object of lively interest to all present. And there is no doubt about it, we shall have to take more interest in the subject for several reasons: (1) it is developing rapidly, (2) it is eminently suitable for educational purposes, (3) the present ignorance of geography is truly alarming and deplorable." If this be true of New Zealand, with its excellent educational system, it is still more applicable to this country. One of the most valuable papers in the geology section was "The Organisation and Functions of a State Geological Survey," by Mr. P. G. Morgan. This gave a brief account of most of the existing State geological surveys in the United Kingdom, Europe, India, Canada, the United States, Australia, and New Zealand, with suggestions for the organisation of such surveys in general and for New Zealand in particular.

In *Section* 3, *Chemistry, Physics, and Engineering*, Mr. D. M. Y. Sommerville described an improved planisphere and a slide rule for solving the quadratic equation. Dr. C. E. Adams, Government Astronomer, read a paper on "Tables of Mathematical Functions." Mr. Evan Parry, Government Electrical Engineer in New Zealand, said these tables constructed by Dr. Adams were of great value, for the ordinary tables of natural logarithms were not sufficiently minute for practical use in electrical work. Dr. Adams also gave another very interesting paper on "The Harmonic Analysis of Tidal Observations and the Prediction of Tides." No arithmetical approximations are used, so that a criterion is obtained with which to test the application of Fourier's series to tidal observations. The method of tide-prediction used in New Zealand is a graphic one, controlled by calculation, and is fully illustrated and described in the Survey Reports of the Lands and Survey Department for the years 1910–14. The results for Wellington and Auckland are published in the New Zealand Nautical Almanac by the Marine Department.

In his paper on "The Porosity of Porcelain," with special reference to high-pressure insulators for electric transmission lines, Mr. C. C. Farr said that the tests were made at the suggestion of the engineers of the Lake Coleridge electric supply system, who desired a method for determining whether the porcelain of the insulators was porous or not. The tests were carried out in the physical laboratory of Canterbury College by immersing specimens of porcelain in a fuchsin or red-ink coloured solution under a pressure of 2000 lb. per square inch, the solution being contained in a hole 3 in. in diameter and 6½ in. deep bored in a block of solid steel and covered with a steel cap 1 in. thick and a leather washer by means of eight bolts. Both glazed and unglazed porcelain was subjected to test, and it was concluded from the results that (1) density and porosity have little or no connection with each other, (2) porcelain can be made which shows no penetration after fifty hours' immersion under the pressure named, (3) porcelain is not always so made, and may contain a porous layer with abrupt edges in the mass of the substance. The experiments are being continued.

In a paper on "The Interference of Power Circuits with Telephone Circuits" Mr. E. Parry presented a mathematical treatment of the subject, as complete as possible, with the view of co-ordinating results of past experience and enabling effects to be predicted under given conditions, with special reference to the Lake Coleridge transmission lines. The New Zealand Public Works Department, together with the Post and Telegraph Department, has for some time been studying the influence of power circuits on telegraph and telephone circuits, since the wires for both services are supported on the same poles.

In Mr. E. E. Stark's paper on "The Effect of Low Power-factor from the Viewpoint of Electric Power Station Operators" it was suggested that the power stations using the alternating current system should charge the consumer for the total current taken, including both power-producing and wattless current—that is to say, the charge should be based on kilovolt amperes instead of kilowatts. If it is desired to equalise the rates without raising the price of electricity, an average power factor could be taken on a given system and a reduction made. Mr. H. Hill read a paper on "National Hydro-electric Schemes for New Zealand," in which he said it was difficult to understand the delay in formulating a national electric scheme for the Dominion. Mr. E. Parry's great North Island scheme should be put in hand at once, including the electrification of the East Coast railway. The people in the South Island also should insist on a national scheme.

Dr. Adams, in addition to his papers already noted, read others on (1) "Determination of the Position of the Moon by Photography," illustrated by photographs from the Lick Observatory. The very fine star images secured indicate the high efficiency of the Crossley reflector telescope, which was driven without any guiding, and the photographs prove that the position of the moon and terrestrial longitude can be determined with high precision. (2) "The Almucantar Method for Determination of Time and Latitude." (3) "A Nomogram for Transit Instrument Star Factors." Dr. Adams exhibited also some photographs on glass of the solar corona received by the Hector Observatory from Dr. W. W. Campbell, of the Lick Observatory in California. The photographs were taken by the Crocker Eclipse Expedition on June 8, 1918, at the total eclipse of the sun, with a 40-ft. camera pointed directly at the sun, and using 10 in. by 12 in. plates. The Lick Observatory had most remarkably good fortune at this eclipse: the sky had been completely cloudy all day, but cleared up in the neighbourhood of the sun one minute before totality, and this small portion of the sky remained clear until a few seconds after totality. The small region of unclouded sky containing the totally eclipsed sun seemed to be quite clear and was the bluest sky seen by the expedition.

Section 4, *General*, had papers on "Moriori Art," by Mr. H. D. Skinner, lecturer on ethnology at Otago University; "The Language of the Chatham Islands," by Archdeacon H. W. Williams; and "The Natural Laws of Poetry," by Mr. J. C. Andersen. The following papers, read in the General Section, should more properly have been included in Section 1, viz. "Afforestation in New Zealand," by Mr. W. H. Skinner; "Some Proposals with regard to Natural Afforestation in a New Zealand Mountain Area," by Mr. W. G. Morrison; and "Preservation of New Zealand Fauna," by Mr. E. G. Stead.

THE AFRICAN RIFT VALLEY.[1]

AFTER the discovery of Lake Rudolf in 1888, Suess showed that the Jordan, Dead Sea, and Red Sea fractures were not continued along the coast of Africa, but through the East African lake chain, the basins of which had been formed by the foundering of their floors between parallel faults. During an expedition to British East Africa in 1892–93 Prof. Gregory confirmed Suess's conclusions, with some modifications as to the age and origin of the Great Rift Valley, the formation of which he attributed to successive faulting during the great earth movements of the Kainozoic era.

The Rift Valley has been traced from northern Palestine to southern Africa. Its structure varies with its age and the nature of the country traversed. Thus the fault-scarps are better preserved along the Gulf of Akabah than in the older sections which enclose the Red Sea and the Gulf of Suez. The section in southern Abyssinia which connects the Red Sea with Lake Rudolf and the Rift Valley in British East Africa is locally irregular where intersected by the cross fractures that bound the sunk land of the Gulf of Aden. Across British East Africa the valley is a comparatively simple trench; its walls are often so steep that Sir John Bland-Sutton describes them as "as steep and abrupt as those of a grave," and for long the Uganda Railway worked its trains between the valley and plateau by a rope incline, and there is still no road for wheeled traffic from Nairobi to the floor of the Rift Valley.

[1] From a paper read before the Royal Geographical Society on January 5 by Prof. J. W. Gregory, F.R.S.

South of British East Africa it has been claimed that the Rift Valley comes to an end, only its western wall being continued as a fault-scarp. This arrangement occurs near Lake Mänyara, where the eastern side is a long, smooth slope which ends westward at the foot of the fault-scarp that bounds the Giant Cauldron Mountains. The structure may be explained as an extreme case of the asymmetry due to the different strengths of the rocks on the two walls. In southern British East Africa at Lage Magadi the western wall is a high, steep scarp, while the eastern side consists of a number of wide, flat steps due to parallel faults. At Lake Manyara, as the rocks on the eastern side are softer, the scarp has been dressed down to an even slope. This arrangement does not extend far; the eastern wall soon reappears, and, though Suess left a gap of 350 miles long between Lakes Manyara and Nyasa, the Rift Valley has now been traced across most of it.

That Nyasa is a Rift Valley basin has been proved by Andrews and Bailey. Its northern end is joined by the western branch, which includes Tanganyika, the Albert Nyanza, and the Upper White Nile. In the western branch the valley is in places irregular, as branches run off or the course is deflected along the grain of the country, to which that branch as a whole is oblique. South of the Zambezi the Rift Valley has been traced by Teale and Wilson, who have shown that a post-Eocene rift valley separates the Sheringoma plateau from the eastern front of Rhodesia. The long meridional section of the coast from Beira to Cape Corrientes appears to have been determined by the southernmost of the crustal movements of the Great Rift Valley.

The valley, therefore, extends from Lebanon to the Sabi River; its branches reach the mouth of the Gulf of Aden, and westward include the rift valleys of the Eastern Congo. Its length is about one-sixth of the circumference of the earth; hence it must have had some world-wide cause, the first clue to which is its age. The view that its history is geologically short commends itself by the freshness of its walls, by the legends of catastrophes, such as the destruction of Sodom and Gomorrah and the drowning of many villages on the formation of Tanganyika, having occurred along it during the time of man, and also by the fact that many of its faults are certainly recent. Nevertheless, the fuller evidence now available confirms the classification advanced in 1896, which attributed some of its lavas to the time of Chalk, and represented some of its faults as older than the uplift of the Alps. Some beds attributed to the Miocene on physiographical evidence are now proved of that date by the evidence of fossils. The rift valley of the Red Sea was certainly in existence by the Oligocene, and the southern end of the valley is shown to be of the same date by a fossil sea-urchin which has now been proved to be an East African species.

The history of the Rift Valley is largely dependent on the volcanic history of the country traversed. The first step in its formation was the uplift of a broad band of highlands extending from Palestine to Natal. The weakening of the support led to the collapse of the summit of this ridge. The sinking of the keystone caused volcanic eruptions along the adjacent fractures. The earliest of the great eruptions probably dates from the formation of the Arabian Sea and the breaking up of Gondwanaland, which originally included both India and Africa. These subsidences became more rapid about the end of the Chalk period, and led to volcanic eruptions on a colossal scale. On the eastern side of the foundered area were discharged the Deccan Traps, covering more than 200,000 square miles in India, and probably an equal area under the Indian Ocean. On the northern and western sides volcanic eruptions probably contemporary with the Deccan Traps formed the plateau-lavas of southern Arabia, Abyssinia, and the Kapite Plains in East Africa. These lava plains are older than the Rift Valley faults, and after them the East African arch fell in and initiated the Rift Valley; then followed eruptions from fewer vents building up higher volcanoes. They were followed by a lake period, the age of which is fixed by the remains of *Dinotherium Hobleyi* as Miocene.

That the whole volcanic history of British East Africa cannot be restricted to the post-Miocene is indicated by the evidence of Mount Kenya, since the glaciation of its valleys shows that they were in existence, the mountain had been deeply dissected before glacial times. It is incredible that the long volcanic history of the country, from the oldest plateau-lavas to the reduction of Kenya to its present form, should be restricted to only one period, the Pliocene.

If the first eruptions of the Rift Valley area were contemporary with the Deccan Traps, and therefore of the age of the Chalk, and the faulting lasted from the Oligocene to the Pliocene, the formation of the Rift Valley was connected with two great systems of earth movements, the foundering of the Indian Ocean and the uplift of the Alpine and Himalayan mountain systems. During the Mesozoic a slow deformation of the earth's crust caused the downward sagging of the North Polar regions and the buckling of the tropical and temperate zones by broad folds running east and west. Then elevation on lines trending north and south raised the East African highlands, while the collapse of the floor of the Indian Ocean caused widespread volcanic disturbances round the Arabian Sea. Later earth movements, which lasted for about the same time as the faulting of the Rift Valley, buckled the crust into the fold mountains of Europe and Asia. This corrugation was due to pressure, which in Europe was northward and in Asia southward. The reversal of direction may be explained by the difference in structure between Eur-Africa and Asia. Africa was a high plateau undergoing further uplift, while regional subsidence was taking place in and off northern Europe. The combined subsidence to north and uplift to south left Europe laterally unsupported on the north: the crust north of Africa was pressed northward, and buckled the country in front of it into fold mountain chains. In Asia the conditions were reversed; the massive plateau was to the north, and the sinking area was to the south in the Indian Ocean; so Asia was corrugated by a southward movement. The reversal from the European to the Asiatic direction occurred near the Sea of Azov and due north of the Rift Valley, which is the rift between the segment of the earth moving northward and that moving southward.

The structural contrast between Africa and America, due to the difference between the later mountain-forming movements, is explained by the fact that Africa is antipodal to the Pacific Ocean, and by the well-established principle that antipodal areas of the crust are subject to contrary conditions. While the Pacific was sinking, Africa was being upraised. The subsidence of the Pacific buckled its borders into the fold mountain chains of Western America, and those of which fragments can be traced from Japan to New Zealand. As Africa was being stretched by its uplift, and left unsupported on each side by the foundering of the adjacent oceans, it was rent by fractures between which the summit of its highlands fell in and formed the Great Rift Valley. "There may," says Sir George Adam Smith, "be something on the surface of another planet to match the Jordan Valley; there is nothing on this." That remark may be extended to the whole Rift Valley; for, in addition to the other unique features of Africa, its Rift Valley has no parallel elsewhere on the globe. The character of that valley may be explained by the special stresses in Africa due to its position antipodal to the great subsidence of the Pacific Ocean, while its course was determined by the wrench in the crust between the segment in which the pressure was northward against Europe and that pressing southward from the Asiatic highlands towards the infallen basin of the Indian Ocean.

PHYSIOLOGY AT THE BRITISH ASSOCIATION.

A JOINT discussion with Section F (Economic Science and Statistics) and the Subsection of Psychology on "The Influence of the Six-hour Day on Industrial Efficiency and Fatigue" was opened by Dr. H. M. Vernon. It has been suggested by Lord Leverhulme that two six-hour shifts may be more economical than one eight-hour shift, because the former would obtain twelve hours' use of expensive machinery instead of only eight hours. Examples were given of cases in which shortening of the hours of labour had increased the output, but in other cases the output had been decreased. The determining factor seems to be the amount of muscular effort put into the work. Heavy muscular work can be speeded up for shorter hours to produce a greater output, but where heavy labour is not involved the production falls with shorter hours.

Mr. P. Sargant Florence gave statistics from the United States which supported the concluding portion of Dr. Vernon's paper. He further pointed out that the average age of the working population should be taken into account as indicating whether the labour was too long or too heavy. Noise in factories is particularly fatiguing.

Prof. E. L. Collis advocated a reduction of working hours for the sake of health, but said that it must be done slowly. Unequal distribution of wealth is being remedied, but output must be increased.

Sir Hugh Bell pointed out the difference between various trades. Where the labour bill is only a small part of the cost of the manufactured article, it is easier to increase wages than when wages form the main portion of cost. He objected to legislation and uninformed interference, because agreement between employers and employees had reduced the hours of labour without the bad effects of legislative interference.

Miss C. Smith-Rossie advocated a wider educational system on the lines followed by Denmark, so that more interest can be aroused in the working people, thus eliminating fatigue.

Dr. H. H. Dale opened a discussion on "The *Rôle* of Capillaries in the Regulation of the Blood-flow." Previously the control of the blood-pressure had been considered to be brought about by the state of contraction of the arterioles, but it is now necessary to discuss whether the capillaries may or may not take some part in the regulation. Small doses of histamine cause a dilatation of capillaries if injected into the circulation, but fail to do so in a perfused organ unless both red-blood corpuscles and adrenaline are present in the perfusion solution. Large doses of histamine cause a condition like secondary shock. The blood accumulates mainly in the capillaries, so that, although the heart is beating vigorously, so little blood passes through the veins to reach the heart that the blood-pressure falls. Actual counting of capillaries by Krogh shows that during rest only a few capillaries contain blood. During activity many more open up, so that the volume of blood that can be accommodated in them is greatly increased.

The discussion was continued by Prof. W. M. Bayliss, Prof. E. H. Starling, Prof. A. D. Waller, and Prof. N. Noël Paton. The trend of the discussion was that the arterioles regulate the blood-supply to the larger areas, and that variation in the size of capillaries may allow more or less blood to accumulate in them, thus affecting both the local and general circulation.

Three papers on accessory food substances were read before the Section. Prof. W. D. Halliburton contrasted butter and margarine. Margarine can be made from various substances, but liquid oils must be hardened. The hardening process destroys fat-soluble vitamines, so that even if these are present at the outset they are absent from the finished article. Sophistication of food is dangerous because it may remove accessory food substances. Children should be given the butter and milk, as adults can better withstand the absence of fat-soluble vitamines.

Dr. E. M. Delf read a paper on the effect of heat on the antiscorbutic food substance. Heating rapidly destroys antiscorbutic substance, but orange-juice withstands heating better than most of the anti-scorbutic substances.

Miss A. J. Davey recorded the effect of preservatives on the antiscorbutic substance. Lemon-juice is a much more powerful antiscorbutic than lime-juice. Lemon-juice was preserved by metabisulphite or by its own rind-oil. The latter is more stable, and retains its antiscorbutic effect for more than a year without much deterioration.

Prof. A. D. Waller demonstrated the decrease in the electrical resistance of the hand that takes place when a disturbance occurs in the central nervous system. Coughing, burning, or even threatening to burn the opposite hand causes a decrease in electrical resistance. Some people are more imaginative and respond more to the threat than to the actual stimulus, whilst others are more phlegmatic, and give the greater response to the actual stimulus. Prof. Waller also demonstrated the effect of walking, running, and swimming on the output of carbon dioxide.

Dr. H. E. Roaf read a paper on the pathology of pellagra. Pellagra is due probably to the unsuitable nature of the protein in the diet. The symptoms point to an interference with the sympathetic nervous system. No previous record is known of distinctive pathological changes in pellagra. The sympathetic nervous system showed marked plasmolysis of its ganglion cells. It is possible that the sympathetic nervous system may be affected by diet through the adrenal medulla. It is, however, necessary to investigate the condition of the sympathetic nervous system in other diseases. Dr. Roaf also showed readings of climatic conditions made in Egypt and in Palestine. Heat loss and the effect of clothing on heat loss were shown by readings made with Prof. Leonard Hill's katathermometer. The protection by clothing from sun radiation was measured by sun-radiation thermometers.

BOTANY AT THE BRITISH ASSOCIATION.

THE influence of the great war was distinctly to be noted in the character of the papers presented at the first post-war meeting. The Botanical Section was fortunate in having a president so well able to review the actual and potential plant resources of our Empire, and to lay stress upon the pressing necessity for their scientific development. This note was struck again in the Forestry discussion, which took place jointly with the Agricultural Section. To this discussion Prof. A. Henry contributed a paper on the afforestation of water-catchment areas. He urged the planting of all suitable portions of gathering grounds (which probably vary in different cases from 10 per cent. to 70 per cent.), largely on account of the paramount importance of ensuring the purity of the water-supply, which can so adequately and profitably be done by this means. The scheme practically necessitates co-operation between State and corporation for the acquirement of the necessary land.

What may be regarded as a real war paper was furnished by Capt. H. Hamshaw Thomas, who gave an account of the desert flora of Western Egypt some twenty-five miles north-west of Cairo. The small rainfall, coupled with hot days and dewy nights, constitutes a set of conditions unfavourable to plant-life, so that, unlike the sandy, rocky desert of Eastern Egypt and Sinai, the Libyan Desert includes vast stretches totally devoid of vegetation. The pruning effect of the "khamseen" or sand-storms is very marked, and reduces the plants to a dwarfed, tufted habit.

Other floral and ecological papers included the flora of the district of the London Clay, by Mr. Horace W. Moncton, and the northern invasions of New Zealand, with special reference to Lord Howe Island, by Dr. J. C. Willis. Mr. Moncton pointed out that the flora of the London Clay in the Thames basin differs greatly from that on contiguous areas of different geological formation, and he illustrated his point from the sedges. In addition to the twenty-eight species characterising the London Clay, there are some twelve others recorded, which, however, "do not seem to occur where the London Clay forms the *actual* surface," since "a covering of gravel or sand too slight to mark on a geological map is sufficient to alter the flora."

Dr. Willis added to his well-known series of observations and conclusions concerning the origin of floras data with regard to that of New Zealand and Lord Howe Island, which led him to conclude that the New Zealand flora includes a western invasion, which probably "followed the ridge upon which stands Lord Howe Island." In consonance with his general position, Dr. Willis put forward the view that the endemics of Lord Howe Island are furnished by the larger (older) families and genera.

Considerable general as well as local interest was raised in connection with Col. Godfrey's paper on the orchids of Hants and Dorset, and the members of the section were privileged to see on their expedition to the New Forest one of the rare orchids mentioned, viz. *Malaxis paludosa*. The author enumerated a surprising number of natural hybrids occurring in the district.

As part of the joint discussion with the Zoological Section in the field of Genetics, Mr. W. Brierley and Dr. Ruggles Gates presented papers in which notable contributions to our concepts of species and the transmission of characters were put forward. Mr. Brierley treated of species in relation to his study of fungi, and claimed that it is the inner *physiological constitution* rather than the chance *morphological facies* which makes up the true species complex. It can be demonstrated that in certain fungi, at any rate, the morphological expression varies with every medium, *i.e.* with environment, and must rightly be regarded as a resultant of a comparatively fixed physiological constitution and a variable environment, *i.e.* of two sets of interacting physico-chemical factors.

In his paper on mutational *versus* recapitulatory characters Dr. Gates endeavoured to distinguish between new characters which result from nuclear changes in the germ-cell, which he classed as mutational and referred to as "a new Mendelian character," and new characters which result from "the impress of the environment," which he classed as recapitulatory and described as "gradually developed, involving adaptation to new conditions, and, if permanent, the principle of inheritance of acquired characters." He went on to say: "The theory of antithetic alternation of generations, which is widely held as regards archegoniate plants, implies a gradual lengthening in the sporophyte through the addition of cell-divisions to its subterminal stages. This can scarcely be supposed to have resulted from an alteration in the cell-unit."

Miss Saunders's paper on a graded series of forms in Matthiola added very important data bearing on the relation between continuous and discontinuous characters. She has traced the genetic origin of a perfectly continuous series of forms between the glabrous variety and the normal densely hairy plant. These were produced as the result of crossing the familiar glabrous variety with a rare half-hairy form. "The phenomenon is explicable on the supposition of multiple allelomorphs."

Dr. Scott, in a paper entitled "The Relation of the Seed-Plants to the Higher Cryptogams," discussed the prevailing view that the pteridosperms, and hence the spermophytes as a whole, are to be derived from some unknown group of ferns. Dr. Scott combated this view, and took the stand that "pteridosperms have always been distinct from any of the known phyla of vascular Cryptogams . . . parallel in important aspects to the ferns, but of unknown and remote origin." He adduced anatomical and geological evidence in support of his view.

Another morphological paper concerned itself with the vexed question of the nature and origin of the pith and inner endodermis in medullated ferns. Dr. McLean Thompson concluded from his extensive investigation of *Platyzoma microphylla* that it furnished very good proof of the intrastelar or potentially vascular nature of the pith in this form. Not merely does the basal protostele pass gradually into the medullated condition once in the development of the individual, as in many other forms, but in this species the protostelic structure appears again in later-formed regions.

In a paper entitled "Monocotyledonous Features of the Ranunculaceæ, with Special Reference to the Floral Structure," Dr. Salisbury reviewed the similarities met with in the two groups in relation to number of parts, *dédoublement*, meristic variation, apocarpy, nature of fruits, placentation, etc.

As the result of her extensive work on movable-cell inclusions or statoliths, Miss Prankerd has found that they may be (1) starch grains, (2) chloroplasts, or (3) crystals, and that the nucleus may move with these inclusions. Even when this is not so, the nucleus of the statocyte may be markedly differentiated from that of neighbouring cells.

Under the heading of "Mychorrhiza and the Ericaceæ," Dr. M. C. Rayne added to her former work new facts tending to establish obligate symbiosis in Vaccinium similar to that in Calluna, and raising the question of the possibility of nitrogen fixation by the fungus.

Prof. Priestley put forward a very important contribution to the theoretical consideration of the phenomenon of root-pressure, involving an ingenious use of the rapidly accumulating knowledge of the behaviour of a colloid gel in respect to its variability towards water. It is hoped that this important subject will come up again for discussion at the Cardiff meeting in 1920.

The formal meetings of the section were brought to a close by a semi-popular lecture of exceptional interest given by Prof. F. W. Oliver on Spartina and Poole Harbour.

E. N. T.

EDUCATION AT THE BRITISH ASSOCIATION.

AFTER the presidential address by Sir Napier Shaw the Section settled down to discuss a varied and interesting programme, which attracted large and appreciative audiences throughout the week. It was a great disappointment that Sir A. Quiller Couch was unable to be present himself, but his paper on the teaching of English admirably expressed a need now widely felt by thoughtful teachers that English should be the root of all learning for an English-speaking child; that until the age of fourteen or fifteen he should practise the language natural to his mind in addition to one other; that the plainest, most everyday speech should be clear, expressive, accurate, graceful whenever possible, and at any rate decent; that a child should learn to define and clarify in his mind the terms in which he thinks, to think in real English, not in jargon. Therefore, to attain this, teachers should aim through English in preference to any foreign language, alive or dead. English should not be treated as a special subject, but should be the basis of all others. He deprecated the inordinate amount of time given in the lower forms to linguistics and mathematics, since these are mainly ancillary, the former to literature and history, the latter to natural science; they are formal studies, studies in the abstract, and lacking the content of the other three, employing processes alien to a child's thought.

Mr. W. D. Eggar read a paper on the teaching of English in relation to school science, and claimed that the teaching of English was as much the concern of the science master as that of any other master—perhaps more so, as he is concerned with the live end of the language. He strongly urged that a broader and more intelligent study of English should take the place of much of the mathematical and linguistic work in preparatory schools.

Prof. H. E. Armstrong opened a discussion on "Method and Substance of Science Teaching" by criticising the Government report on the position of natural science in the educational system of Great Britain. This report he thought would prove of little value to teachers, and not likely to influence educational opinion to any degree. He looked upon it as a lost opportunity for examining and utilising experiments already tried. He combated the absurd statement made in Paragraph 43 of the report: that the heuristic method involves the rediscovery by the pupil in his school hours of all that he may fairly be expected to know. The method does, however, involve neither more nor less than learning the art of inquiry. The method employed must be disciplinary—the method of science; scientific outlook must be acquired if scientific knowledge is to be of any avail.

On the same topic Sir Richard Gregory, although advocating heuristic methods, thought that the substance of instruction suffered from concentration upon method, and that laboratory work should be supplemented by a broad general course of descriptive lessons given quite independently of the practical work. Dr. E H. Griffiths said he hesitated to accept this divorce of lecture and practical work. Mr. Mangham spoke of the neglect of biological science in education, and asked for a closer co-operation between the lecturers in various branches of science at the universities. Dr. Lilian Clarke gave some interesting details of a sound practical course of elementary science in girls' schools, showing how the spirit of inquiry can be aroused in botany as well as in chemistry. Her plea for more time should not go unheeded; for it is impossible to go far in such valuable work with only one to one and a half hours per week. Miss Shove discussed the necessity of a thorough course of elementary chemistry and physics preliminary to a botanical course.

A joint session was arranged with Section F, when a paper from Sir Herbert E. Morgan was read. The paper had for its theme the real need of the country for educated men in directing business affairs, men educated in the right way, with technical training added to sound general knowledge and broad views. Mr. C. R. Fay emphasised the value of university influence in business, and claimed that a central school for all branches of economic science at the university would co-ordinate effort and effect a rapid diffusion of new methods. Mr. H. N. Sullivan thought that young men entered business too early. Prof. Oldham described the work of the faculty of commerce in Dublin University. Sir Hugh Bell said that the bold step of appointing university men in railway business was a success, but that it was objected to by men whose promotion had thereby been affected.

A discussion on continuation schools was opened by Sir Robert Blair, who, speaking from the point of view of the largest urban district, suggested that for the first two years education should be general, and for the second two may have a technical or commercial bias derived from the occupation; that residence is the basis of obligation on the authority; that the required eight hours per week should be taken in two four-hour periods; that it would be inadvisable to divide the four-year period between two schools, one from fourteen to sixteen, the other from sixteen to eighteen; that schools may be mixed, not dual; that continuation schools will be ends in themselves and, for some, "stepping-stones" to higher things. Interest, he declared, is the key to the problem of instruction; the schools will be what the staff makes them. Extra class-room activities are no less important—libraries, clubs, games, and societies will attract the adolescent.

Mr. A. P. M. Fleming followed with a paper on works schools, in which he illustrated their advantages, such as the close correlation between the school work and the practical training in the works, the increased facilities for the selection for employment, promotion, systematic training, and for ensuring harmonious relations between the management and the worker. Mr. J. S. Rainer took a rather contrary view of works schools, and in a very able paper presented the W.E.A. point of view as being opposed to works schools. He contended that for efficiency and success these schools must be entirely independent of employers' control; for distrust of the employing interest, as being almost entirely personal and mercenary, would prevent such schools from giving suitable and adequate education. The subjects of study must be related to the interests of the pupil, and not determined by the needs of trades or industries. Mr. G. F. Daniell dealt with the problem in rural districts, and pointed out the need for transport facilities. He urged close relations with the village clubs and institutes, and thought that attendance could be arranged either for one day per week for forty weeks, or for a seasonal attendance. Mr. C. A. Buckmaster pleaded for full liberty to the teachers and for the provision of school societies and games, and thought that the content of the curriculum was secondary to the training of character. Lord Malmesbury advocated the gradual elimination of those unable to profit by the education provided out of public funds, but would encourage and spend as much as possible on the best boys and girls.

Dr. Vincent Naser, of Copenhagen, submitted proposals for an exchange of students between Denmark and Great Britain, and suggested the formation of bureaux of international information in connection with universities.

Sir Richard Gregory spoke on the educational value of the kinema—not to make learning easy, but to awaken interest and synthesise instruction. An exhibition of some instructive films was given by the Community Picture Bureau.

Bishop Welldon, in opening a discussion on training in citizenship, said that something must be done through co-operation or co-partnership to create a fellow-feeling between capital and labour, and that an enlightened patriotism as well as the dignity and history of the Empire should be taught.

Lt.-Gen. Sir Robert Baden-Powell made an eloquent appeal for the need of out-of-school training and environment as auxiliary to education for producing efficient human citizens. The wonderful success of the Boy Scout movement suggests that the most important duty of the schoolmaster is to discover what particular portion of his environment appeals most to each of his pupils, and to use that as the medium for inducing mental activity.

In a valuable paper on fundamental principles in education Prof. A. N. Whitehead claimed that all education is the development of genius, and showed that the true ultimate problem before the educator is how to impart knowledge so as to stimulate genius. He showed that language is essential, but argued that a child should not study a dead language until a modern literature has gripped the imagination; that classical learning is the superstructure of a literary education, and not the foundation.

Mr. F. S. Preston submitted a paper in which he emphasised the value of literary studies in the development of imagination and the moral faculties. A paper from Prof. Marcus Hartog on the function of examinations in education followed.

The final sitting of the Section was occupied with two excellent papers on the present position of private schools in the educational system, one by Mr. R. H. Hume, the president of the Private Schools Association, the other by Mr. Alex. Devine. These papers, and the discussion that followed, brought out the fact, little realised by many, that the number of children educated in private schools approaches in many places 50 per cent. of the school population.

Reports by special committees of the section were read and discussed, that on the free-place system by Mr. C. A. Buckmaster and Mr. D. P. Berridge, that on museums by Mr. Herbert Bolton, and that on the registration of schools by Lady Shaw—all embodying valuable information and suggestions for the educational reformer.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

IN connection with the London County Council addresses to teachers on recent developments in science, Dr. W. Bateson will give a lecture on biology at King's College, Strand, W.C.2, on Saturday, January 24, at 11 a.m. The chair will be taken by Dr. S. Russell Wells, Vice-Chancellor of the University of London.

A WHITE Paper (Cd. 221, 1919) just issued sets forth the proposed text of the Order in Council by which, subject to the approval of Parliament, certain powers and duties in relation to public libraries, museums, and gymnasiums, formerly exercised by the Local Government Board and latterly by the Ministry of Health, are to be transferred to the Board of Education. This forms part of the proposal made by the Reconstruction Committee on Adult Education, to which, as we have previously recorded (NATURE, October 9, 1919), exception was taken by the museum officials and librarians. On the face of it, however, the proposed Order seems unobjectionable and, indeed, natural. The powers in question relate to the making of various by-laws and to the sales of buildings or land, and there can be no ground for supposing that they will be exercised in other than a liberal spirit conducive to the best ends of the institutions concerned. The questions of financial control, apportionment of rates, and general management do not seem to fall within the scope of this Order, and nothing is said in it about bringing museums and libraries under the control of the local education authorities. At the same time, the present step may be regarded as only the first of a contemplated series, and as, in any case, the necessary preliminary to those more fundamental changes concerning which opinions differ.

SOCIETIES AND ACADEMIES.

LONDON.

Faraday Society, December 15, 1919.—Prof. A. W. Porter, vice-president, in the chair.—A. G. **Tarrant**: The measurement of physical properties at high temperatures. An account is given of experiments made upon refractory materials with the view of measuring certain physical properties at high temperatures, particular attention being paid to thermal expansion, tensile strength, and thermal conductivity.—Lieut. W. A. **Macfadyen**: An aspect of electrolytic iron deposition. The experiments detailed were carried out in seeking the best conditions for obtaining thick, hard, adherent deposits of iron on steel-mechanism parts which had been machined too much or worn down in a few places, and thus rendered useless, so as to enable the scrapped parts to be replaced in use after treatment.—J. G. **Williams**: The electrolytic formation of perchlorate. It is pointed out that present practice in electrolytic preparation of perchlorate uses much higher temperature of liquor and current density than is given in text-books.—Prof. A. W. **Porter**: The vapour pressure of binary mixtures. In order to remove difficulties in connection with the proof of the Duhem-Margules formula for the vapour pressures of binary mixtures, a simplified proof is given which makes clear the extent of the usual approximations in each step of the proof.—Prof. E. D. **Campbell**: The solution theory of steel and the influence of changes in carbide concentration on the electrical resistivity. Baly's force-field theory is applied to the case of the solid solution of the non-ferrous elements in steel. The experimental portion of the paper describes a research on the influence of the decarburisation by means of hydrogen of a series of alloy steels on the electrical resistivity, when the metal is in both the annealed and hardened condition.—S. **Horiba**: Some relations between the solubilities of solutes and their molecular volumes.—Dr. E. J. **Hartung**: (1) An accurate method for the determination of vapour pressure. (2) Some properties of copper ferrocyanide.

PARIS.

Academy of Sciences, December 15, 1919.—M. Léon Guignard in the chair.—H. **Douvillé**: The annular Foraminiferæ (Cyclostègnes) of Orbigny. The annular development taken by Orbigny as a basis of classification is the result of a particular mode of growth, and is a secondary character.—G. **Bonnier**: Comparative culture of seedlings at high altitudes and in the plain. After experiments, lasting thirty or thirty-five years, low-level plants grown on the same soil at different altitudes acquire completely the form and structure of plants of the same species growing naturally at the higher altitude. Detailed examples are given.—E. **Ariès**: A new improvement of the equation of state of fluids.—V. **Grignard**, G. **Rivat**, and Ed. **Urbain**: The chloro-derivatives of methyl formate and carbonate.—G. **Friedel**: The calculation of the intensity of X-rays diffracted by crystals.—M. Louis Lumière was elected a member of the division of the applications of science to industry.—M. **Plancherel**: The method of integration of Ritz.—J. **Drach**: Determination of the first integrals of the differential equation of geodesic lines, rational with respect to the first differential of the unknown function.—Ed. **Fouché**: A characteristic equation for atmospheric air.—P. **Jolibois**: A new method of physico-chemical analysis of precipitates. Application to the study of the calcium phosphates.—A. **Recoura**: A new complex form of chromic sulphate.—A. **Kling**, D. **Florentin**, A. **Lassieur**, and E. **Schmutz**: The properties of the chloromethyl chloroformates.—M. **Godchot** and F. **Taboury**: Some new bicyclic ketones. Further applications of the reaction between ketones and calcium hydride.—L. **Bertrand** and A. **Lanquine**: The relations between chemical composition, microscopic structure, and the ceramic qualities of clays. The usual method of calculating the proportion of mica in clay from the chemical analyses can be shown by microscopic examination to be erroneous. The chemical composition of a clay is an insufficient guide to its ceramic properties.—R. **Anthony**: The determination of the lobulation of the kidney in mammals.—A. **Pézard**: Alimentary castration in cocks submitted to an exclusively carnivorous diet. A strictly carnivorous diet sets up a slow intoxication to which the genital glands are peculiarly sensitive. The latter are either atrophied or do not develop.—R. **Bayeux**: The urinary toxicity and its modifications by hypodermic injections of oxygen during a prolonged stay at the Mont Blanc Observatory.—F. **Bordas**: Milk contamination. Remarks on the importance of reducing infant mortality, with especial reference to tuberculosis produced by dirty milk.—P. **Achalme** and Mme. **Phisalix**: The preservation of vaccine.

BOOKS RECEIVED.

The Child's Unconscious Mind. By Dr. W. Lay. Pp. vii+329. (London: Kegan Paul and Co., Ltd.) 10s. net.

The Elements of Analytical Conics. By Dr. C. Davison. Pp. vii+238. (London: At the Cambridge University Press.) 10s. net.

A Geographical Bibliography of British Ornithology from the Earliest Times to the End of 1918. By W. H. Mullens, H. Kirke Swann, and Rev. F. C. R. Jourdain. Part ii. Pp. 97–192. (London: Witherby and Co.) 6s. net.

DIARY OF SOCIETIES.

THURSDAY, JANUARY 15.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. R. R. Terry: Renaissance Music in Italy and England (with Musical Illustrations).
ROYAL SOCIETY OF ARTS (Indian Section), at 4.30.
LONDON MATHEMATICAL SOCIETY, at 5.—Major P. A. MacMahon: The Divisors of Numbers.—H. Steinhaus: Fourier Coefficients of Bounded Functions.—S. P. Owen: The Lag of a Thermometer in a Medium whose Temperature is a Linear Function of the Time.
LINNEAN SOCIETY, at 5.—Dr. B. Daydon Jackson: Methods of Botanic Illustration during Four Centuries (Lantern Lecture).
ROYAL INSTITUTE OF PUBLIC HEALTH, at 5.—Prof. E. W. Hope: Schemes and Methods in Tuberculosis Work.
CHEMICAL SOCIETY, at 8.—L. E. Hinkel and H. W. Cremer: The Condensation of Acetoacetic Ester with *p*-Dimethylaminobenzaldehyde and Ammonia.—G. S. Butler and H. B. Dunnicliff: The Action of Alcohol on the Sulphates of Sodium.—M. Nierenstein, C. W. Spiers, and, in part, the late K. C. R. Daniel: Guarana Tannin.—R. Lessing: Studies in the Composition of Coal: (1) The Behaviour of the Constituents of Banded Bituminous Coal on Coking; (2) The Mineral Constituents of Banded Bituminous Coal.—P. Ray and P. V. Sarkar: The Hydrazino-thiocyanates of certain Divalent Metals.

FRIDAY, JANUARY 16.

INSTITUTE OF AERONAUTICAL ENGINEERS (at the Holborn Hall), at 2.30.—Prof. G. H. Bryan: Presidential Address.
ROYAL SOCIETY OF MEDICINE (Otology Section), at 5.—Dr. A. A. Gray: A Few Anatomical Details of the Anatomy of the Vestibule, not previously described.
INSTITUTION OF CIVIL ENGINEERS (Students' Meeting), at 6.—R. B. Dunwoody: The Economic Requirements for Inland Navigation Transport in the British Isles (Vernon Harcourt Lecture).
INSTITUTION OF ELECTRICAL ENGINEERS (Students' Meeting) (at the City and Guilds (Engineering) College), at 7.—J. H. Reyner: The Development of Automatic Telephony.
JUNIOR INSTITUTION OF ENGINEERS (at 39 Victoria Street), at 7.30.—B. E. D. Kilburn: Meteorology and Engineering.
ROYAL SOCIETY OF MEDICINE (Electro-Therapeutics Section), at 8.30.—C. Thurstan Holland: Lessons of the War.
SOCIETY OF TROPICAL MEDICINE AND HYGIENE, at 8.30.—Dr. P. Manson-Bahr and Others: Discussion on Bacillary Dysentery.
ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Prof. Sir James Dewar: Low Temperature Studies.

SATURDAY, JANUARY 17.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—A. Noyes: The Anglo-American Bond of Literature.

MONDAY, JANUARY 19.

VICTORIA INSTITUTE (Committee Room B, Central Hall, Westminster), at 4.30.—Dr. A. T. Schofield: The Psychology of the Female Mind.
ROYAL COLLEGE OF SURGEONS, at 5.—Prof. A. Keith: John Hunter's Observations and Discoveries in Anatomy and Surgery; His Contributions to our Knowledge of the Heart and Blood Vessels (Hunterian Lecture).
INSTITUTION OF ELECTRICAL ENGINEERS (Informal Meeting) (at Chartered Institute of Patent Agents), at 7.—S. M. Hills and Others: Discussion on Functions of a Trade Journal.
SURVEYORS' INSTITUTION (Junior Meeting), at 7.—R. E. A. Dash: The Housing Question and how it is affected by Recent Regulation.
ARISTOTELIAN SOCIETY (at 74 Grosvenor Street), at 8.—Prof. J. A. Smith: The Philosophy of Giovanni Gentile.
ROYAL SOCIETY OF ARTS, at 8.—Capt. H. Hamshaw Thomas: Aircraft Photography in War and Peace (Cantor Lecture).
ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 8.30.—Lt.-Col. J. Tilho: Tibesti to Darfur.

TUESDAY, JANUARY 20.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. Sir John Cadman: Modern Development of the Miner's Safety Lamp.
ROYAL SOCIETY OF MEDICINE (Therapeutics and Pharmacology Section), at 4.30.—J. Barcroft and Others: Discussion on the Therapeutic Uses of Oxygen.
ROYAL STATISTICAL SOCIETY, at 5.15.—G. H. Knibbs: The Organisation of Imperial Statistics.
MINERALOGICAL SOCIETY, at 5.30.—Dr. E. S. Simpson: Gearksutite at Gingin, Western Australia.—C. E. Barrs: Fibroferrite from Cyprus.—Dr. G. T. Prior: The Classification of Meteorites.—A. F. Hallimond: On Torbernite.
INSTITUTION OF PETROLEUM TECHNOLOGISTS (at Royal Society of Arts), at 5.30.—H. Moore: Spontaneous Ignition Temperatures of Liquid Fuels.
ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN (Technical Meeting), at 7.—T. H. B. Scott: Pictorial Suggestions.

WEDNESDAY, JANUARY 21.

ROYAL SOCIETY OF ARTS, at 4.30.—A. H. Powell: Ancient Cottages and Modern Requirements.
ROYAL METEOROLOGICAL SOCIETY (at the Royal Astronomical Society) (Annual General Meeting), at 5.—Sir Napier Shaw: Pioneers in the Science of Weather (Presidential Address).
ROYAL SOCIETY OF MEDICINE (Occasional Lecture), at 5.—Surg.-Comm. K. Digby Bell: The Position of the Medical Profession with regard to National Physical Education.
ROYAL COLLEGE OF SURGEONS, at 5.—Prof. A. Keith: John Hunter's Observations and Discoveries in Anatomy and Surgery: His Contributions to our Knowledge of the Lungs and Pleuræ (Hunterian Lecture).
GEOLOGICAL SOCIETY OF LONDON, at 5.30.
ROYAL AERONAUTICAL SOCIETY (at the Royal Society of Arts), at 8.—A. P. Cole: Principles of Rigid Airship Construction.
ROYAL MICROSCOPICAL SOCIETY (Annual Meeting), at 8.—J. E. Barnard: The Present Status of Microscopy (Presidential Address).

THURSDAY, JANUARY 22.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. R. R. Terry: Renaissance Music in Italy and England.
ROYAL SOCIETY, at 3.30 (Special General Meeting). At 4.30.—Prof. E. G. Coker and K. C. Chakko: The Stress-strain Properties of Nitro-cellulose and the Law of its Optical Behaviour.—S. Marsh: Alternating-Current-Electrolysis.—W. H. Eccles and J. H. Vincent: The Variations of Wave-length of the Oscillations Generated by the Three-Electrode Thermionic Tube due to Changes in Filament Current, Plate Voltage, Grid Voltage, or Coupling.—S. D. Carothers; Plane Strain. The Direct Determination of Stress.—F. Horton and Ann C Davies: An Investigation of the Effects of Electron Collisions with Platinum and with Hydrogen, to ascertain whether the Production of Ionisation from Platinum is due to Occluded Hydrogen.—L. Bairstow, R. H. Fowler, and D. R. Hartree.—The Pressure Distribution on the Head of a Shell moving at High Velocities.
INSTITUTION OF MINING AND METALLURGY (at the Geological Society), at 5.30.—W. Broadbridge: Froth Flotation: Its Commercial Application and its Influence on Modern Concentration and Smelting Practice.
INSTITUTION OF ELECTRICAL ENGINEERS (at the Institution of Civil Engineers), at 6.—J. L. Thompson: Transformers for Electric Furnaces.

FRIDAY, JANUARY 23.

PHYSICAL SOCIETY OF LONDON (at the City and Guilds Technical College, Leonard Street), at 5.—Dr. J. H. Vincent: Maintained Oscillations in Triode Valve Circuits.—Dr. W. Eccles: Measurements of the Chief Parameters of Triode Valves.—F. W. Jordan: Measurement of Amplification of a Radio-frequency Amplifier.—F. E. Smith: The Measurement of Amplification given by Triode Amplifiers at Audible and at Radio Frequencies.—Hon. C. W. Stopford and C. R. Darling: Exhibition of a Method of Determining the Hardening Temperature of Steel.—C. R. Darling: Exhibition of a Thermal Cell of Constant Voltage.
ROYAL COLLEGE OF SURGEONS, at 5.—Prof. A. Keith: John Hunter's Observations and Discoveries in Anatomy and Surgery; His Contributions to our Knowledge of the Alimentary System (Hunterian Lecture).
INSTITUTION OF MECHANICAL ENGINEERS, at 6.—E. M. Bergstrom: Recent Advances in Utilisation of Water Power.
ROYAL SOCIETY OF MEDICINE (Epidemiology and State Medicine Section), at 8.30.—Dr. F. G. Crookshank: Principles of Epidemiology.—Dr. Cleland and Dr. Campbell: Epidemiology of Acute Encephalomyelitis.
ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Hon. Sir Charles Parsons: Researches at High Pressures and Temperatures.

SATURDAY, JANUARY 24.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—A. Noyes: Aspects of Modern Poetry.
PHYSIOLOGICAL SOCIETY (at King's College), at 4.

WIND AND BAROMETRIC GRADIENT.

Manual of Meteorology. Part iv.: *The Relation of the Wind to the Distribution of Barometric Pressure.* By Sir Napier Shaw. Pp. xvi+166+3 plates. (Cambridge: At the University Press, 1919.) Price 12*s.* 6*d.* net.

THE other parts of this manual are not yet published, but Part iv. deals with the question of the extent to which the motion of the lower strata of the atmosphere can be inferred from the ordinary working chart prepared on receipt of the telegraphic information of the surface conditions by a meteorological office, a question of great importance to the aircraft service.

As the author informs us in the preface, many inquiries of this sort were addressed to his office in London during the war, and he sets out here the extent to which and the means whereby answers to such questions can be given.

The matter is a complicated and difficult one, but Sir Napier Shaw is to be congratulated on the mass of information he has brought together and on the clear way in which he has arranged it and correlated together the different parts, which are sometimes more or less contradictory.

In chaps. i. to iii. the relation of the surface wind to the isobars is set out. The principle that the motion of the air will be at right angles to the direction of the pressure gradient and have the velocity deduced from the gradient equation is accepted as a working hypothesis, and the reasons why the rule does not hold close to the surface are explained. The principle was set out by the author thus in 1913: "In the upper layers of the atmosphere the steady, horizontal motion of the air at any level is along the horizontal section of the isobaric surface at that level, and the velocity is inversely proportional to the separation of the isobaric lines in the level of the section." How far this principle holds is a fundamental question in meteorology. Admittedly, it only applies to first order terms, and the author, in chap. x., shows that there is a systematic departure from the rule near the centre of a travelling cyclone. On the other hand, if a meteorologist is asked to give the velocity and direction of the wind at 1500 ft. height at any given time and place, it has been found, in the absence of information from pilot balloons, that the best answer he can give is to quote the gradient wind as shown by an isobaric chart.

In chaps. iv. and v. the author discusses the increase of wind with height in the lower strata, and gives G. I. Taylor's theory of the diffusion of eddy motion and its effect on the wind and on the formation of thin sheets of low cloud. Taylor's formula takes the form $W/G=\cos\alpha-\sin\alpha$, where W denotes the actual surface wind, G the geostrophic wind, and α the angle between them. It will be noticed that this formula makes a value of α exceeding 45° impossible.

Chaps. vi. and vii. deal with the variations of the wind in the upper layers and their dependence on the form of the distribution of temperature. It is shown how the cessation of the lapse rate, *i.e.* the fall of temperature with height, in the stratosphere, and the higher temperature over the cyclonic area that is found above 10 km., produce the rapid falling off of the wind that is also shown by direct observation.

Chap. x. is perhaps the most suggestive in the book, and throws fresh light on the well-worn theme of the mechanics of a travelling cyclone. It is there shown that in what is called a normal cyclone there are three centres: the instantaneous or kinematic centre; the "tornado centre," which is the centre of the supposed rolling disc; and the dynamic centre, which is the centre shown by the isobars on the chart. This representation leads to a systematic difference between the true and the gradient wind in the parts that are near the centre, a difference that has been noticed, but was supposed to be accidental, on some working charts.

In chap. xi. Sir Napier Shaw discusses Rayleigh's and Aitken's papers on revolving fluid, and gives diagrams and reproductions of instrumental records relating to some noted storms of the last twenty years or so. Synoptic charts are reproduced which show a good agreement with the method of treatment in chap. x. The diagrams Figs. 5 and 6, on p. 154, are especially striking; they refer to the storm of September 10, 1903, at Holyhead, and show the velocity and direction of the wind on that occasion corrected for the known peculiarities of the exposure due to the local configuration.

In theoretical discussions of the mechanics of a cyclone, especially if there is much mathematical analysis, one is unavoidably compelled to make hard-and-fast suppositions, and the point arises as to what extent the real cyclone will submit to be bound by such suppositions. The author questions how far the "normal cyclone" of chap. x. is the real cyclone as shown on the charts, and one wonders how far Rayleigh's conclusions are vitiated by his leaving out the effect of the rotation of the earth. Doing so greatly simplifies the equations of motion, but it is the earth's rotation which ensures that every cyclone in the northern hemisphere without exception shall rotate in one direction only, and every cyclone in the southern hemisphere in the opposite direction. It must therefore be of supreme importance.

Every serious student of meteorology should obtain Part iv. of the manual and read it, and all will hope that the other parts may be published shortly.

W. H. DINES.

RESEARCHES ON FLUORESCENCE.

Researches in Physical Optics. Part ii. *Resonance Radiation and Resonance Spectra.* By Prof. R. W. Wood. (Publication No. 8 of the Ernest Kempton Adams Fund for Physical Research.) Pp. viii + 184 + x plates. (New York: Columbia University Press, 1919.)

THIS is the second instalment of a valuable re-publication of Prof. Wood's papers. The first half of the volume deals with the spectroscopic properties of iodine vapour, particularly the study of the fluorescent spectrum with high resolving power. The difficulty with this, as with most other modern optical experimenting, is lack of light, and the success attained in overcoming the obstacle by well-thought-out optical arrangements is very remarkable; but the complexity of the phenomena brought to light is such as may well make theoretical progress seem almost hopeless.

It has been possible to obtain monochromatic stimulation at one particular absorption line of the iodine spectrum by the ingenious but simple device of using the mercury vacuum arc as illuminant. If the arc is run at low-current density, one line only of the iodine spectrum is covered by the green mercury line. Even in this case the result is to stimulate not merely the line primarily excited, but also a series of doublet lines, extending along the spectrum on either side of the latter. Stokes's law of fluorescence is thus completely violated.

All this results from the stimulation of one line only of the iodine spectrum.

But this line is one of forty thousand, and it appears that we can scarcely rely on it as being typical, since the iodine lines are of many varieties, as shown by their minute structure and by the Zeeman effect and the magnetic rotatory properties.

No doubt what is wanted for this class of research is some means of obtaining intense monochromatic stimulation of great purity, and with its frequency under control over a wide range. Prof. Wood is able to do something in this direction by altering the current through the mercury arc, and thereby the width of the green mercury line; this makes it overlap several of the iodine lines, and the complexity of the phenomena is thus greatly increased. It is perhaps worthy of consideration whether the Doppler effect obtained by moving the source could be of service, but this method would probably be very difficult of execution, and the range that could be hoped for very far short of what is desired.

The second half of the volume deals with other phenomena of fluorescence in gases of a miscellaneous kind, but is marked throughout by the same fertility of resource in devising experimental methods. The re-emission of the mercury radiation at wave-length 2536 when cold mercury vapour is stimulated by this radiation is an observation of special importance; the question presses for answer how this resonance is related by the scattering of white light by gases when there is no resonance.

R.

SCIENTIFIC STUDY OF THE SUGAR GROUP.

The Simple Carbohydrates and the Glucosides. By Dr. E. Frankland Armstrong. Third edition. (Monographs on Biochemistry.) Pp. x + 239. (London: Longmans, Green, and Co., 1919.) Price 12*s.* net.

THE third edition of Dr. E. F. Armstrong's monograph is something more than a new and revised issue; it is, to all intents and purposes, a new book. Such a statement may not, on first inspection, seem to be well founded, as the general scheme adopted by the author in the earlier editions has been retained, and the subdivision of the material into chapters remains much as before. A comparative reading of the texts, however, shows that some of the changes introduced are fundamental, and a reader making his first acquaintance with the specialised chemistry of the carbohydrates through a study of the latest edition will thus acquire not only much new information, but also an entirely new perspective.

The seven years which have elapsed since the appearance of the second edition have been marked by considerable activity in sugar research, and the fact that Emil Fischer closed his career by once more directing the work of his school to this subject would almost in itself be sufficient to make a fresh edition necessary. Many novel and unexpected types of compounds have been isolated, and these are now fully described and classified under an improved nomenclature; but this alone does not explain the advances made in the present book.

Dr. Armstrong has been quick to realise that the recent recognition of the specially reactive forms of sugars which are regarded as ethylene-oxides has opened out many new fields of inquiry, and has made clear much that has hitherto been obscure. He has therefore introduced the new structural ideas at an early stage of his narrative, and keeps them continually before the reader, adding on the way many fresh suggestions and criticisms. His treatment of this difficult subject is extremely lucid, and the result is strikingly successful.

Although the book has been considerably expanded by the inclusion of much new experimental material, little need be said regarding the details of the subject-matter, as nothing of present or potential importance has been overlooked, and the enlargement of the various chapters is well balanced. The high standard of accuracy maintained throughout the text extends to the comprehensive bibliography, which is carefully classified according to the topics discussed—a plan which saves time when a rapid search through the original literature is necessary.

Monographs suitable for both the research worker and the advanced student play a part of ever-increasing importance in our scientific education, and the present book is a model of its kind. Considering the magnitude and the wide appeal of carbohydrate chemistry, it is no easy task to compress within narrow limits an accurate account of the most important features of the sugars, and at the same time to avoid the dangers of merely cataloguing compounds or of losing all style in telegraphic brevity. Dr. Armstrong has skilfully avoided these dangers, and has succeeded in making his narrative interesting without sacrificing any essentials, and that this has been possible is ample testimony to the excellence of the scheme upon which the original edition was planned. The leanings of the author, as a practical worker in this field, to the biological aspects of sugar chemistry are well known, but Dr. Armstrong is a firm believer in the value of structural study, and he therefore establishes constitutional principles before proceeding to descriptive details.

It is, then, on the elastic framework of structural chemistry that Dr. Armstrong has arranged the complex facts of sugar chemistry, and he has done so systematically, thoroughly, and with scholarly judgment. No point of view is neglected. The organic chemist is not allowed to forget that Nature is the great sugar laboratory, and that he must work in association with the biologist. On the other hand, the biochemist is forced to think in the exact terms of structure, and the lesson is probably necessary.

For several years the reviewer has been in a position to appreciate the merits of the earlier editions by observing the use made of them by graduates commencing research work on the sugars. The monograph has answered most successfully to this practical test, and as the latest edition is a distinct advance on its predecessors, students of the sugar group will have access to a thoroughly satisfactory book—a book written with the authority of the expert and conveying the stimulus of the enthusiast.

NUTRITION AND LONGEVITY.

(1) *The Newer Knowledge of Nutrition: The Use of Food for the Preservation of Vitality and Health.* By E. V. McCollum. Pp. ix+199. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1919.) Price 6*s*. 6*d*. net.

(2) *On Longevity and Means for the Prolongation of Life: Founded on a Lecture delivered before the Royal College of Physicians on December* 3, 1903. By Sir Hermann Weber. Edited by Dr. F. Parkes Weber. With a preface by Sir Clifford Allbutt. Fifth (enlarged) edition, revised and partly re-written. Pp. xxii+292. (London: Macmillan and Co., Ltd., 1919.) Price 12*s*. net.

(1) PROF. E. V. McCOLLUM sets forth in volume form the results of, and conclusions to be drawn from, his well-known researches on food accessory bodies, the discovery of which was initiated by Dr. Gowland Hopkins. These bodies, called "vitamines" by Funk, are now realised to be of the greatest importance to growth, health, and resistance to disease, the lack of them making the body susceptible to the rank growth of microbes.

Prof. McCollum inclines to doubt that scurvy is due to the lack of a water-soluble accessory body A, strong evidence for the existence of which has been adduced by the workers at the Lister Institute, Dr. Harden, Miss Chick, and others. He lays the greatest stress on the fat-soluble A accessory body, which is of supreme importance for growth, and is to be found in growing cells and in milk, eggs, and the germ of seeds (wheatberry, etc.), substances specially formed with growth principles in them. The miller removes the germ in the preparation of white flour, and, classed as offal, it goes to feed and promote the growth of pigs and chickens.

Dairy produce from cows fed on green leaves and the green leaf itself supply "fat-soluble A," and are thus the great protective foods, and every endeavour must be made to keep up the supply of these. Green vegetables must not be regarded as a luxury, but as a most essential part of the diet. The citizen is divorced from gardens and allotments, and the cost of transport makes a cheap supply of greenstuff prohibitive. Milk has become costly, and even when cheap was not much drunk by the children of the poorer classes. How many schools recognise the imperative needs of children for green vegetables, fruit, and abundance of milk?

The fatality of the recent epidemics of influenza may have been closely associated with deficiency of fat-soluble A in the diet, for there is none in the vegetable-oil margarine which has so largely replaced butter.

(2) The fifth edition of the late Sir Hermann Weber's book on longevity, edited by his son, Dr. Parkes Weber, is prefaced by Sir Clifford Allbutt by many wise and illuminating remarks. The motto of the author is no less old than true. "Work, moderation, and contentedness are the main sources of health, happiness, and long life." A great apostle for open-air exercise, he justly extols walking and climbing above all forms of exercise. He lived to ninety-seven himself, following the wise tenets which he lays down.

It is often asserted that longevity is an inborn quality, and the cases of men are cited who have attained old age and yet have been heavy eaters or drinkers. Inquiring into the manner of living and other antecedents of more than 100 persons living to between 86 and 102 years, Weber found that although most of these persons belonged to the well-to-do classes, and were not obliged to restrict themselves, there were not more than six amongst them who had more or less habitually indulged themselves by eating or drinking largely; many, on the contrary, were remarkable for great moderation. He records the cases of many middle-aged people with bad family histories and showing themselves signs of breaking up in health who, by his regimen of open-air exercise and great moderation in food and alcohol, were carried on in good health to eighty years or more, while their brothers and sisters, following no such regimen, died twenty years or so before them. The evidence Weber thus adduces seems strong enough to support his claim that great moderation in eating and drinking, and plenty of open-air exercise, can promote the duration of life of the middle-aged to a marked extent. The degenerations of the blood-vessels and other organs which hasten the end of life are primarily due to toxins absorbed from the bowels or from infections—*e.g.* rheumatic fever, syphilis, etc. A clean, healthy life keeps these away.

CHEESE- AND BUTTER-MAKING.

(1) *The Book of Cheese.* By Charles Thom and Prof. Walter W. Fisk. (Rural Text-book Series.) Pp. xvi+392. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1918.) Price 8*s.* net.

(2) *Practical Butter-making: Fourth Revision. A Treatise for Butter-makers and Students.* By C. W. Walker-Tisdale and Theodore R. Robinson. Pp. 143. (London: Headley Brothers, Publishers, Ltd., n.d.) Price 5*s.* 6*d.* net.

(1) THE greater interest which is being taken in the manufacture of cheese will assure a welcome for this volume. It is one of the well-known series edited by Prof. L. H. Bailey, and it thoroughly warrants its inclusion in the list.

Practical cheese-making has not had in this country the study it requires to have, and whilst a number of the standard cheeses have originated here it cannot be said that, apart from Prof. Lloyd's investigations in the making of Cheddar cheese, any serious attempt has been made to throw light upon the details of manufacture or to explain the causes of the failures which arise from time to time.

In this volume the authors deal systematically with the general method of cheese-making, and state in simple language the process of milk coagulation and the theories which have been advanced in explanation. A chapter is devoted to "starters," and it would be well if our dairy students could receive greater facilities for preparing and judging the cultures and noticing the effect upon the cheese of a bad starter. A clean acid starter has a great influence upon the texture and flavour of the cheese, as is well known, and a maker who works with a bad starter cannot hope to produce a first-class cheese. Inability to judge a good starter may mean the continuance of flavours and faults which would have disappeared had the proper type of starter been used.

Amongst the hard cheeses, chief place is naturally given to Cheddar, as this type is the one commonly made in America and Canada. The appliances suitable for a factory making Cheddar cheese are described, and the process of making the cheese is followed step by step. Various types of cheese made in different countries, but all prepared upon the Cheddar principle with greater or less modification, are reviewed.

The "Book of Cheese" has many other interesting chapters, one even upon the food value of cheese, the method of using it, and recipes for dishes in which cheese plays an important part.

Milk-testing by the Babcock method is described, and numerous other tests, such as Hart's test for casein, and the testing of cheese for fat by a modified Babcock method, are given. The accuracy of the latter test is questionable.

(2) Butter-making is somewhat under a cloud at the present time, owing to the impossibility of producing it commercially at a profitable price. The information given by the authors is, however, excellent, and the best up-to-date methods and appliances are described.

The extension of the practice of selling milk, and the facilities now afforded the farmer by the wholesale dealer or the condensing factory, have not encouraged the breeding of cows giving a high percentage of fat in the milk, and it is difficult to see how butter-making can for some time to come compete with cheese-making or milk-selling. Nevertheless, there will always be a good demand for high-class butter, and it is most necessary that the maker should produce an article of prime quality. This volume would not have reached a fourth revision unless it had met with success in previous editions, and both as a manual and a reference book it takes a very high place.

OUR BOOKSHELF.

Enjoying Life: and Other Literary Remains of W. N. P. Barbellion [B. F. Cummings]. Pp. xvi+246. (London: Chatto and Windus, 1919.) Price 6*s*. net.

THIS book is welcome because it raises a much pleasanter picture of its author than did the rather peevish "Journal" reviewed in these columns in July last. Some of the essays, excluded from the "Journal" for reasons of space, would have illuminated its shadows. One is called "Crying for the Moon," but Barbellion wanted to swallow the Universe. Even those of us who would be content with the World have to learn that it is too large an oyster. Life is a perpetual renunciation of the unattainable. Barbellion had yet to realise that the half is greater than the whole; his only limitations were those of a sickly body, and so he seemed to scorn those who restrained the appetite of the soul. Hence, in the diarist, an apparent poverty of human kindness. But in his outward relations, as Cummings, the defect is made good or hidden. There is sympathy as well as skill in his sketches of Spallanzani, Montagu, Rousseau, and Goldsmith of the "Animated Nature," and even for his colleagues, the Scarabees, he has a good word, for he has begun to realise that the driest museum entomologist may have beneath his dusty coat something of a Barbellion.

It is ungracious to criticise lapses in a posthumous publication, but "Sir Hercules Reed," "Museo di Stovia Naturale," and "Sir Francis Galten" might have been avoided.

The Manufacture of Chemicals by Electrolysis. By Arthur J. Hale. (A Treatise of Electrochemistry.) Pp. xi+80. (London: Constable and Co., Ltd., 1919.) Price 6*s*. net.

IN this monograph a brief account is given of the application of electrolysis to the preparation of chemical products. Most of the electrolytic preparations of which a description has been published are referred to, and references to the original publications are given throughout, so that the book is likely to prove a useful guide to the literature of the subject. The reader is, however, left to guess that certain groups of preparations, such as chlorine, sodium, and the alkalis, to which no reference at all is made either in the text or in the preface, are to be described in other monographs of the series. This probably accounts for the impression created on reading the text that the academic aspects of the subject have secured in this volume undue prominence as compared with its industrial applications. If, however, all the really productive processes have been reserved for other writers, and the author of the present volume has been left to cultivate only the more barren areas, he cannot be blamed for the unfruitfulness of so large a proportion of the preparations which he describes, and is rather to be congratulated on having given so good an account of the minor applications of electrolysis to chemical industry.

A Synoptical List of the Accipitres. (Diurnal Birds of Prey.) Parts i. and ii. By H. Kirke Swann. (London: John Wheldon and Co., 1919.) Price 4*s*. per part.

THE literature of an attractive Order of birds receives a notable addition in this work. It is now nearly half a century since the late Dr. Bowdler Sharpe's "Catalogue of the Accipitres," the latest complete work on the subject, appeared. During this long interval innumerable contributions have been made to the knowledge of the Order relating to the discovery of new species, the recognition of numerous racial forms, changes in nomenclature and classification, extension of geographical range, and much else. Thus a treatise, however modest, which might bring the subject down to date was a desideratum, and now, in a measure, has been supplied in a highly epitomised form by this synoptical list, which furnishes concise diagnostic characters of families, genera, species, and subspecies, and also an indication of the geographical range of each bird. For the species, however, it has been found impossible to deal with any but the plumage of adults, for the varied feather changes through which many species pass ere they assume the garb of maturity could only be satisfactorily described in an elaborate monograph on the Order; as yet there does not appear to be any signs of the advent of such a much needed work. Great care has been bestowed upon the preparation of this list—a task of no small difficulty—and it will be much appreciated by all who are engaged in systematic ornithological studies.

Gravitation and Light.

IN a recent letter (NATURE, December 25, p. 412) and elsewhere I have expressed doubt as to the security of the inferences regarding the influence of gravitation on the light from distant celestial bodies, which are advanced as tests of the Einstein formulation. A closer and less sceptical general scrutiny is possible. The difficulty was to recognise how a theory which professes to supersede an æther with its definite space and time, by concepts purely relativist, could manage to effect direct comparison, at a distance and without tracing transmission across the intervening space, of the radiations of a molecule at the sun and those of a molecule of the same substance at the earth. This body of doctrine seems, in fact, to consist of two chapters. A blind man could work out the purely relativist theory, which would indeed represent rather closely the process of groping from point to adjacent point in space and time by which he must acquire his own scheme of knowledge. But to compare his results with the world of experience a practical astronomer is needed, with very different equipment; he relies on the rays of light, in conformity with the optical theory that prescribes their function as messengers across space.

It thus appears to be necessary to examine directly what changes in the propagation of rays of light would arise under the modified gravitation, and, if possible, to bring out more explicitly and demonstratively the further postulate that is needed to reconcile them with the proposed test-relations. The postulate which is sufficient to sustain the optical predictions proves to be this: that all the way to the sun and throughout the solar system the formula for the element of fourfold length by which the nature of the space is determined does not contain explicitly that one co-ordinate which is more especially related to time, but involves only its differential. This is, of course, a reasonable assumption; but it is of an absolute type regulating the whole space, assumed to be thus settled in advance on the Newtonian plan, not of the relativist type which would profess only to explore it gradually from place to place as it arises.

But we can analyse further and more definitely. The new theory implies that if this quadratic formula characteristic of the space involved in its product terms the differential of that co-ordinate which stands closest to time, then the velocity of the rays of light in any direction at any place would be different according as they are travelling forward or backward. That could only mean that the co-ordinates define at such a locality a frame of reference which is itself in motion. But in motion with reference to what? The relativity of language is doubtless capable of supplying an answering formula; but it would only be wrapping up in abstractions the simple statement that when at any place the quadratic characteristic of the spacial extension involves the differential of the co-ordinate specially related to time in its product terms, then there is latent in it a specification of its own mode of change at that place with respect to uniform space-time. If no such products are contained, the space is not locally in motion, and we may say that the frame of reference is fixed in the æther. That is, the fourfold space-time frame in which we set the universe is everywhere deformed and awry, but it is then nowhere in movement relative to light; or, in graphic terms, the co-ordinate system would involve a fourfold curvilinear frame instead of a rectangular one when it is set in a uniform fivefold extension, but it is to be nowhere in movement when set in that higher auxiliary space. The physical properties of the rays of light can scarcely be invoked to obtain an astronomical test of results, by providing in their vibrations a universal scale of time, without becoming to the same degree a criterion of the relation to light of the whole construction; if they can settle universal time by optical vibrations, they can equally well be applied to settle absolute space in each locality. It comes to this, that radiation can be utilised to determine the space and time absolutely.

This point of view involves no destructive criticism of the substantial and brilliant mathematical theory, which, of course, ought to evolve correctly the consequences of the postulates that are put into it. But it does demur to the popular presentation which asserts that space and time and the æther have now been transcended. The outstanding problem, stripped to its essentials, was to find whether gravitation could be brought into line with radiation in this very arresting feature: that the time which is most appropriate by far for its analytical formulation is a changing local time mixed up definitely, though very slightly, with spacial relations. The value of the new theory is that it opened out a way by which this problem could be attacked, while previously no approach was in sight; and, still more important, that it has not improbably led to an answer, in the affirmative. This, of course, is a very remarkable consummation, comparable to Faraday's detection of an influence of magnetism on light, though more fundamental in that it relates to free space; it must promise substantial advance as regards the formulations on which we construct our ultimate plan of physical activity, either along its present lines or some other that would represent the result with equal approximation. But beyond that the extreme relativist developments, where they are not metaphysical dogmatics, are a very interesting extrapolation towards the possible or probable physical formulation of a universe in which bodies are moving thousands of times as fast as the stars are found to move in our own.

Cambridge, January 17. JOSEPH LARMOR.

The Outlook of British Technical Optics.

THE symposium and general discussion on "The Microscope: Its Design, Construction, and Applications," held in the rooms of the Royal Society at Burlington House on January 14, under the auspices of the Faraday, Royal Microscopical, Optical, and Photomicrographic Societies, in co-operation with the Optical Committee of the British Science Guild, with Sir Robert Hadfield, president of the Faraday Society, in the chair, was a landmark in the history of British optics. Whether judged by the number, value, and variety of the exhibits and the papers contributed, or by the number of people who attended, the symposium was a success.

At the present time the microscope possesses a unique interest for those concerned with British optical industries. It demands greater technical knowledge and skill in its designer and producer than any other optical instrument, and the demand for it, both actually and potentially, for work of the most far-reaching importance is so great that it may fairly be said to be the keystone in the arch of an industry which has already been recognised as one of such vital national importance as to constrain the Government to treat it as a "key industry." But there is no royal road to success even in manufacture and commerce. If this country is ever to stand in the forefront as a producer of microscopes for the world's needs the position to-day must be boldly and courageously faced. The lessons of the war must not be forgotten. We shiver yet when we remember the single thread upon which the production of optical munitions depended in this country. Our glass-makers, beaten by their foreign rivals, receiving neither help, encouragement, nor even recognition from the Government, had been content to continue their patriotic efforts to maintain the industry, on the urgent representations of a few far-seeing scientific men, until long after those efforts held out any promise of pecuniary reward. That danger, happily, has passed, and the complete solution of the optical glass problem is now only a question of time. Many of the glasses now produced in this country compare favourably with the best of those of our foreign rivals. The varieties available are limited, but the leeway is being rapidly made up.

It is often stated that the late supremacy of the Germans in optical production was the direct and necessary result of the glass-making labours of Abbe and Schott completed in the year 1886. This is not a correct statement of the case. The fact is that, when Abbe and Schott broke down the barriers to optical progress imposed by the limited varieties of glass available, Germany had in reserve a small army of scientific workers, equipped with the necessary technical knowledge and skill, ready to fill the breach and carry on the work of utilising the new glasses in the invention of new optical systems and in the improvement of old. But the world moves quickly, and inventions and discoveries, however valuable intrinsically, are likely to remain barren unless a country has a sufficient number of men equipped with the necessary knowledge to exploit them instantly and to the full. Indeed, it is only such men that can appreciate the value of inventions and discoveries. The necessity for a broad and generous scheme of national education in optical matters thus becomes apparent. When the users of optical instruments are sufficiently educated to be able to distinguish and appraise good designs and work, makers will be encouraged to meet their demands. In the absence of such education the faddist has his day, and the maker concerns himself too often in meeting the demands of fashion.

It is satisfactory to know, then, that, so far as this country is concerned, a great deal has already been done to foster optical education. The establishment of the Technical Optics Committee, which includes representatives of the British Optical Instrument Makers' Association, the War Office, the Admiralty, the National Physical Laboratory, the London County Council, the Royal Society, and the Imperial College of Science, is in itself sufficient evidence that the question has been taken up with great thoroughness. The establishment of a department of optical engineering and applied optics at the Imperial College will ensure a supply of capable and well-educated young men for the needs of the industry generally. Prof. Conrady is doing yeoman service in the establishment of an English school of optical designers and computers, the need for which was so acutely felt during the war. The outlook, then, so far as education is concerned, is decidedly promising. Indeed, in some important respects the scheme of education here is already in advance of that of any other country.

When we turn, however, to the purely engineering side—the production of the microscope as a mechanical instrument—the outlook is not so satisfactory. At the present time the Government is pledged to afford protection to the optical industries. This will probably be done by a continuation of the licensing system, which has for the moment been suspended because of Mr. Justice Sankey's decision, but there is little doubt that the system will be reimposed, either by the reversal of that decision or by legislative enactment. Now the public at the present time, with just cause, are very suspicious of anything in the nature of Protection. During the past few years Protection has so often resulted in unscrupulous profiteering at the expense of the community that the public may well be excused for looking with suspicion upon any proposal to continue the system. In the case of the microscope, for example, there is little doubt that at the back of the minds of many people there is a fear that Protection will be taken advantage of by manufacturers to foist upon the market inferior goods at greater prices than could be obtained in a free market. But the symposium has proved conclusively that this danger, in the case of microscopes at any rate, is a very small one. One or two important makers exhibited new models, designed for mass production, which showed clearly how thoroughly and seriously the problem had been taken up. Microscope production in this country is now a young, vigorous, and promising organism, which, in the course of a year or two, will probably be able to stand up and fight its way in the world without artificial support.

The real difficulty at the present moment lies in the fact that efficient production means mass production, and mass production means large enterprises carried on with large capital. Everyone is agreed that production by the old methods, requiring the employment of a large proportion of highly skilled craftsmen—the artistic method—must be replaced by machine methods. Efficient and successful production in the case of the microscope involves, as it does in so many other cases, specialisation, standardisation, and the use of repetition machinery attended by unskilled labour to produce interchangeable parts, the whole of the activities being supervised and directed by the highest technical knowledge and skill. But this involves the speculative investment of capital. The maker, on the other hand, who can ensure a moderate success with little risk by carrying on producing operations on a small scale to meet the immediate needs of the country is under a great temptation to do so rather than risk everything in an attempt to secure large profits by mass production. The present position, therefore, is a serious one for the trade generally. If the mass production of optical instruments is necessary to the success of the industry and to the realisation of the end and aims of the Government, then it is very unlikely that that success will be achieved by Protection alone. Some much more substantial assistance must be given, and this assistance is not likely to be given by private enterprise.

An interesting fact brought out by the papers and discussions at the symposium was the urgent demand for greater resolving power in the microscope. This matter was particularly dealt with by Mr. J. E. Barnard, who showed a very interesting series of slides taken with the ultra-violet microscope to demonstrate the greater resolution obtainable with the shorter wave-length light. The metallographers, on the other hand, in some cases appeared to be insisting upon large magnifications without always clearly recognising that these do not involve greater resolution. The half wave-length limit to resolution, first advanced in effect by Fraunhofer, cannot substantially, at any rate, be evaded, and this fact must be clearly recognised.

Power from the Sun.

WITH reference to Mr. A. S. E. Ackermann's letter in NATURE of January 15, in which he states that, in putting the possible efficiency of obtaining power from the sun with the heat engine at less than 2 per cent., I have used too low a figure, I may point out that, whereas Mr. Ackermann's figure of 4·32 per cent. was a maximum obtained presumably under specially favourable conditions, and as I understand in Egypt, in suggesting a figure of less than 2 per cent. I was referring to what could be expected "in this latitude and in this climate"—that is to say, in England, and also as an average during the hours of daylight throughout the whole year.

For the purpose of my argument, and in comparison with the very much higher efficiencies that are theoretically possible if the radiation can be directly utilised without first turning it to heat, with the consequent avoidance of the second law of thermodynamics, I do not think that the difference between 2 and 4 per cent. is of much importance; but, even so, I should be surprised to learn that Mr. Ackermann would expect to obtain an efficiency of even 2 per cent. anywhere in England throughout the year.

66 Victoria Street, S.W.1, January 17.

Sedimentation of Blood Corpuscles.

I HAVE noticed lately that if oxalated or defibrinated blood is put to stand in narrow tubes, the corpuscles sediment a good deal faster if the tube is inclined than when it is vertical. Thus with tubes about 2·7 mm. internal diameter there were, after 20 hours, 4, 23, 35, and 42 per cent. of clear serum with tubes inclined at 0°, 22½°, 45°, and 67½° respectively. In another rough experiment with tubes of different diameters, all filled to a height of 40 mm. with diluted blood, after 5 hours there were the following proportions of clear serum:—

mm. diam.	Vertical Per cent.	11¼° Per cent.	22½° Per cent.	33¾° Per cent.
2·7	6	20	29	51
8	5	10	15	21
14	4	5	9	12

The phenomenon seems to depend on the *vertical* height of the columns of blood, and it occurs to me that the slight Brownian movement of the lower corpuscles may interfere with the sedimentation of those above. But I should be glad if someone would tell me the explanation: the phenomenon is perhaps well known in some other form. A. E. BOYCOTT.

Medical School, University College Hospital, W.C.

The Einstein Theory and Spectral Displacement.

ONE of the "crucial phenomena" in connection with the Einstein theory is the displacement of the spectral lines towards the red when the emitting atom is in a position where the gravitational potential is large.

In the case of the sun this displacement is so small that its existence is a matter of doubt. But the amount of the displacement varies as the mass of the sun or star concerned, divided by its radius, and in the case of giant stars, such as Canopus, Arcturus, or Antares, should give a result corresponding to a recession of many hundreds, if not thousands, of kilometres per second, whereas, in fact, these stars show no abnormal radial velocities.

It may be pointed out that the effect varies as the product of the area and density, factors as to which the magnitude and spectrum of a star enable astronomers to make a fair approximation, at any rate as to minimum values.

These facts must, of course, have been considered by the supporters of the theory, and I think that an explanation would be interesting and useful.

H. FLETCHER MOULTON.

11 King's Bench Walk, Temple, E.C.

MR. FLETCHER MOULTON is quite correct in stating that the shift of the spectral lines varies as mass/radius, but his expectation of spectral shifts measured by hundreds or thousands of kilometres per second does not appear to be justified. All the evidence available, deduced from visual binaries, Algol variables, and spectroscopic binaries, points to the conclusion that the masses of the stars vary between much narrower limits than their brightness. We have no clear evidence of any star having a mass so great as forty times that of the sun; moreover, the most massive stars known to us are apparently in a much more diffused state than the sun, so that the ratio of spectral shifts is much less than that of masses.

We cannot use individual stars to test the Einstein effect, for we do not know the radial motion independently of the spectroscope, as we do in the case of the sun. All that we can do is to take the mean of a large number of spectra and see whether there is a systematic shift towards the red; such a shift does exist, and the difficulty is rather that it is too large than too small to ascribe wholly to the Einstein effect. Thus Campbell ("Stellar Motions," p. 199) says: "Of Type II. stars (that is, F5 to M), 371 have positive velocities and 352 negative. Of Type I. stars (that is, O to F4), 215 have positive velocities and 122 negative." Subdividing further, he gives the following mean velocities of recession in km. per second: B to B9, 4·93; A, 0·18; A2 to F8, 0·60; G to M, 0·91. Dr. de Sitter, taking the average mass and density of a B star as 10 and 1/10 respectively, finds 1·4 for the Einstein effect, about one-third of the observed quantity.

We do not know the character of the atmospheric circulation in the stars; this, as well as pressure effects, may well have some influence on the mean results. Taking the stars as a whole, it must be admitted that their verdict, though by no means conclusive, is, so far as it goes, in favour of Einstein.

ANDREW C. D. CROMMELIN.

Use of a Prismatic Binocular for Viewing Near Objects.

A FEW years ago, with a view to the observation of close objects out of doors, I procured some glass adapter lenses for use on the object glass of the half of a prism binocular (×12) which I carried about with me. Finding, however, that this method involved the use of several glass adapters, and that with it I had to know the exact distance of my objective, I prevailed on an optician—after lengthy argument, he deeming the experiment impracticable—to remove the eyepiece and refit it for use with a long screw thread. The result was most satisfactory; by this device I can draw out the eyepiece and adjust it to the proper distance for any observation down to four feet off. This device is also very useful for indoor work, such as observation on the occupants of an aquarium.

The device may be useful to other observers, who will find that the necessary alteration can be easily made. D. WILSON BARKER.

Flimwell.

THE NITROGEN PROBLEM.[1]

I.

THE Nitrogen Products Committee was appointed in June, 1916, as a Committee of the Advisory Panel of the Munitions Inventions Department with the following terms of reference:—

To consider the relative advantages for this country and for the Empire of the various methods for the fixation of atmospheric nitrogen, from the point of view of both war and peace purposes; to ascertain their relative costs, and to advise on proposals relevant thereto.

To examine into the supply of the raw materials required and into the utilisation of the by-products obtained. Since some of the processes depend on the provision of supplies of cheap power, to ascertain how this can best be obtained.

To consider what steps can be taken to conserve and increase the national resources in nitrogen-bearing compounds, and to limit their wastage.

To carry out the experimental work necessary to arrive at definite conclusions as to the practicability and efficiency of such processes as may appear to the Committee to be of value, and to advise as to starting operations on an industrial scale.

It will be seen that the terms of reference are pretty wide, and the Committee, as is stated, have, moreover, interpreted them "in a liberal manner." The inquiry accordingly has resulted practically into a detailed examination of the nitrogen problem in its relation to the military, agricultural, and industrial requirements of the United Kingdom and other parts of the British Empire. The Committee submitted an interim report in February, 1917. As the conclusions and recommendations of that report are closely connected with the final conclusions and recommendations of the Committee, they are incorporated in the present report. The final report, with its appendices, charts, and diagrams, is a somewhat formidable document of upwards of 350 pages, the report itself occupying no fewer than 137 pages. It has been somewhat loosely constructed, and there is a certain amount of recapitulation, which was, perhaps, inevitable when regard is had to the many points of view the subject presents. But of its great value there can be no doubt. Considering the difficulty and complexity of the inquiry, it cannot be said to have been unduly protracted, and, as the result of the 106 sittings of the Committee and its Sub-Committees, we have now presented to us the most complete and comprehensive statement of the problem, as it affects this country, which has yet appeared.

The report will doubtless receive the most serious study, for it deals with matters of the gravest importance—the world's production of food, our industrial supremacy, and our national security. Indeed, its appeal is so wide, and the whole question affects so many interests, that there is a fear that no immediate action will come of it, on the principle that what is everybody's business is nobody's business. It is pre-eminently a national question, and demands the consideration of statesmen. But in the present condition of the political and industrial atmosphere we cannot hope that it will receive this. The State will wait upon private enterprise, and private enterprise will wait upon the State, each trusting, like Mr. Micawber, that "something may turn up" to avert the main conclusions to which the report inevitably points. But in view of the menace which will come from a resuscitated Germany, it would be nothing less than criminal folly to neglect the warning which the evidence now summarised conveys. Our chemical manufacturers and our producers of fertilisers must be brought to realise that synthetic nitrogen products have come to say. The days of the Chile nitrate industry are apparently numbered. If we accept the estimates of the Committee, retort nitric acid cannot, even in this country, be produced so cheaply as the synthetic product, and synthetic fertilisers are serious competitors with the natural nitrate and by-product sulphate of ammonia.

It would be impossible in the space at disposal to deal in detail with the many points and issues raised by the Committee's inquiry, and set out at length in the report. We must content ourselves, therefore, with a summary statement of the principal conclusions at which it has arrived.

With respect to the world's demand and production of nitrogen compounds before the war, it is shown that the world's consumption in 1913 was almost double what it was in 1903. The demand up to this time was practically wholly met by Chile nitrate and by-product ammonia, the nitrogen fixation processes contributing only a small, but still growing, proportion, notwithstanding their notable development during the years 1903–13. Up to 1914 the market price of combined nitrogen was governed by that of Chile nitrate, and was characterised by a general upward tendency, showing that the supply was not in excess of the demand. At the same time, synthetic nitrogen products could be placed upon the market at prices which competed favourably with ammonia nitrogen and nitrate nitrogen. That these fixation industries were in a healthy condition was shown by the fact that they had expanded more than 150 per cent. during the period, 1903–13, or more than double the expansion during the same interval of the Chile nitrate industry.

The war has profoundly modified the relative position of the natural and synthetic nitrogen industries. Before the end of 1914 the productive capacity of the nitrogen fixation installations represented 10 per cent. of the world's supply of combined nitrogen; at the present time it is about 28 per cent. The post-war production of ammonium sulphate, both synthetic and by-product,

[1] "Ministry of Munitions of War. Munitions Inventions Department. Nitrogen Products Committee. Final Report." Pp. vi+357. (London: H.M. Stationery Office, 1919). Cmd. 482. Price 4s. net.

is calculated to amount to 39 per cent. of the world's supplies of combined nitrogen, Chile nitrate accounting for about 41 per cent. War developments are now challenging the supremacy of the Chilean industry. The market price of the synthetic products, and of ammonium sulphate, bids fair to govern that of Chile nitrate instead of following it as hitherto. The Committee estimates that the post-war supply of fixed nitrogen potentially available is likely to show an increase of from 30 to 40 per cent. upon the pre-war production, or to be of the order of a million metric tons per annum. It is, however, of opinion that this amount is not greater than would have been the case under normal conditions, to judge from the pre-war rate of growth in consumption. But it is significant that this increase is almost wholly due to the development of synthetic processes. There would seem to be no fear that over-production will be a serious factor in the post-war situation.

As regards the uses of nitrogen products prior to the war, at least 70 per cent. of the world's total supplies of nitrate and ammonia nitrogen was utilised in agriculture. Owing to their comparatively limited employment in this country, and the somewhat conflicting experience of our experiment stations, which, as the evidence presented to the Committee shows, have scarcely given sufficient study to the question, there is no absolute proof, as yet, that synthetic fertilisers are wholly suited to the particular circumstances of this country. The Committee, however, has no doubt as to their utility, and specifically makes mention of the value of nitrate of lime, as now manufactured, and of calcium cyanamide when free from dicyanodiamide, in which opinion it would seem to be supported by the Board of Agriculture.

Dr. E. J. Russell, of the Rothamsted Experimental Station, in a recent paper published in the Journal of the Society of Chemical Industry, states that the results of all published field trials show that the three fertilisers—nitrate of soda, sulphate of ammonia, and cyanamide—when compared on the basis of equal nitrogen content have the following values:—

Nitric nitrogen	100
Ammoniacal nitrogen	97
Cyanamide nitrogen	90

But, he adds, these include cases where the cyanamide nitrogen could have had no proper chance of acting. Cyanamide, he points out, presents the characteristic that it is not at once available for plants, but has to undergo change in the soil whereby ammonia is formed, which afterwards nitrifies. The whole value of the material, therefore, depends on the rate at which the change proceeds. In some soils it goes on rapidly, and here cyanamide is very effective. In others, however, it proceeds more slowly. The production of the ammonia would appear to take place in two stages, the first being purely chemical, and the second bacterial; further, the agent producing the chemical change is not always present in sufficient quantity in the soil. Under better advice, such as is now obtainable, the farmer could be warned beforehand, and the use of cyanamide kept to those numerous cases where it can decompose rapidly and act well. In these circumstances the value of cyanamide nitrogen might rise well above 90, and, what is more important, the risk of failure might be considerably reduced.

Of course, the war made imperative calls upon the nitrogen industries, and these, notwithstanding their expansion, were quite unable to cope with the demands for both explosives and fertilisers. The needs of agriculture were consequently largely set aside, to the great detriment of the world's food supply. The effect has been the almost universal recognition of the vital importance of nitrogenous fertilisers. The difficulties of obtaining them and the consequences which have followed from the shortage have together furnished an object-lesson which the world will not soon forget. The Committee learns that the visible demand for nitrogenous fertilisers is everywhere considerably in excess of the pre-war consumption.

With respect to the relative costs of synthetic and non-synthetic processes, the Committee concludes that under favourable conditions in regard to the cost of power and of raw materials, the nitrogen fixation and allied processes, speaking broadly, stand at a very considerable advantage as compared with non-synthetic methods. It ought to be stated, however, that all its estimates are based upon pre-war prices and factory costs, and it by no means follows that the price of coal and of water-power will advance *pari passu*. A waterfall does not "down tools" like a miner, nor does it attend football matches and go on strike for any or no cause in particular. But still, fallible as the basis may possibly be under present or prospective conditions, the comparison of costs is instructive and significant. The average market price of a metric ton of combined nitrogen in the United Kingdom during 1911–13 was 67*l.* and 66*l.* in the forms of Chile nitrate and ammonium sulphate respectively. The synthetic processes can produce a metric ton of available combined nitrogen at a cost, at the factory, of from 20*l.* to 30*l.* These processes can produce a metric ton of concentrated nitric acid (93 to 96 per cent.) at about half the cost of retort (Chile nitrate) nitric acid. Nitric acid can be produced by the oxidation process from by-product ammonia, even at its highest pre-war price, cheaper than by the old process.

It may, however, be doubted whether any of the synthetic processes, with the possible exception of the arc process in very favourable circumstances, can produce a nitrate fertiliser that would compete with Chile nitrate under conditions that the Chilean industry might be willing to adopt. Whilst improvements in the method of absorbing and recovering the oxides of nitrogen in the arc process are certain to occur, it must not be forgotten that the capital expenditure needed in installing this process is high, and bears a large proportion to the market value of the annual production.

It follows, therefore, from these conclusions that the industrial demand for nitric acid in the future will probably be met by means of synthetic processes. It is conceivable that the marketing of large quantities of synthetic sulphate of ammonia and cyanamide, made in Germany, will influence the future price of combined nitrogen, and may even control it. The Committee thinks that the producers of combined nitrogen may eventually have to face a competitive price of 7*l.* or 8*l.* per metric ton for ammonium sulphate, and 6*l.* or 7*l.* per metric ton for cyanamide. The by-product ammonia industry in this country may thus be seriously menaced. It can scarcely recoup itself by raising the price of the other by-products to any serious extent, and considering the relation of combined nitrogen to the food of the country, public opinion, whilst willing to tolerate, up to a certain extent, the protection of "key" industries, would strongly resent any action which seriously interfered with the productive capacity of the land.

(*To be continued.*)

THE MICROSCOPY OF METALS.

AT the very successful symposium on the microscope organised by the Faraday Society on January 14 in the rooms of the Royal Society, about one-half of the papers presented dealt with the microscopical examination of metals, a striking indication of the importance which this branch of microscopy has now acquired. It was therefore appropriate that the president, himself a distinguished worker in this field, should deal historically with the development of micro-metallography, as well as contributing an original paper to the discussion. Sir Robert Hadfield's introductory address surveyed the history of microscopical invention, and was illustrated by portraits of some of the pioneers in the art—Jansen, Lipperhey, Leeuwenhoek, Sorby, and Dallinger. We were reminded of the fact that, so far back as 1665, Robert Hooke described in his "Micrographia" the appearance of the point of a needle and the edge of a razor, and his faithful drawings of these two objects, revealing most accurately the features which could be observed under a low magnification, are reproduced in the paper. The next instance of the application of the microscope to the examination of metals is that by Réaumur, whose work on steel, published in 1722, contains many drawings of the magnified fractures of iron and steel bars. Such a method, however, gave little information, and did not lead to any further development. In 1808 Widmanstätten studied the structure of meteoric irons by polishing a plane section and heating until the constituents became differentially coloured by oxidation, thus introducing the method now familiar as "heat-tinting." The structure of these irons is so coarse that magnification is unnecessary, but the method gave hints to later workers, of whom Sorby is the chief. The work of Sorby, in view of its great importance, was dealt with by the president in a separate note.

Henry Clifton Sorby, one of those amateur scientific investigators who have contributed so wonderfully to the progress of science in this country, was led to devise the modern method of microscopic petrography by seeing sections of bone, teeth, etc., rendered transparent by affixing one surface to glass and then grinding down to an extreme thinness, as practised by the botanist Williamson. Sorby treated rocks in the same way, and in 1849 he prepared the first rock slice

ever made. By 1851 he had become expert in the new process, and was able to publish his observations of the microscopic structure of limestones. In 1857 he presented to the Geological Society his famous paper on the fluid inclusions in quartz crystals, in which he ventured to draw

2 mm. Apochromat. Structure of fine lamellar and sorbitic pearlite. The steel used in this experiment had the following composition: C 0·84, Si 0·30, Mn 0·45, Cr 1·12, Ni 0·12 per cent.

conclusions as to the conditions under which rocks had been formed in Nature from the examination of the minute quantities of liquid enclosed in the microscopic cavities in crystals. The paper was received without enthusiasm, and even with ridicule, so absurd did it seem to study geological problems on the minute scale of the microscope. Nevertheless, Sorby's conclusions came to be accepted by all geologists, and his paper is now accepted as one of the classics of the science. In 1863 he turned his attention to iron and steel, being led to their study by an examination of meteorites. Just as he had fused masses of silicates artificially in an attempt to solve some of the problems connected with igneous rocks, so he proposed to use the information to be derived from artificial masses of iron and steel for the explanation of the characteristics of meteoric irons. He exhibited sections of iron and steel, and photographs taken from them, at Sheffield and also at the Bath meeting of the British Association in 1864, and even these early photographs, taken, of course, at low magnifications, leave little to be desired in regard to sharpness and beauty. A collection of Sorby's original polished and etched sections of metals is carefully preserved by the University of Sheffield, and was lent on the occasion of the symposium.

Sorby's discovery aroused little interest, and when, in 1877, Prof. Martens, of Berlin, soon followed by Osmond and by Le Chatelier in Paris, began the study of metals with the aid of the microscope, the work of their predecessor had been forgotten. By this time, however, a general interest in the subject had been awakened, and Sorby's important papers in the Journal of the Iron and Steel Institute in 1886 and 1887 met with a more appreciative audience. By employing higher magnifications, Sorby was able to show that the "pearly constituent" of steel, as he had called one of its principal constituents, owing to the mother-of-pearl lustre often exhibited by it, was in reality an aggregate of parallel plates of a soft and a hard material. This discovery placed the metallography of steel on a firm basis, and prepared the way for the complete explanation of its structure when thermal methods were added to those of the microscope. Great as were the services of other investigators, it is to Sorby that we owe, without question, our modern metallographic methods.

Sorby laid great stress on the extension of our knowledge by the use of higher magnifying powers, so well illustrated by his own discovery of the true nature of pearlite. Most metallographic work is done at magnifications not exceeding 500 diameters, but excellent results have been obtained by some workers with magnifications of 1000 and even of 1500 diameters. The minuteness of many metallic structures, especially those of hardened and tempered steels, has made many metallographers wish for a means of applying much higher magnifications. Since the discovery of new detail depends, not on the magnifying power, but on the resolving power of the microscope, it is necessary to increase the latter. This may be effected either by increasing the numerical aperture of the objective, or by shortening the wave-length of the light used for illumination. The numerical aperture can be increased beyond its present maximum only by the use of other materials than glass, a plan which is likely to be adopted at some future time, whilst the use of ultra-violet light, the magnificent results of which in bacteriology were shown at the meeting by Mr. J. E. Barnard, has so far given disappointing results with metals.

A valuable contribution to the study of highly magnified metal sections was made by the third paper under notice, that by Sir Robert Hadfield and Mr. T. G. Elliot. The numerous and very beautiful plates illustrate both the advantages of high magnifications and the pitfalls which have to be avoided if success is to be obtained. For example, a field containing ferrite and pearlite is shown in three photographs, all taken at a magnification of 600 diameters, but with objectives of different resolving power. With a 12-mm. objective, the pearlite is structureless (Fig. 1), and only when a 2-mm. apochromat is used is its minute lamination fully revealed (Fig. 2). Another pearlite has its structure revealed at 1500 diam. (Fig. 4), but becomes much clearer at 5000 (Fig. 5), using the same objective. No further advantage is shown at 8000 diam. The effect of narrowing the aperture too much is shown by the apparent broadening of the cementite lamellæ in the pearlite, the true breadth being seen very clearly when the iris diaphragm is opened sufficiently. The photographs, all of which are remarkably good, may be said to be most successful in the case of pearlitic structures. The structure of martensite at 5000 diam. is not so clearly seen as at a much lower magnification, whilst the minutely granular structures of troostite and sorbite evidently call for a higher resolving power rather than for mere enlargement to indicate their true nature. The paper will serve a most useful purpose in directing attention to the nature of the problem, and perhaps attracting skilled optical workers and physicists to its solution.

C. H. D.

REPORT OF THE CALCUTTA UNIVERSITY COMMISSION.[1]

AT first sight a report in five volumes, each of upwards of four hundred pages, on the Calcutta University Commission would appear somewhat portentous; but anyone alive to the importance of university education in India who makes a study of these volumes will be quickly reconciled to their length and number. For it may be fairly claimed that they contain scarcely a sentence which one would desire to see omitted. The whole report of the Commission, including evidence and appendices, comprises no fewer than thirteen volumes, but we are here concerned only with the first five. Vols. i., ii., and iii. contain a very masterly analysis of the present conditions of education obtaining in Bengal, and vols. iv. and v. the actual recommendations of the Commission.

Although this report ostensibly deals only with education in Bengal, the greater part of it naturally has bearing on our educational systems throughout India. The whole report is a model of style, and bears testimony to the infinite pains and care taken by its editors. The names of the members of the Commission were a sufficient guarantee of its thoroughness and accuracy. The review of the present conditions of education in Bengal constitutes in itself one of the most valuable documents for the student of British rule in India. Reports, annual and quinquennial, have been issued in quantity from the various secretariats in India, but we know of nothing to compare for thoroughness and instructiveness with the chapters under review.

It is, of course, impossible for us in this place to do more than refer briefly to one or two of

[1] Reports of the Calcutta University Commission, 1917–19. (Calcutta Superintendent Government Printing, India, 1919.) Prices: Vol. i., Part i. 3s.; Vol. ii., Part i., 3s. 6d.; Vol. iii., Part i., 1s. 6d.; Vol. iv., Part ii., 2s 6d.; Vol. v., Part ii., 2s.

the many important topics dealt with, but before discussing any of these we may mention that the key to the reforms recommended by the Commissioners is the establishment of a Board of Secondary and Intermediate Education. The object they have in view is to secure the admission of students to the university who are duly prepared for higher studies, and the exclusion of those who are not. Under existing conditions an enormous number of candidates are sent up for the matriculation examination who are totally unfit to enter on university studies.

There are, of course, a number of excellent high schools in Bengal, and especially in Calcutta, but there are a fai greater number of inferior schools. Their inferiority is due in a great measure to the low standard of the teaching staff. English, for example, is often taught by an Indian on a poor salary, who is not really qualified to teach it. As the time approaches for the matriculation examination, a test examination is held in each school, and on the result of that test candidates are allowed to go in for the university examination. A percentage of marks is demanded of students who are allowed to proceed, but the test varies very much from school to school, and owing to the solicitations of parents and other causes there is a tendency to show great leniency, for so important is the prestige attaching to higher English education that to have failed in the matriculation is already regarded as an achievement. All Anglo-Indians are familiar with the claims that are supposed to attach to a man who has failed in the B.A., his value in the marriage-market being far greater than that of a man who has not sat for the B.A. at all.

The main problems, therefore, which the Commission set itself to solve were: (1) how to improve the higher classes of the secondary schools, and (2) how to secure the admission only of qualified students to university courses. Having convinced themselves of the impossibility of exercising full control of all the secondary schools in the province, which would involve an extensive inspectorate and interference with many private enterprises, the Commissioners came to the conclusion that control could be exercised at the stage now represented by the intermediate stage at universities, and they therefore suggest the establishment of intermediate colleges, which should be either attached to selected high schools or organised as distinct institutions. These colleges should be under the immediate control of the Board of Secondary and Intermediate Education, the constitution of which is representative of all classes. The intermediate colleges should afford instruction not only for the ordinary degree courses of the university in arts and science, but also for the medical, engineering, and teaching professions, and for careers in agriculture, commerce, and industry. There should be two secondary-school examinations: the first, approximately corresponding to the present matriculation, to be taken at the end of the high-school stage, at the normal age of sixteen, or, in special cases, at the age of fifteen, and to be known as the high-school examination; the second, approximately corresponding to the present intermediate, but much more varied in its range, to be taken at the end of the intermediate college course, at the normal age of eighteen, and to be known as the intermediate college examination. Success in this examination should constitute the normal test of admission to university courses.

The constitution of the board is, of course, a very important matter. It is to consist of from fifteen to eighteen members, with power to appoint outside members to sub-committees. The president of the board should be a salaried official appointed by Government, of high status. This board will naturally take a good deal of responsibility out of the hands of the universities, which will, however, be represented on it by seven members, for they will define the curricula, not only of the intermediate colleges, but, as naturally follows, also of the high schools; and they will further conduct the two secondary-school examinations which we have mentioned above. This board will also, of course, relieve the Director of Public Instruction of much detail work, without, however, reducing in any way the importance of his department.

Such is the Commission's proposal for improving the system. The Commissioners have also gone very thoroughly into the all-important question of improving the teaching staffs, which is chiefly a matter of finance. In this connection they have made several important proposals, of which the three following are the most important: (1) That facilities should be given for the interchange of teachers between privately managed schools and Government schools; (2) that teachers in Government schools and colleges should be placed upon a professional rather than a service basis; (3) that a superannuation fund should be instituted to replace the existing pension system for future recruits to the profession. This last suggestion, which is based upon the federated superannuation scheme which has been adopted in the home universities, should do much to encourage recruiting for the Bengal educational service.

One of the most difficult subjects with which the Commission has had to deal was the question of the medium of instruction to be used in secondary schools. Although, as is natural, there is a general desire among Indians that their children should be educated on a bilingual basis, there is an overwhelming mass of opinion in favour of English as the chief medium from the intermediate stage upwards. The difficulty is to decide at what stage to begin to use English as a medium, and for what subjects. The Commission is of opinion that the vernacular should be used for instruction throughout secondary schools for all subjects other than English and mathematics. It was convinced that the use of English in secondary schools as a medium is excessive. The Commissioners are, however, "emphatically of opinion that there is something unsound in a system of education which leaves a young man, at the conclusion of his course, unable to speak or write his own mother tongue fluently and correctly."

There is, we are aware, an ever-increasing desire on the part of Indians to see the vernaculars encouraged and developed; for a long time Englishmen also have aimed at fostering the development of vernacular literatures, and post-graduate research in the vernaculars is already a recognised branch of study. But it is, we feel, important to keep distinct the two objects in view, namely, (1) to provide the best education for schoolboys, and (2) to cultivate the vernacular languages.

Space will not permit us to discuss at any length the cognate subject of the teaching of English, but it may fairly be claimed that hitherto university instruction in English has been conducted on unpractical lines. Textual analysis of seventeenth-century literature on the part of students who have not mastered the modern idiom tends to unintelligent cram. What is wanted is the more rapid perusal of standard modern works. Nothing can be more pitiable than to see a class of Indian students taking down verbatim notes (always in English) from a lecturer on such a book as "Samson Agonistes." This is not the way to learn English for practical purposes, which is the main object of all except those who take English as a subject for their degree. It is satisfactory to note that the Sanskrit College and the Madrasahs have received ample treatment by the Commission, and are to be placed on a better footing.

We have not space to deal now with the important proposals of the Commission in regard to the organisation of the University of Dacca, the reorganisation of the University of Calcutta, and their many recommendations in regard to examinations, women's education, medical education, agricultural education, engineering and technological education, and Oriental studies. We can only congratulate the Commissioners on the admirable report they have produced, and express a hope that their main proposal, the Board of Secondary and Intermediate Education, may become before long a practical reality.

E. DENISON ROSS.

NOTES.

ONE of the most useful functions that can be performed in these days of minute specialisation of scientific research is the promotion of meetings at which workers in various fields can discuss subjects of common interest. Since Sir Robert Hadfield became president of the Faraday Society in 1914, fifteen such discussions have been held, the last, of which an account is given elsewhere in this issue, being in the meeting-room of the Royal Society on January 14, in association with the Royal Microscopical Society, the Optical Society, and the Photomicrographic Society. Sir Robert Hadfield and the secretary of the Faraday Society, Mr. F. S. Spiers, are to be heartily congratulated upon the great interest taken in this discussion, the subject of which was "The Microscope: Its Design, Construction, and Applications," and the exhibition of instruments connected with it. There were meetings in the afternoon and evening, and on both occasions it is scarcely too much to say that as many people were unable to find places in the meeting-room as those who filled it to the doors. With characteristic generosity Sir Robert Hadfield entertained a large company to dinner at the Ritz Hotel between the two meetings. The whole session was most successful and encouraging to all who are interested in the advance of British optical science, both theoretical and applied. By organising such joint meetings the Faraday Society is indeed promoting the best interests of both science and industry, and doing what might be undertaken even more appropriately by the Royal Society itself.

AN interesting pamphlet on the work of Faraday and the Faraday Society was prepared by Sir Robert Hadfield in connection with the joint discussion on the microscope held on Wednesday, January 14. It appears that the Faraday Society was chiefly responsible for the appointment of a special Nitrogen Products Committee by the Munitions Inventions Department, and this Committee was, in turn, instrumental in establishing a research department, which provided much valuable information for the practical consideration of sources of nitrogen supply when the submarine campaign made the subject a matter of national concern. One of the members of the council of the society, Dr. J. A. Harker, was entrusted with the direction of this work, and the final report of the Nitrogen Products Committee, which has just been published (Cmd. 482, 4s. net), is a most substantial survey of the position of supplies of nitrogen compounds and the practical problems involved in the establishment of processes for nitrogen fixation in this country. Referring in the pamphlet to his own particular lines of work, Sir Robert Hadfield mentions that Faraday, in his experiments on alloys of iron with other elements carried out in 1821 and 1822, was the pioneer of the great technical advances which have been made in alloy steels during the past thirty years. It was Sir Robert's own discovery and invention of manganese steel in 1882 which led others to explore the rich field first entered by Faraday, and has resulted in the production of chromium steel, silicon steel, nickel steel, tungsten steel, and many other types.

THE recent death of Dr. John Wilson, lecturer in agriculture and rural economy in the University of St. Andrews, robs the University and science of a keen and brilliant agricultural biologist. Dr. Wilson was one of the few who regarded agriculture as a sister science of biology rather than as a branch of chemistry, and his work on the improvement of farm crops has borne excellent fruit. Whilst demonstrator in zoology he devoted considerable attention to the development of the common mussel, and published an elaborately illustrated memoir on the subject, but his name will be more permanently associated with his successful investigations on the improvement of such plants as the potato, turnip, and oat. He raised an enormous number of new varieties. Amongst those of the potato were many of exceedingly fine quality and disease-resisting properties, and they have been taken up by growers all over the country. His most successful varieties in this connection were perhaps Templar, Bishop, and Rector. Dr. Wilson's experimental work on oats was equally successful, and he was hoping shortly to place on record a full account of his investigations. Many other plants at different times claimed his attention with equally interesting results. Handicapped by lack of means and assistance, he never spared himself. His unflagging enthusiasm and remarkable energy deserved better and more liberal support, and had it been forthcoming there is not the slightest doubt that the nation would have greatly benefited by his researches.

FATHER JOHANN NEPOMUK STRASSMAIER, S.J., the distinguished Assyriologist, who died on January 11 at the Jesuits' Church, Mount Street, London, W., was born in Bavaria in 1846. Soon after the beginning of Bismarck's *Kulturkampf* against the Catholic Church in Germany, Strassmaier left his native land in 1872 and came to England, where he remained for the rest of his life. From his early youth he had been deeply interested in Oriental studies, and in London his attention was soon directed to the numerous Babylonian tablets in the British Museum, which had not yet been interpreted and translated, and among which were many astronomical texts. Strassmaier was fortunate enough to become associated with Father Epping, S.J., who undertook the necessary calculations and the scientific discussion of the texts interpreted by Strassmaier. The first results of their labours were published in a book, "Astronomisches aus Babylon" (1889), which was followed by several papers in the *Zeitschrift für Assyriologie*. They showed clearly that the astronomers of Babylon during the two or three centuries before Hipparchus (if not earlier) possessed a considerable amount of accurate knowledge of the motions of the sun, moon, and planets. Epping died about 1895, but some years later his work was taken up by Father Kugler, who published his "Babylonische Mondrechnung" in 1900, and began to issue his great work, "Sternkunde und Sterndienst in Babel," in 1907. Kugler repeatedly bore testimony to the great patience and skill of Strassmaier in deciphering many text, which but for him might have remained unread for ever, as they were gradually deteriorating owing to damp and other climatic influences.

THE Lord President of the Council has approved the appointment of Col. Sir Frederic Nathan, K.B.E., late R.A., to be Power Alcohol Investigation Officer under the Fuel Research Board of the Department of Scientific and Industrial Research. The appointment of the Power Alcohol Investigation Officer has been made as a result of the consideration given by the Committee of Council for Scientific and Industrial Research to the report of the Interdepartmental Committee on the Production and Utilisation of Alcohol for Power and Traction Purposes, which recommended the establishment of a small permanent organisation under the Department of Scientific and Industrial Research to continue investigations into these problems. The Fuel Research Board proposes to begin by bringing the work already being done as regards both the production and the utilisation of alcohol into proper focus. Sir Frederic Nathan, who before the war was Superintendent of the Royal Gunpowder Factory at Waltham Abbey, and later works manager of Messrs. Nobel's Explosives Factory, Ardeer, was the officer in control of alcohol under the Ministry of Munitions during the war, and chairman of the Production Section of the Interdepartmental Committee referred to above. Prof. Pierce Purcell, who was Secretary of the Irish Peat Inquiry Committee, has also been appointed to act as Peat Investigation Officer under the Fuel Research Board. The duties of the Peat Investigation Officer will be to keep the Board informed of all progress in connection with research into the utilisation of peat, to continue and extend experiments on the mechanical cutting and winning of peat, and to make arrangements for careful tests of the use of peat as a fuel under boilers.

PROF. R. T. LEIPER, reader in helminthology in the University of London, has been awarded the Straits Settlement gold medal by the Senate of the University of Glasgow. The medal was founded some years ago by Scottish medical practitioners in the Malay States, and is given periodically to a graduate in medicine of the Scottish universities for a thesis on a subject of tropical medicine.

THE council of the British Medical Association is prepared to consider an award of the Middlemore prize (value 50*l.*) and an illuminated certificate for the best essay on "Perimetry (inclusive of Scotometry): Its Methods and its Value to the Ophthalmic Surgeon." The competing essays must reach the Medical Secretary of the Association, 429 Strand, W.C.2, on or before April 30 next.

MR. C. T. KINGZETT writes to suggest that airmen rising to great altitudes should carry bottles of water which, by being emptied at such heights, could then be sealed, and would enable samples of the air there to be secured for purposes of analysis. The late M. Teisserenc de Bort obtained specimens in this way and had them analysed, but found no difference from normal air. His specimens were obtained from registering balloons beyond the reach of any manned balloon or aeroplane. Glaisher no doubt also obtained air from the highest points he reached in his ascents about 1862.

THE death of Mr. Alexander Izat on January 2 is announced in *Engineering* for January 16. Mr. Izat joined the Indian Public Works Department in 1863, and had much to do with the development of the Indian railways. For several years he was on the Legislative Council of the Lieutenant-Governor of the United Provinces; he was made a Companion of the Indian Empire in 1898, and served for several years as a member of council of the Institution of Civil Engineers. At the time of his death he was in his seventy-sixth year.

WE learn with regret that Prof. George Macloskie, professor of biology, Princeton University, U.S.A., died on January 4 in the eighty-fifth year of his age. Prof. Macloskie was born at Castledawson, Ireland,

and educated at Queen's University, Belfast, from which he received degrees in both law and theology. During his student days he was twice a gold medallist of the college. He was called to Princeton in 1875, during the administration of President McCosh. Since 1907 Prof. Macloskie had been professor emeritus of biology in Princeton University. He is best known for his work on the flora of Patagonia.

THE *Times* of January 21 contains the following announcement with reference to the Dartmoor hydro-electric supply scheme:—"In deference to the opposition from the Duchy of Cornwall and the Devon County Council, the promoters have decided to drop that part of the Hydro-electric Bill by which they sought to utilise Dartmoor water for generating electricity. They will modify the Bill to restrict their powers to erecting overhead mains for supplying to consumers such surplus power beyond the requirements of their proposed copper-refining industry in mid-Devon, which they produce from lignite beds they intend to develop."

STRONG earthquakes continue to be felt in Mexico. At La Fragua, in the State of Puebla, shocks have been almost continuous since the great earthquake of January 3. At Coatzlan, another shock occurred on January 9, by which the destruction of the town was completed. San Joaquin, a village of 3000 inhabitants in the State of Vera Cruz, was destroyed by an earthquake on the morning of January 12. On January 8 the volcano of San Miguel, 35 miles north-east of Cordoba, broke into eruption; streams of lava flowed down the south-east side of the mountain, destroying villages and ranches.

ACCORDING to the Bulletin of the Science Division of the Royal Academy of Belgium for March, 1919, at the meeting on March 1 it was decided:—(1) To break off relations and exchange of publications with the scientific societies of Germany, Austria, Hungary, and Turkey. (2) To employ only booksellers to procure such publications as shall be considered strictly necessary, whatever be the additional cost involved. (3) Not to send any publication to the men of science of the above nations. (4) To decline and return to the societies or authors of the above countries any publications sent to the academy.

AN interesting interview with Prof. Einstein appeared in the *Daily Chronicle* of January 15. A German by birth, Prof. Einstein went to Switzerland in his early youth, where he became naturalised. For some years he was professor of physics at the Federal Polytechnikum in Zürich, and for a short time also at the University of Prague. Shortly before the outbreak of war he was "called" to the University of Berlin, where he is still working, being at the same time director of the Kaiser Wilhelm Institute for Physical Research. Now little more than forty years of age, this eminent man of science conceived the outlines of the theory of relativity at the early age of eighteen, and presented his special theory to the scientific world at the age of twenty-seven. Prof. Einstein regards Prof. Lorentz (Leyden) as his "co-operator" in the special theory of relativity. He points out that, far from vitiating the results of Newton, the theory of relativity rather enhances the greatness of this genius. Though these new ideas will not overthrow the general conceptions of mankind, they will leave their impress on men's thinking in the philosophical and allied sciences.

FOR some years there has been a vigorous Phytopathological Society in the United States, and recently a Canadian branch of this has been formed, the first annual meeting being held in Ontario. Dr. A. H. R. Buller, formerly of Birmingham University, and now professor of botany in the University of Manitoba, was elected president for 1920. Dr. E. C. Stakman, of Minnesota, was the guest of the society, and gave an account of the very valuable investigations which he and his colleagues have carried out into the races of cereal rust fungi and their bearing on the problems of immunity and susceptibility to disease. Among the attractive list of papers presented to the meeting, those of Mr. J. E. Howitt on "Leaf-roll and Mosaic of Potatoes" and of Mr. Paul A. Murphy on "Diseases of Potatoes which Cause the Running Out of Seed" may be mentioned. Both are welcome additions to our very meagre knowledge of extremely obscure subjects of primary importance. There is in this country no society devoting itself exclusively to phytopathology, and perhaps this is well, for we possess already more than enough small specialised organisations running a precarious separate existence. The need is not for increase in their number, but for some kind of amalgamation or federation of those now existent. The study of diseased crops is merely one branch of applied biology, and this subject is excellently catered for by the Association of Economic Biologists, which performs valuable work in synthesising all the many aspects of investigation which centre round the economic utilisation of plants.

POWELL's classification and map of the linguistic families of America allotted twenty-two families, or parts of families, to California. This classification has hitherto been generally accepted. But in recent years the study of these dialects has been fully investigated by Messrs. R. B. Dixon and A. L. Kroeber; the results of their work being now published in the University of California Publications in American Archæology and Ethnology (vol. xviii., No. 3, September, 1919). It has now become possible to regroup these dialects into seven main groups. The most important of these are the Penutian in the north-western region and the Uto-Aztekan to the south-west. The remaining language-groups form a sort of fringe round the two greater groups, the most important being the Hokon, and of less extent the Algonkin, Athabaskan, Yokian, and Lutuamian. Full grammatical details on which this new classification is based are given by Messrs. Dixon and Kroeber.

MR. J. W. GOWEN has made (*Genetics*, May, 1919) a biometrical study of the phenomenon of heredity known as crossing-over, basing his conclusions on extensive data derived from the behaviour of the Mendelian factors in the third chromosome of *Drosophila melanogaster*. It is shown that double crossing-over is an extremely variable phenomenon. The reduplication hypothesis is regarded as definitely disproved, and all detailed interpretations are based upon the structure of the chromosomes. Crossing-over between two fixed points on a chromosome is found to be highly variable. It is also found that a change in genes between two fixed points in the third chromosome slightly disturbs the ratios of crossing-over between those points. Biometric analysis shows that the results are all in harmony with the hypothesis that the factors are represented by particles arranged along the chromosomes. A cross-over in one region of the chromosome is more likely to be accompanied by a cross-over 25–35 units away than elsewhere.

Vol. ix. of the *Bulletin Statistique* has just been published by the International Council for Fishery Investigations. Particular interest attaches to this report, as it deals with the year 1913, the last of a long series during which there has been a continuous, progressive development of the sea-fishing industry in North European countries, and vol. ix. is likely to remain a standard of comparison of two periods, in the interval between which many conditions will be found greatly to have changed. The council has in preparation a Bulletin describing the effect of the war upon the fisheries, and this, it is hoped, will soon be ready. Several changes have been made in the arrangement of the present volume; the use of two languages has been dropped, and the results are now published only in English. There are many useful diagrams. A feature of exceedingly great interest, the estimation of the capital employed industrially, in factories, curing works, etc., in 1913, as well as in the vessels, might be included in the next volume as a help to the understanding of the great change in economic conditions that is now taking place.

The Tôhoku Imperial University, Sendai, Japan, continues to publish beautifully illustrated memoirs on fossils in the geological series of its Science Reports. In the latest part received (vol. v., No. 1), Mr. I. Hayasaka describes the microscopical structure of three Permian species of the remarkable sponge Amblysiphonella from Japan and China. Prof. H. Yabe also illustrates in three fine plates the microscopical structure of a Tertiary foraminiferal limestone from Borneo.

The United States Geological Survey has published Professional Papers Nos. 112 and 120, dealing respectively with Cretaceous plant-remains from Tennessee, Mississippi, Alabama, and Georgia, and Cretaceous fish-scales from various American localities. The plant-remains, described by Dr. E. W. Berry, are chiefly leaves of dicotyledons, and represent a lowland coast flora. The sudden appearance of dicotyledons as the dominant plants in Middle Cretaceous times is still a mystery, and Dr. Berry thinks this modern flora may have originated in the Arctic regions. The description of the fish-scales by Prof. T. D. A. Cockerell is a bold attempt to use fragmentary fossils in stratigraphical geology.

Part iii. of vol. iv. of the Records of the Geological Survey of India, which has just reached us, contains a review of the mineral production of India during 1918. Upon the whole the position is satisfactory, most of the important minerals showing an increased production. Thus the coal output rose from 18,212,918 to 20,721,543 tons; it is worth noting that the most substantial increases are shown in the important coalfields of Jharia and Raniganj, which produced respectively 52·85 per cent. and 30·74 per cent. of the total Indian output. The output of iron ore, too, increased, namely, from 413,273 to 492,484 tons, most of which was smelted in the works of the Tata Iron and Steel Co. and the Bengal Iron and Steel Co.; the latter produced also 12,114 tons of ferro-manganese during the year under review. There was a large increase in the production of chromite, mainly through the development of some recent discoveries in the State of Mysore. The output of manganese ore, on the other hand, fell from 591,000 to 518,000 tons, the falling off being probably caused by the difficulties of procuring the necessary shipping facilities. The Bawdwin mine in the Northern Shan States again shows an increase of output, namely, 19,074 tons of lead and 1,970,614 oz. of silver, as against 16,962 tons of lead and 1,580,557 oz. of silver. Gold, on the other hand, declined somewhat, namely, from 574,293 oz. to 536,118 oz. The falling off under this head has, of course, a far less effect upon the prosperity of India than has the increase noted under such minerals as coal and iron, which contribute essentially to the industrial development of the country.

The oscillations in the luminosity of incandescent electric lamps illuminated by alternating currents forms the subject of a short report by Dr. Luigino Fabaro in the *Atti dei Lincei* (xxviii. (1), 7, 8). The phenomena had been previously studied by Prof. Corbino, and the present experiments refer mainly to certain recent types of lamp. Diagrams are drawn showing the relation between the fluctuations of intensity and those of the electromotive force, and, at the same time, the difference of phase between the luminosity and the exciting electromotive force. These are in conformity with the theory that the effect can be reduced by increasing the mass of the filament.

From the Laboratorio di Ottica pratica e Meccanica di Precisione we have received the first numbers of a new periodical, *Rivista d'Ottica e Meccanica di Precisione*. Hitherto Italy has not had a technical periodical on the lines of the German *Zeitschrift für Instrumentenkunde*, and the new journal is a modest attempt to fill the want. Like other countries, Italy has made great progress in the construction of optical and other scientific instruments during the war, and the need for a medium in which matters of interest to practical optical workers can be discussed is now being felt. The November–December number contains articles on Galileo and the pendulum clock, the application of interference methods over simple observations with the naked eye, the first instalment of a paper by P. G. Nutting on "Dispersion

Formulæ for Optical Glass," and a description of the focimeter of the Royal Precision Laboratory, as well as a selection of abstracts from foreign periodicals.

IN an article entitled "The Æther *versus* Relativity" in the January issue of the *Fortnightly Review* Sir Oliver Lodge contends that as the current ideas that the æther is an infinitely extended uniform medium as a whole at rest, and that absolute motion is to be measured with respect to this æther, are simple and straightforward, they should be retained so long as no clear proof that they are false is forthcoming. The new theories express the facts of experience in other terms, but they attribute the property of wave-transmission to geometrical space free from any medium, and are, in consequence, repugnant to those "with a competent faculty for rational philosophising." Sir Oliver Lodge urges the desirability of comparing the speeds of light along and against a strong magnetic field as a promising means of determining the density of the æther. Such a result would entirely discredit the theory of relativity as a statement of real fact.

A REPORT on the general theory of blade-screws, forming Report No. 9 of the American National Advisory Committee for Aeronautics, has been drawn up by Mr. George de Bothezat, of Dayton, Ohio (Washington: Government Printing Office, 1919). In a problem like the present, in which the conditions are far too complex to admit of an exact hydrodynamical solution, any theory necessarily involves assumptions which at best are only approximate. The author applies elemental methods, first, to the slip stream, and, secondly, to the region surrounding a blade element, and, in common with many previous investigations, neglect of the effects of radial motion is one of the assumptions made in a first approximation. The theory appears to constitute an advance on previous investigations, especially in the matter of a detailed examination of the elements of fluid, and the author is very careful in stating the assumptions on which the work is based, and the justification for which will necessarily depend on comparison of the results with those of experiment. An appendix deals with the geometry of screw-blade drawing. The method appears to neglect compressibility, and will therefore be applicable to air-screws of which the tip velocity does not come too near the velocity of sound.

AN important paper on radio-transmission and reception by Mr. J. H. Dellinger has been published by the Bureau of Standards, Washington. The difficulty experienced by practically every man of science in understanding the ordinary radio theory is in mastering the proof of the formula which gives the magnetic force at a distance from the sending antenna in terms of the wave-length of the radiation. He objects to accepting it without proof, and he has not time to puzzle out the intricate theory given by Hertz. Mr. Dellinger gives a rough proof of this formula based on well-known laws. This formula being accepted, the rest of radio theory follows very simply. The formula has been tested in practice many times, and found accurate within a small percentage of error. The author makes a theoretical comparison of the relative values of antennæ and closed coils for sending and receiving purposes, and it is shown how the limitations of each follow directly from theory. Although the theory is sufficiently accurate to be a great help in the design of radio stations, yet the necessity for further research, both experimental and theoretical, is urgent, and a long list of such researches is suggested. To everyone desiring a knowledge of the practical theory of radio communication this paper can be recommended.

THE lot of the inventor is always hard unless he is exceptionally placed, and combines commercial with inventive ability. *Engineering* for January 9 points out two ways in which it is becoming increasingly difficult. Experiment is becoming much more costly, and at the same time the protection afforded by the patent laws becomes less and less. Nevertheless, the essential importance of invention from the national point of view is now recognised, and research laboratories are being set up which are to afford every facility for experiment. The success of this movement depends upon getting the inventors into the laboratories, and upon their doing their best work when they are there. But we find that men entering these laboratories are being required to sign away all rights of every kind to any invention they may make. They are to rely solely upon a reward at the discretion of the firm. Our contemporary suggests that a research laboratory should be an independent organisation, financed by the parent firm, but receiving royalties on a liberal scale to be divided among its members by agreement among themselves, and also hints that it may be useless to put forward such a scheme. Apart from the fact that the British business man feels that he is less and less "master in his own house," there is the other point which appeals to research workers, viz. victimisation; he may find himself no longer required in the laboratory, and, after his discharge, may look in vain for his share of the royalties.

Engineering for January 9 contains an article on works management by Mr. F. C. Van Dyke, which will be found to give a very clear discussion of the principles involved. There is a growing tendency to demand that the works manager should be a college-trained engineer, but it is essential that he should have the same practical and varied engineering experience as is required from the self-made man; whatever may have been his initial training, however, mere opportunity without fitness will not produce the successful works manager. The requirements as regards his principles and education may be summarised as consisting essentially of organisation, foresight, co-ordination, supervision or control, and diplomacy. A works manager should recognise that, notwithstanding scientific effort and research, the efficiency given by plant and machines is regulated by human effort, wasteful by instinct, and that to obtain the reduction of such waste it will be necessary to save lost efforts, so that the recovery of waste may add new resources to the community. He must also understand that science in industry will generally be resented by the average worker. Owing to the workers' insufficient knowledge of the economics ruling industry, he believes that the extra profit thereby derived passes to the employer without relative advantage to the worker, and that the efficiency of employees penalises others by unemployment; hence scientific improvements must be introduced with foresight and tact.

AMONG forthcoming books we notice the following: "Wireless Telegraphy, with Special Reference to the Quenched-spark System," B. Leggett; "Aeronautical Engineers," Major A. Graham Clark; "Theory and Practice of Aeroplane Design," S. T. G. Andrews and S. F. Benson; "Physical Chemistry of the Metals," R. Schenk, translated by R. S. Dean; "Manufacture and Uses of Alloy Steels," H. D. Hibbard; and "Mathematics for Engineers," W. N. Rose, vol. ii. (*Chapman and Hall, Ltd.*); "The Principles of Anatomy as Seen in the Hand," Prof. F. Wood-Jones, illustrated; "A Text-book of Organic Chemistry," E. de Barry Barnett, illustrated; and "Laboratory Manual of Elementary Colloid Chemistry," E. Hatschek, illustrated (*J. and A. Churchill*); "Coal Economy: For Steam Users, Engineers, Enginemen, Boiler Firemen, etc.," W. H. Casmey, and "The Mineralogy of the Rarer Metals," Cahen and Wootton, second edition (*C. Griffin and Co., Ltd.*).

THE new list of announcements of *Mr. John Murray* contains many books of scientific interest, *e.g.* "Science and Life: Aberdeen Addresses," Prof. F. Soddy; "Springtime, and Other Essays," Sir Francis Darwin, illustrated (this week); "Splendours of the Sky," Isabel M. Lewis, illustrated; "Conifers and their Characteristics," C. Coltman-Rogers, illustrated; "Life of Sir William White, K.C.B., F.R.S.," F. Manning, illustrated; "New Light on Ser Marco Polo," Prof. H. Cordier (a supplement to Sir Henry Yule's "The Book of Ser Marco Polo"); "The Shibboleths of Tuberculosis," Dr. M. Paterson; "Wild Life in Canada," Capt. A. Buchanan, illustrated; "The Heron of Castle Creek, and Other Sketches of Bird Life," A. W. Rees, with a memoir of the author by J. K. Hudson, illustrated; volumes dealing respectively with Hides and Skins, Rice, and Oil Seed (in the Imperial Institute Reports on Indian Raw Materials), and "Tungsten Ores," R. H. Rastall and W. H. Wilcockson (in the Imperial Institute Monographs on Mineral Resources); also new editions of "The Interpretation of Radium and the Structure of the Atom," Prof. F. Soddy, illustrated; "Microscopy: The Construction, Theory, and Use of the Microscope," E. J. Spitta, illustrated; "Hydrographical Surveying," the late Rear-Admiral Sir W. J. L. Wharton, revised, etc., by Admiral Sir Mostyn Field; "The Soil," Sir A. D. Hall; and "The Small Farm and its Management," J. Long.

OUR ASTRONOMICAL COLUMN.

LARGE FIREBALL ON JANUARY 16.—In the evening twilight of January 16, at 4h. 50m., a fireball was observed from London and other places in the Eastern Counties. It gave a brilliant flash and left a luminous trail which assumed curious forms during fully 5½ minutes. The observations already received of this object are not sufficiently exact or numerous to allow the real path to be trustworthily determined, but the meteor probably had a radiant in Cygnus at about $290° + 53°$, and was situated over Lincolnshire. We hope to give more details next week.

In recent years January has proved itself a month in which fireballs are notably abundant. In 1895, on January 16, three large fireballs were observed, and the period from January 12 to 17 seems to have been unusually productive of these brilliant objects.

PROF. W. H. PICKERING'S LUNAR STUDIES.—Prof. W. H. Pickering has for many years made careful studies of various regions of the moon during the whole period of their illumination by the sun. He has traced several cases of notable changes of relative illumination of adjacent regions, some growing brighter, others darkening, as the sun rises higher. *Popular Astronomy* for November contains a number of drawings and photographs of the crater Eratosthenes. The author suggests that the white regions are snow, and the dark regions some low form of vegetation. He imagines that a limited amount of water may remain in certain regions, being held in the soil by capillary attraction. It seems, however, that the phenomena might be otherwise explained by neighbouring regions being formed of different kinds of rock, or even by their being of different degrees of smoothness. Observations of occultations made on the dark limb show with certainty that no refraction occurs exceeding $1''$; those made on the bright limb are less precise, but even there the greatest admissible refraction is some $4''$. Comparing this with the $68'$ of a tangential ray in our atmosphere, we see how exceedingly rare any lunar atmosphere must be. The suggestion of vegetation is perhaps not absolutely impossible, but presents grave difficulties.

With regard to the suggestion made in a publication of the Smithsonian Institution, Washington, D.C., of a rocket to reach the moon, irresistibly recalling the well-known romance of Jules Verne, it seems clear that the propulsive effect of the escaping gases must be trifling beyond the atmosphere. A velocity of seven miles per second would therefore be required at the limits of the atmosphere, and considerably more evidence is needed before this can be admitted as attainable.

THE SOLAR ECLIPSE OF MAY 29, 1919.—The January number of *Conquest* contains an article by Mr. C. R. Davidson, one of the observers of the eclipse at Sobral, Brazil. It is illustrated by many views of the locality, eclipse camp, and instruments, and gives a clear statement of the problem which the expedition was sent to solve, and of the successful result. A deflection of light amounting to $1{\cdot}98''$ at the sun's limb was indicated by the measures, which is close to the value $1{\cdot}75''$ predicted by Einstein. Photography of the corona and prominences was not part of the aims of the expedition; indeed, the author points out that if the observers could have dispensed with these they would gladly have done so, since they veiled some stars near the sun that would have been very useful. However, a good record of the corona was obtained. Its shape is a blend between maximum and minimum types; it would conform more closely to the latter, save for a large streamer at the South Pole. Mr. Davidson and Mr. Woodman directed attention, at the meeting of the R.A.S. on January 9, to the advisability of repeating the observations, with still greater refinement, at the eclipse of September, 1922. They exhibited a model of a simple form of equatorial mounting, suitable for low latitudes, which would obviate the necessity for employing cœlostats. These are admirably adapted for physical researches, but have some defects in a case where extreme precision of position is required.

SYMPOSIUM ON THE MICROSCOPE.

THE symposium and general discussion on the microscope, held on January 14 by the Faraday Society, the Royal Microscopical Society, the Optical Society, and the Photomicrographic Society, in conjunction with the Optical Committee of the British Science Guild, attracted a very large audience, which the meeting-room of the Royal Society proved quite inadequate to accommodate. The objects of the symposium, as stated by Sir Robert Hadfield in his introductory address, were:—

(*a*) Improvement in the technique of the microscope itself, including its manufacture.

(*b*) Improvement in lenses, including eyepieces and objectives of high power.

(*c*) Improved application of the microscope for research in ferrous and non-ferrous metallurgy.

With such extensive ground to be covered it is not surprising that the programme of papers presented was much longer than could possibly be read during the meeting. Many of these were of great interest, and, as the majority were in type before the meeting, the aims of the symposium might perhaps have been more fully achieved had these been taken as read and the time thus saved utilised for discussion. It will only be possible in the space available for this article to record a few of the more salient points brought forward at the meeting.

Sir Robert Hadfield, who was in the chair, opened the afternoon session by giving a brief history of the microscope and its applications in metallurgy down to the present day. In addition, he contributed papers on the Faraday Society and on the work of Sorby, a bibliography of the chief literature relating to the microscope, and a series of photomicrographs of steel and iron sections at magnifications ranging from 9 up to 8000 diameters. He was followed by the presidents of the various participating societies, by microscope manufacturers, and by other prominent workers, who each dealt with some special aspect of microscopy. Prof. Cheshire indicated the importance of microscope production as a measure of the standing of the optical industry of any country. Other speakers touched on ground which was to a considerable extent traversed by many other contributors. On one subject, at any rate, all the speakers were agreed—the necessity for proper training in the use of the microscope, whether for visual or photographic use. This will be clearly realised by those who note how frequently those with extensive experience in microscopical research refer to the importance of securing proper conditions of illumination. The absence of proper courses in this subject was compared by Sir Herbert Jackson with the very thorough courses now available in spectroscopy. That instruction is needed in our universities in the use of the microscope and in the interpretation of the effect seen—nay, more, in the proper appreciation of optical theory itself—was proved beyond any doubt to the meeting.

Compared with the unanimity on the need for education, there were very marked divergences in the views expressed by nearly all the speakers on detailed matters. Consider, for instance, the desirability of obtaining increased magnification with greater resolving power. Many of the most experienced metallurgists who expressed their views anticipated that any considerable increase in resolving power would be likely to afford clues to some of those problems which to-day are most baffling in the production of metals with specific properties. It is suggested, for instance, that with improvements in the resolving power the mysterious alterations in the mechanical properties of metals brought about by cold working would be explained. The papers abound with examples of the valuable information that has been derived from past increases of aperture; nevertheless, some workers are satisfied that further advantage in this direction is not to be expected, and it is even suggested that the N.A. of objectives has already been increased too greatly.

The same extent of disagreement was shown in discussing the relative merits of British and German stands and lenses. For some purposes, at any rate, very experienced workers give decided preference to the English stand, though this is said to be less convenient for metallurgical work. No stand now made, it was said, is sufficiently rigid to enable the microscope to be changed from the vertical to the horizontal position without disturbing the relative adjustment of the specimen and the optical system. Modern designers were recommended to study Powell's model of 1841 as an admirable example of what is required. One important criticism was to the effect that the materials employed by the British makers were too soft, particularly for such working parts as the racks and pinions, with the result that after a few years all the movements were too loose. In this respect German instruments had been found more satisfactory by some workers, though this was not the experience of all.

As regards objectives, it was not denied that the best home-made products were fully as good as those made abroad, but it was contended that this standard of excellence was reached in a smaller proportion of the objectives produced than in the foreign lenses. The importance of a highly trained test-room staff was emphasised in this connection. It may be noted as a point of interest, mentioned by Mr. F. Twyman, that good objectives have been found to show differences of phase in the emergent wave-front of about one wave-length.

During the meeting it was announced that one or two makers would shortly place upon the market new designs of objectives made from English glasses. It is satisfactory to learn that the different varieties of glass required for these objectives have been produced in this country. To determine how these glasses compare with the German lenses of Zeiss, a committee of expert microscopists was appointed to investigate and issue a report. In view of what was said regarding the general standard reached, it would be as well if this proposal were carried a step further, and it became customary for manufacturers to issue with their objectives a certificate issued, say, by the National Physical Laboratory. If the required standard for a certificate were maintained at a reasonable level, with due regard to periodical improvements, such a system should go far to remove the impression that it is *necessary* to go to Germany for a thoroughly good objective.

There are many other points to which attention might be directed, but for these reference must be made to the printed papers. The apparent lack of enterprise on the part of the manufacturer since the war has, however, been fully explained. He has been busy for the first time in making arrangements for the mass production of microscopes by modern machine methods. This is of the first importance, for in the past few years nearly all the microscopes required for biological work—and this covers possibly as much as 90 per cent. of all microscopes made—have been imported. The hand-made English instrument could not possibly compete either in price or in quality with the machine-made article. Should it be possible to regain a large share of this trade while retaining the best features of the more expensive and elaborate models, the future position of the industry in this country will be assured. It is to be hoped that this development will not be hindered, as was suggested, by lack of capital.

Perhaps the most significant and satisfactory feature of the symposium is that it should have been possible to attract for a meeting which extended from 2.30 to 10.15 so large an audience for the discussion of the microscope and its applications to industry. It is more than doubtful if such interest could have been aroused before the war. The optical industry of the country, it is clear, will not fail to establish itself on a secure footing for want of a market. If the home products reach the necessary standard of perfection and keep abreast of the advances which scientific achievement in whatever field renders possible, the reward is certain. This, we are convinced, needs much more systematic investigation in advance of immediate requirements than has been undertaken in the past, greater readiness to be guided by scientific principles rather than by tradition, and not least the design of instruments with special reference to the accuracy obtainable in the various manufacturing operations by the best machine tools. It is a hopeless enterprise with one scientific adviser to attempt to compete with another firm of similar size which employs twenty such advisers. At present such assistance is difficult to obtain. It devolves upon our universities, no less than upon our manufacturers, to consider where they stand, and to do their part towards the country's well-being by making optics a living subject rather than resting satisfied with the knowledge of a hundred years ago. Research on their part and on that of other institutions is necessary; the field is wide. We look to them for that interest which we have every right to expect.

The afternoon session was preceded by an exhibition of microscopes and auxiliary apparatus. The historical collection of microscopes from the South Kensington Museum was of special interest. New models of microscopes attracted much attention. Messrs. Beck and Swift exhibited models fitted with the changing device they have adopted, and some exhibits by Messrs. W. Watson and Sons were greatly admired. Many other exhibits of much interest were shown, but for particulars of these reference must be made to the catalogue specially prepared for the occasion.

The publication of the proceedings of the symposium will be awaited with interest. We trust that all the papers will be collected into a single volume, and be available as a separate publication for all who have special interests in microscopy.

CONSTRUCTION AND USE OF MICROSCOPES.[1]

A CONSIDERATION of the microscope resolves itself of necessity into two parts, the mechanical and the optical. From the mechanical point of view there are two designs in general use, those referred to as the Continental and the English form of microscope. In the Continental type it has usually been customary to have what is known as the horseshoe foot, mainly, I imagine, because of its ease of construction by mechanical engineering methods; whereas the English design of microscope, which has hitherto been mainly made by hand, is of a more steady type, and the points of support are so distributed as to give more stability to the instrument in any position.

The essential parts of the instrument are a coarse adjustment, to give the body tube a quick motion in the direction of the optic axis, and a fine adjustment, which gives it a much slower motion in the same direction. The tube is adjustable in length, to enable correction to be made for varying thicknesses of cover-glass, although a large number of workers appear to regard it as a ready method of obtaining greater or less magnification, with disastrous effects on the resulting image.

There is only one fixed part of a microscope for biological purposes, and that is the stage. But metallographers require that the stage shall also be adjustable in the direction of the optic axis. The body tube itself should be made so that it can be closed to a length of 140 mm., including any objective-changing device that may be on the nose-piece; and it should be possible to lengthen it to at least 200 mm. or 250 mm. if long-tube objectives are used.

All these adjustments are in the direction of the optic axis of the instrument. Two others are usually provided which are at right angles to this direction—that is, a mechanical stage for actuating the object, and in certain of the best-class instruments an arrangement for centring the sub-stage condenser to the axis of the objective.

While there are many points which might be raised on the mechanical side, there are only one or two that I have time to mention. The main point about most microscopes appears to be that they are unstable. I have a considerable number in my own possession, but I do not think I have one even now which, if I centre an object on the stage with the instrument in a vertical position, still maintains its centration accurately if the instrument is put into the horizontal. The probability is, therefore, that there are few microscopes made at the present time that exactly fulfil the conditions necessary for high-class photomicrographic work or for observational microscopic work of an exacting order. I trust, however, that an instrument exhibited at this symposium will embody the necessary improvements to rectify this matter.

Some misapprehension appears to me also to exist as to the relative purpose of the coarse and the fine adjustments. The coarse adjustment appears to me to be one which should be sufficiently well made, and with which the user is sufficiently expert, to enable him to bring into view any object, whether it is being observed with a low- or a high-power objective. The fine adjustment is then used for accurate focussing and for getting a conception of the object in depth. In biological work, at any rate, this is very rarely the state of affairs as carried out. In using an oil-immersion objective, for instance, a common method is to immerse the objective, and then to lower it so that it all but touches the top surface of the cover-glass. The objective is then raised by means of the fine adjustment until the object comes into view. While this may act fairly well with very thin cover-glasses, it is a haphazard method when cover-glasses of varying thicknesses are used. It should be realised that when microscope-users are sufficiently educated they will be able to tell how far they are from the actual image by the appearance of the light in the field of view—that is, if the object is illuminated with reasonable accuracy.

Mechanical stages also appear to need some consideration. The stages which will on actuation cause no shift of the object other than in the direction intended, or any alteration of focus, are rare. Further, those in which the screws project for a considerable distance, with the result that any slight jar or knock causes them to be displaced, and, it may be, actually bent, are objectionable when used under laboratory conditions.

There is, I think, much to be said for the type of stage which has either co-axial milled heads on a vertical axis, or, if inconvenient to make, milled heads which are on separate axes. This method of con-

[1] Opening paper of a discussion on "The Microscope: Its Design, Construction, and Applications," organised by the Faraday Society and held at the Royal Society on January 14. By J. E. Barnard, president of the Royal Microscopical Society.

struction of necessity results in a much stiffer and more stable stage. There is, in fact, a general lack of stability going through nearly all parts of a microscope. But it is significant that, even so long ago as the beginning of last century, the instrument as then designed had much greater attention paid to this point. The microscope an illustration of which I show on the screen is, to my mind, an embodiment of a principle that should receive attention. So soon as English makers are in a position to consider the production of an instrument of a special type, it is my intention to have one made. In this the general principle is that all the optical parts are carried on a bar which is, in effect, an optical bench, and that this is strutted in such a way as to give stiffness to the instrument as a whole. The only effort that I am aware of that has been made in this direction is in the microscope designed by Dr. Rosenhain, particularly for metallography, but which is adaptable for ordinary work. This instrument, to my mind, is such an improvement on any other type of stand that I am at a loss to understand why metallographers have not more generally taken it up. It might appear that I am exaggerating the importance of stability in the stand, but it should be realised that any lack of centration in the optical parts, or of alignment in the optic axes of these parts, results in more serious deterioration of the resulting microscopic image than any other single factor. The optical parts of a microscope are the objective, for obtaining the primary magnified image of the object; the ocular, for further enlarging that image and transmitting it to the eye; and the sub-stage condenser, for illuminating the object with a larger or smaller cone of light. The limitations of time will prevent me from doing more than refer very briefly to some properties of the optical parts.

It is generally assumed that magnification is the primary function of an objective, but in point of fact the main point is not magnification, but resolution. By resolution is meant the power the objective has of separating and forming correct images of fine detail. The theory known as the Abbe diffraction theory is the one on which modern optical calculations are based; and it is safe to say that it was never more fully accepted than at the present time, and never rested on a surer basis. There has been much discussion in this country of that theory, and probably a good deal of misconception has arisen from its inapt designation, for the term "diffraction theory" is perhaps somewhat unfortunate. I cannot do better than quote the late Lord Rayleigh in reference to this matter. He said: "The special theory initiated by Prof. Abbe is usually called the diffraction theory, a nomenclature against which it is necessary to protest. Whatever may be the view taken, any theory of resolving power of optical instruments must be a diffraction theory in a certain sense, so that the name is not distinctive. Diffraction is more naturally regarded as the obstacle to fine definition, and not, as with some exponents of Prof. Abbe's theory, the machinery by which good definition is brought about." This very clearly and accurately sums up the position. The Abbe theory tells us that there are two main factors determining resolution; that is, the numerical aperture of the objective used and the wave-length of the light. Numerical aperture is determined for us by the optician, and it is well known that, with an oil-immersion objective, a numerical aperture of 1·4 is at the present time the practical limit. Metallographers are in a somewhat stronger position, as a monobromide of naphthalene immersion objective was, and presumably still is, made by Zeiss which had a numerical aperture of 1·6. This represents the absolute limit at the present time, and there is no indication that numerical aperture will be increased in this sense by present methods.

The other factor governing resolution is the wave-length of light, and in this connection it must be borne in mind that to resolve a regularly marked structure the distance between the markings must be more than half a wave-length. Under ordinary conditions of illumination we cannot go very far in the direction of increased resolution unless we resort to an illuminant such as a mercury vapour lamp which is rich in blue and violet radiations. There is much room for investigation in this direction, as the ideal illuminant for microscopic work has yet to be found. But I do not know of any one that approaches so nearly to it as the one I have mentioned, the mercury vapour lamp. It suffers only from one disadvantage that I can see, and that is that the differentiation due to staining is not so clearly brought out as when ordinary light is used. But as staining is itself an artificial process, and is simply done to differentiate structures, it only means a certain amount of education to enable us to appreciate the differences even under the light from this lamp. The only stains which it does not show quite well, or rather in which the colour-tint is altered, are those in which red predominates. Any other colour is shown perfectly and in proper gradation. The advantages of this illuminant are that it is even and uniform. It has a fairly large area, and can be used, therefore, for any class of work. Its intensity can be varied within considerable limits by having a resistance in series, so that the current density is altered to suit the particular work under observation. Further, it is possible, by interposing neutral screens, to vary the light intensity if the electrical method is inconvenient. Owing to its possessing practically no red radiations its mean wave-length is shorter, and by using suitable screens light which is truly monochromatic, yellow, green, blue, or violet, can be obtained at will. These lamps are made both in glass and quartz, but the quartz ones are preferable, because they admit of the use of heavier currents with greater luminosity; and, further, they have a much longer life. I have exhibited two of these lamps, because I regard them as far in advance of any other form of light available to the microscopist at the present time, whether he is a biologist or a metallographer.

The whole subject of illumination needs investigation also, because there is, I think, little doubt that a modification in the intensity of the illumination of any particular object enables us to use a larger light-cone than we could do in ordinary circumstances —that is, variation of the intensity is an alternative to the use of the iris diaphragm in the sub-stage of the microscope. But it is in the direction of using invisible radiations in the ultra-violet, or, it may be, radiations which are still shorter than the ultra-violet, that developments in microscopic work are, in my opinion, likely to occur.

There are two other points worth mention, which I trust may be dealt with more fully in succeeding papers. One is that, while the resolution limits are so inflexible, that does not by any means apply to mere visibility. By illuminating small particles by means of an annular cone of rays—that is, what is ordinarily known as dark-ground illumination—or by illuminating them at right angles to the optic axis of the microscope—what is known as the ultra-microscopic method—particles of a very much smaller order of size can be made visible. But we cannot tell anything about their form, nor can we accurately tell their size. We are only conscious of their mere existence.

Another point to remember is that magnification is definitely limited to something like 750 diameters with microscopes under ordinary conditions if we want to get the best optical effect. We may, as a matter of convenience, have still higher magnifications, because it is not given to everybody to appreciate fine detail unless an image is somewhat enlarged. But it must be appreciated that any increase beyond 750 or 800 diameters does not result in our seeing anything more. It simply allows us to see the object on a somewhat larger scale. We may, therefore, summarise as follows: An object which is much smaller in size than the resolution limit can be rendered visible provided the light with which it is illuminated is of sufficient intensity and sufficiently different in refractive index from the medium in which it lies. To resolve a series of equidistant points or lines in an object, their distance apart must exceed half a wave-length of light in the medium in which the object is immersed. Johnstone Stoney has shown that a pair of lines or objects can be separated when their distance apart is rather smaller than the resolution limit required for a number of points or lines in a row. But it should be borne in mind even here that the resolution limits apply if a clear standard of definition is required. An isolated object or pair of objects are not so well defined if they exceed the resolution limits as laid down for recurring structures. It cannot be too fully appreciated that illumination is the keynote of all sound microscopic work, and this applies whether the illumination is by means of visible radiation under ordinary conditions of work, or whether it is in experimental work in which the use of invisible radiations are concerned.

There is much room for research in this direction, and it is to be hoped that this is one of the points which will be seriously taken up. Apart from any question of research, the education of the user is perhaps of vital importance. It is of little use for opticians to make great efforts to turn out a satisfactory instrument if the user is incapable of taking advantage of the quality of the optical or other parts. I trust, therefore, that this symposium will give an impetus in this direction, and that it will help microscope-users to realise how much remains to be done.

MICROSCOPICAL OPTICS.[1]

In the opening paragraphs attention is directed to the methods of treating the aberrations on the principle of equal optical paths (A. E. C., Monthly Notices of R.A.S., January and March, 1904, and April, 1905) and to the author's recent determination of the actual light distribution at and near the focus in the presence of aberration (Monthly Notices, June, 1919). The sine-condition is also discussed.

The origin and effects of the secondary spectrum are then dealt with, and the paper proceeds:

The attempts to produce varieties of *glass* free from this secondary spectrum have been unsuccessful so far as the microscope is concerned, for the existing crowns and flints with proportional dispersion have so little difference in dispersive power that an impracticable number of lenses would have to be used to secure the desired effect. We therefore still depend on the material the value of which for this purpose was discovered by Abbe, the natural mineral fluorite, used instead of crown glass in combination with heavy crown glasses or very *light* flint glasses in place of ordinary *dense* flint glass. It was by the use of fluorite that Abbe produced the apochromatic objectives, and fluorite of good optical quality must be used to this day to secure the result. Apart from the difficulty of finding this material, there is no obstacle to the designing by exact calculation of apochromatic objectives.

I now come to a defect of nearly all microscope objectives, and especially of highly corrected ones, which is well known to all practical microscopists, namely, the pronounced curvature of the field, invariably in the sense of requiring a shortening of the distance from object to lens in order to obtain a sharp focus in the outer parts of the field of view. The general theory of the primary aberrations of oblique pencils shows that any lens system when freed from astigmatism will have the curvature of field defined by the Petzval theorem, and that in the presence of astigmatism the two focal lines which then represent the strongest concentration of the light always lie both on the same side of the Petzval curve and at distances from it which are in the approximate ratio of three to one. When the astigmatism is undercorrected the natural curvature of the field defined by the Petzval equation becomes aggravated, whilst overcorrected astigmatism tends to flatten the field, and is deliberately introduced for this purpose in ordinary photographic objectives. The presence of considerable amounts of astigmatism, of course, renders really sharp marginal images impossible in either case, so that its absence, or, better still, a modest amount of overcorrected astigmatism, must be regarded as the ideal in microscope objectives. Unfortunately, this desirable state cannot be reached in the existing types of objectives. The binary low-power objectives up to the ordinary 1 in. and ⅔ in. come nearest to it, and are, therefore, justly liked by microscopists for all work for which they are sufficiently powerful. In the ordinary ternary objectives of the ⅙-in. type, with approximately plano-convex components, the curvature of the field is also of reasonably moderate amount. But it is a general experience that highly corrected objectives are very much worse as regards curvature of field. In the light of my most recent work on the general theory of lenses (Monthly Notices, November, 1919), this curious and objectionable peculiarity is easily explained, and becomes revealed as a *necessary* consequence of high spherical and chromatic correction if the usual number of components is adhered to. In the Lister and Amici types of ordinary objectives, which are fairly satisfactory as regards curvature of the field, the front lens is of such a form as to produce strong outward coma, and there is in the back lens or lenses a corresponding amount of inward coma.

The simple extensions of Seidel's theory, given in the paper last referred to, show that this is the state of affairs which tends to diminish undercorrected astigmatism, or even to reverse it into the more desirable overcorrected form. High correction of the zonal spherical aberration, and to a still greater extent complete removal of the spherical variation of chromatic correction, necessitate a more or less complete reversal of the coma effects in front and back components. In other words, with the usual types of objectives reductions of curvature and apochromatic or semi-apochromatic correction are completely antagonistic and incompatible; what benefits one correction is detrimental to the other. Fortunately, the extended theory also indicates a way out of this dilemma. It appears fairly certain that by building the objective itself on the lines required by the apochromatic condition, but leaving it spherically undercorrected, perhaps also chromatically overcorrected to a moderate extent, and with a considerable amount of outward coma (this is the most important), and by correcting these residuals in a *widely separated* additional back lens, it will be possible to combine moderate curvature of field with apochromatic perfection, and thus to remove the worst outstanding defect of the best objectives.

[1] From a paper by Prof. A. E. Conrady presented at a discussion on "The Microscope: Its Design, Construction, and Applications," organised by the Faraday Society at the Royal Society on January 14.

Condensers for the proper well-regulated *illumination* of microscopic objects are identical in optical design with objectives, the only difference being that the light passes through in the reverse direction, and that a lower degree of correction is sufficient not only on theoretical, but also on practical grounds, for nearly always condensers are used in conjunction with the "plane" mirror, which invariably is very far from optical perfection, and so introduces irregular aberrations of unknown magnitude and kind, and, moreover, the light from the condenser has to pass through the slide on which the object is placed. This slide is practically little better than window-glass so far as optical quality and perfection of surfaces are concerned, and the great variation in thickness is another source of imperfection, especially with dry condensers of high N.A.

Moderate amounts of residual aberrations in condensers can always be effectively neutralised by using a sufficiently large source of light of uniform brightness or by magnifying the source by a sufficiently well-corrected "bull's-eye," if the source of light is naturally small.

A great and very serious defect in the construction of nearly all condensers of the present day, with the exception of the modest Abbe condenser of two simple uncorrected lenses, is that the iris and the ring for dark-ground stops are placed too far from the back lens instead of being close to the anterior focal plane of the condenser. It is easily shown that such a remote iris-opening or dark-ground stop produces decidedly oblique illumination of the extra-axial points of the object. With direct light this leads to an undesirable variation in the type of image and in resolving power in different parts of the field. With dark-ground illumination the result is even more serious, for it is then necessary to use a far larger central stop to secure a dark background over the whole field than would suffice if the stop were placed close to the anterior focal plane of the condenser; such an unnecessarily large stop is highly objectionable, because it reduces the visibility of the coarser structures in the object.

The increasingly bad position of the iris in the condensers of higher power and shorter focal length supplies practically the whole explanation of the universal experience that high-power condensers will not work satisfactorily with low-power objectives, especially for dark-ground illumination.

The great thickness of the mechanical stage in English stands of the highest quality is the chief *reason* why the iris and "turn-out ring" of high-power condensers have to be mounted so far below the back lens, and a profound modification of the design of the stage with the view of making the part projecting over the condenser as thin as possible therefore appears to be the most desirable improvement of microscope stands from the optical designer's point of view.

As regards the *actual making of microscope objectives*, it must be borne in mind that the excellence of a computed lens system may be completely swamped by comparatively slight imperfections of workmanship, and that high accuracy in this respect is therefore of the utmost importance. In lenses of high N.A. computation shows that a departure from the prescribed radii and thicknesses by a fraction of a thousandth of an inch may lead to a notable loss of perfection, and the polished surfaces must also be truly spherical within less than half a wave-length of light. These limits can be easily observed if modern methods of gauging and measuring are adopted, and if all surfaces are polished to accurately made and conscientiously used test-plates. The tools and methods employed in really *manufacturing* lenses on this system were shown by Messrs. W. Watson and Sons, Ltd., at the exhibition at King's College in January, 1917, and will be found described and illustrated in the record of that exhibition.

In old English practice the component lenses of microscope objectives and condensers used to be fixed in their cells by cement of the sealing-wax type. Many old lenses which are still found in perfect adjustment fifty or more years after being mounted demonstrate that the cement may hold the lenses in correct position almost indefinitely; but other experiences, especially with lenses used in tropical countries, suggest that shifting may occur, and it is therefore strongly to be urged that all microscope lenses should be held between metallic shoulders at both ends by being bevelled into their cells, care being naturally required to avoid pressure and distortion through too tight a fit.

A point on which users of objectives err to their own detriment is an excess of faith in numerical aperture. I have heard microscopists boast of possessing an objective, say, of 1·43 N.A., whereas somebody else had one of barely 1·40; and a careful test would show that whilst the 1·43 was an indifferent lens, the 1·40 was excellent. The fancied advantage of 2 per cent., then, is really a disadvantage of perhaps 25 per cent. or more.

One of the few disservices which Abbe did to microscopy was the pushing of the N.A. of dry lenses to 0·95, and to a less extent the increase of that of oil lenses to 1·40. The extreme marginal zone of the apochromatic dry objectives of 0·95 N.A. is particularly badly corrected, so much so that the lenses will only bear a solid illuminating cone of about 0·65 N.A. even on the Abbe test-plate, and that with annular light bringing only the marginal zone into action correction-collar and tube-length combined do not allow of reaching a point of good spherical correction. There is no doubt that Abbe's own earlier dictum still holds, to the effect that beyond about 0·85 N.A. the higher aberrations become unmanageable unless the free working distance is reduced to a very few thousandths of an inch. A carefully computed objective of 0·85 N.A. will bear a full illuminating cone on suitable objects, and can thus realise its fullest resolving power. An objective of 0·95 with a condenser of 0·65 has the resolving power of the mean, or of 0·80 N.A., and is thus actually inferior, except for freak resolutions, with extremely oblique light. Oil objectives of more than 1·30, or at most 1·35, N.A. are also of very doubtful added value.

In closing this section I will once more quote without comment an anecdote of Fraunhofer, who received a complaint that a telescope supplied by him, although giving magnificent images, displayed certain fine scratches when examined with a magnifying-glass! The reply sent by Fraunhofer is reported to have been: "We have constructed the telescope to be looked through, not to be looked at."

A few sentences may perhaps be added as to the prospects for further improvements of microscopic performances. I have stated earlier in this paper that there is a bright ray of hope with regard to diminishing the curvature of field without loss of definition.

Advances in numerical aperture offer very little attraction. Abbe, in my opinion, carried the N.A. too far rather than not far enough, and I am not aware that any notable discovery has been achieved with the few monobromide immersion objectives of N.A. 1·60 which he designed.

The use of a shorter wave-length, *i.e.* ultra-violet light, is a little more promising. There would be none but technical difficulties to the construction of lenses suitable for this work. But as only very few microscopists would be likely to go to the trouble of working in invisible light and of passing through a long apprenticeship in mastering the difficulties, apparatus of this description would necessarily be extremely costly, as the whole expense of designing and of constructing special tools would fall on a small number of outfits, or possibly on only a single one. And there would still be the grave drawback that the vast majority of objects would be opaque to extreme ultra-violet rays, and yield only black-and-white outline pictures.

The so-called ultra-microscope does not represent any advance in *resolving* power at all, but most decidedly the reverse. It is highly valuable for the detection of very minute particles and of their movements, which it achieves simply by intense dark-ground illumination, but the structure of the particles remains unrevealed, and only that would amount to an advance in resolving power. The seeing of these minute particles is, in fact, of precisely the same kind as the seeing of stars subtending less than 0·001 second of arc at night with the naked eye, the resolving power of which is of the order of 60 seconds.

PARIS ACADEMY OF SCIENCES.

BONAPARTE AND LOUTREUIL FOUNDATIONS.

Of the 72,500 francs placed at the disposal of the Academy by Prince Bonaparte, it is proposed to allocate 30,000 francs as follows:—

5000 francs to Charles Alluaud, travelling naturalist to the National Natural History Museum, for a geological and botanical expedition in the Moroccan Grand Atlas Chain.

2000 francs to A. Boutaric, for the construction of an apparatus for recording nocturnal radiation.

1000 francs to Emile Brumpt, for continuing his work on parasitic hæmoglobinuria or piroplasmos of cattle.

3000 francs to E. Fauré-Fremiet, for undertaking a series of studies on histogenesis and certain surgical applications.

3000 francs to A. Guilliermond, for pursuing his researches on lower organisms and on mitochondria.

3000 francs to Joseph Martinet, for continuing his researches on the isatins capable of serving as raw material for the synthesis of indigo colouring matters.

3000 francs to A. Vayssières, for the continuation of his researches of the marine molluscs, family Cypræideæ.

10,000 francs to the Fédération française des Sociétés de Sciences naturelles, for the publication of a fauna of France.

The committee appointed to allocate the Loutreuil foundations recommend the following grants:—

(1) To establishments named by the founder:

10,000 francs to the National Museum of Natural History, for the reorganisation of its library.

7500 francs to the Paris Observatory, at the request of the Central Council of the Observatories, for purchasing an instrument.

(2) Grants applied for direct:

6000 francs to the Société Géologique du Nord, to enable it to take up work interrupted by the war.

10,000 francs to l'Ecole des hautes études industrielles et commerciales de Lille, for restoring the material of its chemical laboratory.

20,000 francs to the Observatory of Ksara (near Beyrout). This laboratory was practically destroyed by the Turks and Germans. The grant is towards its restoration.

8000 francs to Henri Deslandres, for the study of the radial movements of the solar vapours and the thickness of the gaseous atmosphere of the sun.

7500 francs to Maurice Hamy, to carry out certain improvements in astronomical apparatus of precision.

3500 francs to Félix Boquet, for the publication of Kepler tables.

1000 francs to G. Raymond, for the continuation of his actinometric experiments.

10,000 francs to Charles Marie, for exceptional expenses connected with the publication of the "Tables annuelles de constants et données numériques de chimie, de physique et de technologie."

10,000 francs to the Fédération française des Sociétés de Sciences naturelles, for the publication of a French fauna.

2000 francs to P. Lesne, for his researches on the insects of peat-bogs.

2000 francs to A. Paillot, for his researches on the microbial diseases of insects.

2000 francs to Just Aumiot, for the methodical study of the varieties of potato.

5000 francs to Albert Peyron and Gabriel Petit, for the experimental study of cancer in the larger mammals.

3000 francs to Th. Nogier, for completing the installation of the radio-physiological laboratory of the Bacteriological Institute of Lyons.

THE MATHEMATICAL ASSOCIATION.

The annual meeting of the Mathematical Association was held in the London Day Training College, Southampton Row, on January 7 and 8, under the presidency of Prof. E. T. Whittaker. At the advanced section on the evening of January 7 the president gave a lecture on "A Survey of the Numerical Methods of Solving Equations." He described in some detail "iterative processes" for approximating to the roots and graphical methods of circumscribing the regions on the Argand plane, in which the various roots lay. The Lobachefsky-Graeffe method of approximating to the roots of equations and power series was described in considerable detail. In the animated discussion to which this lecture gave rise it was clearly seen that a wider knowledge of practical computative processes is a desideratum in all branches of mathematical work, which has been practically neglected hitherto in the schools and universities. It was also felt that such practical numerical work was the best possible introduction to the formal study of function theory, many of the ideas underlying which are usually presented in an entirely abstract way, whereas they present themselves naturally and of necessity in less general forms in the science of computation.

Next day, at the general section, Mr. C. Godfrey, of the Royal Naval College, Osborne, surveyed the whole question of the modern teaching of geometry in schools. He strongly favoured a preliminary course of practical instrumental work, to be followed by a more formal course in which "logic" is not too prominent. He advocated the entire postponement of a really rigorous course of abstract geometry until the post-school stage. Prof. T. P. Nunn strongly supported the general tenor of Mr. Godfrey's views, and urged the earlier teaching of "ratio and proportion" as a practical instrument for solving many problems, such as map-drawing, villa construction, etc.

Prof. E. H. Neville, of University College, Reading, next read a paper on "Convention and Duplexity in Elementary Mathematics," in which he protested against the usual "positive-sign" convention with regard to vectors. Miss H. M. Cook dealt with "The Place of Common Logarithms in Mathematical Training," and Prof. W. P. Milne strongly urged the necessity of making both logarithms and numerical trigonometry compulsory for the university matriculation, because the work of the intermediate classes in the universities was being seriously hampered by the lack of such knowledge on the part of a large number of the students. Prof. Whittaker gave a most interesting paper on "Some Mathematical Problems awaiting Solution," which suggested themselves chiefly in computative work, such as the question of the convergence of certain approximative processes in the case of a large number of simultaneous equations. Mr. R. C. Fawdry opened a discussion on the teaching of mechanics to beginners, and said that, after many years' experience, he still could not decide whether to teach statics or dynamics first. A vigorous protest was entered by Dr. S. Brodetsky, Prof. W. P. Milne, and Mr. A. W. Siddons against the practice that had just arisen of teaching "pure mathematics" in the new advanced courses in secondary schools, thereby promoting undue specialisation at a young age and losing entirely the outlook which a combined course of pure and applied mathematics can supply.

The meetings were extremely well attended and very enthusiastic. WILLIAM P. MILNE.

INDUSTRIAL RESEARCH ASSOCIATIONS.

THE Department of Scientific and Industrial Research has just issued the following list of research associations which have been approved by the Department as complying with the conditions laid down in the Government scheme for the encouragement of industrial research, and have received licences from the Board of Trade under section 20 of the Companies (Consolidation) Act of 1908:—

British Boot, Shoe, and Allied Trades Research Association, Technical School, Abington Square, Northampton. *Secretary:* Mr. John Blakeman.

British Cotton Industry Research Association, 108 Deansgate, Manchester. *Secretary:* Miss B. Thomas.

British Empire Sugar Research Association, Evelyn House, 62 Oxford Street, London, W.1. *Secretary:* Mr. W. H. Giffard.

British Iron Manufacturers Research Association, Atlantic Chambers, Brazennose Street, Manchester. *Secretary:* Mr. H. S. Knowles.

British Motor and Allied Manufacturers Research Association, 39 St. James's Street, London, S.W.1. *Secretary:* Mr. Horace Wyatt.

British Photographic Research Association, Sicilian House, Southampton Row, London, W.C.1. *Secretary:* Mr. Arthur C. Brookes.

British Portland Cement Research Association, 6 Lloyd's Avenue, London, E.C.3. *Secretary:* Mr. S. G. S. Panisset.

British Research Association for the Woollen and Worsted Industries, Bond Place Chambers, Leeds. *Secretary:* Mr. Arnold Frobisher.

British Scientific Instrument Research Association, 26 Russell Square, W.C.1. *Secretary:* Mr. J. W. Williamson.

British Rubber and Tyre Manufacturers Research Association, c/o Messrs. W. B. Peat and Co., 11 Ironmonger Lane, E.C.2.

The Linen Industry Research Association, 3 Bedford Street, Belfast. *Secretary:* Miss M. K. E. Allen.

Glass Research Association, 7 Seamore Place, W.1. *Secretary:* Mr. E. Quine.

British Cocoa, Chocolate, Sugar Confectionery, and Jam Trades Research Association, 9 Queen Street Place, E.C.4. *Secretary:* Mr. R. M. Leonard.

Schemes for the establishment of research associations in the following industries have reached an advanced state of development:—

Research Associations Approved by the Department but not yet Licensed by the Board of Trade.—British Music Industries Research Association, British Refractory Materials Research Association, British Non-Ferrous Metals Research Association, and Scottish Shale Oil Research Association.

Proposed Research Associations the Memorandum and Articles of Association of which are under Consideration.—British Launderers Research Association, British Electrical and Allied Industries Research Association, and British Aircraft Research Association.

Industrial Organisations Engaged in Preparing Memorandum and Articles of Association.—Silk Manufacturers, Leather Trades, and Master Bakers and Confectioners.

In addition to the industries included above, certain others are engaged in the preliminary consideration of schemes for forming research associations.

THE ORGANISATION OF IMPERIAL STATISTICS.[1]

POINTING out that it was almost emphasising the obvious to say that any great nation should be thoroughly informed as to its numerical, its social, and its economic drift, the author directed attention to the fact that this had been recently recognised in a petition to his Majesty's Government so late as November 1 last. It was also emphasised by the calling together of a Conference of the Statisticians of the Empire, under the ægis of the British Government. In view of the position of the British Empire in world affairs, it was but little short of amazing that an Imperial Bureau of Census and Statistics was not long ago established. A bureau, to be really Imperial, must recognise the community of interest of all parts of the Empire. It was not something to be created mainly for the purposes of the United Kingdom, but something which would meet equally well the purposes of each part of the Empire. For this reason the needs of the autonomous Dominions must be quite as carefully considered as those of the United Kingdom itself, and it was implied in the paper that any part of the Empire which could not at present meet the common requirements of the whole must be prepared to do so. The interest would be general only in so far as it was Imperial.

In order to overcome departmental frictions and to secure the sympathy and co-operation of all public departments, it was suggested that a Central Statistical Commission should be created, the president of which would, of course, be the Director of the Bureau of Statistics. Such a Commission would be a body of expert advisers, and could make its departments helpful. The scope of an Imperial Statistical Bureau, both as to administrative procedure and as to subject-matter to be dealt with, was outlined, as was also the question of compilation and publication.

To attempt to organise an Imperial Bureau of Statistics with a small and humbly qualified staff would foredoom it to failure, said the author. In its higher professional section it must necessarily have experts in statistical theory, in the technique of the collection and compilation of statistical data, in pure and applied mathematics, in the languages which are important in the statistical field, in statistical editor-

[1] Abstract of a Paper presented to the Royal Statistical Society on Tuesday, January 20, by G. H. Knibbs, Statistician of the Commonwealth of Australia.

ship, in draughtsmanship and graphical representation, and in the interpretation and explanation of statistical results. In this last field the Director himself would, of course, be the expert *par excellence*, and not a mere administrator. It was also pointed out that to put the whole of the work in the hands of a mere administrator would lead to failure. The staff would, of course, include persons who specially studied demography, trade, production, finance, labour and industrial affairs, shipping, railways, tramways, and transport and communication.

In concluding, the author said that if the United Kingdom, by appropriate effort, were to supplement the efforts of some of the autonomous Dominions, it would be possible to build up a statistical edifice for the whole British Empire which, in meeting the needs of a great people—with its reactions upon the human race—would constitute the bureau a sort of *temple expiatoire* for our remissness in the past. The keynote of the whole paper was that an important duty has been left unfulfilled, and that we must not go on neglecting it, for such a work is needed by publicists and statesmen, and for the general purposes of intelligent criticism and intelligent government.

ITALIAN PAPERS ON RELATIVITY.

DR. ATTILIO PALATINI, of the University of Padova, Italy, dedicates a special paper (*Ac. d. Lincei*, April, 1919), entitled "Traiettorie dinamiche dei sistemi olonomi con tre gradi di libertà," to the investigation of what may shortly be called irreversible systems, *i.e.* systems the Lagrangian function of which contains the velocity (apart from its square) also linearly. The paper is but a generalisation of Birckhoff's investigation on "Dynamical Systems with Two Degrees of Freedom" (Trans. Amer. Math. Soc., vol. xviii., No. 2, 1917) to three degrees of freedom. The result arrived at is that the trajectories of such a system coincide with those of an ordinary system of three particles with appropriate constraints moving in a conservative field of force which spins uniformly about an axis. The analogy with such systems leads Dr. Palatini to take up in a second note, entitled "Moti Einsteiniani stazionari" (Ist. Veneto, May 11, 1919), the relativistic problem of what the author proposes to call *stationary* motions, *i.e.* such for which the four-dimensional line-element ds^2 contains non-vanishing, though constant, coefficients g_{14}, g_{24}, g_{34} (coefficients of the mixed, space-time terms, as $dx\,dt$, etc.). The chief result is again the equivalence to a three particles system in a uniformly revolving conservative system. It strikes one that this result could be read off the ds^2 almost directly. The result concerning the "anisotropic and irreversible" behaviour of energy is again obvious and, physically, of comparatively small interest.

The paper is inspired by Prof. Levi-Civita's recent investigations on *static* Einsteinian motions (*Ac. d. Lincei*, 1917, *et seq.*), for which g_{14}, etc., are permanently zero—elegant investigations, no doubt, but of purely formal interest.

Dr. Palatini's third recent article, "La Teoria di Relatività nel suo sviluppo storico" (*Scientia*, September–October, 1919), which, though not without many happy ideas as to the popular presentation of the "old" (1905) and the new or generalised relativity and gravitation theory, lacks that plasticity and freshness which would be imparted to it by a more intimate contact with existing physical ideas. This absence of contact goes in the present case (concluding section of part i., dedicated to the older theory of Einstein) even so far as to ignore the numerous and famous experimental proofs of the variability of mass with velocity. The author does not seem ever to have heard of the beautiful experiments of Kaufmann, Bucherer, Hupka, and others which have made the variability of β-particles an almost tangible fact. The second part of the article, devoted to general relativity, has the indisputable positive feature of being very enthusiastic, and gives, no doubt, some general idea of Einstein's newest doctrine. Yet even here one cannot help being surprised at one or two misconceptions, marring the introductory section on the concept of space-curvature, defects the more inexplicable as they emanate from a pure mathematician. Thus on pp. 16–17 we are invited to imagine some practically one-dimensional beings or animalcules living in three kinds of capillary tubes, a straight, a circular, and a hyperbolic one (devices not unfamiliar to any reader of the great Clifford). Having endowed these unfortunate beings with a sufficient amount of intelligence, Dr. Palatini (speaking of the first of them) proceeds to say: "In order to arrive from one to another point of its space, the being would state (*constatare*) that it had to follow the straight road." As if that poor thing had a choice in its one-dimensional abode! Equally misleading is not only the remainder of the history of these fictitious three beings, but also the presentation (p. 18) of our own concepts of the "spazio ambiente" in which we live.

Carlotta Longo gives, in her doctorate dissertation of 1918 (Padova), published in *Nuovo Cimento* (vol. xv., 1918, pp. 191–211), a very attractive and geometrically elegant investigation on the elementary electrostatic law according to Einstein's generalised relativity and gravitation theory. She confines herself to the special but most important case of a radially symmetric electrostatic distribution, and, integrating the field-equations in Prof. Levi-Civita's form adapted to the present case, finds for the electrostatic force a law which differs from Coulomb's inverse square law only in so far as the distance r from the centre of the field is replaced by the curvature radius of the geodetic sphere passing through the point in question. A further result of the investigation is that, in a radially symmetric field at least, there can be electric charge only where "there is also matter," unless it be a point-charge at the centre ($r=0$) itself. This striking result would deserve a more definite and critical enunciation. We are not told what kind of "matter" is meant, while, on the other hand, the energy of an electrostatic field is, for Einstein, also a kind of "matter." Yet another very interesting result is reached at the end of the paper. It relates to the "mechanical" force exerted by an electron, *if* its usual "electromagnetic mass" is assumed to be not only an inert, but also a gravitating (heavy) mass. The result is that, in addition to the quasi-Newtonian attraction, there is a *repulsion*, which, however, is comparatively small. Thus, for example, at a molecular distance from the centre the repulsion would be only one-hundred-thousandth of the gravitational attraction.

The paper is clearly written, and, being very suggestive, will certainly attract the attention of Einstein's followers. Nevertheless, one cannot help mentioning here that an excellent paper on this subject (which pushes the analytical, if not the geometrical, solution much farther) was published in 1916 by H. Reissner (*Annalen d. Physik*, vol. l., pp. 106–20). This paper, however, seems to have entirely escaped the notice of the author, whom nobody will fail to congratulate upon her elegant results.

L. SILBERSTEIN.

AGRICULTURE AT THE BRITISH ASSOCIATION.

As might have been expected, the papers read before the Agricultural Section at the Bournemouth meeting had special reference to the abnormal conditions brought about by the war. Most of the members had been engaged either directly or indirectly in food production work, and there was a very marked reduction, as compared with normal years, in the amount of research work reported to the meeting.

[The presidential address appeared in NATURE of December 25, 1919, and need not, therefore, be further considered now.]

Two important papers dealing with the work of "Food Production" were read by Sir Thomas Middleton, formerly of the Food Production Department of the Board of Agriculture and Fisheries, and by Mr. J. M. Caie, an Assistant Secretary of the Board of Agriculture for Scotland, dealing with the methods and results of the food production schemes in England and Scotland respectively.

Sir Thomas Middleton revised the estimates, which he had brought forward at the Manchester meeting, of the number of persons who could be supported on the meat produced on 100 acres of average land under various conditions.

As compared with twelve to fourteen persons who could be supported on the meat produced on 100 acres of average grass land he estimated that:—

	Persons for a year
100 acres average wheat, milled as it was before the war, would support ...	200
100 acres milled (80 per cent.) would support	230
100 acres average barley (60 per cent.) would support	180
100 acres average oats (54 per cent.) would support	160
100 acres average potatoes would support	400
100 acres average mangolds would support	40
100 acres average meadow hay would support	14

Before the war the ploughed land in the United Kingdom was feeding about 84 persons per 100 acres, while the grass land was feeding about 20. Altogether we grew food for about 17,500,000 out of 46,000,000 people, or, in other words, we supplied the week-end requirements of the entire population throughout the year. The Food Production Department was set up in December, 1916, and by April, 1917, plans had been developed for bringing 2,700,000 acres of extra arable land into cultivation in 1918 over the 1916 area; and the agricultural returns for 1918 showed that, as compared with 1916, 1,842,000 additional acres in England and Wales were growing other crops than grass—roughly, two-thirds of the total additional area aimed at. Sir Thomas Middleton paid a high tribute to the assistance given by the scientific staffs of the agricultural departments of the universities and research stations.

As regards Scotland, Mr. J. M. Caie referred to the essential differences in the agricultural conditions of the two countries as exemplified by the following figures relating to 1917:—

Country	Percentage of total cultivated area under: Permanent grass Per cent.	Rotation grass Per cent.
Scotland	30	31
England	58	9

The increased cropping was therefore to be secured much less by ploughing up old grass land and more by a shortening of the rotations on arable farms than was the case in England.

The increased area aimed at in 1918 was 350,000 acres, and of this 241,000 acres were obtained, or approximately 75 per cent. of the extension aimed at. It is a notable fact that the increased cropping was obtained without any appreciable reduction in the number of horses, cattle, and sheep.

It is believed that a noteworthy feature of the schemes for increased food production for Scotland will be their relatively low cost to the State. No special Food Production Department of the Board was set up; the number of officials attached to the Committees was kept down to a minimum, usually one, or at most two, to each Committee, many of them being officers of the agricultural colleges.

Dr. E. J. Russell read a paper of much interest on "War-time and Post-war Problems of Food Production," in which the author referred to the necessity for devoting renewed attention to drainage and liming in particular, and for providing an adequate amount of organic matter in the soil. He referred to the enormous waste in the preservation of farmyard manure, and to the difficulties of conserving the manure from dairies. The ploughing in of green crops was advocated and an increase in the clover crop, as a means not only of providing more keep, but also of increasing the amount of organic matter in the soil. With reference to manures, Dr. Russell stated that the production of ammonium sulphate had risen to 269,000 tons in 1919. Similarly, the production of superphosphate had risen from 560,000 tons in 1916 to 750,000 tons in 1919, and the amount of basic slag from 321,000 tons in 1916 to 540,000 tons in 1919. The British farmers are probably now using more artificial fertilisers than any other farmers in the world. The change in the composition of basic slag due to the alteration in the methods of manufacture was also dealt with, and the necessity for a complete revision of experimental field work with basic slag was insisted upon.

The possibility of the increased recovery of nitrogen from sewage by means of the "activated" process was also considered.

Amongst the other papers communicated were:—"The Value of Lupins in the Cultivation of Light Land," A. W. Oldershaw: "The Past Neglect and Future Improvement of Livestock in British Husbandry," K. J. J. Mackenzie; "The Electrical Treatment of Seeds," Dr. A. E. Blackburn; "The Composition of Linseed Recovered from Flax Crops," T. W. Fagan; and "The Classification of Cattle Foods," J. Alan Murray.

In the last-named paper Mr. Murray pointed out that the object of the classification should be to bring together in natural groups those foods that are of similar character and quality, irrespective of the concentration and the nutrients in them, and he suggested that the amount of available energy per pound of dry matter should be made the basis of classification. If the foods were arranged in this order the distinction between fresh and dry foods would vanish. No sharp line of demarcation between coarse and fine could be drawn, but the foods could be arranged in groups according to quality, and then might be subdivided according to the amount of digestible protein.

The more important foods in the main natural groups are as follows:—

(1) Cereal and pulse straws.
(2) Inferior hays.
(3) Grasses and clovers in flower, good hays, undecorticated cotton-cake.

(4) Mangels, pasture grass, wheat-bran, brewers' grains.

(5) Swedes, molasses, cabbages, oats, pollards, rape-cake.

(6) Potatoes, barley, sharps, peas, beans, decorticated cotton-cake.

(7) Locust beans, rye, wheat, middlings, cotton-seed, maize-germ cake, palm-nut cake, linseed cake.

(8) Maize, maize meal, gluten meal, gluten feed.

Mr. J. Mackintosh dealt with the outlook in dairying, especially with regard to the return obtained (*a*) on the sale of milk, (*b*) on cheese-making. The effect of the control of prices was discussed, and the possible effect of the high prices now allowed for fresh milk on the use of condensed and dried milk imported from other countries where milk is more cheaply produced. Similarly, in connection with the control of cheese, it was pointed out that if the British cheese-maker cannot produce at a much lower price when control is removed, he will have to meet very severe competition, and the outlook cannot be regarded as satisfactory.

A joint meeting was held with Section K (Botany) to discuss forestry problems. Prof. A. Henry, in a paper on "The Afforestation of Water-catchment Areas," advocated the afforestation of all gathering grounds, not only as a hygienic measure, but also as a means of increasing the timber reserves of the nation.

The enormous extent of these gathering grounds, more than 928,000 acres in extent, has not hitherto been recognised. Of this area 183,416 acres are owned by local authorities, but only in a few cases, *e.g.* Leeds, Liverpool, Manchester, and Birmingham, has the work of afforesting these gathering grounds been taken up seriously. Prof. Henry urged that all catchment areas still privately owned should be compulsorily acquired either by the corporation or by the State, and that all ground suitable for planting should be utilised.

Mr. R. L. Robertson, of the Forestry Commission, gave an interesting account of the work of his Department, but had little to say as to its future policy—a question on which the audience would have been glad of some information. Other speakers included Sir Daniel Morris, Prof. Somerville, and Mr. Duchesne. Mr. W. E. Hiley read a paper on "Sources of Infection of Forest Trees by Fungi."

The work of the Section concluded with an excursion to Iwerne Minster, by kind invitation of Mr. Ismay, where the home farm and stock were inspected.

ALEX. LAUDER.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE annual oration in connection with the Medical Society of London will be delivered on Monday, May 10, at 9 o'clock, by Sir D'Arcy Power, who will speak on "The Rev. John Ward and Medicine."

THE Irish Geographical Association, which now enters upon its second year in close connection with the Geographical Association in Great Britain, has elected Prof. Grenville A. J. Cole as president for 1920, and Miss F. M. Berry, 15 Lower Leeson Street, Dublin, as hon. secretary.

THE following are among the forthcoming free courses of public lectures at Gresham College:—Physic, by Sir R. Armstrong-Jones (January 20 to 23); Geometry, by W. H. Wagstaff (February 3 to 6); and Astronomy, by A. R. Hinks (February 17 to 20). The lecture-hour will be 6 o'clock.

A MEETING of zoologists was held in the rooms of the Linnean Society on Friday, January 9, to consider, among other matters, the teaching of zoology in schools and the salaries and remuneration of zoologists in general. Prof. S. J. Hickson presided, and after discussion the following resolutions were passed unanimously:—(1) That this meeting of British zoologists considers that paragraph 10 of the Report of the Investigators of the Secondary School Examinations Council, appointed to inquire into the methods and standards of award in the seven approved First Examinations held in July, 1918, referring to the subjects of natural history and zoology, is likely to discourage the teaching of zoology in secondary schools, and requests the Zoology Organisation Committee to take such steps as may seem desirable to submit to the Board of Education the views of zoologists on the subject. (2) That this meeting deplores the present difficulty in filling vacancies in the scientific staff of the Natural History Museum, and regards it as mainly due to the poor pay and prospects of the members of the staff. It is of the opinion that this, if not remedied, will react adversely not only on the work of the museum, but also on the advance of zoology in this country. It therefore requests the Zoology Organisation Committee to make such representations in the matter as may seem desirable.

UNDER the title *Discovery*, Mr. John Murray has just published the first number of a monthly periodical intended to promote intelligent interest in all branches of intellectual activity and practical achievement. The journal had its origin in a conference held a short time ago at which representatives of many literary, educational, and scientific associations were present. It has the blessing of these associations, and support in the form of suggestions for contributors and subjects of articles. It is to be maintained under a deed of trust, and the trustees, whose names appear on the cover of the magazine, include the presidents of the Royal Society and the British Academy. There is also a committee of management, which will apparently advise the editor, Dr. A. S. Russell, as to the suitability or otherwise of articles submitted or solicited. With such distinguished patronage and competent opinion, *Discovery* should be able to provide interesting fare month by month for the delectation and profit of many thoughtful minds. Prof. R. S. Conway, who has been largely responsible for the inception of the journal, opens the first number with an instructive article on "The Secret of Philæ," particularly with regard to Gallus the prefect and his relations with the poet Virgil. The other articles are on smoke-screens at sea, Dr. T. Slater Price; the modern study of dreams, Prof. T. H. Pear; discovery and education, the Master of Balliol; the Conference at Paris, J. W. Headlam-Morley; sound-ranging in war-time, Dr. A. S. Russell; and Spitsbergen, Dr. Rudmose Brown.

SOCIETIES AND ACADEMIES.

MANCHESTER.

Literary and Philosophical Society (Chemical Section), December 18, 1919.—Mr. H. N. Morris in the chair.—**H. Moore**: Future supplies of motor fuel. The author dealt with the possibility of meeting the future demand by an increased production of petroleum spirit; benzol as a motor fuel; alcohol as a motor fuel; and the advantages of mixed motor fuels, with particular reference to the compression pressures of engines and to the vapour tension of mixed fuels.

Literary and Philosophical Society, January 6.—Prof. F. E. Weiss, deputy chairman, in the chair.—**R. W. James**: The Antarctic: Shackleton's Expedition of 1914–17. A description of the life and scientific work of the expedition and of the explorations round the

Weddell Sea, Ross Sea, Elephant Island, and South Georgia. The scientific results especially described included the mapping of two hundred miles of new coast-line, soundings in the Weddell Sea, and the study of the natural history of pack-ice.

DUBLIN.

Royal Dublin Society, December 16, 1919.—Prof. H. J. Seymour in the chair.—Prof. H. H. **Dixon** and T. G. **Mason**: A cryoscopic method for the estimation of sucrose. The depression of freezing point of a solution of sucrose is approximately doubled by inversion. It is evident then that the sucrose content may be estimated by determining the freezing point of a solution before and after inversion. This may be conveniently done by the thermo-electric method of cryoscopy. It is convenient to add the invertase to the fluid to be examined in the cold. Without allowing the temperature to rise above 0°, the freezing point is determined. The mixture is then incubated for forty-eight hours at 30°, and the freezing point again observed. The difference between the two observations is a measure of the amount of sucrose originally present. The method has the advantages that only small quantities of the fluid are required (2·5 c.c.), and treatment to remove proteins and other colloids is unnecessary. Using thermocouples of easily attained sensibility, amounts of about 1 mgr. of sucrose may be detected.—Prof. S. **Young**: Brown's formula for distillation. Evidence, based on the theoretical work of Rosanoff, Bacon, and Schulze, is brought forward in support of the conclusion that Brown's formula is applicable to mixtures of chemically closely related liquids, and that the constant in the formula is equal to the ratio of the vapour pressures of the two pure substances at the boiling point of the mixture.—Miss Anne L. **Massy**: The Holothurioidea of the coasts of Ireland. Twenty-five species are enumerated, belonging to thirteen genera. No new species are described, but the following are added to the British-and-Irish area:—*Stichopus regalis*, Cuvier, *Mesothuria Verrilli*, Théel, and *Benthogone rosea*, Koehler, and the belief is expressed that the previous records of *Bathyplotes natans*, Sars, and *Holothuria aspera*, Bell, are referable to *Bathyplotes Tizardi*, Théel, and *Mesothuria lactea*, Théel. Ten of the species dealt with are restricted in the area to the Irish Atlantic slope.

MELBOURNE.

Royal Society of Victoria, November 6, 1919.—Mr. J. A. Kershaw, president, in the chair.—F. **Taylor**: Australian phlebotomic Diptera, new Culicidæ and Tabanidæ, and synonymy. Descriptions are given of a new mosquito, *Uranotaenia albofasciata*, and two new species of Tabanidæ, *Sylvius distinctus* and *Tabanus Geraldi*; whilst a new genus, Phibalomyia, is suggested for Elaphromyia, previously occupied.—A. J. **Ewart**: The synthesis of sugar from formaldehyde and its polymers, its quantitative relations, and its exothermic character. The author's experiments, conducted over a long period, point to the conclusion that sugar in plants is formed directly, and not by the intervention of formaldehyde.—H. B. **Williamson**: A revision of the genus Pultenæa. The members of this genus present some difficulties as to specific limitations, and the work, of which this is a first instalment, dealing with about thirty species, has been undertaken to place it on a more practical basis. It is expected that few species will be erected, and that there may be a reduction of one or two that have been recently described. The conclusions have been based on an exhaustive examination of specimens from all the Australian States.

SYDNEY.

Linnean Society of New South Wales, October 29, 1919.—Mr. J. J. Fletcher, president, in the chair.—Prof. C. **Chilton**: A new Isopodan genus (fam. Oniscidæ) from Lake Corangamite, Victoria. *Haloniscus Searli*, n.g. et sp., described from a number of specimens obtained from the waters of Lake Corangamite, is assigned to the family Oniscidæ, one of the most strictly terrestrial families of Isopoda. The author suggests that Haloniscus is the descendant of a form that was terrestrial in habits, and that, owing to special circumstances arising from its habitat, it has become re-adapted to aquatic life.—J. H. **Maiden**: Notes on the coloration of the young foliage of Eucalyptus. A series of observations is recorded of the colour of the young foliage in a number of species of Eucalyptus growing wild or cultivated in the Sydney district. The interesting suggestion is put forward that the observations justify the belief that a number of species and some groups can be diagnosed by this means.—E. F. **Hallmann**: New genera of Monaxonid sponges related to the genus Clathria. Ten genera are proposed as new.—A. M. **Lea**: Description of new species of Australian Coleoptera. Part xv. Thirty-one species, belonging to fourteen genera in the groups Scarabæidæ, Melandryidæ, and Cerambycidæ, are described as new.

Royal Society of New South Wales, November 5, 1919.—Dr. R. Greig-Smith, vice-president, in the chair.—R. H. **Cambage**: Acacia seedlings. Part v. The author describes ten species of Acacia seedlings. He records various species having flowered in 5-in. and 6-in. pots. One seedling of *A. montana*, three years old and 4 ft. high, bore about 3000 flowers. A seedling of *A. diffusa* and another of *A. cardiophylla* had flowered when only seventeen and nineteen months old respectively. Seeds of *A. melanoxylon* and *A. penninervis* had readily germinated after having been immersed in sea-water for 889 days.—Prof. C. E. **Fawsitt** and C. H. **Fischer**: The miscibility of liquids. The authors have examined a considerable number of liquids in regard to their mutual solubility or miscibility. The mutual solubility of two liquids depends greatly on the molecular volume of these liquids, and the molecular volume again depends on the chemical composition. The knowledge of the chemical composition of a liquid gives some indication of its behaviour in regard to solubility in other liquids.—J. G. **Stephens**: A new method of measuring molecular weights. The author employs the fact that isotonic solutions have equal vapour pressures as a means of determining molecular weights. Two tubes each containing a solution of different substances in the same solvent are placed in communication. Distillation occurs from one tube to the other until the solutions become isotonic, when the molecular weight of one of the substances may be calculated in terms of that of the other.

DIARY OF SOCIETIES.

THURSDAY, JANUARY 22.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. R. R. Terry: Renaissance Music in Italy and England.
ROYAL SOCIETY, at 3.30 (Special General Meeting). At 4.30.—Prof. E. G. Coker and K. C. Chakko: The Stress-strain Properties of Nitro-cellulose and the Law of its Optical Behaviour.—S. Marsh: Alternating-Current Electrolysis.—W. H. Eccles and J. H. Vincent: The Variations of Wave-length of the Oscillations Generated by the Three-Electrode Thermionic Tube due to Changes in Filament Current, Plate Voltage, Grid Voltage, or Coupling.—S. D. Carothers: Plane Strain. The Direct Determination of Stress.—F. Horton and Ann C. Davies: An Investigation of the Effects of Electron Collisions with Platinum and with Hydrogen, to ascertain whether the Production of Ionisation from Platinum is due to Occluded Hydrogen.—L. Bairstow, R. H. Fowler, and D. R. Hartree: The Pressure Distribution on the Head of a Shell moving at High Velocities.
INSTITUTION OF MINING AND METALLURGY (at the Geological Society), at 5.30.—W. Broadbridge: Froth Flotation: Its Commercial Application and its Influence on Modern Concentration and Smelting Practice.
INSTITUTION OF ELECTRICAL ENGINEERS (at the Institution of Civil Engineers), at 6.—J. L. Thompson: Transformers for Electric Furnaces.
CONCRETE INSTITUTE (296 Vauxhall Bridge Road), at 7.30.—Dr. J. S. Owens: The Attrition of Concrete Surfaces exposed to Sea Action.
HARVEIAN SOCIETY (at the Medical Society of London), at 8.15.—Annual General Meeting.

FRIDAY, JANUARY 23.

ROYAL SOCIETY OF MEDICINE (Study of Disease in Children Section), at 4.30.
PHYSICAL SOCIETY OF LONDON (at the City and Guilds Technical College, Leonard Street), at 5.—Dr. J. H. Vincent: Maintained Oscillations in Triode Valve Circuits.—Dr. W. Eccles: Measurements of the Chief Parameters of Triode Valves.—F. W. Jordan: Measurement of Amplification of a Radio-frequency Amplifier.—F. E. Smith: The Measurement of Amplification given by Triode Amplifiers at Audible and at Radio Frequencies.—Hon. C. W. Stopford and C. R. Darling: Exhibition of a Method of Determining the Hardening Temperature of Steel.—C. R. Darling: Exhibition of a Thermal Cell of Constant Voltage.
ROYAL COLLEGE OF SURGEONS, at 5.—Prof. A. Keith: John Hunter's Observations and Discoveries in Anatomy and Surgery: His Contributions to our Knowledge of the Alimentary System (Hunterian Lecture).
INSTITUTION OF MECHANICAL ENGINEERS, at 6.—E. M. Bergstrom: Recent Advances in Utilisation of Water Power.
JUNIOR INSTITUTION OF ENGINEERS (at 39 Victoria Street), at 7 30.—J. A. Reavell: Evaporation in the Chemical Industry.
ROYAL SOCIETY OF MEDICINE (Epidemiology and State Medicine Section), at 8.30.—Dr. F. G. Crookshank: Principles of Epidemiology.—Dr. Cleland and Dr. Campbell: Epidemiology of Acute Encephalomyelitis.
ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Hon. Sir Charles Parsons: Researches at High Pressures and Temperatures.

SATURDAY, JANUARY 24.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—A. Noyes: Aspects of Modern Poetry.
PHYSIOLOGICAL SOCIETY (at King's College), at 4.

MONDAY, JANUARY 26.

ROYAL COLLEGE OF SURGEONS, at 5.—Prof. A. Keith: John Hunter's Observations and Discoveries in Anatomy and Surgery; His Contributions to our Knowledge of the Kidneys, Bladder, and Urethra, and Diseases connected with these Structures (Hunterian Lecture).
ROYAL SOCIETY OF ARTS, at 8.—Capt. H. Hamshaw Thomas: Aircraft Photography in War and Peace (Cantor Lecture).
ROYAL SOCIETY OF MEDICINE (Odontology Section), at 8.—S. F. St. J. Steadman: Dental Sepsis in Children: Its Consequences and Treatment.
MEDICAL SOCIETY OF LONDON, at 8.30.—Pathological Evening.

TUESDAY, JANUARY 27.

ROYAL HORTICULTURAL SOCIETY (at Vincent Square, S.W. 1), at 3.
ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. G. Elliot Smith: The Evolution of Man and the Early History of Civilisation: I. Man's Origin.
INSTITUTION OF CIVIL ENGINEERS, at 5.30.—J. Mitchell: Whitby Harbour Improvement.—R. F. Hindmarsh: The Design of Harbours and Breakwaters with a View to the Reduction of Wave-action Within Them.—J. W. Sandeman: Wave-action in Harbour Areas; with Special Reference to Works for Reducing it at Blyth and Whitby Harbours.—W. Simpson: The Improvement of the Entrance to Sunderland Harbour, with Reference to the Reduction of Wave-action.
ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN (Lantern Meeting), at 7.—Major W. Bladon: Life on the Gold Coast.
ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—Annual General Meeting

WEDNESDAY, JANUARY 28.

ROYAL SOCIETY OF ARTS, at 4.30.—Sir Cecil Hertslet: The Ruin and Restoration of Belgium.
ROYAL COLLEGE OF SURGEONS, at 5.—Prof. A. Keith: John Hunter's Observations and Discoveries in Anatomy and Surgery: His Contributions to our Knowledge of the Genital and Reproductive Systems (Hunterian Lecture).
BRITISH ACADEMY (at the Royal Society), at 5.—Dr. C. Singer: Magic and Medicine in Early England.

THURSDAY, JANUARY 29.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. R. R. Terry: Renaissance Music in Italy and England.
ROYAL SOCIETY, at 4.30.—*Probable Papers*: Prof. W. Bateson: The Genetics of "Rogues" among Culinary Peas (*Pisum sativum*).—L. T. Hogben: Studies on Synapsis. I. Oogenesis in the Hymenoptera.—H. Onslow: A Periodic Structure in many Insect Scales, and the Cause of their Iridescent Colours.
ROYAL COLLEGE OF PHYSICIANS, at 5.
ROYAL SOCIETY OF MEDICINE (Balneology and Climatology Section), at 5.30.—Dr. N. Wood and Others: Discussion on the Merits and Defects of the British Health Resorts.

WIRELESS SOCIETY OF LONDON (at Institution of Civil Engineers), at 6.—R. C. Clinker: A Portable Valve Set and some properties of C.W. Circuits.

FRIDAY, JANUARY 30.

ROYAL COLLEGE OF SURGEONS, at 5.—Prof. A. Keith: John Hunter's Observations and Discoveries in Anatomy and Surgery; His Contributions to our Knowlege of the Eye, Ear, and Nose (Hunterian Lecture).
INSTITUTION OF ELECTRICAL ENGINEERS (Students' Meeting) (at the City and Guilds Technical College, Leonard Street), at 7.—Major K. Edgcumbe and Others: Discussion on Quantity Production as a Panacea.
ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—S. G. Brown: The Gyrostatic Compass.

SATURDAY, JANUARY 31.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir F. W. Dyson The Astronomical Evidence bearing on Einstein's Theory of Gravitation I. Movement of the Perihelion of Mercury.
PHYSIOLOGICAL SOCIETY (at King's College), at 4.

THE WORKS OF TORRICELLI.

Opere di Evangelista Torricelli. Edite da Gino Loria e Giuseppe Vassura. Vol. i. Parte 1. Pp. xxxviii+407. Vol. i. Parte 2. Pp. 482. Vol. ii. Pp. 320. Vol. iii. Pp. 521. (Faenza: G. Montanari, 1919.) Price 60 franchi the 3 vols.

THIS work consists nominally of three volumes, of which the first contains mathematical papers, the second papers on mechanics, and the third the correspondence of Torricelli. In reality there are four volumes. It is to be hoped that this inconvenient way of describing the volumes of a work will soon go out of fashion. This is the first complete edition of the collected writings of Evangelista Torricelli; it is published under the auspices of the municipality of his native town, Faenza, who have in this way raised a lasting memorial to their celebrated townsman.

Torricelli was born in 1608, and died in 1647. In the introduction to vol. i., Signor Loria has given the few particulars about his life which it has been possible to gather. In 1627 Torricelli went to Rome to study under Benedetto Castelli, a disciple of Galileo, who in the previous year had been appointed professor of mathematics there. He seems to have remained at Rome until October, 1641, when Galileo, who had heard from Castelli of the valuable work in dynamics done by his pupil, invited him to Arcetri. Torricelli gladly accepted the invitation, but was only for a few months able to benefit by the instruction thus offered, as Galileo died on January 6, 1642. Soon after, Torricelli was appointed to the post of mathematician to the Grand Duke of Tuscany held by Galileo, and spent the few remaining years of his life at Florence until his death on October 25, 1647. The subsequent fate of his unpublished papers and letters is told in the introduction; they had a narrow escape from total destruction in 1733, when they were sold as waste paper to a pork butcher. Fortunately, the first customer to whom one of the papers was handed, wrapped round a sausage, was Nelli, the biographer of Galileo, who to his horror recognised the handwriting of the great man, and at once secured the whole pile of papers.

It was the study of Galileo's "Discorsi e dimonstrazioni matematiche intorno a due nuove scienze" which led Torricelli to make further investigations in dynamics and hydrodynamics. His principal results appeared in two books, "De motu gravium naturaliter descendentium" and "De motu projectorum," which appeared in a volume of tracts, "Opera geometrica," published in 1644. It is the second of these which contains his experiments on the flow of fluids from vessels through a small orifice. These experiments had been commenced by Castelli, whose erroneous result, that the velocity of outflow was proportional to the depth from the surface, was corrected by Torricelli. He showed that the quantity of water flowing from a hole in the horizontal bottom of a vessel in equal times was proportional to the series of odd numbers, if the quantity flowing out in the last unit of time was put equal to one. A particle from the surface flows out with a velocity equal to that which it would have acquired by falling from its original height over the opening. Therefore the outflowing velocity is proportional to the square root of the height. From this it followed that the figure of a jet issuing from a small hole in the side of a vessel is a parabola. Among Torricelli's discoveries is also the mechanical principle that if two or more bodies are so connected that their motion will neither make their centre of gravity rise nor fall: they are in equilibrium.

The fame of Torricelli rests, however, mainly on his discovery of air-pressure. He knew from Galileo that water would not rise in a tube closed at the top more than 33 ft., which was supposed to indicate that Nature's dislike to empty space (*horror vacui*) had a limit. Torricelli thought that this was nonsense and that it would be interesting to experiment with a heavier fluid. He anticipated that mercury would rise only to one-thirteenth of the height to which water would rise. At his instigation Viviani made the experiment in 1643, and found that the column of mercury in a tube closed at one end and inverted in a vessel containing mercury sank to about 30 in. and remained there. Torricelli found, however, by repeated measures that the height of the column of mercury was always changing, and he rightly interpreted this as indicating changes in the pressure exercised by the air on the open surface of the mercury. In a letter to his friend Ricci of June 11, 1644 (vol. iii., p. 186), he says that he has made these experiments, not to produce a vacuum, but chiefly to make an instrument for measuring changes in the density of the air. He explains that we live at the bottom of an ocean of air, the weight of which at the surface of the earth is about equal to one-four-hundredth of the weight of an equal volume of water. During the remaining three years of his life Torricelli does not seem to have pursued these researches further, and the new doctrine was not universally accepted until Pascal in 1648 had proved the connection of barometric height with the height of the observer above the surface of the earth, and Guericke soon after had proved by experiments the enormous power of the pressure of the air.

Not a few of the mathematical papers published in the first (double) volume have never been printed before. They deal with conic sections, spirals (Torricelli discovered the logarithmic spiral), maxima and minima, etc. They make us feel that if a longer span of life had been granted him he would have taken his place among those mathematicians who paved the way for the advent of the differential calculus. The quadrature of the cycloid was one of the subjects treated in the "Opera geometrica." It is well known that Roberval charged Torricelli with having stolen his results on this subject, as well as Fermat's method of maxima and minima, and that Pascal was weak enough to publish this accusation in 1658, adding the assertion that Torricelli had confessed the robbery. This outrageous charge was soon after proved by Carlo Dati and Wallis to be utterly groundless, and it only showed that Roberval was not very particular as to the truth of any statement he made. There is no reason whatever to doubt that Torricelli found his results independently.

This new edition is in every way satisfactory, but we could have wished that the pages of the originals had been given in the margin. This is too often neglected by editors of a man's collected works, and the omission makes it very difficult to look up quotations from the original editions.

J. L. E. D.

PROBLEMS OF THE FRUIT-GROWER.

Science and Fruit-Growing: Being an Account of the Results obtained at the Woburn Experimental Fruit Farm since its Foundation in 1894. By the Duke of Bedford and Spencer Pickering. Pp. xxii+351. (London: Macmillan and Co., Ltd., 1919.) Price 12*s*. 6*d*. net.

THE appearance of this volume will be welcomed by all interested in scientific pomology, and the practical fruit-grower should find it indispensable as a work of reference dealing with many of the problems with which in some form or other he is constantly faced. In neither case will the contents be unfamiliar, since the investigations at Woburn have been closely followed throughout their course, and the results have been published at intervals in a series of reports. Some of the latter, however, have been long out of print, and for this and other obvious reasons the publication of a connected and comprehensive account of the many-sided work conducted at Woburn since its foundation will be appreciated.

The preface quotes at length an article which appeared in NATURE of September 19, 1895, dealing with the genesis of the station, which was due entirely to the public-spirited enterprise of the Duke of Bedford, who furnished the necessary financial aid, and of Mr. Spencer Pickering, who has now for a quarter of a century devoted himself to the elucidation of some of the problems of the fruit-grower, and has laboured single-handed and under the additional handicap, in recent years, of ill-health. Under these conditions the volume of achievement has been remarkable; and although the authors recognise the limitation of aim necessitated by force of circumstances and plead for leniency of criticism, they may be assured that, notwithstanding the controversial character of much of their work and the storms of adverse opinion aroused from time to time, the world of horticulture recognises the great debt which it owes to them both for the value of their researches and for the stimulus given to scientific investigation in horticulture in this country.

It is impossible within the limits of a short review to include adequate notice of all the subjects of horticultural importance considered in this volume. Their range is extremely wide, successive chapters dealing with investigations on soil preparation for planting, methods of planting, pruning, manures, spring frost damage and its prevention, the fruiting of trees in successive seasons, the flowering of apple trees, insecticides and fungicides, insect and fungoid pests, soil sterilisation, the effect of grass on trees, the toxic action of one crop on another, the behaviour of plants in masses, and flocculation in soils. Since, however, opportunity for individual treatment has already been provided on the occasions of the appearance of the separate reports previously referred to, attention here may be confined to a few of the more general issues.

Except in the direction of chemistry, the goal aimed at was the investigation of those cultural problems in which much work could be done without the assistance of specialists in the respective branches of science concerned, since the station was not equipped for a more varied programme. The field of work which it was possible to cover within those limits was, however, remarkably wide, as the list of subjects just enumerated indicates. How far towards the solution of such cultural problems progress can be made under these conditions depends obviously on the nature of the individual problem; but, without in any way detracting from the value of the Woburn work, its main result has been to emphasise the need for the co-operation of the plant physiologist, the soil chemist and physicist, the entomologist, and the mycologist with the expert pomologist in investigations of this character. The ideal fruit experiment station, as the authors recognise in their preface, must be equipped to meet that need.

The difficulties experienced in the measurement of results of experiments on fruit culture have been adequately recognised. The Woburn methods of measurement appear, on the whole, satisfactory, although in certain cases to average the combined results of varieties of dissimilar character tends to obscure their significance. Experience at Woburn has apparently but rarely demonstrated that selection of results by the investigator is necessary, but in this respect the authors have perhaps been particularly fortunate in escaping anomalous behaviour on the part of individual trees caused by pest damage, local soil variations, or other accidental circumstances. It is interesting to note that their conclusions as to the minimum number of trees or plants which each plot under treatment should contain accord closely with those based on recent work in the United States.

The extent to which the results in the experiments with fruit trees may have been affected by root-stock variations cannot be estimated, since the nature of the root-stock and the precautions taken to ensure uniformity are not generally specifically stated. Recent investigations at East Malling and Long Ashton have demonstrated such wide variations in the characters of both Paradise and free stocks in the case of the apple, for example, that it is clear that uniformity of root-stock must be secured if the results are to be beyond criticism.

The investigations on insecticides and fungicides are of particular interest to plant pathologists, since, even if few or none of Pickering's formulæ for individual spray fluids establish themselves in general use, much light has been thrown upon the chemical side of the subject, especially in the case of Bordeaux and Burgundy mixtures. The view adopted as to the method of fungicidal action of the copper compounds concerned in the latter spray fluids has been the subject of considerable controversy, and there are, probably, too many weak points in the evidence adduced and in the line of argument taken in the discussion to permit of its general acceptance.

In a work of this description, covering so wide a range of subjects, it is not surprising to find a few mis-statements, such, for example, as that the scale insect, *Aspidiotus ostreaeformis*, occurs only under glass in this country. Again, the assertion that the greater part of the naphthalene in naphthalene-paraffin-soft soap insecticides of the paranaph type separates out on dilution does not hold in cases where the naphthalene is first dissolved in the paraffin. They are, however, but minor defects in a work distinguished for interest and originality, and sure to serve as a fruitful source of inspiration in many directions.

METAPHYSICAL RESEARCH.

Proceedings of the Aristotelian Society. New series. Vol. xix. Containing the papers read before the Society during the fortieth session, 1918–19. Pp. iii+311. (London: Williams and Norgate, 1919.) Price 20s. net.

Problems of Science and Philosophy. Aristotelian Society. Supplementary Volume II. The Papers read at the Joint Session of the Aristotelian Society, the British Psychological Society, and the Mind Association, held at Bedford College, London, July 11–14, 1919. Pp. iii+220. (London: Williams and Norgate, 1919.) Price 12s. 6d. net.

THE old idea of metaphysics, that it marks a stage of human intellectual activity when, dissatisfied with a primitive anthropomorphic projection of images which peopled the unseen world with gods and developed a theology, man formed for himself abstract entities and quiddities and put these in the place of his gods—a stage of intellectual activity from which we have now passed to the clear, sane world of positive science—has long passed away. The well-worn joke of the metaphysician looking for a black hat in a dark room no longer raises a smile. Metaphysical research is coming into ever closer relations with scientific problems. It is now seen to penetrate deeply into every problem of physics and biology, as well as of psychology. The annual volume of the "Proceedings of the Aristotelian Society" and the supplementary volume entitled "Problems of Science and Philosophy" clearly indicate this new orientation.

The supplementary volume is of special interest from the point of view of science. The Aristotelian Society has organised for some years past an extra session, in which representative leaders in the sciences are invited to join professed philosophers in discussing the fundamental problems of science. The session was held this summer at Bedford College, London, and attracted very wide interest. This volume contains the published papers which were issued for the discussions. They reach a high standard, and are likely to influence the direction of scientific speculation for some time to come.

In the first paper Mr. Bertrand Russell has given a very lucid example of what he has described as scientific method in philosophy. He submits "pure experience" to exhaustive scientific analysis. The outcome, if we follow and accept the writer's argument, is surprising, and probably to most people disconcerting. Like Hume, he fails to discover anything in experience corresponding to the subject, or anything like an act of perceiving which might constitute a subject, and he concludes, therefore, that the subject of experience is a logical construction. The next article is of more distinctively scientific interest. It is a symposium on the subject of "Time, Space, and Material." It is discussed from several points of view, scientific and philosophical, by Prof. Whitehead, Sir Oliver Lodge, Prof. J. W. Nicholson, Dr. Henry Head, Mrs. Adrian Stephen, and Prof. Wildon Carr. The keynote is Prof. Whitehead's criticism of the concept of "all Nature at an instant" and his insistence that the ultimate datum of science is an event. The continuity which science must hypostatise is not an ether of space, but an ether of events. There are two other symposia of present interest, one on the problem of individuality with particular reference to the concept of the relation of the individual to God, the other on the epistemological problem: "Is there 'knowledge by acquaintance'?"

The annual volume contains ten papers read during the past session of varied, but without exception of high, interest. The presidential address by Dr. G. E. Moore on "Some Judgments of Perception" is an admirable piece of close reasoning in analysis of a simple judgment, such as "That is an inkstand." Methodological problems of various kinds are discussed in papers by Prof. Laird, Mr. C. D. Broad, Mr. A. E. Heath, and Prof. J. B. Baillie. Prof. Wildon Carr expounds and defends the concept of "windowless" monads. Mrs. Duddington, in a paper on "Our Knowledge of Other Minds," develops an interesting theory of the immediacy and directness of this knowledge. Principal Jevons writes an appreciation of Tagore. Mr. A. F. Shand has an original study of deep psychological interest on "Emotion and Value." The last paper in the volume is by the Dean of St. Paul's on "Platonism and Immortality." It is a philosophical treatment of the most profound problem in social and political ethics, one which, moreover, is of great scientific interest—is there any reason to believe in human progress? The Dean holds that there is not.

MEDICAL AND SOCIAL WAR-WORK IN EGYPT.

(1) *The Australian Army Medical Corps in Egypt. An Illustrated and Detailed Account of the Early Organisation and Work of the Australian Medical Units in Egypt in* 1914–1915. By Lt.-Col. J. W. Barrett and Lt. P. E. Deane. Pp. xiv+259. (London: H. K. Lewis and Co., Ltd., 1918.) Price 12*s*. 6*d*. net.

(2) *The War Work of the Y.M.C.A. in Egypt.* By Sir J. W. Barrett. Pp. xx+212. (London: H. K. Lewis and Co., Ltd., 1919.) Price 10*s*. 6*d*. net.

(1) THE first book gives a detailed account of the early organisation and work of the Australian Army Medical Corps in Egypt. Prior to the outbreak of war the Corps was of meagre dimensions, in spite of the fact that compulsory medical training had come into operation in Australia in 1911. When war was declared, the Australian Government decided to raise and equip a division, 18,000 strong, the medical establishment of which consisted of regimental medical officers and three field ambulances. Later, further divisions were raised and sent to the front. It soon became clear that "lines of communication medical units" were required, and the first hospital units with a 520-bed hospital arrived in Egypt in January, 1915, and were housed at the Heliopolis Palace Hotel. This afterwards expanded into hospital and convalescent accommodation consisting of 10,600 beds, and in the three days April 30–May 2, 1915, no fewer than 1352 cases were admitted from Gallipoli, and were successfully dealt with—a sufficient tribute to the completeness of the organisation. A general review is given of the sickness and mortality among the Australians, and of the steps taken to prevent epidemics. A chapter is devoted to venereal diseases—described as being the greatest problem of camp life in Egypt—in which much sound advice is given for dealing with these scourges. A further chapter deals with the work of the Red Cross in Egypt, and in another suggestions are made with the view of increasing the efficiency of the Australian Army Medical Service. Sir James Barrett and Lt. Deane have compiled a very readable and useful narrative, and the volume is illustrated with many plates.

(2) This volume deals not with the general work of the Young Men's Christian Association, but with the special war work so successfully undertaken by it in Egypt and Palestine. A brief account is first given of the foundation and general policy of the association and of its pre-war work in Egypt. Two months after war broke

out 20,000 Territorials reached Egypt, and the Y.M.C.A. at once began its work among them. At Heliopolis 5000 troops encamped in the desert, with nothing to do after the day's routine ended, and within four days a marquee had been obtained, and writing accommodation, followed by a circulating library and canteen, provided. In addition, postal facilities were arranged for three weeks until the Government post-office was established, and some 1500–2000 letters were dealt with daily. From 1915 onwards soldiers' clubs were established in all the principal military centres of the Near East. Sir James Barrett bears eloquent testimony to the invaluable work of the Y.M.C.A. In a concluding sentence he says: "The strength, in my judgment, of this organisation lies in the fact that its members possess an ideal which finds expression in services to their fellows of the most practical character. . . . Whether we shall all agree with their ideals in the abstract or not is outside the question, for all can join in admiring and respecting their single-minded efforts to better humanity." Gen. Allenby, who contributes a preface, writes in a similar strain: "No one has more reason than I to be grateful to the Y.M.C.A. for its work in connection with the army. Throughout the campaign its workers have followed closely the fighting line, and their labours have done much to keep up the moral, mental, and physical efficiency of my troops. . . . Broad-minded Christianity, self-regardless devotion to work, a spirit of daring enterprise, and sound business guidance have built up an organisation which has earned the gratitude of the Empire."

SCIENTIFIC BIOGRAPHY.

(1) *Herschel.* By the Rev. Hector Macpherson. (Pioneers of Progress: Men of Science. Edited by Dr. S. Chapman.) Pp. 78. (London: S.P.C.K.; New York: The Macmillan Co., 1919.) Price 2*s.* net.

(2) *Lectures on Ten British Physicists of the Nineteenth Century.* By Alexander Macfarlane. (Mathematical Monographs: No. 20.) Pp. 144. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1919.) Price 7*s.* 6*d.* net.

(3) *Joseph Dalton Hooker.* By Prof. F. O. Bower. (Pioneers of Progress: Men of Science. Edited by Dr. S. Chapman.) Pp. 62. (London: S.P.C.K.; New York: The Macmillan Co., 1919.) Price 2*s.* net.

IN most directions we have had to abandon our aspirations and sanguine prophecies of a reconstruction which should lead to a better world and almost justify the horrors of war. But in one direction hope remains; there has certainly been a growth in the popular appreciation of science. However, like most good things, it has its dangers; it was the applications of science, rather than science itself, which stimulated popular interest during the war. We are not yet sure that the better judgment of value is based on a better understanding; and, if it is not, if science is to be appreciated merely because it is useful in the arts of war and peace, we shall soon be wishing fervently that interest may once more be replaced by apathy.

The danger is partly our own fault. We complain that the populace have neglected science; but science has also neglected the populace; we have not offered the laity of our best. "Popular science" has too often consisted of superficial lectures with showy experiments or trashy sentimentalism about the romance of radium and the starry heavens. We ought not to be surprised if those to whom science is presented in so unscientific a guise are indifferent to its value and ignorant of its meaning.

In order to make the laity understand rightly, we must start from a common ground. And there is a common ground: the proper study of mankind is man. Great men of science are often great men as well; by utilising the universal interest in great personalities, we may lead the way to a true comprehension of their work. Science, it is true, has a strong impersonal element; but it has also a strong personal element; it is on the latter that we must found a comprehension of the former. It is significant that an abstruse scientific problem has been noticed recently in the daily Press under such headlines as "Newton *v.* Einstein." The personal element of the matter was the first to appeal to the popular imagination.

For these reasons the volumes before us would have been welcome, even if they had represented an attempt rather than an achievement. It would not have been surprising if first attempts at popular scientific biographies had been partial failures; but here they are not. We have left little space to speak in detail of Mr. Macpherson's and Mr. Macfarlane's books, because all that there is to be said of them can be adequately conveyed in a single sentence. They are as good as they can be, and a great deal better than we should have imagined possible. Mr. Macpherson's task was perhaps as easy as that of a scientific biographer can be, for Sir William Herschel's work is easy to understand and the facts of his life might have been taken from a romantic novel; but everything looks easy when done by a master of the craft. Mr. Macfarlane's book is even more remarkable;

he gives about fourteen pages (it was originally an hour's lecture) to each of his subjects, and in that short compass manages to bring before his audience the picture of a complete personality, clearly distinguished from all the rest, and an adequate idea of the nature of his scientific work. There are a few minor inaccuracies, but our only quarrel is with the title, for of the ten (Maxwell, Tait, Rankine, Kelvin, Stokes, Airy, Adams, Whewell, Babbage, John Herschel) not all can strictly be said to be physicists. However, this is the fault of the editors, not of the author, for the book is posthumous; and we would not willingly part with any of the ten; Babbage, the least physical, is perhaps the most interesting. We are glad that neither of the authors is ashamed to tell again the old stories; the younger generation must learn them somewhere, and they could not be better told. But did Freddy Tait really drive that golf ball?

Concerning Prof. Bower's "Hooker," little also need be said. It is scholarly, as we should expect from its author, but, alas! it is not interesting. Prof. Bower has not, we think, managed to convey to his readers why either Hooker or his work was great. But some failures in an enterprise of this kind there must be; let us be thankful for the successes. Everyone ought to read Mr. Macpherson's and Mr. Macfarlane's books, and make all his acquaintances do the same. N. R. C.

OUR BOOKSHELF.

The Aviation Pocket-book for 1919–20. A Compendium of Modern Practice and a Collection of Useful Notes, Formulae, Rules, Tables, and Data Relating to Aeronautics. By R. Borlase Matthews. Seventh edition, revised and enlarged. Pp. xxiv + 536. (London: Crosby Lockwood and Son, n.d.) Price 12*s.* 6*d.* net.

THE impression received from a perusal of this book is that the author's chief aim in life is the classification of data, and that the value of the data is of secondary importance. The elaborate arrangements which make the pocket-book suitable for cutting up to fit a number of standard loose-leaf books or card index cabinets are valuable in proportion to the value of the information contained on its leaves. Since many of the tables are inaccurate, it would appear that the author holds a different view.

The resistance of the wings of an aeroplane is stated to have an average value equal to 15 per cent. of the total for the aeroplane, whereas it is probably never less than 50 per cent., and certainly greater than 60 per cent. in the case of modern aeroplanes at economical flying speeds. In the case of engines, the variation of power with height is represented in a table which is seriously wrong when the height exceeds 10,000 ft. Even the tabulated characteristics of a standard atmosphere do not agree with those used in British aeronautics. The weight per horse-power of engines to be used in preliminary design is given too high; the maximum of 200 h.p. there quoted is insufficient to cover the needs of aviation in 1920.

One also wonders why some twenty pages are devoted to tables and formulæ referring to flat plates, whilst four suffice for what the author describes as "modern wings." These instances of defective data suggest that the author would have been better employed in correcting his data than in developing a classification system. It is fortunate that much of the data is taken solidly from the publications of such bodies as the British Engineering Standards Committee and the Royal Aeronautical Society, and it is as a very full index to these works that the pocket-book appears to find a justification for its existence.

A Manual of the Electro-Chemical Treatment of Seeds. By Dr. Charles Mercier. Pp. viii + 134. (London: University of London Press, Ltd., 1919.) Price 3*s.* 6*d.* net.

THIS book is essentially a personal statement, and the reviewer is under the serious disadvantage that the distinguished author died soon after writing it, and can no longer make the rejoinder that a suitable critique would inevitably call forth. It deals entirely with a proprietary process for the treatment of seeds before sowing.

The process consists in placing the seeds in a 2½–5 per cent. solution of sodium or calcium chloride through which an electric current is passing, then taking them out and drying them. Five gallons of solution are needed per bushel of seed, and 8 watts of electricity per gallon. The drying is carried out by means of a blast of air heated to 100° F. The seed must then be sown as early as possible, as the effect lasts only a month.

Extraordinary increases in crop are claimed, and some astonishing photographs are reproduced in the book. Very few actual figures of crop weights, however, are available, and the author did not deal adequately with the awkward fact that the method had not been a success at the experimental stations where treated seed supplied by the proprietors had been tested. No useful purpose would, however, be served by referring further to such points as these, for Dr. Mercier cannot reply.

The New Hazell Annual and Almanack. By Dr. T. A. Ingram. Pp. 873. (London: Henry Frowde, Hodder and Stoughton, 1920.) Price 6*s.* net.

ON p. 206 of this useful annual we find a list of the Nobel prizemen for physics, chemistry, medicine, literature, and peace from 1901 onwards, together with a note on the Nobel foundation. This is an example of the kind of information which we expect to find in "Hazell," but not in other general annuals; and we are rarely disappointed. The sections on scientific and educational subjects are full of facts concisely presented, and the whole volume rightly claims a place upon every reference bookshelf.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Deflection of Light during a Solar Eclipse.

IT may be worth while to give my endeavour to obtain a rough value for the refraction effect of the atmosphere during a total eclipse of the sun. The simplest case possible is when the sun is in the zenith.

I will assume that the air density of the normal atmosphere has been removed, and that there is left the atmosphere which produces the abnormal effects in question. This is not necessary, but it makes the calculation somewhat simpler.

If O be the place on the earth's surface of maximum air density, the density ρ_0 of the residual atmosphere there will be one-seventieth of the density of the normal atmosphere if we assume that it corresponds to a fall of 4° C. in the atmosphere when in equilibrium. Take Ox in the direction opposite to that of the motion of the shadow, and Oy the vertical passing through the centre of the moon's disc. This assumes that the density is greatest at the centre of the shadow, which is almost certainly incorrect. I will take the density at any point of the residual atmosphere in the plane of xy to be given by

$$\rho = \rho_0(1 - \kappa x)e^{-\beta y},$$

where β, although it varies with temperature, is assumed to be constant and equal to $1 \cdot 3 \times 10^{-6}$, distances being measured in centimetres. If we assume that the density of the atmosphere becomes normal at 150 miles distance from O, κ will be $4 \cdot 17 \times 10^{-8}$.

With these values of the two constants, the above formula expresses that the horizontal density gradient is uniform and independent of height, and that the atmosphere has its normal density at a distance of 150 miles. None of these statements is correct. The shadow-cone in the earth's atmosphere acts like a down-draught chimney or a kind of thermal air-compression pump, increasing the density in the central region of the shadow and diminishing it in surrounding regions. Thus κ may have a very much greater value than that given above, and, indeed, the factor $1-\kappa x$ may be quite incorrect in form.

However, taking this formula for the density, the index of refraction of the residual atmosphere at any point is

$$\mu = 1 + (\mu_0 - 1)(1 - \kappa x)e^{-\beta y},$$

where $\mu_0 = 1 \cdot 000004$.

The path of any ray in the plane of xy might be got by solving the usual differential equation for this case, but I have not succeeded in getting a solution. However, the amount of the deviation can be obtained without knowing the actual path.

If ϕ be the angle which the tangent to a curve of equal refractive index makes with the axis of x, we have

$$\tan \phi = \frac{\partial \mu}{\partial x} \Big/ \frac{\partial \mu}{\partial y} = \frac{\kappa}{\beta(1-\kappa x)}.$$

It can easily be shown that the radius of curvature of the lines of equal density or refractive index in the neighbourhood of the axis of y is much greater than the radius of the earth. Thus, as we have assumed the earth's surface to be plane, we can assume these lines to be straight in the portion of the atmosphere concerned. On the axis of y, $\tan \phi = 0 \cdot 032$, and for an observer at O the refraction of the light coming from a star near the edge of the sun's disc will be the same as if he were looking through an atmosphere stratified in parallel planes, making an angle ϕ with the horizon. A ray coming from such a star will make an angle of $\phi - 15'$ with the normal to these planes, and the refraction will be

$$(\mu_0 - 1)\tan(\phi - 15')$$
$$= 0 \cdot 000004 \times 0 \cdot 0277$$
$$= 1108 \times 10^{-10} \text{ or } 0 \cdot 023''.$$

If the ray come from a star the angular distance of which from the sun's centre is 45′, the result is 0·0082″, which is a little more than one-third of 0·023″. But if, as I believe, κ has been greatly underestimated, the possible values of these refractions are much greater.

If the observer be not at the origin, but at a distance along the positive direction of the x-axis, the refraction of the light from stars on the other side of the sun's disc will not be away from the sun's centre, but towards it, and *vice-versa*, if he be on the other side of the origin. But no difficulty of this kind occurs for refraction in planes perpendicular to Ox if the position of the observer be on the x-axis. Perhaps it is worth mentioning that, from the only account of the observations I have seen, it appears that, with the exception of one star, all the changes in right ascension were of the same sign, whereas the changes in declination were all in the right direction.

I ought to mention in reference to Sir Arthur Schuster's letter (NATURE, January 8, p. 468) that I never thought of a ray that, in its passage through the earth's atmosphere, lay partly inside and partly outside the umbra. And I thank him for correcting the slip that I made in the angular radius of the sun's disc. In these days of relativity, an error of fifteen minutes either of arc or of time is, perhaps, excusable.

ALEXR. ANDERSON.

University College, Galway, January 14.

"The White Water."

IT is possible that some readers of NATURE can enlighten me on the cause and nature of what the Arabs call "The White Water." This phenomenon was witnessed by me on two occasions at the entrance to the Persian Gulf in the vicinity of the Quoin. On both occasions the time was about 8 p.m. There was no moon on the first occasion, but a moon on the second.

I first observed what appeared to be a line of breakers ahead of the ship; this was not possible because we were in deep water and the position of the ship was known. As we approached, it seemed that these supposed breakers were a succession of phosphorescent waves of a period of about sixty to the minute. The waves extended, so far as could be seen, for about two miles.

In addition to these waves there were also phosphorescent Catherine-wheels, both right- and left-handed, also phosphorescent light apparently coming to the surface and radiating out in all directions.

The phenomena lasted for about half an hour, gradually fading away, apparently sinking. There were strong atmospheric disturbances at the time. Both nights were clear and the sea was calm. I could obtain no local information. I may add, in conclusion, that I was not the only person who witnessed this display.

A. R. PALMER.

Portsmouth, January 13.

I HOPE that Capt. Palmer's letter will induce officers of the Indian Marine to investigate any cases of "White Water" that come under their notice. I am sure that the director and staff of the Indian Museum at Calcutta, where the collections of the I.M.S. investigator are deposited, will give them every assistance, and examine any specimens they may obtain. We want to know what are the organisms concerned in the production of the phosphorescence, and the physical conditions of the water in which they were living. The organisms can be strained out of the water by a silken or muslin net—or the hose turned to run through a piece of either cloth—and preserved in spirit or formic aldehyde (1 part in 30 of sea-water). They should be accompanied by exact information as to position, state of weather and moon, and temperature of the water; a sample of the actual water in a green beer-bottle would also be useful.

Phosphorescence so diffused as to make the sea appear absolutely white is, in my experience, rare. Indeed, I have seen "White Water" only on two occasions; the first halfway between Ceylon and Minikoi, on a dirty night towards the end of May, 1899 (heavy weather from south-west, maximum effect about 9.30 p.m., dark again by 11 p.m.); the second seen from Minikoi, about five weeks later, at the commencement of the Great Monsoon (south-west), time 9–10 p.m. A bottled sample of the water of the first showed only the same organisms as normally produce "sparks," but a tow-net sample of the second was so rich in the eggs, etc., of the organisms, which inhabit the slopes of Minikoi, and in breeding worms that normally bore into its corals, that I regarded it as perhaps a seasonal breeding phenomenon.

Waves of fire produced by myriads of sparks from minute water-fleas (especially Ostracods) and Protozoa are common in such tropical seas, but they merely mark the wind waves, and are not the same as the waves described by Capt. Palmer, which I think must be due to an optical effect. Globe or lantern-like effects produced by umbrella or barrel-shaped jelly-fish I associate with calm weather. They are most noticeable in the early part of the night, and do not usually last for more than an hour or two. As patches up to a few hundred yards across occur, and as the jelly-fish are sometimes so abundant that they can be collected in a bucket thrown overboard, the sea might be described as "White Water," but I am sure that this is not what the fishermen of the Indian Ocean know by that name. Fish passing through water highly charged with phosphorescent organisms frequently execute Catherine-wheels, etc., but fish themselves are often phosphorescent from bacteria living upon their skin. J. STANLEY GARDINER.

Zoological Laboratory, The Museums, Cambridge.

Proposals for a Plumage Bill.

PROF. DUERDEN's letter in NATURE of January 15 might by its phrasing lead to the supposition that a few persons only are agitating for a novel Bill to prohibit the importation of plumage. The trade has been keenly opposed by all naturalists, not only in Great Britain, but also in the United States, Canada, Australia, and nearly every country in Europe for many years. The arguments now used were all urged by the trade when the Government Bill of 1914 passed its second reading in the House of Commons.

We are told that the introduction of another Bill will be "viewed with alarm in South Africa," although the ostrich-feather trade is a British Colonial industry carried on under totally different conditions from those of the trade in wild birds' (or "fancy") plumage. In December, 1913, the hon. secretary of the Ostrich Farmers' Association of South Africa, representing 1700 farmers, wrote to the Royal Society for the Protection of Birds as follows:—"My association has from time to time taken the feeling of its members on the subject-matter of the Bill about to be introduced by Mr. Hobhouse, and they have expressed their entire sympathy with, and approval of, the Bill. . . . The attitude taken up by the feather dealers in London is inexplicable to my association, and you have my assurance that they have not the least support from a single ostrich farmer in South Africa."

With regard to the "serious slump" said to have resulted from the Anti-Plumage Bill of 1914, it may readily be supposed that all such luxuries as feathers would suffer a slump during the war; but, as a matter of fact, one of the chief London brokers reported in 1915 that, "in spite of many difficulties, a large quantity of goods has been dealt with," and that there had been "a sudden improved demand from America." This demand followed the passing of the tariff clause prohibiting the importation into the United States of all "fancy" feathers.

Prof. Duerden himself reasons that decrease in "fancy" feathers would improve trade in ostrich feathers when he argues that the æsthetic tastes we have inherited from our barbarian ancestors demand that we should decorate ourselves with feathers of some sort.

The argument that we must encourage a French industry is also well-worn. It is true that the traders in Paris cried out in 1914 that the Hobhouse Bill was designed to protect the ostrich feather industry of the Cape at the expense of Parisian feather-dressers; but the Société d'Acclimatation de France replied: "The interests of workpeople will not be affected. . . . It is only a very small batch of speculators that can have to suffer. They are very rich."

Prof. Duerden has "grave doubts" whether the "ruthless destruction of birds" for trade can best be prevented by discouraging or prohibiting that trade. It is open to him to suggest a better way. The proposition that birds-of-paradise, lyre-birds, egrets, herons, trogons, orioles, terns, kingfishers, and all the rest of the feather-traders' victims, from albatross to humming-bird, might be "farmed" after the manner of the flightless ostrich, and plucked or killed for the market "in conformity with the highest humane demands," may be of interest to aviculturists; it has no practical bearing on the question of to-day. What science and humanity alike demand is immediate action to save the birds of the world from the ruthless and stupendous slaughter on which the trade now lives. L. GARDINER,

Secretary, Royal Society for the Protection of Birds.

23 Queen Anne's Gate, S.W.1, January 20.

THE suggestion made by Prof. Duerden (NATURE, January 15) for special breeding of birds as an alternative to prohibiting imports of their plumage is unacceptable to us for several reasons, but of these I need now only mention one, since this one appears to us conclusive. We hold that it would be impossible for the Customs to differentiate between the feathers of those birds which had been "farmed" and of those which had fallen victims to the ruthless plume-hunter. Prof. Duerden is, perhaps, unaware that a scheme similar to that which he adumbrates was advanced in 1914 by the Committee for the Economic Preservation of Birds, and was considered by the Government of the day to be unworkable.

The idea of our desired Bill being dangerous to the ostrich-farming industry has surprised us, previous Plumage Bills having been warmly supported by the direction. Whitman's most cogent evidence is derived from a knowledge of the juvenal plumage in many wild species, and naturalists can scarcely fail to agree with his interpretation on this point, for he shows that many species which have more or less completely lost their chequers or bars in the adult plumage pass through a stage in which these markings appear.

(2) This brings out another aspect of Whitman's work—his strong support of the recapitulation theory. In his own words, "all development . . . is essentially a repeating or recapitulating process. This is the central fact of heredity and the doctrine of descent." Elsewhere he refers to heredity as "nature's silent rehearsal of past history." In this connection he pointed out that the formula, "ontogeny recapitulates phylogeny," places the emphasis in the wrong place, since phylogeny can be nothing more than the lineal sequences of ontogeny regarded from the historical point of view, while recapitulation is simply reproductive repetition. The orthogenetic process is considered to be the primary and fundamental one, which bridges the incipient stages of characters until natural selection can get a foothold, and may even sweep onwards and completely erase a pattern which selection would have retained.

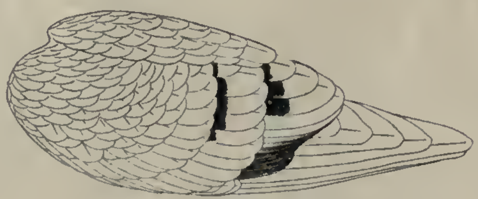

FIG. 3.—Wing of *Columba aenas*, related to *C. livia*. The two bars are incomplete.

That something other than selection is at work on these patterns is indicated also in such species as the European stock-dove, *Columba aenas* (Fig. 3). In this species the reduction of the bars has proceeded farther than in the rock pigeon, but the spots composing some of the partial bars are completely concealed by overlying feathers.

The same process is studied in great detail in the crested pigeons of Australia, the phylogeny being interpreted as "always advancing in one predetermined direction, like a tidal flow guided along a prepared channel, and flowing to varying distances, according to the initial momentum."

(3) Perfect continuity in development and variation is another feature which Whitman is at great pains to demonstrate. By plucking feathers at intervals from the juvenal plumage, he showed that underlying the apparent discontinuity in pattern between one moult and the next there was complete continuity of the underlying physiological processes. The exact nature of this physiological developmental continuity is a nice problem on which we have very little light at the present time. But the author carries his conception of continuity much farther. In his many crossing experiments he found usually a blending result, with a fluid condition and no halting places from character to character. Granting that this may be generally true of species crosses in pigeons, yet the author himself describes cases of sex-linked inheritance and other phenomena which indicate some fixed boundary line between certain characters. We therefore feel that a universal philosophy of continuity is misleading because untrue. The enormous Mendelian literature is not based entirely upon superficial or hasty observation, although such cases no doubt occur. The author would have been on safer ground had he recognised, with Galton, that both continuity and discontinuity exist in Nature, and both are equally worthy of an explanation. We may perhaps look forward to a harmonisation of these two opposing principles on the basis of cell structure.

(4) Several aberrant birds arising in these experiments are described as "mutations." For example, a Zenaida (Fig. 4, *a*) produced a mutant in which the juvenal plumage (Fig. 4, *b*) was more primitive than in the type, but the adult plumage was normal. This condition was transmitted through five generations in a generic cross. It recalls a type of yellow seedling occurring in maize which, if carefully nurtured, finally grows up into a green plant. Similarly, a Japanese turtle-dove (Fig. 5) produced three partial albinos in her old age. In this case there was also inbreeding. The orthogenetic interpretation assumes that the colour pattern is being progressively reduced, and that albinism is the final condition to which the whole group of pigeons is tending. This being the case, we may expect the reduction series to be hastened in a weakened germ, so that a long step in this direction might be anticipated. Here it would seem possible to find a basis for adjusting the conception of mutation with that of orthogenesis, even in pigeons.

(*b*) (*a*)

FIG. 4.—(*a*) *Zenaida vinaceo-rufa*, normal juvenal plumage. The light apical edge of the feathers is a primitive character in birds. (*b*) Mutant, juvenal plumage, showing a mesial extension of the light apical edge. This condition is a specific character in *C. guinea*.

(5) The conception of germinal weakness or strength is one on which Whitman lays great stress, and it is supported by much experimental evidence. Differences in "strength" or develop-

mental power are shown not only in hybrids, but also in pure species. By removing their eggs when laid, the birds can be overworked in reproductive activity, with a corresponding decrease in energy of the offspring. The result is more females and a shorter term of life. Even in normal reproduction there is found to be a gradual diminution in developmental power of the germs throughout the season.

This idea of relative and varying germinal weakness and strength runs through all the work, and will be found difficult to controvert. It is probably but the beginning of a theory of evolution founded primarily, not on morphological, but on energy conceptions.

(6) Another important relationship which was studied in great detail is that between fertility and sex. The problems involved are too many-sided to discuss here. It was found, for example, that while in crosses between closely related species the sexes appear in equal numbers, in inter-

FIG. 5.—The Japanese turtle-dove, *Turtur orientalis*. Believed to represent the primitive colour pattern in pigeons, from which the chequers of *C. livia* were developed by the disappearance of pigment along shaft of feather.

family crosses only or chiefly males are produced. In wide crosses the development may only begin, or it may stop at any stage between hatching and maturity, resulting in short-lived birds. All these and many other results are interpreted in terms of developmental energy, the difference between the sexes being regarded as essentially a difference in metabolic level. This view is in accord with the classical theory of sex of Geddes and Thomson. Some means must be found of harmonising it with the chromosome theory.

(7) The study of voice, instincts, and behaviour in pigeons has added much to the value of the whole work. Whitman's intimate knowledge of pigeons from this side frequently furnishes corroborative evidence of relationships. It also made possible his singular success in crossing many species which had never been crossed before. The differences in the instincts of the reproductive cycle are often surprisingly marked and definite in different species. In a discussion of instinct in relation to intelligence, the author's view is that as instincts become more complex and plastic the possibility of choice finally enters, so that without any added brain structure the organism is encouraged or constrained by circumstances to *learn* to use its privilege of choice.

These notable volumes, two of which are sumptuously illustrated with coloured plates by Japanese artists, will doubtless arouse much discussion. It is to be regretted that an index has not been added, to make their contents more readily available.

R. R. G.

THE NITROGEN PROBLEM.[1]

II.

BEFORE the war the United Kingdom produced and exported large quantities of ammonia nitrogen, upwards of 70 per cent. of the home production being, in fact, exported. Indeed, the British export trade in ammonium sulphate was larger than that of any other country. On the other hand, she was entirely dependent upon the Chile product for her nitric nitrogen. Agriculture accounted for the major portion of the home consumption of fixed nitrogen, but this only represented 23·5 per cent. of the total home production and importation. Indeed, in proportion to the total area under cultivation, the United Kingdom uses less artificial nitrogenous fertilisers than any other progressive agricultural country.

The war has had a serious effect upon the home industry. Whereas the estimated output of by-product ammonia in America and of by-product and synthetic ammonia in Germany in 1917 was more than double what it was in 1913, with us it declined in 1914 and 1915, slightly recovered in 1916, and in 1917 showed only an increase of 6 per cent. over the amount in 1913. Our export trade in ammonium sulphate practically ceased in 1917. Countries which formerly imported our sulphate of ammonia are now making their own by-product ammonia. This result is due to the action of the Government in controlling the export and price. As is well known, there has been a remarkable development in agriculture in this country during the last four years, and the home demand for nitrogenous fertilisers has been in excess of the supply. There can be no doubt that both the industrial and the agricultural demand for nitrogen products will continue to increase. The Committee estimates that on the assumption that the present scale of food production is at least maintained, the demand in the near future will probably represent a quadrupling of the average pre-war requirements. Our export trade in ammonia fertilisers will have in future to reckon to a still greater extent with synthetic products. It can only successfully compete by this country itself manufacturing such products. No doubt economies and improvements in existing by-product processes are conceivable and possible, but

[1] "Ministry of Munitions of War. Munitions Inventions Department. Nitrogen Products Committee. Final Report." Pp. vi+357. (London: H.M. Stationery Office, 1919.) Cmd. 482. Price 4s. net. Continued from p. 535.

it is unlikely that low-temperature carbonisation will have any considerable influence on the main result, and attempts to utilise peat and sewage afford no certain promise of success. Although our existing processes have admittedly shown themselves to be a national asset of the greatest value in times of war, they need to be supplemented, in a time of national emergency, by methods which will render this country independent of external supplies of nitrates.

The cost of power is, of course, a vital factor in connection with the establishment of any synthetic process of nitrogen fixation; and to this question the Committee necessarily devoted great attention and with special regard to the conditions of the United Kingdom. It has considered such water-power schemes as appeared practicable, and the cost of obtaining electrical energy from coal. The comparison is complicated by the many complex factors involved, and especially by the uncertainty concerning the future cost of coal and labour. At the same time, it offers an estimate of the cost of a particular water-power scheme which it has investigated, but of which it gives no details, and it is of opinion that for a power of more than 28,000 continuous kilowatts the running cost, under post-war conditions, would be 3·93*l*. per full kilowatt-year, inclusive of capital charges. The only possible chance of obtaining electrical energy from coal at a cost which would compare with this would be by direct firing at a power station operating on a very large scale. This with coal at 10*s*. per ton and an annual load factor of 97·5 per cent. works out at about 4·5*l*. per kilowatt-year of 8540 hours.

After careful consideration of the main features of the various nitrogen fixation processes and of the ammonia oxidation process, in the light of British conditions and requirements, the Committee concludes that (*a*) the *arc* process, in spite of certain disadvantages, viz. its large power requirements, its low electro-chemical efficiency, and the costly character of its chemical plant, would compete with the retort process of obtaining nitric acid so long as the cost of electrical energy was below 9*l*. per kilowatt-year. (*b*) The *calcium cyanamide* process affords a cheaper marketable form of combined nitrogen, so long as electrical energy is below 5*l*. per kilowatt-year, than any other established fixation process, and gives a solid nitrogenous fertiliser as a primary product. The manufacture may be combined with that of calcium carbide and crude cyanides, and, as the raw materials are cheap and abundant in this country, there is good ground for assuming that it would be successful with us, in spite of the relatively high cost of electrical energy. The Committee is of opinion that a steam-power station of 30,000-kw. maximum load is the minimum size that would be justifiable under British conditions. (*c*) The *Haber* process, with pure hydrogen at 2*s*. 6*d*. per 1000 cu. ft., is capable of producing ammonia at a cost below that of any ammonia process as yet established. The Committee, of course, had no opportunity of inquiring into the Claude process, the details of which have only recently become known. Both these processes are the most promising of all the synthetic methods of making ammonia and ammonium sulphate. It is too soon to express any definite opinion as to their relative merits as commercial processes, but it is certain that both of them have a great future.

The *ammonia oxidation* process for making nitric acid, although probably not in its final form, can even now furnish concentrated acid at a lower cost than the retort process from Chile nitrate, and ammonia oxidation converters are well adapted for use in the chamber process of making oil of vitriol. It is not unlikely that such converters will soon supersede the wasteful system of nitre-pots.

It should be stated, however, that the last word has not been said in favour of existing by-product processes. It is pointed out that improvements in the metallurgical coke industry, such as the more rapid replacement of beehive ovens by recovery ovens, and improvements in the existing practice in gasworks, both large and small, would do much to augment the yield and recovery of by-product ammonia, and the Committee was unanimously of opinion that energetic measures should be taken to ensure that industries making such a large annual demand upon our coal reserves should be made to utilise them to the maximum advantage, and it indicates in outline what these measures should be. The waste that has hitherto taken place in the potentiality of coal, as regards both its energy and its products, is a national scandal that ought no longer to be tolerated. Its continuance would be the strongest argument that the advocates of nationalisation could adduce.

Considerations of space prevent any attempt to deal with many other points which have engaged the attention of the Committee, and are set out in detail in its voluminous report, such as the question of the nitrogen problem as it affects other parts of the Empire. The Dominions beyond the seas are rich in latent resources in coal and other raw materials, and some of them possess exceptional water-power facilities, accessible to the seaboard and capable of easy development. Nor have we been able to devote much space to the question as it affects national defence. It must be evident, however, from past experience that, notwithstanding our maritime supremacy, the military situation has been, as the Committee states, fundamentally changed. We must no longer be dependent upon Chile nitrate for the manufacture of explosives. We agree with the Committee that a wise policy in regard to defence can well go hand in hand with a sound economic policy.

The Committee recommends that:—

1. The calcium cyanamide process should be established in Great Britain without delay, either by private enterprise (supported, if necessary, by the Government) or as a public work, and that the scale of manufacture should be sufficient to produce 60,000 tons of cyanamide per annum,

equivalent to about one-eighth of the present home production of ammonium sulphate, the necessary water-power being obtained in Scotland, or from a large steam-power station.

2. That the synthetic ammonia (Haber) process should be established forthwith on a commercial unit scale and extended as rapidly as possible, as a post-war measure up to a minimum manufacturing scale of 10,000 tons of ammonia (equivalent to 40,000 tons of ammonium sulphate) per annum; and it suggests that the factory at Billingham-on-Tees, which the Government, in 1918, decided to erect, mainly for the manufacture of ammonium nitrate, might be utilised for the purpose.

3. That an ammonia oxidation plant should be established in conjunction with the synthetic ammonia factory on a scale sufficient to produce 10,000 tons of 95 per cent. nitric acid, or its equivalent in nitrates, and that the plant should be designed to utilise either synthetic or by-product ammonia.

4. That steps should be taken with the view of conserving and increasing the output of combined nitrogen from existing by-product ammonia industries, of securing the better utilisation of the national resources in coal, and of reducing the consumption of *raw* coal as fuel. (The various steps which it is suggested should be taken to secure these ends are set forth.)

5. The Committee further recommends that certain nitrogen fixation processes—*e.g.* the Häusser process, certain cyanide processes, and sulphate recovery processes—should be systematically investigated on a small works scale. It understands that the question of low-temperature carbonisation of coal is being investigated by the Fuel Research Board. It suggests that the researches on the nitrogen problem initiated during the war should be continued under the auspices of the Government for the general benefit of the country; and that the results of the researches carried on up to the present should be edited, and published at the earliest possible moment, subject to such reservations as may be considered necessary by the Government, members of the Research Staff of the Munitions Inventions Department being allowed to communicate to scientific societies the details of their work, subject to such reservations as may be considered necessary by the Government.

The Committee concludes its report with a recommendation that a co-ordinated policy should be framed by an Imperial authority for safeguarding the future nitrogen requirements of the Empire. It points out that, so far as the United Kingdom is concerned, nitrogen fixation and allied industries will constitute a new "key" industry. The Committee is of opinion that the initiation and development of the industry will require the active support of the Government.

It is not to be anticipated, in the present state of the political position, and in view of the large arrears in its programme of reconstruction with which the Government is faced, that any immediate consideration will be given by it to the Committee's recommendations, or that any practical steps will be taken to give effect to them beyond attempting to dispose of the Billingham-on-Tees property, and possibly permitting the Research Section of the Munitions Inventions Department to continue its investigations. We understand that negotiations on behalf of an important group of firms are in progress for the purchase of the Billingham works. But whether the Haber process or the American modification of it will be carried on there remains to be seen. Within the last few days it has been announced that an influential financial syndicate is about to establish a factory in the neighbourhood of Maryport, West Cumberland, to work the Georges Claude process, which is already in operation at Montereau, near Fontainebleau, by which it is claimed that the production of ammonia is increased fourfold as compared with the Haber process, as worked by the Badische Anilin & Soda-Fabrik at Oppau, near Ludwigshafen. The first unit of the synthetic plant will be of sufficient size to produce the equivalent of 50,000 tons of sulphate of ammonia per annum. If this consummation is reached it will go far to solve the problem which the Nitrogen Products Committee has been considering with such thoroughness and care during the last three or four years.

EXPLORATION IN TIBET AND NEIGHBOURING REGIONS.[1]

COL. LENOX CONYNGHAM has done right good service to the science of geography by compiling in one comprehensive volume the complete story of the early exploration of the great Tibetan uplands before that land of mystery and romance became attractive to European geographers, who evolved the map of Tibet as we now know it on a more scientific basis. It would indeed have been useful if the brief preface to the volume had included a somewhat more detailed explanation of the means and the methods employed by these early native surveyors in those amazing journeys which gave us the first (and sometimes the last) outlines of Tibetan geography, and laid the foundations for subsequent map superstructure. The narratives of the individual explorers are given in chronological order, commencing with the journey of Pandit Nain Singh, in 1865, from Nepal to Lhasa, and terminating with that of Atma Ram, who accompanied our first adventurer, Capt. (now Sir Hamilton) Bower, when he traversed Tibet from Kashmir to China in 1891–2, following a route which was not very far removed from that of Nain Singh in earlier days. Then for the first time were the eyes, not only of geographers, but also of archæologists, opened to the immense wealth of scientific and historical knowledge which was to be gathered in that remote part of Asia.

[1] "Records of the Survey of India." Vol. viii. (in two parts). Part i., "Exploration in Tibet and Neighbouring Regions, 1865–79." Pp. xi+213+charts. Part ii., "1879–92." Pp. xi+215–411+charts. (Dehra Dun: Office of the Trigonometrical Survey, 1915.) Price 4 rupees or 5s. 4d. each part.

For some twelve years the native explorers of the Indian Survey had the field to themselves, and it may safely be said that no Asiatic geographers of the past, not even the Arab adventurers of the Middle Ages, or the Chinese pilgrims of yet earlier times in search of such evidences of their Buddhist faith as were to be found on the frontiers and plains of India, ever established such a remarkable record of geographical accomplishment as did these Lamas and Pandits of Indian Survey history in so short a time. Their success was due primarily to the fact that they were well selected for the special line of exploration which they were expected to follow. Then they were thoroughly well trained in the first elements of geographical reconnaissance by Indian Survey officers.

As a rule their methods were simple, for they included no more than the first principles of traversing on bearings taken by the prismatic compass, distances being measured by pacing, and occasional most valuable checks being derived from latitude observations with the sextant. This involved the use of small instruments which were concealed either in their clothes or in false bottoms to their boxes. A rosary was the convenient means of checking their paces. Considering that many thousands of miles were covered in this way, and that the final reduction of their voluminous records (concealed usually in the lining of their coats) was most satisfactory, no higher and better evidence of the patience and determination of such men as Nain Singh, Kishen Singh (the A–K of the Survey records), or of Ugyen Gyatso could be desired. They were frequently engaged for years on the same quest; they were occasionally caught and enslaved, but almost always managed to save their instruments and their records; and their journeyings carried them across the great plateau to Mongolia and China, and into regions where hitherto no European has followed them.

With the influx of European explorers, started by the remarkable discoveries of Bower, the later stories of Tibetan exploration became public property, but it should be noted that many of the most successful of these later white adventurers have employed native explorers to do the spade work of their geographical mapping, and that with the close of the period indicated in this useful volume (which has conveniently brought together information hitherto scattered and rather difficult to retrieve) the work of the native geographer has by no means come to an end. Another and an even greater volume might follow which should show how much our well-known Tibetan travellers owe to the indefatigable perseverance and the remarkable skill as topographers of their native assistants.

Col. Lenox Conyngham's compilation merely brings together the narratives of the earliest native adventurers, and no book of travel that ever was written contains such a wealth of thrilling personal incident as underlies the simple (and sometimes prosaic) account of these humble Indian workmen. T. H. H.

NOTES.

A special meeting of the Royal Society was held on Thursday, January 22, when the Prince of Wales was admitted a fellow, following election by ballot, which took place on May 22, 1919. This election was in pursuance of a clause in the society's statutes which permits any one of his Majesty's subjects who is a Prince of the Blood Royal to be proposed at one of the ordinary meetings by any fellow, provided such proposal shall have been made at a preceding meeting. Under this provision King George V. was elected in 1893 when Duke of York. His Royal Highness was received in the society's vestibule by Sir Joseph Thomson and the officers and vice-presidents, whence, preceded by the mace-bearer, a procession was formed through the ranks of the fellows to the meeting-room. The Prince occupied a seat on the front bench among the fellows. The senior secretary having announced the attendance, his Royal Highness advanced to the president's table and subscribed his name in the charter book, thereupon taking a seat on the left of the president. An attractive discourse was then given by Prof. W. H. Bragg on methods of detecting submarines by sound. Upon its conclusion the Prince thanked the society for his admission, and assured the fellows of his interest in the advancement of scientific research.

Disturbances of wireless messages are commonly known to all operators, and are usually regarded as atmospheric effects. Mr. Marconi, however, in a statement published in the *Daily Mail* of January 27, describes interruptions which occur simultaneously in London and New York, and in which certain long and short signals are repeated more frequently than others, as, for example, the three dots signifying the letter S in the Morse code. In the absence of a physical explanation of these regular and simultaneous interruptions, it is perhaps human, and certainly sensational, to suggest that the signals represent attempts of intelligent beings on another planet, or the moon, to communicate with the earth. The *Daily Mail*, therefore, refers to "recent investigations by Prof. Lowell with his giant telescope" of Martian canals (Prof. Lowell died in 1916), and to Prof. W. H. Pickering, who "has caused extraordinary interest in the United States by recently announcing that he sees signs of life on the moon," though these views have been before the astronomical world for many years, and the phenomena observed admit of other interpretations. The interruptions described by Mr. Marconi are no more wonderful than the magnetic disturbances long registered in magnetic observatories. Such disturbances of the photographic records are often very definite in character, and occur at about the same hour on successive days, while they are also found to occur simultaneously at stations so far apart as Christchurch (N.Z.) and Kew. The magnetic and wireless effects are closely related, but whether they originate in the sun or arise from a common cause operating throughout the solar system has yet to be determined. That they are signals from other worlds is attractive to the imagination, but the hypothesis is more of popular than of scientific interest.

It is with deep regret that we record the death of Dr. C. R. C. Lyster on January 26 at the age of sixty years. Dr. Lyster held the position of head of the X-ray and electro-therapeutic departments at the Middlesex Hospital during the last seventeen years. Even in quite the early years of radiology Dr. Lyster made extensive use of X-rays in the treatment of disease, especially cancer. It was at this period, when the harmful nature of repeated fractional doses was not known, that he himself sustained damage which afterwards developed into the disease he sought to alleviate in others. Dr. Lyster fully realised the additional risks he ran by continuing his work, but nothing could deter him from pursuing it, and his work of later years should be viewed in the light of a sacrifice on his part to the cause of advance in medicine. Dr. Lyster was president of the electro-therapeutic section of the Royal Society of Medicine for the year 1918–19, and served on its council and on that of the Röntgen Society for a number of years. His publications were few, and provide no adequate guide to the value of his services to medicine, especially to medical radiology. The recent institution of a diploma in radiology and electrology by Cambrige University was largely due to the efforts which Dr. Lyster made in the first instance. Throughout the whole of his work he combined in a rare degree a breadth of outlook and an unselfishness of purpose which ensured a respect for his views and counsel. Of his personal charm and character a wide circle will preserve a permanent memory.

The Rev. Edmund Warre, D.D., who died at Eton on January 22, the anniversary of the death of Queen Victoria, was a notable and commanding figure in the Victorian age. During his headmastership of Eton, which lasted from 1884 until 1905, many new buildings, including three science laboratories, were added, and science teaching, more particularly with a view to military requirements, was extended and developed. Dr. Warre was in the habit of saying that, like the horse-leech, Madam Science had many daughters, all crying "Give, give"; but he was a generous and wide-minded man, whose own scientific tastes lay in the direction of botanical work. His ruling passion, however, was for the river, and he used frequently to lament that, because his mathematical training had been neglected, he was unable to work out satisfactorily the ideal lines of a racing-boat. Dr. Warre had been for some years an invalid, and he retired from the Provostship of Eton in 1918. No man can have had a wider circle of friends, and he will be remembered with affection and esteem by many men of science.

The award of the Straits Settlement gold medal, founded by Scottish graduates in the Malay States, to Dr. R. T. Leiper was announced in our last issue. The medal is given for the best thesis for M.D. on a subject of tropical medicine offered during the last five years, and is awarded by the Senate of the University of Glasgow. Dr. Leiper's thesis, for which he gained a Bellahouston gold medal in 1917, comprised an account of the brilliant work which he did on Bilharzia disease in Egypt (1915–16), whither he was sent by the Government as consultant parasitologist and Lt.-Col., R.A.M.C., to investigate the disease and to advise as to preventive measures in connection with the troops. It will be recalled that by his researches Dr. Leiper established the existence of two species of parasites in human bilharziosis, traced their life-history outside the human body in molluscs, and demonstrated the modes of infection, besides elucidating numerous other points. The award of this medal by Dr. Leiper's university is a fitting recognition of an epoch-marking advance in parasitology.

British botanists have an opportunity of showing practical sympathy with the eminent French bryologist, M. Jules Cardot, who has suffered severely from the effects of the war. Driven from his home at Charleville by the German advance in 1914, M. Cardot had to abandon all his possessions. He has now returned to find that the greater part of his property has been destroyed or removed, including his books and MS. notes and a large portion of his collections. Fortunately, his mounted herbarium of mosses, containing between 30,000 and 40,000 specimens, representing more than 10,000 species, is practically intact. The herbarium is a valuable one, containing the types of a large number of new species described in M. Cardot's numerous monographs of various families and works on the geographical distribution of mosses. It is M. Cardot's wish that his herbarium should find a home in the Paris Natural History Museum, but with his present restricted means he is unable to make a gift of it to the nation, and the museum has not sufficient funds at its command for the purchase. A suggestion has been made by bryological friends, simultaneously in the United States and this country, that if the museum authorities will find half the amount required the remaining half might be raised in Great Britain and in America. The authorities in Paris have gratefully expressed their willingness to agree to such a scheme, and the price of 10,000 francs has been mentioned. The proposal to raise one-fourth of that amount in this country would at the present rate of exchange entail a sum of between 60*l.* and 70*l.* The well-known British bryologist, Mr. H. N. Dixon, is acting as treasurer of the fund, and his address is 17 St. Matthew's Parade, Northampton.

Dr. Edwin Deller, secretary of the Brown Animal Sanatory Institution, University of London, has been appointed assistant secretary to the Royal Society.

With the approval of the Lords Commissioners of the Treasury, Major H. E. Wimperis, R.A.F., has been transferred from the Office of the Crown Agents for the Colonies to the Air Ministry, to take up the position of Head of the Air Navigation Research Section.

We are informed that the council of the Glass Research Association has appointed Mr. R. L. Frink, Lancaster, Ohio, U.S.A., director of research. The secretary of the association says:—"Mr. Frink has a lifelong experience of the American glass trade and glass research, is well known to the foremost English glass manufacturers, and his appointment is welcomed by the British glass industry."

The death is announced, in his seventy-second year, of Mr. R. L. Garner, the American author who published a book on "The Speech of Monkeys" in 1892, and afterwards visited the Gaboon, the country of the gorilla, where he stated he lived for some months in a steel cage to study the language of the great apes. On his return to London, early in 1894, Mr. Garner delivered a lecture on his experiences, which attracted a large audience, but clearly showed that science had nothing to expect from his enterprise.

We regret to record the death on January 24 of Mr. R. F. Wallace, who retired from the Meteorological Office at the close of last year. Mr. Wallace was in his sixty-eighth year, and should have retired some two years ago, but remained in the service during the closing period of the war. He entered the Meteorological Office in 1883, and first served in the marine division. About twenty years ago he took general charge of the meteorological instruments.

Influenza seems to threaten to be prevalent in this country before long, judging by the outbreaks in America and elsewhere. Since the commencement of October influenza has been present to a limited extent in the British Isles. The deaths in the ninety-six great towns of England and Wales have risen from 14 and 20 in the two closing weeks of September last to 70 or 80 deaths per week at frequent intervals during the autumn and winter. In London the deaths rose to 22 in the weeks ending November 15 and 22, but they have not touched 20 in any week since, according to the returns of the Registrar-General to January 17. The highest death-rate is between twenty and sixty-five years of age, the deaths for those ages in the last thirteen weeks being 59 per cent. of the total number.

In the current number of the *Annales de la Société Royale Zoologique et Malacologique de Belgique* appear the names of ten honorary members who have recently been elected to that society. Among the names are those of Prof. L. Cuenot, Faculté des Sciences, Nancy; Prof. M. Caullery, the Sorbonne, Paris; Dr. A. E. Shipley, Christ's College, Cambridge; Senator B. Grassi, Italy; Prof. E. G. Conklin, Princeton University; and Prof. Th. H. Morgan, Columbia University.

The annual meetings of the Institution of Naval Architects will be held on Wednesday, March 24, and the two following days, in the hall of the Royal Society of Arts, John Street, Adelphi, W.C.2. The Right Hon. the Earl of Durham, president, will occupy the chair. A gold medal will be awarded by the council to any person not being a member or associate member of council who shall at the forthcoming meetings read a paper which, in the judgment of the council, is deemed to be of exceptional merit.

Owing to the prevalence of diseases in prepared timber, and in view of the impending increase in the use of timber—much, possibly, of immature growth—in building construction, the Science Standing Committee of the Royal Institute of British Architects, under the chairmanship of Mr. Alan E. Munby, has had the question of such defects under review, and Dr. C. J. Gahan, of the Natural History Museum, has been asked, and has consented, to associate himself in an advisory capacity with this inquiry. The committee will welcome any information which seems likely to further such investigations. Correspondence should be addressed to the Secretary, Royal Institute of British Architects, 9 Conduit Street, W.1, and marked "Science Committee."

The following awards have been made by the council of the Institution of Mining and Metallurgy:—(1) Gold medal of the institution (premier award, and the highest distinction within the power of the institution to confer) to Mr. H. Livingstone Sulman, in recognition of his contributions to metallurgical science, with special reference to his work in the development of flotation and its application to the recovery of minerals. (2) "The Consolidated Gold Fields of South Africa, Ltd." gold medal to Mr. William Henry Goodchild, for his papers on "The Economic Geology of the Insizwa Range" and "The Genesis of Igneous Ore Deposits." (3) "The Consolidated Gold Fields of South Africa, Ltd." premium of forty guineas to Dr. Edward Thomas Mellor, for his paper on "The Conglomerates of the Witwatersrand."

At the annual general meeting of the Royal Meteorological Society, held on January 21, the following officers and council were elected:—*President:* R. H. Hooker. *Vice-Presidents:* J. Baxendell, F. Druce, Sir Napier Shaw, and F. J. W. Whipple. *Treasurer:* W. V. Graham. *Secretaries:* W. W. Bryant and J. S. Dines. *Foreign Secretary:* R. G. K. Lempfert. *Council:* C. E. P. Brooks, Dr. J. Brownlee, Capt. C. J. P. Cave, J. E. Clark, R. Corless, Capt. G. M. B. Dobson, J. Fairgrieve, Lieut. H. D. Grant, H. Mellish, Dr. J. E. Petavel, M. de Carle Sowerby Salter, and G. I. Taylor. The Symons gold medal awarded to Prof. H. H. Hildebrandsson, of the University, Upsala, was presented on his behalf to the Swedish Minister.

Mr. Ikbal Ali Shah gives in *Folk-lore* for December last (vol. xxx., No. 4) a comprehensive account of the folk-life of Afghanistan, a subject about which little information has hitherto been available. He traces the life of an Afghan from the cradle to the grave, his account of the marriage and death ceremonies being particularly interesting. On the whole, though Mr. Shah is perhaps influenced by his natural prepossessions, he gives a pleasing impression of the family life of the people, and the general result is that, as Afghanistan borders on both Persia and India, the domestic rites of the Afghans have been influenced both by Persians and by the Hindu or Mussulman culture of the Punjab.

In *Sudan Notes and Records* (vol. ii., No. 3, July, 1919) Dr. C. Crossland treats the question "Comfort and Health in the Tropics." "Remove the mosquitoes and the fevers they carry, and most tropical countries can be made fairly healthy." He gives good advice on clothing. "Air which is already moist can have little drying or consequent cooling effect unless it is in fairly rapid motion. Consequently what is known as ventilation in Europe is of little use in the tropics, and houses designed in Europe are never, so far as I have seen, sufficiently airy for the Red Sea coast." Hence he lays down, with the help of diagrams, what is his idea of a suitable house. The author does not appear to have any experience of India, where the subject has been carefully investigated. But the paper will be useful to all who intend to reside in the tropics.

MR. H. BOLTON, Director of the Bristol Museum and Art Gallery, in his report for the year 1918–19, points out that the museum suffered from the necessity of exercising a strict economy in order that the changed conditions of the cost of labour, supplies, and museum material may be met as well as possible by the unaltered pre-war income—conditions affecting institutions of this kind throughout the country. But the educational work has been carried on with success, no fewer than 60,000 visits having been made by wounded soldiers during the war period. The important collection of guild banners has been increased by some welcome gifts; Mrs. C. Ryland presented a valuable series of pictures, and Mr. H. Mardon a large collection of European engravings and his extra-illustrated copy of Nichol and Taylor's "History of Bristol," extended to fourteen volumes and containing almost every known illustration and map of importance relating to Bristol.

SIR C. HERCULES READ describes in the January issue of *Man* an ancient Chinese bronze from the collection of Mr. H. Oppenheim. It represents a monstrous mammalian quadruped, winged, with a long neck and a feline head, which seems to be struggling with a snake-like form. Figures of a similar kind are said to have been used as a refrigerator for food, or as a brazier for heating water or wine. Sir C. H. Read remarks that "the practical identity of the Tartar figures and the surrounding animals would further suggest that if one be of the Han dynasty type, the other is also. In any case, the suggestion helps my theory as to the affinities of the Oppenheim bronze, viz. that in some respects it has clear connection with the later Bronze age in the Far East. The architectural treatment of the base is quite un-Chinese, and at the present moment I can think of nothing nearer than Gandhara with which to compare it. Ten years ago such a suggestion would have been thought fantastic, but Sir Aurel Stein's discoveries have reduced it to a commonplace."

DR. J. W. H. HARRISON, continuing his experiments with the Geometrid subfamily Bistoninæ, finds peculiar sex-relationships particularly in inter-generic hybrids of these Lepidoptera (*Journal of Genetics*, vol. ix., No. 1). Occasional inter-sexes, intermediate between males and females, were produced, and in several crosses only males appeared, although all the fertilised ova developed. In such cases the male parent in the cross is found to be "phylogenetically older" than the female. Thus *Nyssia zonaria* × *Lycia hirtaria* yielded males only. A further complication is found in the fact that *hirtaria* has fourteen (haploid) chromosomes, while *zonaria* has fifty-six. An explanation of the results is attempted in terms of intensity of sex-factors.

"NOTES on the Survey of India Maps and the Modern Development of Indian Cartography," by Lt.-Col. W. M. Coldstream, R.E., is the title of a volume recently published by the Survey of India. The author traces the history of map production in India and the development of colour printing. The size of sheets, use of symbols, selection of colours, and lettering and other problems in cartography are discussed at length, and the volume is illustrated by forty coloured plates showing specimens of all the most important maps published by the Survey of India, as well as illustrations of several old maps. The collection of these plates alone makes the volume of great interest.

MILITARY operations in the Libyan desert in 1914–18 gave Dr. J. Ball opportunities of taking the latitude and longitude of several places of which the position had not been accurately determined. These are published by the Egyptian Survey (Survey Department Paper No. 34). The positions determined extend from the Nile west to the Siwa oasis and Jarabub, and south to the oases of Kharga and Dakhla. The position of Bir Terfawi, which had hitherto only been guessed at, was determined by Lieut. Moore, who places the well nearer to Wadi Halfa than had been previously supposed.

THE question of Suess's "sal" and "sima" magmas is dealt with by Dr. Holtedahl in relation to continental margins in a paper on the causes of large earth-movements, which appears in *Naturen*, 1919, p. 266.

MR. F. L. HESS proposes (*Amer. Journ. Sci.*, vol. xlviii., p. 377, November, 1919) a new and useful geological term, "tactite," for the body of rock altered by contact with an igneous mass. The abbreviation rendered possible in descriptions of contact-phenomena by the adoption of so simple a word is at once obvious and welcome to geologists.

MEMOIR 111 of the Geological Survey of Canada, on "The Silurian Geology and Faunas of Ontario Peninsula," is of special interest, since it includes the well-known Niagara group and its development in the Niagara district. Few new species of fossils are described, but the fauna is admirably illustrated by photographs, and two coloured maps are added in a pocket at the end.

ALL known occurrences of platinum in Canada are described and usefully set down upon a general map by Mr. J. J. O'Neill in Part G of the Summary Report of the Geological Survey of Canada for 1918 (issued in 1919). The conclusion is that "Canada certainly has possibilities of becoming one of the world's largest producers of metals of the platinum group." It appears that at present a very large quantity of platinum, here estimated at 50,000 oz. annually, is lost by the absence of proper methods of recovery in placer working.

M. EMILE BELOT (*Revue Scientifique*, 1919, p. 686) begins in the happiest manner a discourse on vulcanicity in general and on an artificial volcanic field of his own manufacture, by reminding his audience of the "big Bertha" that assailed their lecture-hall in the Sorbonne. While the usual height attained by the vigorous projection of volcanic material is 8 km. to 10 km., the dust from Krakatoa rose to 27 km. The experimental volcanoes of the "Bertha" type threw projectiles to a height of 30 km. into a layer where atmospheric pressure is reduced to about 1 mm. of mercury, and the horizontal range thus rendered possible was as much as 120 km. Though the conception was that of a Jules Verne, we must remember that its brilliant realisation was due to the scientific thoroughness of the Germans. M. Belot goes on to show that the lunar crater-rings can be accounted for by normal volcanic projection *dans le vide*, and he then describes and illustrates a model volcano that derives its water from the percolation of an artificial sea.

AT the end of the article upon the Physical and Optical Societies' Exhibition, in the issue of NATURE for January 15, reference was made to the comparative absence of simple forms of apparatus for teaching purposes. The Zenith Manufacturing Co. showed a representative series of its regulating resistances and controllers of very simple form, and the manager of the electrical department writes to say that a special aim is made at instructional needs. We are aware that the company devotes much attention to the details of rheostats for electrical testing, but this affects very slightly the point of the paragraph in question, namely, the desirability of making all apparatus for use in schools and colleges so simple that the principle can be readily understood.

AN important paper by Otto Hahn and Lise Meitner on "The Genesis of Actinium" appeared in the December 1 issue of the *Physikalische Zeitschrift*. In 1908 Boltwood examined a number of uranium minerals, and found that the ratio of their actinium and uranium contents was constant—a result which indicated a genetic connection between actinium and uranium. From these results Rutherford calculated that 8 per cent. of uranium disintegrates along the actinium series. In 1917 Fussler found a value somewhat less than 8 per cent., though only three values were obtained, and these vary as much as 60 per cent. St. Meyer and Hess re-examined the question in 1919, and found a constant relation Ac : U for a set of uranium minerals from various parts of the globe. Hahn and Meitner separate the eka-tantalum [called prot-actinium (Pa) in Germany] from Joachimsthal pitchblende, and compare the total α-ray ionisation from this product with that due to the uranium in the pitchblende. Three methods of separating the eka-tantalum were used, both solutions and residues being examined. The authors find that only 3 per cent. of uranium disintegrates along the actinium series, and the probable error in their results is 10 per cent. This result is in accord with the work of Antonoff and of Hahn and Meitner on UY, which appears to be the mother of eka-tantalum. These workers found that the branch ratio of UY to uranium was about 2 per cent. Hahn and Meitner discuss the available evidence, and conclude that the actinium series originates from UII according to the scheme

$$\mathrm{UII} \underset{\alpha}{\longrightarrow} \mathrm{UY} \underset{\beta}{\longrightarrow} \text{Eka-Ta} \underset{\alpha}{\longrightarrow} \mathrm{Ac},$$

which agrees with that suggested by Soddy in the Trans. Chem. Soc. (vol. cxv., p. 1, 1919). The atomic weight of actinium would thus appear to be 226.

FROM the annual report of the Government Chemist for the year 1918–19 (Cmd. 419) it appears that the total number of samples analysed at the Government Laboratory was 289,180. This represents an increase of more than 20,000 compared with the previous year. Owing to the cessation of hostilities and the subsequent demobilisation of a part of the combatant forces, about 16,000 fewer samples were analysed at the central laboratory; but, on the other hand, the partial revival of trade led to a considerable increase in the number of samples of wine examined, and many more samples also were analysed for the Food Controller and the Air Board. Among other items of interest in the report, two unusual instances of the contamination of foods with metallic poisons may be noted. In one case chocolate sweetmeats were found to contain mercury; this was traced to the metal trays used in the processes of manufacture. In the second instance pastry made from self-raising flour contained antimony, due to the use of tartar emetic as a substitute for cream of tartar instead of the acid phosphate of lime intended to be used as a "tartar substitute."

HORSE-CHESTNUTS have in recent years been utilised for the production of acetone and normal butyl alcohol by a special process of fermentation. The distillate yields a "mixed oil," of which about one-third consists of acetone and the remainder is the butyl alcohol. In the Journal of the Society of Chemical Industry for December 31 Mr. A. Gill gives an account of some experiments carried out at H.M. Factory, King's Lynn, in studying certain aspects of the fermentation. Outstanding features of the operations were (1) frothing and (2) slowness; these were attributed to the presence of æsculin or æsculic acid—a bitter, saponin-like substance which, besides producing froth, is apparently inimical to the development of the special micro-organisms employed. The æsculin can be extracted by treatment of the nuts with water or alcohol. The mature nuts contain about 12·5 to 14·5 per cent. of husk, and immature specimens may have nearly double this proportion. It has been stated that, for successful fermentation, the husk must be completely removed; this was not found to be necessary, though it is an advantage to remove as much as possible, since an excessive quantity retards the fermentation. About 19 per cent. of "mixed oil" was yielded by the nuts.

LLOYD'S shipbuilding returns for the quarter ended December 31 last—commented upon by *Engineering* for January 16—indicate that Great Britain has now regained her foremost position in the world of shipbuilding, having 757 vessels under construction, with an aggregate gross tonnage of 2,994,249. This figure is 27,734 tons in excess of the tonnage now in hand in the United States. In all other countries of the world, including the United States and the British Dominions, but excluding Germany (for which country the figures are not yet available), there are 1381 vessels, making 4,867,114 tons in all; so that British tonnage building now amounts to more than 38 per cent. of the world's total. Our shipbuilding industry is thus in a highly satisfactory condition. More than one-third of the total British tonnage now under construction is building in Clyde shipyards.

An interesting paper on radio direction and position finding was read by Capt. H. J. Round to the Institution of Electrical Engineers on January 14. Capt. Round gave a history of the development of the radio goniometer for war purposes which took place immediately war broke out. The record of the difficulties that were overcome is instructive. It was soon found out that the German Navy directed its Zeppelin fleets by direction-finding from land stations. On several occasions, however, when there were nine or ten Zeppelins in a raid all doing their utmost to communicate with their base stations for bearings the German messages got into a hopeless tangle. Our Naval Intelligence operators believed that one special German operator was so skilful that whenever he took control everything proceeded smoothly. The Germans had two radio phare stations which enabled their Fleet and submarines to determine their positions in the North Sea without the necessity of transmitting signals. In each station there was a rotating frame continually sending messages and giving a special zero signal once every revolution. Any operator noting the time-interval between the zero signal and the instant at which the received signal was a minimum could tell at once the angular position of the ship with respect to the station. Doing this for both stations, the position of the ship was determined. During night-time many anomalous results were obtained when direction-finding, the reasons for which have not yet been satisfactorily explained.

Messrs. A. and C. Black, Ltd., announce "Insect Life," by C. A. Ealand, illustrated, and a new edition of "Studies in Fossil Botany," by Dr. D. H. Scott, part i., Pteridophyta, illustrated. *Messrs. Crosby Lockwood and Son* promise "Oils, Fats, and Waxes: Their Manufacture, Refining, and Analysis, including the Manufacture of Candles, Margarine, and Butter," by Dr. G. Martin; "Applied Chemistry for Technical Students," by Dr. C. K. Tinkler and H. Masters; and "The Principles of Air Navigation," by J. E. Dumbleton. The *S.P.C.K.* is bringing out an edition of Clerk Maxwell's "Matter and Motion," revised and brought up to date by Sir Joseph Larmor; also the following new books: "Archimedes," by Sir Thomas L. Heath (in the Pioneers of Progress: Men of Science Series); "The Nature-Study of Plants in Theory and Practice for the Hobby-Botanist," by T. A. Dymes; and "The Book of the Sea-shore," by W. P. Pycraft (the first of a new series entitled The Nature Lovers' Library).

OUR ASTRONOMICAL COLUMN.

NEW COMET 1920*a*.—A comet of the 10th magnitude has been discovered by Señor Comas Sola at Barcelona. It was photographed by Mr. Wilson at Carleton College Observatory, Northfield, Minnesota, U.S.A., on January 20d. 15h. 51·8m. G.M.T. R.A. 7h. 57m. 40·5s., N. decl. 21° 40′ 54″, referred to the equinox of 1920·0. No information is to hand about its motion. The comet's appearance is almost stellar.

SPECTRUM OF COMET BRORSEN-METCALF.—Pubs. Astr. Soc. Pac. for December contains an account by Prof. Slipher of the spectrum of this comet photographed at Flagstaff on October 17. It resembles that of comet *b* 1914 (Zlatinsky) fairly closely. The third and fourth carbon bands and the first, second, and third cyanogen bands are shown, also six unidentified lines between 4016 and 4074. There is also a faint continuous spectrum.

THE FIREBALL OF JANUARY 16.—A few additional observations of this brilliant object have come to hand, and they prove it to have been of a very exceptional character. At Diss, in Norfolk, the streak it left remained visible for fifteen minutes.

The height of the meteor was from about 52 to 44 miles, and its velocity 15 miles per second. Its course at first lay above Saffron Walden, whence it travelled to above Watford, and then disappeared. Its radiant point appears to have been in the northern region of Cancer, which was not far above the north-east horizon at the time of the meteor's apparition.

This particular part of the sky seems to be the focus of emanation of many fine meteors in January, but they do not appear to favour any particular date. Thus on January 1, 1913, January 21, 1898, and January 29, 1905, bright meteors were traced to the same point, and it has also been conspicuously active in the months of November and March.

OPEN STELLAR CLUSTERS.—Dr. Harlow Shapley has extended his studies of the globular clusters to include the more widely extended clusters chiefly found in the Galaxy (Proc. Nat. Acad. Sci., Washington, August, 1919). He determines the distances of these objects by methods similar to those employed for the globular ones; the distances range from 60 parsecs for the Pleiades to 16,000 parsecs for one cluster and 14,000 parsecs for four others (1 parsec=3¼ light-years). The average of the seventy clusters discussed is 6000 parsecs. Their centroid is distant some 3000 parsecs from the sun towards galactic longitude 270°. Since these clusters would seem to be embedded in the galactic star-clouds, these results would indicate a greater distance for the latter than that which was until lately thought probable.

Dr. Shapley is inclined to abandon his earlier view that the globular clusters cannot exist in the galactic plane, and break up as soon as they enter it. He realises the cogency of the evidence that there is much absorbing matter in this plane, which conceals objects lying beyond it. He still thinks that the open clusters are the remnants of former globular ones, but does not postulate such a sudden transformation from one type to the other as he did at first.

The Astronomer Royal and Mr. Melotte give some details about one of these veiled regions, which lies in the constellation Taurus (Monthly Notices R.A.S., November, 1919). Since the paucity of stars in the region is the same for all magnitudes, it is concluded that the obscuring cloud is comparatively near us. This diminishes the difficulty of the great mass that would be required if the cloud were more remote.

PARIS ACADEMY OF SCIENCES.

PRIZES PROPOSED FOR 1921.

Mathematics.—The Francœur prize (1000 francs), to the author of discoveries or works useful to the progress of pure or applied mathematics.

Mechanics.—The Montyon prize (700 francs), for the invention or improvement of instruments useful to the progress of the mechanical arts; the Poncelet prize (2000 francs), to the author (of any nationality) of the work most useful to the progress of applied mathematics; the Boileau prize (1300 francs), for new researches concerning the motion of fluids (if theoretical, experimental confirmation is required); the Henri de Parville prize (1500 francs), for original work in mechanics; the Pierson-Perrin prize (5000 francs), for a discovery in mechanics.

Astronomy.—The Lalande prize (540 francs), for the most interesting observation or memoir most useful to the progress of astronomy; the Benjamin Valz prize (460 francs), to works conforming to the same conditions as the Lalande prize; the Pierre Guzman prize (100,000 francs), for the discovery of a means of communicating with a celestial body (excluding Mars); the G. de Pontécoulant prize (700 francs), for encouraging research in celestial mechanics.

Geography.—The Gay prize (1500 francs), for a memoir on the most recent improvements introduced into geodesy; the Tchihatchef foundation, for the assistance of explorers in the less known parts of Asia.

Navigation.—The prize of 6000 francs, for progress of any nature tending to increase the efficiency of the French naval forces; the Plumey prize (4000 francs), for improvement in steam-engines or any other invention contributing to the progress of steam navigation.

Physics.—The Gaston Planté prize (3000 francs), for the author of a discovery, invention, or work important in the domain of electricity; the Hébert prize (1000 francs), for a treatise or discovery useful for the popularisation or practical use of electricity; the Henri de Parville prize (1500 francs), for original work in physics; the Hughes prize (2500 francs), for an original discovery in physical science, especially electricity and magnetism or their applications; the Clément Félix prize (2500 francs), for facilitating the continuation of researches concerning the applications of electricity.

Chemistry.—The Montyon prize (Unhealthy Trades) (a prize of 2500 francs and a mention of 1500 francs), for the discovery of a means of rendering some mechanical art less unhealthy; the Jecker prize (10,000 francs), for work in organic chemistry; the Cahours prize (3000 francs), for encouraging young workers already known by their chemical researches; the Berthelot prize (500 francs), for researches in chemical synthesis; the Houzeau prize (700 francs), for a young deserving chemist.

Mineralogy and Geology.—The Cuvier prize (1500 francs), for the most remarkable work in mineralogy and geology; the Delesse prize (1400 francs), for a work on geological or mineralogical science; the Victor Raulin prize (1500 francs), for facilitating the publication of works relating to geology and palæontology; the Joseph Labbé prize (1000 francs), for geological work or researches contributing to the development of the mineral resources of France, its colonies and its protectorates.

Botany.—The Desmazières prize (1600 francs), for the best work on Cryptogams published during the preceding year; the Montagne prize (1500 francs), to the author or authors of important works or discoveries on cellular plants; the Jean Thore prize (200 francs), for the best memoir on European algæ, mosses, lichens, or fungi; the de Coincy prize (900 francs), for a work on Phanerogams; the Jean de Rufz de Lavison prize (500 francs), for work on plant physiology.

Anatomy and Zoology.—The Da Gama Machado prize (1200 francs), for the best memoir on the colour of animals; the Savigny prize (1500 francs), for the assistance of young travelling zoologists, not receiving Government assistance, who make a special study of the invertebrates of Egypt and Syria.

Medicine and Surgery.—The Montyon prize (three prizes of 2500 francs, three honourable mentions of 1500 francs, and citations), for improvements in medicine or surgery; the Barbier prize (2000 francs), for a valuable discovery in surgery, medicine, pharmacy, or in botany in relation to the art of healing; the Bréant prize (100,000 francs), for the discovery of a cure for Asiatic cholera or of a means of eradicating it; the Godard prize (1000 francs), for the best memoir on the anatomy, physiology, and pathology of the genito-urinary organs; the Mège prize (10,000 francs), to the author who continues and completes the essay of Dr. Mège on the causes which have retarded or favoured the progress of medicine; the Bellion prize (1400 francs), for discoveries profitable to the health of mankind or for the amelioration of the human species; the Baron Larrey prize (750 francs), to a physician or surgeon (Army or Navy) for the best work dealing with military medicine, surgery, or hygiene; the Argut prize, for a discovery of a means of medically treating a disease hitherto amenable only to surgery.

Physiology.—The Montyon prize (750 francs), for work in experimental physiology; the Lallemand prize (1800 francs), for work on the nervous system; the Philipeaux prize (900 francs), for experimental physiology; the Fanny Emden prize (3000 francs), for the best work treating of hypnotism, suggestion, and in general of physiological actions exerted at a distance from the animal organism.

Statistics.—The Montyon prize (one prize of 1000 francs, two mentions of 500 francs), for statistical researches.

History and Philosophy of Sciences.—The Binoux prize (2000 francs), for work on the history and philosophy of science.

Medals.—The Arago medal, awarded at the discretion of the Academy; the Lavoisier medal, for eminent work in chemistry; the Berthelot medal, with each prize in chemistry awarded annually.

General Prizes.—The prize founded by the State (3000 francs)—subject proposed for 1921: to establish a methodical classification of the vascular palæozoic plants; the Le Conte prize (one prize of 50,000 francs, encouragements), for notable discoveries in mathematics, physics, chemistry, natural history, medical science, or new practical applications of these sciences; the Jean Reynaud prize (10,000 francs), for original work in science; the Baron de Joest prize (2000 francs), for work in physical science; the Parkin prize (3400 francs), for work on the relations between volcanic action and abnormal atmospheric disturbances; the Saintoin prize (3000 francs), for contributions to the mathematical sciences; the Henri de Parville prize (1500 francs); the Lonchampt prize (4000 francs), for the best memoir on diseases of man, animals, or plants from the point of view of the introduction of mineral substances in excess as the cause of these diseases; the Henry Wilde prize (one prize of 4000 francs or two of 2000 francs), for discovery or work in astronomy, physics, chemistry, mineralogy, geology, or experimental mechanics; the Gustave Roux prize

(1000 francs), for a young French scientific worker; the Thorlet prize (1600 francs).

Special Foundations.—The Lannelongue foundation (2000 francs), to one or two persons in need of assistance belonging either themselves or through their parents to the scientific world; the Laplace prize, to the first pupil leaving the Ecole Polytechnique; the L. E. Rivot prize (2500 francs), between four pupils leaving each year the Ecole Polytechnique.

Research Foundations.—The Trémont foundation (1000 francs); the Gegner foundation (4000 francs); the Henri Becquerel foundation (3000 francs); the Bonaparte foundation, for assisting researches by workers who have already given proofs of their capacity and lack sufficient resources to undertake or pursue their investigations (minimum grant, 2000 francs); the Loutreuil foundation (125,000 francs); the Charles Bouchard foundation (5000 francs), for the assistance of researches in medicine or physiology.

APPLIED PLANT MORPHOLOGY.

THE importance of a knowledge of the special physiology of a crop plant in attempting to improve the yield or quality of the product needs no demonstration. The case for the study of the morphology of the plant is no less clear, and is reinforced by the fact that the two lines of investigation should go hand in hand. There are numerous familiar instances where successful cropping depends upon the correct understanding of morphological principles, and those botanists wise enough to reflect upon the lore of the intelligent practical man are aware that the knowledge possessed by him of the essential morphology of the plants with which he deals is frequently of no mean order.

There can be little doubt that fuller investigation of the morphology of economic plants (and especially of those of the tropics) would be profitable from both the scientific and commercial points of view. An example of such work is afforded by the fourth of Dr. C. A. Barber's memoirs on Indian sugar canes, in which he deals with the tillering or underground branching of the plants (Memoirs of the Department of Agriculture in India: "Studies in Indian Sugar Canes," vol. x., No. 4, June, 1919). Since in the sugar cane (Saccharum) the crop comprises aerial stems derived from the branching of the underground rhizome, the desirability of a full knowledge of the methods of branching and of the factors regulating the process is evident. By careful organisation Dr. Barber and his assistants have dissected and examined a large series of canes (both adult plants and seedlings), and the results so far obtained are of considerable interest and promise.

The chief classes of canes occurring in India include "thick" canes obtained from tropical sugar-growing countries, and Indian cultivated canes, together with wild Saccharums not used for sugar production. The results of the research show that branching in the various groups, from the wild Saccharums to the thick tropical canes, is of the same nature, but of very different degree. Taking a to represent main shoot, and b its branches, c branches of b, and so on, Dr. Barber arrives at a series of formulæ for the structural composition of the clumps at crop time varying from $a+mb+c$ in the thick canes to $a+mb+nc+nd+me+f$ in the wild Saccharums; while the different groups of Indian canes can be arranged in a series between these two extremes. The difference in form and size between the branches of different orders in the same plant have also been carefully studied. The general tendency is for the later branches to be successively thicker, to have longer joints, and to show greater curvature at the base. The characters of the branches of different orders are found to be so definite that the harvested canes can be easily separated at the mill and classified into early and late canes. This opens up a new line of work, since it becomes possible to examine these different classes of canes separately at the mill and to ascertain their relative sugar content and milling qualities. A further point of practical interest arises in connection with this question. The differences exhibited by canes of varying ages in the same clump are often much more marked in clumps raised from seedlings than in those grown from cuttings. The question as to whether this variation is handed on when the seedling is propagated vegetatively is not yet definitely known, and experiments are being conducted to determine this point, which is of considerable importance in the proper selection of seedlings.

The factors influencing the amount of tillering in a plant are, of course, both inherent and external. Different species and varieties, as well as seedlings from the same parents, differ widely, but such differences are complicated and often masked by others brought about by variations in environment which in the case of the sugar cane appear to be translatable into terms of amount of food available. Dr. Barber points out that light, spacing in the field, moisture, soil constituents, and manuring appear to be the chief controlling factors, and of these he regards the light as "probably the most important limiting factor in the production of the greatest number of canes per acre." The results obtained in the investigation raise the hope that it may be found possible to develop the work along the lines indicated by Dr. Barber.

THE ROYAL SOCIETY OF WESTERN AUSTRALIA.[1]

WESTERN AUSTRALIA has followed the other Australian States in the development of its senior scientific society into a Royal Society, and has issued the first four volumes of the Journal in its new form. Thanks to the enlightened support of the State, which undertakes the printing and publication, the society is able to issue a better journal than would be possible if it were dependent on its still small roll of members. The society has started well owing to the cordial co-operation of the new and democratic local university with the scientific services of the State. The first four presidents have been Profs. Dakin and Ross, Mr. Gibb Maitland (the Government Geologist), and Mr. Montgomery (the Government Mining Engineer).

As the reorganisation of the society marks a new start, the journal appropriately includes some synopses of existing knowledge of Western Australia; thus Mr. Alexander begins an interesting series of papers on the early history of Australian zoology, and he also contributes a list of the Orthoptera; Mr. Hedley has compiled a useful catalogue of Westralian Mollusca; and the third volume is mainly occupied by W. V. Fitzgerald's memoir on the botany of Kimberley, including the description of two new genera and eighty-eight new species. In the presidential addresses Prof. Dakin deals with vitalism, adopting a non-committal conclusion, but being quite unconvinced that there is in life any non-material factor; and Prof. Ross discusses the problems of national scientific organisation and education in the light of

[1] Journal and Proceedings of the Royal Society of Western Australia. Vol. i. Pp. xxx+251+16 pls. (1914–15.) Vol. ii. Pp. xv+112+7 pls. (1915–16.) Vol. iii. Pp. xii+227+2 pls. (1916–17.) Vol. iv. Pp. xii+54+1 pl. (Perth, W.A., 1916–19.) Price 5s. each.

the lessons of the war and offers some illuminating personally collected information.

Mr. Gibb Maitland begins his address with the unexpected claim that geology has nothing to do with war, ignoring the many millions that might have been saved had geologists been employed earlier on our side; the Germans, of course, had a large geological staff at the beginning. Mr. Maitland's address is devoted to the problems connected with the Nullagine formation, and his most generally interesting conclusion is that the scratched stones found in it are not, as has been claimed by some Australian geologists, evidence of an early glaciation, but are due to friction during earth-movements. Mr. Montgomery's address is a new statement of his view that the level surface of the plateau of Western Australia is a plain of marine denudation, and that the escarpments, locally known as "break-aways," are sea-cut cliffs. Mr. Montgomery's arguments are, as usual, interesting, ingenious, and fair. It is important to remember that a geologist who knows the arid regions of Australia so intimately as Mr. Montgomery should have arrived at conclusions as to wind-action so different from those adopted in Africa. The view that in recent times nearly all Western Australia was covered by the sea does not explain the restriction of the marine deposits to a relatively narrow band or the change in the topography above their margin. These deposits have a wide extension in the zone seaward of Norseman; the limestones there he accepts as Miocene.

The paper by Messrs. Jutson and Simpson in vol. ii. on the geology of Albany gives further evidence of these marine deposits, as their "Plantagenet beds" are a narrow coastal series ending inland on the slope of the ancient plateau. The marine origin of the "break-aways" is rejected by Messrs. Talbot and Clarke (vol. iii., p. 79) in their valuable contribution to the geology of the little-known country toward the eastern frontier. These authors claim the discovery of an upper Cretaceous or early Kainozoic glaciation in the Wilkinson Range (lat. 26° S.) on the basis of a bed with striated boulders, which, as they recognise, must have been formed by icebergs in shallow water. The evidence for the age of this boulder bed seems, however, quite inadequate. The chief contribution to anthropology is by Mr. W. D. Campbell on the natives of Sunday Island, who make their boomerangs of tank-iron and obtain their firewood from the mainland, although the author describes the wide intervening channel, owing to its fierce currents, as "dangerous to small craft."

The treasurer of the society, Mr. Allum, of the Royal Mint, Perth, discusses the decimalisation of currency in a paper which conveys a warning how strongly some authorities feel against it. He quotes the view of the *Engineering and Mining Journal* of New York that the compulsory adoption of the metric system would be a "calamity of the first order." Mr. Allum is less emphatic, but he is opposed to the decimal system, as its advantages may not be equalled by its drawbacks, and holds that if it be adopted the sovereign should be the standard of value, and the shilling should be retained and divided into ten pence.

J. W. G.

A NEW DEVELOPMENT IN AGRICULTURAL RESEARCH.

ALL interested in agricultural progress will welcome as one of the most significant events in the history of British agriculture the establishment of a research department by the Olympia Agricultural Co., Ltd.

The company, under the chairmanship of Mr. Joseph Watson, is farming on a scale probably unprecedented in this country, having purchased for its operations agricultural estates totalling practically 20,000 acres in the counties of Yorkshire, Northamptonshire, Cambridgeshire, Suffolk, Warwickshire, and Wiltshire. The research department will exercise advisory functions in connection with the farming operations of the company, but its primary object is to conduct research in various branches of agricultural science and practice for the general welfare of British agriculture, to which end liberal financial provision for its activities has been made.

The direction of the department has been assumed by Dr. Charles Crowther, lately professor of agricultural chemistry in the University of Leeds and director of the institute for research in animal nutrition in that University, who will continue and extend his experimental work in that subject.

Plant-breeding research will be a further prominent feature of the department's activities, under the direction of Capt. Hunter, lately in charge of the plant-breeding work carried out in Ireland under the Department of Agriculture and Technical Instruction; whilst provision has also been made for research on soil problems and plant nutrition under the direction of Capt. C. T. Gimingham, late chemist to the agricultural research institute of the University of Bristol.

The headquarters of the department have been located on the company's estate of some 2700 acres at Offchurch, near Leamington, where the ancient mansion of Offchurch Bury is being adapted to provide the necessary laboratories, etc., which are now approaching completion. From this centre experimental work with crops and stock on all the company's estates will be carried out under the general supervision of Capt. F. H. Billington, late of the staff of the Irish Department of Agriculture.

It is the desire and intention of Mr. Watson and his co-directors that the department shall be an "agricultural research station" in the fullest sense of the term, and that the results of its work, in so far as they may be of general interest, shall be made fully available to the general body of British agriculturists.

For some time the activities of the department must necessarily be directed to the experimental work essential to the establishment of a sound basis for its advisory work, but this is bound to produce much information of general interest.

The enhanced appreciation of the importance of research to British industries is one of the most significant effects of the war, and it is gratifying to find that British agriculture, despite its traditional conservatism and suspicion of academic "theory," is not to lag behind other industries, and a good omen that it should contain in its ranks men so alive to the value of research as to provide for it within the industry without the stimulus of subvention from the public purse.

MATHEMATICAL STATISTICS.[1]

PARTS III. and IV. of the twelfth volume of "Biometrika" contain papers of interest to all classes of statistician. Those especially attracted by work on the general mathematical theory of probability will welcome the continuation of Prof. Tchouproff's paper on the "Expectation of the Moments of Frequency Distributions." It will be agreed that the notation of mathematical expectation offers certain ad-

[1] "Biometrika." A Journal for the Statistical Study of Biological Problems. Vol. xii., Parts iii. and iv. Pp. 185–376+iv+viii plates. (London: Cambridge University Press, November, 1919.) Price 20s.

vantages over the forms of expression more commonly adopted in this country, but Prof. Pearson does well to point out that the supposed fundamental distinction of method claimed by some Continental writers is non-existent. He himself contributes a very interesting paper on a method of generalising Tchebycheff's first theorem. He finds that the method of approximating to the limits of a probability is unlikely to be of much practical value in the classes of function of usual occurrence. This result does not, of course, deprive Tchebycheff's work of its interest in permitting of the establishment of Bernoulli's theorem and of Poisson's generalisation of that theorem by elementary methods.

Papers of importance both to the student of theoretical statistics and to the practical computer are those of Miss Pairman and Prof. Pearson on the correction of the moment coefficients in limited range frequency distributions, of "Student" on deviations from the Poisson limit to the binomial in actual data, and an editorial, entitled "Peccavimus," correcting errors in various published formulæ.

Those who are engaged in psychological investigation will turn to Dr. G. H. Thomson's memoir on psychophysical curves and to the same author's discussion of hierarchical order among correlation coefficients, a subject to which other recent papers have been devoted. In the miscellanea and in a co-operative study of the eggs of the common tern, the biometrician will find much to interest him. It is invidious to cite any one paper as deserving of special praise, but, from the point of view of practical statistics, the discussion of the correction of moment coefficients in the cases to which the classical method of Sheppard does not apply is of chief interest. The volume includes a touching tribute to the memory of Dr. Charles B. Goring, whose untimely death has deprived criminology of one of its most devoted and skilful workers.

THE KINEMATOGRAPH IN SCHOOLS.

THE use of the kinema for schools, and not merely for school children, has been definitely carried a few stages nearer realisation by two recent developments which were brought to the notice of teachers attending the annual meeting of the Geographical Association. In the first place, a portable instrument at the fairly reasonable price of 60*l.* is now on the market. The case itself is fireproof; the lamp is in one separate fireproof chamber within the case, and the film is contained in another, all except the four inches or so actually in the gate; while the instrument is operated by pressing two or three buttons on the outside. The adaptation of the kinema to the class-room in this way has two incidental advantages which are in themselves very great advances. Owing to the fact that the light required is not nearly so strong as for a hall, (1) the instrument can be run off one of the lighting points in the ordinary lighting circuit, and (2) the reduction in light is accompanied by a reduction in heat, so that the film can actually be stopped for some minutes for discussion by the class.

Secondly, the provision of the films seems to be in process of being placed on a more satisfactory basis. Films were used during the war for the instruction of soldiers, and the kinema takes its place in the university, notably in the instruction of medical students. The difficulty in the past has been to know what there was to choose from, and how to choose what one wanted. It is not easy to choose lantern-slides, and it is less easy still to choose films. It cannot be said that this difficulty is wholly met, but the establishment of the Community Motion Picture Bureau goes a long way towards meeting it. There is, at any rate, somewhere to go to inquire whether that exists which one desires, and there is a central body which will gradually learn what it is that schools demand, and with the demand will come the supply. The firm receives films and edits them to make them more or less suitable for schools. One of the sessions of the recent annual meeting of the Geographical Association was taken up by a demonstration by Capt. Hodges of the value of the kinema in the teaching of geography. The films showed varied greatly in quality; the most ambitious, an American film dealing with the life-history of a volcano, was the least successful for several reasons, the most fundamental of which was that it suffered from the distinctly American failing of being non-regional. Other films, dealing with Egypt and the Nile, lumbering, and coffee culture in Java, could very easily be fitted without any jars into geography courses. This is, perhaps, not all that is desired, but it shows, at any rate, that the problem is being tackled, and that there is every prospect of a satisfactory solution ere long.

IRRIGATION IN EGYPT.

WE had occasion in NATURE of September 18 and October 9 last to allude to the controversy which has arisen out of the proposals put forward by the Egyptian Government, under British advice, for the development of the agricultural districts of Egypt and the Sudan by means of additional irrigation works on a very extensive scale. The controversy culminated in the appointment of a Foreign Office Committee, which sat in London to inquire into the charges brought by Sir William Willcocks against the Egyptian Public Works Department. The Committee's findings exonerated the Department, but failed to satisfy Sir William, who forthwith reiterated and amplified his accusations with increased vehemence. Criticism so trenchant and persistent from an engineer of undoubted standing and experience could not be ignored, and now it has been decided to submit the whole question to an International Commission consisting of three members—an irrigation engineer, nominated by the Government of India, as president; a British physicist, nominated by the University of Cambridge; and an irrigation engineer, nominated by the Government of the United States. The terms of reference are:—"To advise the Egyptian Government upon the projects prepared by the Public Works Department, with a view to the further regulation of the Nile for the benefit of Egypt and the Sudan, and in particular to examine and report upon the physical data upon which the projects rest, and to report upon the propriety of the manner in which, as the result of these projects, the increased supply of available water thereby provided will be allocated at each stage of development between Egypt and the Sudan, and to advise as to the apportionment of the cost as between Egypt and the Sudan." In a matter so seriously affecting the welfare and development of two important countries, it is to be hoped that the decisions arrived at by the Commission will be such as to command a general consensus of expert approval.

The Cairo correspondent of the *Times* states, in a message published in the issue of January 23, that the Commission is constituted as follows:—Mr. F. St. John Gebbie, Chief Engineer, Bombay, who was last engaged on the Sukkur barrage scheme—nominated by the Indian Government (chairman); Dr. G. C. Simpson, meteorologist at Simla—nominated by Cambridge University; and Mr. H. T. Cory, who directed the Salton sea works, California, in 1906—nominated by the American Government. Mr. J. L. Capes, of the Egyptian Ministry of Education, will be secretary of the Commission.

VERTEBRATE REMAINS IN THE CAVERNS OF GRIMALDI.

PROF. MARCELLIN BOULE has completed his studies of the remains of vertebrate animals found with primitive man in the caverns of Grimaldi, and the final results of his work have just been published as the concluding part (fasc. iv.) of the first volume of the Prince of Monaco's "Les Grottes de Grimaldi (Baoussé-Roussé)." The new instalment deals with the Carnivora, Insectivora, Cheiroptera, and Rodentia, and various fragments of birds and lower vertebrates, and ends with a valuable general summary. Besides the technical descriptions of the fossils, illustrated by beautiful plates in heliogravure, Prof. Boule continually introduces short discussions of the relationships and distribution of the various animals with which he deals, adding several maps and some genealogical diagrams. He has therefore produced a most interesting and readable treatise on the European Pleistocene vertebrate fauna, which we commend to the notice of both geologists and zoologists. He specially emphasises the importance of the discovery that in the low latitude of the south coast of France there is the same succession of Pleistocene mammalian faunas that has already been observed throughout the rest of Central and Western Europe. In the bottom layers on the floor of the caverns of Grimaldi there are the animals of the warm Chellean episode (*Elephas antiquus, Rhinoceros Mercki*, hippopotamus, etc.); in the next layers is the cold fauna of the Acheulian and Mousterian (glutton, ermine, marmot, reindeer, etc.); in the upper layers are the ordinary mammals of historic times. Among the animals now described Prof. Boule considers he can recognise every gradation between the Pliocene bears and the modern brown bear; he also sees some approach to a Pliocene species in the Pleistocene leopard. He agrees with other observers that the wild cat most nearly approaches that of Africa, now named *Felis ocreata*. Equally interesting is his account of the fossil lynx, which proves to be exactly intermediate between the northern and the Spanish races of the lynx at the present day.

APPARATUS FOR VAPOUR-PRESSURE DETERMINATIONS.

DIRECT measurement of the vapour-pressure of solutions for the estimation of molecular weights has never been much used, Raoult's barometric method being too cumbersome for general use. A simple apparatus for this purpose is, however, described by Mr. Robert Wright in the Journal of the Chemical Society for October. It consists of a flask (150 c.c.) and test-tube (20 cm.×3 cm.) connected by a delivery tube fused into well-fitting glass stoppers. This delivery tube is provided with a stopcock just above the flask; it reaches nearly to the bottom of the test-tube, but does not pass through the stopper of the flask. The stopper to the test-tube is provided with an exit tube carrying a stopcock. To carry out a vapour-pressure determination, a weighed quantity of the solute is placed in the test-tube, flask and tube are half-filled with solvent, and the apparatus connected together and evacuated by means of a filter-pump attached to the exit tube of the test-tube in order to boil all the air out of both solvent and solution. Expulsion of the air is facilitated by gently warming the flask. After exhaustion is complete both stopcocks are closed, and the apparatus left for two or three hours to attain the ordinary temperature. Then the tap above the flask is gently opened, and the extent to which the column of liquid in the delivery tube is depressed below the level of the solution in the test-tube is a measure of the vapour-pressure. The observed depression must be corrected for capillarity. The test-tube is then removed and weighed in order to ascertain the mass of the solution, and if the latter is concentrated its density must be measured. As a solvent water is unsuitable, alcohol and carbon tetrachloride are satisfactory, but benzene cannot be used because of the action of its vapour on the tap-lubricant.

EXPERIMENTS ON TRAIN RESISTANCE.

TO railway engineers Bulletin 110 of the University of Illinois is of special interest, because it contains a report of some experiments on train resistance carried out by the experimental station of the University in co-operation with the Illinois Central Railway. Tests were made to measure the resistance of passenger trains in service up to speeds of seventy miles per hour. The main results are embodied in a set of curves. The peculiarity brought out by the experiments is that the resistance is not a function of the speed alone, but a function of the speed and the car-weight. The inference from the experiments is that, other things being equal, the heavier the car the less the resistance.

The results are likely to differ from those obtained by experiments on English railways, because the track is different, the standard of maintenance is probably different, and also the construction of the cars. Experiments on train resistance on British railways have been made by Sir John Aspinall. In these experiments it was found that the train resistance is a function of the speed and the length of the train. Probably if the Illinois experiments could be re-examined in terms of the length of the train, the Aspinall formula might be found to fit the data obtained, because increase in car-weight generally means increase in length of train; one is the function of the other.

Our American friends realise the national advantage to be gained by co-operation between university and railway. They have an experimental station organised and maintained by a university co-operating with a railway company in an experimental research. Similar relations might be hoped for between university and railway in this country. There is no doubt that both would gain considerably by mutual co-operation.

THE EVOLUTION OF BOTANICAL RESEARCH.[1]

A MEETING of the American Association in St. Louis is of special interest to botanists. When this city was little more than a frontier town, Dr. George Englemann became one of its citizens. In spite of his duties as a successful physician, he became one of our greatest botanists; in fact, in the days when taxonomy was practically the whole of botany, and our virgin flora was being explored, the great American trio of botanists was Asa Gray (of Cambridge, Mass.), John Torrey (of New York), and George Englemann (of St. Louis). Englemann's distinction was that he published no general botanical works, but selected a series of the most difficult problems in taxonomy, and in a masterly way organised for us many perplexing groups. With these groups his name will always be associated. To a botanist, therefore, St. Louis means the home of George Englemann.

There is another association also for the botanist. St. Louis is the home of one of our great botanical

[1] Presidential address delivered at the St. Louis meeting of the American Association for the Advancement of Science, December, 1919, by Prof. John M. Coulter.

gardens, identified for those of us who are older with the name of Henry Shaw; but we are becoming accustomed to its later name, the Missouri Botanical Garden. Its plans and activities represent a fitting continuation of the spirit of Englemann and Shaw adapted to the progress of botanical science.

In consequence of these associations St. Louis may be said to have a botanical atmosphere, of which botanists are very conscious. We have the feeling, therefore, not of a visit, but of a home-coming.

A presidential address delivered to a group composed of investigators representing all the sciences, and including also those interested in science, should deal with some interest common to all. In my judgment, our common bond is interest in research; in fact, the major purpose of this association is to stimulate research by the personal contact of investigators. In selecting as my subject, therefore, the evolution of botanical research, I am assuming that the situation developed may apply in a general way to all scientific research.

My purpose is not to outline the history of botanical research, but rather to direct attention to certain evolutionary tendencies and to project them into the future. We are all familiar with the gradual historical development of different phases of botany, until botanists became segregated into many distinct groups, the only common bond being the use of plants for investigation. This segregation was for a time very complete, so that the interests of one group would not have been affected if none of the other groups had existed. This monastic phase of botany has subsided somewhat, not for all individuals, but for the subject in general. The different groups are coming into contact, and even interlocking, so that the science of botany bids fair to be recognised as an increasing synthesis rather than as an increasing disintegration. In connection with these gradual evolutionary changes, I wish to emphasise three tendencies which seem to me to be significant. As in all evolutionary progress, the tendencies may seem numerous, but the three I have selected seem to me to be especially prophetic of a new era of botanical research.

(1) One of the growing tendencies of botanical research is to attack problems that are fundamental in connection with some important practice. The outstanding illustration, of course, is the increasing attention given to the problems that underlie agriculture; but there are many other practices also which are embedded in botanical investigation. We all realise that this tendency was stimulated by the war; in fact, this has been the experience of all the sciences, more notable, perhaps, in physics and chemistry than in the other sciences, but a very obvious general result. This tendency is so strong at present that I do not believe it will ever subside, but it should be understood. There is no evidence that it is tending to diminish research, the sole purpose of which is to extend the boundaries of knowledge, which all of us must agree is the great objective of research. It merely means that experience developed in connection with an important practice has suggested fundamental problems the solution of which is just as important in extending the boundaries of knowledge as in illuminating some practice. In fact, among our most fundamental problems are those that have been suggested by experience. The injection of such problems among those not related to general experience is not to the detriment of the latter, but simply extends the range of research.

I have no sympathy with the artificial segregation of science into pure and applied science. All science is one. Pure science is often immensely practical, applied science is often very pure science, and between the two there is no dividing line. They are like the end-members of a long and intergrading series—very distinct in their isolated and extreme expression, but completely connected. If distinction must be expressed in terms where no sharp distinction exists, it may be expressed by the terms "fundamental" and "superficial." They are terms of comparison, and admit of every intergrade. The series may move in either direction, but its end-members must always hold the same relative positions. The first stimulus may be our need, and a superficial science meets it, but in so doing it may put us on the trail that leads to the fundamental things of science. On the other hand, the fundamentals may be gripped first, and only later find some superficial expression. The series is often attacked first in some intermediate region, and probably most of the research in pure science may be so placed; that is, it is relatively fundamental, but also relatively superficial. The real progress of science is away from the superficial towards the fundamental, and the more fundamental the results, the more extensive may be their superficial expression.

Not only are practical problems not a detriment to botanical science, they, incidentally, also strengthen its claim on public interest as a science that must be promoted. As an incidental result, I look with confidence to a future of far greater opportunity for research than has been possible heretofore—research which must be increasingly fundamental and varied. Even if this were not true, my creed for science is that while its first great mission is to extend the boundaries of knowledge, that man may live in an ever-widening horizon, its second mission is to apply this knowledge to the service of man, that his life may be fuller of opportunity. From the point of view of science, the second may be regarded as incidental to the first, but it is a very important incident, and really stimulates research. In short, I regard this so-called practical tendency in research as being entirely in the interest of research in general, in increasing the range of fundamental problems, in contributing a powerful stimulus, and in securing general recognition of the importance of research.

(2) A second tendency, which I regard as more important, is an increasing realisation of the fact that botanical problems are synthetic. Until recently a problem would be attacked from a single point of view, with a single technique, and conclusions reached that seemed as rigid as laws from which there is no escape. In plant morphology, for example—and I speak from personal experience—we described structures with no adequate conception of their functions. Plant physiologists, on the other hand, would describe functions with no adequate knowledge of the structures involved; while ecologists often described responses with no adequate knowledge of either structure or function. The same condition obtained in the other segregates of botany. We all recall the time when plant pathologists described and named pathogenic organisms and paid no attention to the disease, which, of course, is the physiological condition of the plant. In short, not only taxonomists, but all of us, were simply cataloguing facts in a kind of card-index, unconsciously waiting for their co-ordination. This co-ordination has now begun, and is one of the strong tendencies which are certain to continue. The morphologist is beginning to think of the significance of the structure he is describing, and the physiologist to examine the structures involved in the functions he is considering; while the ecologist realises now that responses to environment which he has been cataloguing are to be interpreted only in terms of structure and function. In other words, around each bit of investigation, with its single

point of view and single method of attack, there is developing a perspective of other points of view and other methods of attack.

This does not mean a multiple attack on each problem by each investigator. We must remain morphologists, physiologists, and ecologists, each group with its special technique and special kind of data. But it *does* mean a better estimation of the results, a watchful interest in the possibilities of other methods of attack, a general toning-down of positiveness in conclusions. We all realise now that plants are synthetic, and that is quite a notable advance from that distant time when we thought of them only as objects subservient to laws of nomenclature. This increasing synthetic view is resulting in a proper estimate of problems. The data secured by each investigation constitute an invitation to further investigation. We have in mind the whole problem, and not scraps of information. In short, the synthetic view has developed about our problems the atmosphere in which they actually exist.

(3) A third tendency, which seems to me to be the most significant one, is the growing recognition of the fact that structures are not static—that is, inevitable to their last detail. As a morphologist I may recall to your memory the old method of recording the facts in reference to the development of such a structure as the embryo of seed-plants. Not only every cell-division in the ontogeny was recorded, but also the planes of every cell-division. The conception at the back of such records was that the programme of ontogeny was fixed to its minutest detail. It is probably true that such a structure is about as uniform in its development as any structure can be, but it has become evident now that many of the details recorded were not significant. Instead of cataloguing them as of equal value, we must learn to distinguish those that are relatively fixed from those that are variables.

In the same way, much of the older work in anatomy must be regarded as records of details of which the relative values were unknown. Even the structures involved in vascular anatomy are not static, but many a phylogenetic connection has been formulated on the conception of the absolute rigidity of such structures in their minutest detail. This conception has made it possible, of course, to develop as many static opinions as there are variables in structure.

Perhaps the greatest mass of details has been accumulated by the cytologists in connection with their examination of the machinery of nuclear division and nuclear fusion. In no other field has the conception of the rigidity of the structures involved become more fixed, even to the minutest variation in form and position. Of course, we all realise that any field of investigation must be opened up by recording all the facts obtained, but we must realise that this is only the preliminary stage. The time has come when even the recorded facts of cytology are being estimated on the basis of relative values—that is, the inevitable things are being differentiated from the variables.

The same situation is developing in the field of genetics. We all recall the original rigidity of the so-called laws of inheritance. It was natural to begin the cultivation of this field with the conception that the programme of heredity is immutable, and that definite structures are inevitable, no matter what the conditions may be. There was probably more justification for this conception in this field, on the basis of the early investigations, than in any other, but experience has begun to enlarge the perspective wonderfully. The rapidly accumulating facts are becoming so various that consistent explanations require a high degree of mental agility. More fundamental, however, is the recognition of the fact that the problem of heredity involves not only germinal constitution, which gives such rigidity as there is, but also the numerous factors of environment. In other words, such problems have become synthetic in the highest degree, making possible results that are anything but static.

In considering these illustrations of the tendency to recognise that facts are not all pigeon-holed and of equal value, it is becoming more and more obvious that our botanical problems are, in general, the application of physics and chemistry to plants; that *laws*, when we really discover them, are by definition static, but that their operation results in anything but static structures. In other words, structure must respond to law, but the particular law that is gripping the situation may be one of many.

With such evolutionary tendencies in mind, what is the forecast for botanical research? I wish to direct attention to three important features that seem certain to characterise it:

(1) It will be necessary for the investigator who wishes to have a share in the progress of the science, rather than merely to continue the card-catalogue assembling of random data, to have a broader botanical training than has seemed necessary heretofore. Our danger has been that the cultivation of a special technique, which, of course, is necessary, is apt to limit the horizon to the boundary of that technique. In some cases the result to the investigator has been more serious than limiting his horizon; it has led him to discredit other methods of attack as of little importance. In case this attitude is associated with the training of students, it is continued and multiplied by pedigree culture. The product of certain laboratories is recognised as of this type, and it is out of line with the evident direction of progress.

This demand of the future does not mean that one must specialise less than formerly. It is obvious that, with the increasing intricacy of problems and the inevitable development of technique, we must specialise more than ever. What the new demand means is not to specialise less, but to see to it that every speciality has developed about it a botanical perspective. In other words, instead of an investigator digging himself into a pit, he must do his work on a mountain-top. This secures some understanding and appreciation of other special fields under cultivation, some of which will certainly interlock with his own field. To meet this situation will demand more careful attention to the training of investigators than it has received. Interested, and even submerged, in our own work, as we must be, still we must realise that the would-be investigator must develop his atmosphere as well as his technique, or he will remain medieval.

To be more concrete, the morphologist in the coming days must appreciate the relation that physiology and ecology hold to his own field. This is far from meaning that he must be trained in physiological and ecological investigation, but he must know its possibilities. The same statement applies in turn to the physiologist and ecologist, and so on through the whole list of specialities.

This first forecast of the future applies to the necessary training of investigators rather than to investigation itself.

(2) A second important feature that is sure to be included in the botanical investigation of the future is co-operation in research. During the last few years the desirability of co-operation has been somewhat stressed, and perhaps the claims for it have been urged somewhat unduly. This was natural when

we were desiring to secure important practical results as rapidly as possible. It opened up, however, the possibilities of the future. No one questions that individual research, to contrast it with co-operative research, must continue to break the paths of our progress. Men of ideas and of initiative must continue to express themselves in their own way, or the science would come to resemble field cultivation rather than exploration. It is in this way that all our previous progress has been made. The new feature is that individual research will be increasingly supplemented by co-operative research. There are two situations in which co-operative research will play an important *rôle*.

The more important situation is the case of a problem the solution of which obviously requires two or more kinds of special technique. There are many problems, for example, which a morphologist and a physiologist should attack in co-operation, because neither of them alone could solve it. Two detached and unrelated papers would not meet the situation. Our literature is burdened with too many such contributions now. The one technique must be a continual check on the other during the progress of the investigation. This is a very simple illustration of what may be called team-work. It is simply a practical application of our increasing realisation of the fact that problems are often synthetic, and therefore involve a synthetic attack.

Another simple illustration may be suggested. If taxonomists and geneticists should work now and then in co-operation, the result might be either fewer or more species, but, in any event, they would be better species. The experience of botanists can suggest many other useful couplings in the interest of better results. In the old days some of you will recall that we had investigations of soil bacteria unchecked by any work in chemistry, and side by side with this were investigations in soil chemistry unchecked by any work with soil bacteria.

Perhaps the most conspicuous illustration of discordant conclusions through lack of co-operation, so extreme that it may be called lack of co-ordination, may be found in the fascinating and baffling field of phylogeny. To assemble the whole plant kingdom, or at least a part of it, in evolutionary sequence has been the attempt of a considerable number of botanists, and no one of them as yet has taken into consideration even all the known facts. There is the palæobotanist who rightly stresses historical succession, with which, of course, any evolutionary sequence must be consistent, but cannot be sure of his identifications, and still less of the essential structures involved. History is desirable, but some real knowledge of the actors who make history is even more desirable.

Then there is the morphologist, who stresses similarity of structures, especially reproductive structures, and leaves out of sight not only accompanying structures, but also historical succession.

Latest in the field is the anatomist, especially the vascular anatomist, who compares the vascular structures in their minutest detail, and loses sight of other important factors in any evolutionary succession.

Apparently no one as yet has taken all the results from all fields of investigation and given us the result of the combination. In other words, in phylogeny we have had single-track minds. This has been necessary for the accumulation of facts, but unfortunate in reaching conclusions.

This is but a picture of botanical investigations in general as formerly conducted, and it seems obvious that co-operative research will become increasingly common as co-operation is found to be of advantage.

The second situation in which co-operative research will play an important *rôle* is less important than the first, but none the less real. It must be obvious to most of us that our literature is crowded with the records of incompetent investigations. Not all who develop a technique are able to be independent investigators. They belong to the card-catalogue class. They are not even able to select a suitable problem. We are too familiar with the dreary rehearsal of facts that have been told many times, the only new thing, perhaps, being the material used; and even then the result might have been foretold. It is unfortunate to waste technique and energy in this way, and the only way to utilise them is through co-operative research, for which there has been a competent initiative, and in the prosecution of which there has been a suitable assignment of parts. In my judgment, this is the only way in which we can conserve the technique we are developing and make it count for something. I grant that the product of such research is much like the product of a factory, but we may need the product.

In one way or another co-operative research will supplement individual research. Individuals, as a rule, will be the pioneers; but all cannot be pioneers. After exploration there comes cultivation, and much cultivation will be accomplished by co-operation.

(3) The most important feature that will be developed in the botanical investigation of the future is experimental control. Having recognised that structures are not static, that programmes of development are not fixed, and that responses are innumerable, we are no longer satisfied with the statement that all sorts of variations in results occur. We must know just what condition produced a given result. This questioning as to causes of variable results first took the form of deduction. We tried to reason the thing out.

A conspicuous illustration of this situation may be obtained from the history of ecology. Concerned with the relation of plants to their environment, deductions became almost as numerous as investigators. Even when experimental work was begun, the results were still vague because of environment. Finally, it became evident that all the factors of environment must be subjected to rigid experimental control before definite conclusions could be reached.

What is true of ecology is true also of every phase of botanical research. For example, I happened to be concerned with materials that showed an occasional monocotyledonous embryo with two cotyledons, while most of the embryos were normal. The fact, of course, was important, for it connected up monocotyledons and dicotyledons in a very suggestive way, and also opened up the whole question of cotyledony. Important as the fact was, much more important was the cause of the fact. We could only infer that certain conditions might have resulted in a dicotyledonous embryo in a monocotyledon; but it was a very unsubstantial inference. That problem will never be solved until we learn to control the conditions and produce dicotyledonous embryos from monocotyledons at will, or the reverse. Comparison and inference must be replaced by experimental control, just as in the history of organic evolution the method shifted from comparison and inference to experimental control. It will be a slow evolution, and most of our conclusions will continue to be inferences, but these inferences will eventually be the basis of experiment. In fact, most of our conclusions are as yet marking time until a new technique enables us to move forward.

These illustrations from ecology and morphology represent simple situations as compared with the demands of cytology or genetics, but the same need for experimental control is a pressing one in those fields. The behaviour of the complex mechanism of the cell is a matter of sight, followed by inference, when we know that invisible factors enter into the performance. How the cell programme can ever be brought under experimental control remains to be seen, but we must realise that in the meantime we are seeing actors without understanding their action. In fact, we are not sure that we see the actors; the visible things may be simply a result of their action. The important point is to keep in mind the necessary limitations of our knowledge, and not mistake inference for demonstration.

Even more baffling is the problem of adequate experimental control in genetics. We define genetics as breeding under rigid control, the inference being that by our methods we know just what is happening. The control is rigid enough in mating individuals, but the numerous events between the mating and the appearance of the progeny are as yet beyond the reach of control. We start a machine and leave it to its own guidance. The results of this performance, spoken of as under control, are so various that many kinds of hypothetical factors are introduced as tentative explanations. There is no question that this is the best that can be done at present, but it ought to be realised that as yet no real experimental control of the performance has been devised. The initial control, followed by inferences, has developed a wonderful perspective, but a method of continuous control has yet to come.

Having considered the conspicuous evolutionary tendencies of botanical research and their projection into the future, it remains to consider the possible means of stimulating progress. It will not be accomplished by increasing publication. It is probably our unanimous judgment that there is too much publication at the present time. What we need is not an increasing number of papers, but a larger percentage of significant papers. This goes back to the selection of problems, assuming that training is sufficient. A leader is expected to select his own problems, but we are training an increasing army of investigators, and the percentage of leaders is growing noticeably less. There ought to be some method by which botanists shall agree upon the significant problems at any given time in the various fields of activity, so that such advice might be available. It is certainly needed.

I realise that our impulse has been to treat a desirable problem as private property, upon which no trespassing is allowed. Of course, common courtesy allows an investigator to work without competition, but the desirable problems are still more numerous than the investigators, and we must use all our investigative training and energy in doing the most desirable things. There need be no fear of exhausting problems, for every good problem solved is usually the progenitor of a brood of problems. We shall never multiply investigators as fast as our investigations multiply problems. In the interest of science, therefore, we should pool our judgment, and indicate to those who need it the hopeful directions of progress.

Not only is there dissipation of time and energy in the random selection of problems, there is also wastage in investigative ability. Every competent investigator should have the opportunity to investigate. The pressure of duties that too often submerge those trained to investigate is a tremendous brake upon our progress. I am not prepared to suggest a method of meeting this situation, but the scientific fraternity in some way should press the point that one who is able to investigate should have both time and opportunity. A university regulation, with which we are all too familiar, which requires approximately the same hours of all its staff, whether they are investigators or not, should be regarded as medieval.

In conclusion, speaking not merely for botanical research, but for all scientific research, it has now advanced to a stage which promises unusually rapid development. The experience of the recent years has brought science into the foreground as a great national asset. It should be one of the functions of this association to see to it that full advantage is taken of the opportunity offered by the present evolutionary stage of research and public esteem. We must choose between inertia and some display of aggressive energy.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

London.—The faculty of medicine has elected Dr. H. L. Eason to be its representative on the Senate in succession to Sir Cooper Perry, who has resigned on his appointment to the post of Principal Officer of the University; and the faculty of science has elected Prof. L. N. G. Filon to be its representative on the Senate in succession to Prof. G. A. Buckmaster, who has resigned on his appointment to the chair of physiology in the University of Bristol.

Prof. T. Loveday, professor of philosophy at Armstrong College, Newcastle-upon-Tyne, has been appointed principal of Southampton University College in succession to Dr. Alex Hill, resigned.

Mr. A. V. Hill, F.R.S., fellow of King's College, late fellow of Trinity College, and lecturer in physiology in the University of Cambridge, has been appointed to the vacant chair of physiology in the University of Manchester.

Girton College, Cambridge, has received a gift of 10,000*l.*, the capital and interest of which are to be applied during the next twenty years for the encouragement of scientific research by women in mathematical, physical, and natural sciences.

Lt.-Col. P. S. Lelean, professor of hygiene, Royal Army Medical College, will distribute prizes and certificates at the Sir John Cass Technical Institute on Tuesday, February 3, and will give an address on applied science in gas warfare.

On Wednesday, January 21, Mr. E. Wyndham Hulme was presented by the Patent Office Library staff with an illuminated address, bound in morocco, recording their appreciation of his work as librarian during the last twenty years. We understand that Mr. Hulme will continue his editorial supervision of the "Subject Index to Periodicals" published by the Library Association. Mr. Hulme has been succeeded in his office by Mr. Allan Gomme, son of the late Sir Laurence Gomme, and formerly an assistant examiner in the Patent Office.

The statement of the Rhodes Scholarships Trust for the year 1919 shows that the number of scholars actually in residence for either the whole or some part of the academic year 1918–19 was eighty-seven, viz. sixty-six Colonials and twenty-one Americans. Of these, thirty-one came into residence for the first time. There were also in residence nine ex-scholars, of whom five were Colonials and four Americans. In the United States the elections this year have been held under new conditions. In the first place, there has been no qualifying examination. The competition has been open, limited only by the fact that, in any given State, no one institution could be represented in the competition by more than a small number of candidates, proportioned to the total enrolment of students in the institution. In the second place, selection committees have been composed of old Rhodes scholars, acting under a chairman not himself a Rhodes scholar. It is hoped by degrees to extend this principle elsewhere, to the extent at least of securing representation of Rhodes scholars on all electing committees. In the course of the year 1920, scholars will be elected to represent the years 1920 and 1921, the former coming into residence in January, 1921, the latter in October, 1921. Revised circulars giving information in reference to the award of the scholarships in each of the communities to which they are assigned will be issued shortly. Any further information may be obtained on application to the offices of the Trust, Seymour House, Waterloo Place, London, S.W.1. In the United States application may be made to Prof. Frank Aydelotte, Massachusetts Institute of Technology, Cambridge, Mass.

WE trust that there will be a ready and generous response to the appeal issued by University College, London, with the approval of the Senate of the University, for a sum of 100,000*l.* to extend and re-equip the school of engineering, which has played so important a part in engineering education and research. Founded in 1828, this school has ever since enjoyed the inestimable advantage of the guidance of some of the most eminent scientific engineers of their day, and its influence on practice has been very great. The reconstruction and re-equipment of schools of engineering are inevitable at intervals if they are to exert an effective influence, and there has probably never been so vital a need as now to provide the best scientific education possible for the young men who, in due course, will have to direct our engineering commerce and compete for world markets. The appeal has met with an excellent initial response. Lord Cowdray has given 10,000*l.*, and promised a further like sum when 70,000*l.* has been reached. The members of the family of the late Mr. Charles Hawksley have given 3000*l.* towards an extension of the hydraulic laboratory which will be associated with his name, while other substantial amounts bring the sums subscribed and promised to about 30,000*l.* There is no more vital need at the present time than the highest scientific training for young men who have borne the brunt of war for years, and are now willing to devote further years to preparation for professional careers. It is to be hoped that the remaining 70,000*l.* will be quickly subscribed in order that the plans now made can be carried out.

SOCIETIES AND ACADEMIES.

LONDON.

Geological Society, January 7.—Mr. G. W. Lamplugh, president, in the chair.—F. J. **North**: Syringothyris, Winchell, and certain Carboniferous Brachiopoda referred to Spiriferina, D'Orbigny. This paper is the outcome of a suggestion made in 1913 by Prof. T. F. Sibly, who pointed out the desirability of an attempt to remove the uncertainty which had hitherto existed in the naming of the British species of Syringothyris, and of the Carboniferous Spiriferids possessing a lamellose surface ornament, which it was customary to refer to Spiriferina because there was no other genus for their reception, although it had long been recognised that few, if any, of them really belonged to that genus. After indicating the exact sense in which certain frequently occurring terms are used, and reviewing the history of previous research, the author discusses the history in Avonian times of the genus Syringothyris, and suggests a classification of its species. Variations due to time, to environmental conditions, and to distribution in space are recognised, and distinctive names are given to the mutations characteristic of certain horizons.—S. S. **Buckman**: Jurassic chronology: i., Lias. Supplement 1, West England strata. It is found that the preserved strata of the Gloucestershire–Worcestershire Lias under consideration happen in the main to be deposits of dates when the living Ammonites were rather small; while there is faunal failure, and presumably stratal failure, of the times when large Ammonites flourished. The converse phenomena are mainly illustrated by North Somerset deposits. The times when large and small Ammonites lived appear to follow one another like waves, illustrated even in a short table of Liassic deposits.

Aristotelian Society, January 19.—Prof. Wildon Carr, vice-president, in the chair.—Prof. J. A. **Smith**: The philosophy of Giovanni Gentile. The paper began with a general characterisation of the remarkable re-birth of idealistic philosophy in southern Italy. That philosophy, as exemplified in the systems of Croce and Gentile, builds upon the foundation of history, which it conceives of as the content of experience self-created by the mind that seeks the theory of it. The special problem now before philosophy is the understanding of history, and, *imprimis*, of its own history. An endeavour was made to trace the stages in the formation of Gentile's thought—its gradual enlargement from a theory of education into a universal metaphysics. This development culminates in the assertion of the identity of mind's essence with its existence; it *is* the process of its own gradual self-creation. The doctrine that mind is *atto puro* is taken and employed by Gentile as the guiding principle of a new form of absolute idealism. As compared with Croce, Gentile insists more upon the unity of mind or spirit, while recognising certain absolute forms of it as issuing from it and constituting its concrete being or filling. Philosophy is the supreme form of self-consciousness, and so finds in itself the clue to all that mind is or has created—itself and its world. This principle, once accepted, applies itself and advances by an immanent dialectic. No reality outside mind and its activity is needed to account for experience. The paper concluded with an attempt to render the central idea of Gentile's philosophy more familiar, and to meet a few objections to its apprehension and acceptance.

SYDNEY.

Royal Society of New South Wales, December 3, 1919.—Prof. C. E. Fawsitt, president, in the chair.—Prof. C. E. **Fawsitt**: Presidential address: The uniformities of Nature. The principle of continuity was considered in relation to the phenomena of the natural world, and prominence given to the contributions of Mr. A. J. Balfour to this subject. The problem of the creation of the atoms of all, or at any rate of some (primary), elements is still unsolved, and Clerk Maxwell's original description of the atoms as having the nature of "*manufactured articles*" may still be applied. The discontinuity between inanimate matter and living matter remains unbridged, in spite of the hopes and efforts of many to bridge the existing gap. The irregularities noticed from time to time in the periodic classification of the chemical elements have to a very large extent disappeared as a result of the research of recent years, but the difficulty of placing the elements of the rare earth group satisfactorily remains as a blot on what is otherwise still one of the most fascinating regularities known to chemists. The president then gave the periodic arrangement in a form he considered most suitable at the present time.—J. H. **Maiden**: Notes on Acacias. No. iv. With descriptions of new species. The author describes seventeen new species of Acacia or wattle, together with three new varieties. The present are chiefly natives of New South Wales and Queensland, and also of Western Australia; some promise to be of economic importance. This revision of the species will, it is hoped, enable the author later on to offer a modified classification of the whole of the Australian wattles.—C. A. **Sussmilch** and Prof. T. W. Edgeworth **David**: Sequence and correlation of the Permo-Carboniferous and Carboniferous rocks of New South Wales. Part i. The Carboniferous formation of the Hunter River Valley. The Carboniferous strata of the Hunter River Valley, N.S.W., are divisible into a lower and an upper series, the former deposited under marine, the latter under terrestrial, conditions. The Lower Carboniferous strata consist of marine mudstones, limestones, conglomerates, and tuffs, and contain an abundant and typical marine fauna; they also contain some fossil plants (drift vegetation), of which the genus Lepidodendron is the most characteristic. No angular unconformity exists between the Lower and Upper Carboniferous formations, the passage from one to the other being marked by an extraordinary development of conglomerates from 1000 ft. to 2000 ft. thick; above these conglomerates there occurs a very thick series of volcanic rock (lava-flows and tuffs), with which are inter-stratified conglomerates and shales, the latter containing fossil plants (the Rhacoptens flora).—W. A. W. **de Beuzeville**: Determination of the increment of trees by stem analysis: *Eucalyptus viminalis*. The calculations show that the tree increases in height rapidly until about thirty years old, averaging 2·8 ft. per annum. This rate gradually diminishes, dropping to 1·6 ft. mean annual increase when sixty-six years old. The diameter increase likewise is greater during youth, but is fairly evenly maintained during the whole period, ranging from 0·37 in. to 0·3 in. per annum. The mean annual volume increment, which was 0·1 cub. ft. at ten years, shows a steady improvement, reaching 1·13 cub. ft. at sixty-six years of age.

Linnean Society of New South Wales, November 26, 1919.—Mr. J. J. Fletcher, president, in the chair.—G. I. **Playfair**: Peridineæ of New South Wales. Of a total of sixteen species and twenty-three varieties described or recorded, three species and eighteen varieties are described as new. The material dealt with is mainly from the Sydney and Lismore districts, and, in addition, a few examples are from the Brisbane district.—C. T. **White**: A revised account of the Queensland Lecythidaceæ. A revision of the material belonging to the genera Barringtonia and Careya in the Queensland Herbarium. The following species are retained: *Barringtonia speciosa*, Forst., *B. calyptrata*, R.Br., *B. longiracemosa*, n.sp., *B.* sp. (possibly *longiracemosa*), and *Careya australis*, whilst two species, *B. racemosa* and *B. acutangula*, are excluded.—M. **Aurousseau**: An interesting form of sub-surface drainage. The lines of sub-surface drainage described consist either of series of small holes up to a foot in diameter and 3 ft. in depth, spaced irregularly along definite lines, or partly of series of holes and partly of lengths of trench-like depressions terminating in a tunnel at either end. The formation of these is believed to be due, not to any peculiarity of the soil, but to the climate of the region which is characterised by marked seasonal rainfall. The possibility is suggested that this sub-surface drainage may be a factor in the intake of the coastal artesian basin of Western Australia.—J. **Mitchell**: Some additional Trilobites from N.S.W. Four new species are described, one (*Trinucleus Clarkei*) from rocks of Ordovician age, the other three (*Ceratocephala phalaenocephala, Odontopleura Hartleii*, and *Cyphaspis Filmeri*) from Upper Silurian rocks.—Dr. R. J. **Tillyard**: Mesozoic insects of Queensland. No. 7. *Hemiptera homoptera*, with a note on the phylogeny of the order. Twenty-three specimens of homopterous tegmina from the Upper Trias of Ipswich are dealt with in this paper; one of these, *Mesojassus ipsviciensis*, Till., had been previously described. The results show that the Ipswich fauna contains as its dominant element the Upper Permian family Scytinopteridæ, of which seven species, placed in six new genera, are described.—E. W. **Ferguson** and Marguerite **Henry**: Tabanidæ from Camden Haven District, N.S.W. With descriptions of new species. The species described were collected during the course of investigations as to the means of transmission of *Onchocerca Gibsoni* in cattle, special attention being paid to the Tabanidæ as possible vectors of the larvæ. Of the forty-one species described or recorded, ten are proposed as new. The seasonal distribution of the species is indicated by a table.

DIARY OF SOCIETIES.

THURSDAY, JANUARY 29.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. R. R. Terry: Renaissance Music in Italy and England.
ROYAL SOCIETY, at 4.30.—Prof. W. Bateson: The Genetics of "Rogues" among Culinary Peas (*Pisum sativum*).—L. T. Hogben: Studies on Synapsis. I. Oogenesis in the Hymenoptera.—H. Onslow: A Periodic Structure in many Insect Scales, and the Cause of their Iridescent Colours.
ROYAL COLLEGE OF PHYSICIANS, at 5.
ROYAL INSTITUTE OF PUBLIC HEALTH, at 5.—Dr. O. May: Tuberculosis in relation to Life Assurance.
ROYAL SOCIETY OF MEDICINE (Balneology and Climatology Section), at 5.30.—Dr. N. Wood and Others: Discussion on the Merits and Defects of the British Health Resorts.
WIRELESS SOCIETY OF LONDON (at Institution of Civil Engineers), at 6.—R. C. Clinker: A Portable Valve Set and some properties of C.W. Circuits.
SOCIETY OF ANTIQUARIES, at 8.30.

FRIDAY, JANUARY 30.

ROYAL COLLEGE OF SURGEONS, at 5.—Prof. A. Keith: John Hunter's Observations and Discoveries in Anatomy and Surgery; His Contributions to our Knowlege of the Eye, Ear, and Nose (Hunterian Lecture).
INSTITUTION OF CIVIL ENGINEERS (Students' Meeting), at 6.—R. B. Dunwoody: The Economic Requirements for Inland Navigation Transport in the British Isles (Vernon-Harcourt Lecture).
INSTITUTION OF ELECTRICAL ENGINEERS (Students' Meeting) (at the City and Guilds Technical College, Leonard Street), at 7.—Major K. Edgcumbe and Others: Discussion on Quantity Production as a Panacea.
JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—G. E. Lygo: The Manufacture of Hydrogen Gas by the Silicol Process for Airships and Commercial Purposes.
ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—S. G. Brown: The Gyrostatic Compass.

SATURDAY, JANUARY 31.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir F. W. Dyson: The Astronomical Evidence bearing on Einstein's Theory of Gravitation: I. Movement of the Perihelion of Mercury.
PHYSIOLOGICAL SOCIETY (at King's College), at 4.

MONDAY, FEBRUARY 2.

VICTORIA INSTITUTE (in Committee Room B, Central Hall, Westminster), at 4.30.—Sir Andrew Wingate: India.
ROYAL COLLEGE OF SURGEONS, at 5.
INSTITUTE OF ACTUARIES, at 5.—A. Henry: Some Further Suggestions on the Subject of Approximate Valuations.—H. L. Trachtenberg: A New Method of Valuing Policies in Groups.
ARISTOTELIAN SOCIETY (at 74 Grosvenor Street), at 8.—Mrs. N. A. Duddington and Others: Discussion on Lossky's Intuitive Basis of Knowledge.
ROYAL SOCIETY OF ARTS, at 8.—Capt. H. Hamshaw Thomas: Aircraft Photography in War and Peace (Cantor Lecture).
SOCIETY OF CHEMICAL INDUSTRY (at the Chemical Society), at 8.—H. M. Wells and J. E. Southcombe: The Theory and Practice of Lubrication: The Germ Process.
ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.30.—J. W. Simpson: Presidential Address to Students.
ROYAL GEOGRAPHICAL SOCIETY (at the Central Hall, Westminister), at 8.30.—Major-Gen. Sir Frederick Sykes: Air Routes of the Empire.
MEDICAL SOCIETY OF LONDON, at 9.—Dr. H. R. Spencer: Tumours complicating Pregnancy, Labour, and the Puerperium (Lettsomian Lecture).

TUESDAY, FEBRUARY 3.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. G. Elliot Smith: The Evolution of Man and the Early History of Civilisation. II. Elephants and Ethnologists.
ROYAL SOCIETY OF ARTS (Colonial Section), at 4.30.—Sir Francis Watts: Tropical Departments of Agriculture, with special reference to the West Indies.
ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN (Technical Meeting), at 7.—L. A. Jones: A Non-intermittent Sensitometer.
RÖNTGEN SOCIETY (at the Medical Society of London), at 8.15.

WEDNESDAY, FEBRUARY 4.

ROYAL SOCIETY OF ARTS, at 4.30.—A. E. Hayes: The English Language and International Trade.
ROYAL COLLEGE OF SURGEONS, at 5.
GEOLOGICAL SOCIETY OF LONDON, at 5.30.—J. A. Douglas: Geological Sections through the Andes of Peru and Bolivia: II. From the Port of Mollendo to the Inambari River.
ROYAL AERONAUTICAL SOCIETY (at the Royal Society of Arts), at 8.—Squadron-Leader J. E. M. Pritchard: Rigid Airships and their Development.
INSTITUTION OF AUTOMOBILE ENGINEERS (at the Institution of Mechanical Engineers), at 8.—A. P. Young and H. Warren: The Progress of Ignition.
SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS (at the Chemical Society), at 8.—(Annual General Meeting), Dr. S. Rideal: Presidential Address.—F. S. Sinnatt and L. Slater: An Investigation into the Composition of the Unsaturated Hydrocarbons present in Coal Gas.—H. Trickett: The Estimation of the Available Oxygen in Sodium Perborate and in Perborate Soap Powders.

THURSDAY, FEBRUARY 5.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. A. E. Conrady: Recent Progress in Applied Optics.
ROYAL SOCIETY, at 4.30.—J. H. Jeans and Others: Discussion on the Theory of Relativity.
LINNEAN SOCIETY, at 5.—Dr. R. Ruggles Gates: The Existence of Two Fundamentally Different Types of Characters in Organisms.
CHEMICAL SOCIETY, at 8.

FRIDAY, FEBRUARY 6.

ROYAL COLLEGE OF SURGEONS, at 5.
CONCRETE INSTITUTE (at Denison House, 296 Vauxhall Bridge Road), at 6.—H. J. G. Bamber: The Practical Testing of Cement.
INSTITUTION OF ELECTRICAL ENGINEERS (Students' Meeting) (at the City and Guilds (Engineering) College), at 7.—F. R. Housden: Electric Lifts and Cranes.
ROYAL SOCIETY OF MEDICINE (Anæsthetics Section), at 8.30.—Dr. F. S. Rood: Discussion on Anæsthesia in Throat and Nose Operations.
ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Prof. Sir Walter Raleigh: Landor and the Classic Manner.

SATURDAY, FEBRUARY 7.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir F. W. Dyson: The Astronomical Evidence bearing on Einstein's Theory of Gravitation. II. Displacement of Solar Spectral Lines.

THE NEED FOR AIRCRAFT RESEARCH.

UNDER the stimulus of war the development of aircraft was marvellously rapid, so much so that it not infrequently happened that by the time a squadron of aeroplanes of new and improved design was ready to take the air it was regarded as little else than an obsolete type by its own designers. But with a rate of wastage so high as war conditions made inevitable, one had to get accustomed to such an advance every six months as only the new mental attitude to mechanical developments that the war forced upon us could grasp without surprise. All this is now past. The factories are largely turned to fresh uses, and their skilful staffs scattered to new fields of labour. Even the scientific force of the Government has for the most part returned to the Universities from which it came—notably Cambridge and Oxford.

What is now to happen? Before this question can be answered it must be premised that consequent on the purpose of all this tremendous effort—the defeat of the enemy—having been finally achieved, the diversion of the means to other purposes is no more to be wondered at than regretted; furthermore, we may hope that the need for the re-creation of any such force is remote enough to enable us "to sleep o' nights." The validity of this hope must, however, depend on the sway of politics, and on the political methods followed by the Great Powers—whether a chauvinistic policy be adopted or earnestly avoided.

The enemy to-day is the geographical position with which this country is endowed: as unfavourable for air developments as it is favourable for maritime power. England is not on any air route to anywhere, and its climate deserves, from the air navigator's point of view, all that has been said against it. The sheer march of natural events will not make us an air Power as it has made us a naval Power. Any such result will need to be the consequence of intensely directed effort. But if such an effort can be presumed, then great consequences will ensue, for an air force which can be taught to encounter British climatic conditions and rise superior to them—with the implied possession of the best scientific means of assistance on the ground and in the aircraft—will have been trained in as hard a school as any in the world, and therefore be ready to gain an ascendancy in the easier conditions to be found almost everywhere else.

The experience of the last five years has shown that we have exactly the right kind of *personnel* for air endurance and skill; the work is temperamentally suited to the British type of youth. The aircraft themselves are the best to be found anywhere, and although this does not imply finality it is probable that future important developments will lie in some change of principle, whether thermodynamic (by modification of cycle or change of fuel) or aerodynamic, rather than in greatly improved efficiency in detail. We may, in fact, have to repeat in another fashion our war experience and once more face fundamental problems; we shall not be pressed for time, which will be a great gain, but we shall need all the assistance which can be got from minds trained in the fundamentals of science and as ready as heretofore to face entirely novel conditions. The Universities, at which many of such minds are now again engaged, must help. This, however, is not the most pressing problem; the urgent need is for the provision of means with the utmost rapidity to enable flying in this country, whatever its climate, to be as regular and safe for the traveller as it will surely become in the very near future in other countries.

When the weather is reasonable it is the custom to select that altitude of flight which enables best advantage to be taken of a favourable wind, and perhaps, when flying over Central Africa, that height which adds a pleasant temperature. Under normal winter conditions in this country quite other considerations apply. If the conditions are such as to create, or even to suggest the creation of, local fogs, pilots will choose their altitude from quite another motive; their aim will be to select that altitude which keeps them always within sight of the ground, so that if a fog, or heavy mist, is encountered at ground level, a landing can at once be made. Very often the fog or cloud is not of great thickness, and it would be easy to climb right through it and so to fly in sunshine under a blue sky. By astronomical means the position of the craft could be checked from time to time, and there need be no fear of being blown out to sea when prepared only for a limited number of hours' flight. What makes such flying impossible is not the uncertainty of position, but the doubt whether, when the pilot wishes to land, he will find the lower cloud- or fog-level actually resting on the ground. It is unpleasant enough to walk even a hundred steps along an empty road with one's eyes shut—how much less attractive when one's speed is 100 miles an hour and the feeling of having one's feet on the ground is absent! Unless this difficulty can be removed, the kind of flying which the future demands and other countries can give can never be learnt or practised in this country.

The first need is for some means of flying steadily through thick cloud, either for the purpose of climbing above it, or to approach through it nearer to the destined aerodrome. This problem has lately been solved by the invention of a "turn indicator" which enables the pilot, whether he can see the ground or not, to know when the machine is being flown straight, and it has the valuable effect of allowing the readings of the compass to be relied on; so the gain is double. But in addition to this it is necessary to provide close co-operation with the ground whenever it is wholly or partially fog-enshrouded. The pilot must be told whether his intended aerodrome is fog-free, and, if not, what other aerodromes near his route are sufficiently clear of fog to be safe havens; this will presumably be by means of some increased efficiency in the wireless telephone. Next to this in importance is some means of indicating or conveying to the pilot his height above the ground that happens to be immediately below his machine. These and other such aids are the kind of requirements needed to make all-the-year-round flying possible in this country. It is only a part of the wide field for research, but it is of vital consequence, and it certainly needs (as it is, of course, receiving) Government support, since the immediate financial reward of success must be slight. Moreover, the work is one of public utility, and should be so treated.

Force is lent to what is here urged by the consideration that the air fleet to be maintained by the Government in the near future is so small that it is only by calling in the aid of private craft that the possible needs of an emergency can be met. For this economical procedure to prove a success it is necessary that civil aircraft should exist in sufficient numbers. To facilitate this calls for the encouragement of all who have ability to assist in making flying safe, in making it popular, in making it efficient.

PHYSIOLOGY OF MUSCULAR EXERCISE.

The Physiology of Muscular Exercise. By Prof. F. A. Bainbridge. (Monographs on Physiology.) Pp. ix+215. (London: Longmans, Green, and Co., 1919.) Price 10*s.* 6*d.* net.

IT may reasonably be doubted whether any two physiologists would deal with the subject of muscular exercise along similar lines, nor is it desirable that this should be so, the subject being so complex and presenting so many different points of view. A comparison of the present volume with the writings of thirty years ago on the same subject is an instructive demonstration of the fact that physiology, as regards certain of its branches at least, has in the course of a generation reached a stage at which experimental results begin to show an integrative connection with problems of a broad and complex nature.

It is with the wonderful co-ordination of functions which is displayed in muscular exercise that the book chiefly deals. The energy usage of the body in exercise may be from eight to twelve times that during rest, and of this about one-third may, in the most favourable circumstances, appear as work; this energy is ultimately supplied by oxidation, chiefly of carbohydrates, and the central point of the problems of the physiology of muscular exercise is that the muscles suddenly demand from the blood a supply of oxygen which is from ten to twelve times what they receive when at rest. "If the body is to work efficiently and to develop its physical powers to their full extent, it is absolutely essential that the movements of the muscles on the one hand, and the activities of the circulatory and respiratory systems on the other hand, should be co-ordinated and integrated into a harmonious whole" (pp. 3–4).

The complex co-ordination of circulation and respiration is to a great extent effected by the central nervous system, though the heart and blood-vessels are to some extent autonomous. Chaps. ii. to vii. deal with an analysis of the changes by which the blood and the organs of circulation and respiration are adapted to their several needs. The heart is itself a muscular machine working with a gross efficiency of 20–30 per cent., and the adaptation of this organ is very fully discussed. This is important, since, in ordinary circumstances, it is the working power of the heart which is the limiting factor to the amount of exertion which is possible in any individual; though training may improve the heart, "no man can be an athlete who does not possess a powerful (*i.e.* a muscular) heart." At high altitudes, on the other hand, the limiting factor seems to be the rate at which oxygen can diffuse through the pulmonary epithelium into the blood.

In the eighth chapter the manner of the exact balancing of the various partially autonomous systems by means of the central nervous system is discussed, and it is shown that, as in so many other instances in the body, the promptness in response to altered conditions is owing to the control of the central nervous system, while the coarser adjustment is effected by the influence of various chemical or mechanical factors. The importance of the presidence of the nervous system is well seen in the reduced efficiency of the body during fatigue, and in the enhanced efficiency in circumstances where interest or emotion is aroused; in chap. xi. there is included a brief discussion of the subject of industrial fatigue, on which so much useful work has been done during and since the war, and one of the conclusions, that "the establishment of a uniform length of working day for all classes of manual workers would lead in many cases to inefficiency" (p. 183), is worthy of careful note.

The subject of training is discussed in chap. ix., and in chap. xii. it is shown that the differences between the circulation in the trained and untrained man can be extended to explain the condition of *effort syndrome*, or soldier's heart, in which the heart becomes inadequate to its work abnormally soon, owing to an impaired state of its nutrition.

Considered as a whole, the work is extremely good; it is well written, the viewpoint is broad, and the management of the arguments clear and convincing; indeed, a possible fault is that the inexpert reader may be misled as regards the complexity of the problems dealt with in such a clear and simple manner, or fail to appreciate what a vast deal of work lies behind some of the seemingly plain and obvious conclusions. Should this prove to be the case, it is but an indication of the excellent way in which the author has treated his subject. The references are to modern work chiefly, and in every respect the book is thoroughly up-to-date. Prof. Bainbridge is to be congratulated most heartily on having added to these valuable monographs such a cleverly written exposition of a difficult subject.

THEORIES OF SOUND PERCEPTION.

Some Questions of Phonetic Theory. Chap. v. *The Perception of Sound.* By Wilfrid Perrett. Pp. 39. (Cambridge: W. Heffer and Sons, Ltd., 1919.) Price 2*s.* net.

THIS work may be regarded as a continuation of the interminable discussion regarding the functions of the cochlea, or more particularly the part of the internal ear concerned in hearing. Theories of sound perception may be divided into two classes: first, those which assume that somehow analysis takes place in the cochlea; and secondly, those that relegate the analysis to the brain. The first theory also assumes that the principle of sympathetic resonance is the foundation of the method by which the organ of Corti in the cochlea works, while the second theory, as it involves ganglion-cells and part of the brain, has no experimental basis on which to rest, and leaves the function practically insoluble. The resonance theory owes its clear inception to Thomas Young and its development to Helmholtz. While it explains many experimental facts, and has been supported by many physicists and physiologists, it has now and again been assailed by critics who have advanced some form of the second theory, and founded their objection to the older theory mainly on facts which apparently cannot be accounted for by the Young-Helmholtz theory.

Mr. Perrett supports the second theory, and denies the existence of any resonating mechanism in the cochlea. In a short notice it is impossible to meet all his points, but it seems he does not meet the difficulties of the case. No explanation is offered of the extremely complicated organ of Corti, unless it serves some such purpose as is implied in the older theory; there are obvious difficulties relating to the fibres of the cochlear nerve; and the explanation is hopeless when we reach the ganglionic mechanism of the brain. On the other hand, the resonance theory, on the whole, meets the facts, and, if not free from objections, as Helmholtz and his supporters admit, it serves the purpose of a good theory by stimulating research, while it satisfies the mind. The same may be said of the retina and the action of light, and, indeed, of all the end-organs of special sense. Mr. Perrett, while he has evidently studied the subject, historically and otherwise, seems unduly biased against a fair presentment of the older theory, and we recommend caution and a wider view. J. G. M.

KASHMIR AND INDIAN SILKS.

The Silk Industry and Trade: A Study in the Economic Organisation of the Export Trade of Kashmir and Indian Silks, with Special Reference to their Utilisation in the British and French Markets. By Ratan C. Rawlley. Pp. xvi+172. (London: P. S. King and Son, Ltd., 1919.) Price 10*s.* 6*d.* net.

THIS volume forms a natural complement to the official report on Indian silk by Prof. Maxwell Lefroy and Mr. E. C. Ansorge recently published by the Government of India. In the official report the Indian silk trade is dealt with primarily from the Indian trade point of view; in the volume now under notice Indian silk is considered in its relation to the markets of Great Britain and France. As is well known, raw silk from India at the present day does not occupy a high place in the estimation of manufacturers, and it was with the object of ascertaining the exact requirements of the British and French markets that the present investigation was undertaken by Mr. Rawlley with the financial assistance of the Carnegie Research Trust and the India Office.

In his inquiry the author visited nearly all the principal silk centres in this country and in France, and the chief value of the investigation lies in the fact that it has secured expression of authoritative views of the leading members of the trade. The wide ground covered by the inquiry can be only briefly summarised here. It will be sufficient to say that we have now a consensus of expert opinion that with adequate improvement in quality and reeling (embracing evenness in size, cleanliness, and uniformity of strength), together with improved trade organisation (mainly with a view to regular supplies), there is an assured market in this country, and in France, for Indian raw silks. The comparative success of the improved Kashmir silk, especially in the French market, is already a demonstration of this fact. As regards waste silk, and also wild Eri silk, the position is the same; given better quality, greater cleanliness, and improved trade organisation, there will be no difficulty in finding a European market for these products. The author's inquiry has performed a double function, inasmuch as it indicates the possibilities of a neglected source of supplies to the consumer of raw silk and an undeveloped outlet for the producer.

A GREAT INDUSTRIALIST.

George Westinghouse: His Life and Achievements. By Francis E. Leupp. Pp. xi+304. (London: John Murray, 1919.) Price 15*s.* net.

THE author, in his preface, regrets the lack of all those written records on which biographers usually rely for providing interesting personal reminiscences. Despite this, however, he has succeeded in compiling an interesting, straightforward narrative which will be inspiring to youth for the example it sets forth of success achieved by indomitable courage and persistent effort, and of fame won on sheer merit, without aid from influence or wealth.

Older readers will find the book of interest in so far as it provides an easily assimilated history of many of the important industrial developments of the past generation. On the other hand, they are likely to be disappointed by the feeling that the part accorded by the author to George Westinghouse in bringing about these developments falls short by no small distance of the part he actually played.

Mr. Leupp frankly admits that he confines himself to a portrayal of the human side of his subject. He dwells particularly on a certain bigness which he finds characteristic of George Westinghouse, who was large-minded and large-hearted, and had the grand style as an inventor, worker, optimist, and industrialist. "Nothing was ever big enough for him." Splendid as was the human side, and worthy as it is of this record, we share with the author the hope that one day some well-known technologist will compile the record of the great inventions and achievements of the man.

It is notable that Westinghouse did not excel at school and college, and that during his brief college career he admitted that he might have been more successful if he could have spared his time for study that he spent more pleasurably in investigating machinery and in making mechanical models. His ready grasp of the opportunity that led to his early connection with railroad work, and ultimately to his development of the air brake, with which his name will always be associated; his investigations into natural gas and its industrial application; his fair appreciation of the inventions of others and readiness to put them into commercial use; his fight for alternating electric current; his care for the welfare of his workpeople; his buoyancy, carrying him over financial crises of a most disturbing character; the esteem of his workpeople that held them to him through precarious times—these tell the man of unusual industrial capacity, personality, and courage.

The book does not possess any marked literary value, but all who are not debarred by its high price will find it worthy of perusal.

FARMING IN THE NEW ERA.

(1) *A Large State Farm: A Business and Educational Undertaking.* By Lt.-Col. A. G. Weigall and Castell Wrey. Pp. xiii+82. (London: John Murray, 1919.) Price 2*s.* 6*d.* net.

(2) *The Farmer and the New Day.* By K. L. Butterfield. Pp. xi+311. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1919.) Price 8*s.* 6*d.* net.

(3) *The Sugar-beet in America.* By Prof. T. S. Harris. (Rural Science Series.) Pp. xviii+342+xxxii. plates. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1919.) Price 2.25 dollars.

(4) *Strawberry-growing.* By Prof. S. W. Fletcher. (Rural Science Series.) Pp. xxii+325+xxiv plates. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1917.) Price 1.75 dollars.

(1) A GREAT deal is being spoken and written about the new era into which we are entering, and agriculturists are wondering what will become of their subject, and incidentally of

themselves. The problem is not peculiar to any one country: it is world-wide.

The British problem was discussed some time ago by Sir A. D. Hall in his book, "Agriculture after the War," and not long since by an anonymous writer in a recent number of the *Edinburgh Review*. One aspect of it is discussed by Lt.-Col. Weigall and Mr. Castell Wrey in the first volume on the list. These authors set out the advantages of the large 10,000-acre farm as a business proposition. The farm of 3000 acres, hitherto considered large, they regard as simply inconvenient; it is too small to be a really big farm, but too large to be a satisfactory small one. They suggest that the State should run one large farm as a demonstration and educational institute, and they consider that others would soon follow, with the result that the method would take its proper place in British agriculture. Many of the difficulties of farming disappear when the scale is made sufficiently large, and the authors make out a good case for the 10,000-acre farm. We doubt, however, whether they will induce any Government Department to embark in the business, Government trading being somewhat under a cloud for the moment; but a company might feel disposed to take the matter up.

(2) The American problem is discussed in the second of the volumes before us by Dr. Butterfield, the well-known president of the Massachusetts Agricultural College, who sets out his views with characteristic frankness, saying exactly what he thinks with the engaging candour that has made him so potent a factor in American agricultural life. One great difficulty Dr. Butterfield finds is that farmers are not, and rarely have been, prominent in the councils of the nation; consequently others have had to devise policies for them. The farmers of ancient Rome and the yeomen of medieval England were in a stronger position, and in Germany, Denmark, and Ireland farmers are a power in the land; in the main, however, they have had but little influence. Some serious consequences follow. The great majority of American farmers are said to receive insufficient return for their labours, the average labour income being only 400 dollars per annum. The middleman, on the other hand, obtains too many of the consumers' dollars; the system of distribution is in general against the farmer's interests. Still worse, there is no agricultural policy. Dr. Butterfield writes sternly about this deficiency in the United States, and notes with surprise the same lack of policy in this country and in the Labour Party's memorandum on reconstruction, of which otherwise he approves. He insists on the need for a strong agriculture, which, however, can eventuate only if the farmer conforms to the spirit of the new age. This calls for a better chance for the ordinary man, the intelligent planning of human progress, a reconciliation between organised effectiveness in human life that also leaves individuals and classes truly free, and an insistence on service to fellow men as the great motive in life.

We need not follow Dr. Butterfield in the elaboration of his thesis; he discusses the various agencies in American country life in their relationship to these four aspects of the new age. The position is similar to that dealt with by Sir Horace Plunkett in Ireland, whose famous slogan, "Better farming, better business, better living," has made a vivid appeal in the States also. More fortunate than Sir Horace, however, Dr. Butterfield has no religious problem, and is able to discuss the Churches as candidly as he does the schools. The author makes certain criticisms of the rural education system of the United States—the most remarkable scheme of educational activities on behalf of the farmer to be found in the world. Englishmen visiting the States have marvelled at its completeness; Dr. Butterfield's criticisms, after all, show that it is human; while sound in essentials, it is apt to go wrong in details.

(3) The two other books on the list furnish good examples of the educational work done by the agricultural experts of the States. Prof. Harris, the director of the Utah Experimental Station, describes the growth of sugar-beet in the States, and brings together a good deal of material previously scattered through many books, journals, and bulletins. The industry has developed there in a remarkable manner. In the 'sixties the production of beet-sugar was less than 300 tons per annum; now it is 800,000 tons. This astonishing development has not been at the expense of cane-sugar, for during the same period raw cane-sugar has risen from 200,000 tons per annum to $2\frac{1}{2}$ million tons. The story of the beet-sugar industry in Europe is well known, and is one of the most interesting cases on record of a fostered key industry growing and flourishing. The history of the crop in America is not so well known, and the author devotes an interesting section to it, also reproducing photographs of some of the early pioneers. The first factory, established in Massachusetts in 1838, failed after two years. The second was established in Utah in 1842, and had the advantage of a considerable natural protection, imported sugar having to be hauled all the way from the Missouri River, and, therefore, costing no less than 40 cents to 1 dollar a pound in Salt Lake

City. But the promoters could not crystallise the sugar; they could only make syrup, and before long they gave up the business. The industry was not definitely established until 1890; development was fostered by means of tariffs, and was very rapid during the war. In the early days of the nineteenth century the percentage of sugar in the root was about 5; now it is about 16–18 per cent. It differs in the different varieties, and is affected by the soil and weather conditions. Sufficient irrigation in dry seasons increases the amount of sugar.

The great difficulty in dealing with the crop is the amount of labour involved in lifting. This is now obviated to a considerable extent by the use of suitable implements, two types of which are described.

The crop is liable to attacks by insect pests and fungi; no fewer than 150 species of insects feed on the beet, of which about forty are of economic importance; the number of fungus pests is small at present, but it is increasing.

(4) The last book on the list, on strawberry-growing, is by Prof. Fletcher, of the Pennsylvania State College. The author opens with the statement, which will be new to many people, that "the strawberry is distinctly North American. Most modern varieties sprang from species only found in the Americas. Progress in the domestication of the fruit was coincident with the introduction into Europe of American types." In 1910 the acreage under strawberries in the United States and Canada was 150,000 acres, said to be more than the combined acreage of all other countries.

Bearing in mind the results of fertiliser experiments at the Woburn fruit farm, the English reader turns with interest to discover what results have been obtained in America. Curiously few fertiliser experiments with strawberries seem to have been made. At the Missouri Station phosphates were beneficial, but nitrogenous and potassic manures were harmful. At the Tennessee Experimental Station no fertilisers proved effective. At Cornell phosphates and potassic fertilisers were beneficial, while nitrogenous manures were harmful. But the experiments lasted only a year or two, and hence the results do not yield as much information as they might as to the needs of the plant. In nature the strawberry flourishes on an acid soil, and in cultivation lime is not found necessary.

As usual in the Rural Science Series, the author brings into the book information on all aspects of the crop, dealing with such diverse subjects as the shape of boxes for packing, the raising of new varieties, insect and fungus pests, etc. It is obvious that no one man can be competent to deal adequately with all branches of the subject, but the general treatment is good and gives the practical man all the help he needs; there are also references to experimental station bulletins, where further information by experts on particular subjects can be obtained.

Some years ago productivity figures were worked out for the farm workers of the different countries of the civilised world. America easily headed the list, which was as follows:—

America	292
Great Britain	126
Germany	119
France	90
Italy	45

Looking through this Rural Science Series, edited by Dr. L. H. Bailey, and seeing how earnestly the authors strive to deal with the conditions actually obtaining in the States, we find at least a partial explanation of the striking superiority of the American worker. Such books could scarcely be written in this country as yet, but there are hopeful signs for the future. A body of young men and young women is gathering at the agricultural experimental stations and colleges of this country capable of doing good work that will bear comparison with anything done elsewhere, and there are increasing signs that their work is favourably and respectfully received by the agricultural community.

E. J. RUSSELL.

OUR BOOKSHELF.

The Building of an Autotrophic Flagellate: Botanical Memoirs. No. 1. By A. H. Church. Pp. 27. (London, etc.: Humphrey Milford and Oxford University Press, 1919.) Price 2*s*.

"THE story of the evolution of the plant regarded as expressed in simplest terms as an autotrophic flagellate of the plankton-phase from nothing at all but ionized sea-water" is the subject of Mr. Church's extremely condensed and technical paper. In reality it is rather the requirements of the problem than its solution which Mr. Church indicates, and, whilst he realises the magnificence of the factors with which he has to deal (the sea, for example, is "a medium complex beyond the possibilities of human computation"), he presents the results of much learning in huge unbroken and almost unintelligible paragraphs. Who, for example, would imagine that the following sentence refers to the origin of seaweeds from free-floating algæ? "In the case of initial benthic organism, the first inception of such a continuous deposit [he is talking of cell-walls] prepares the way for the general formula adopted in describing the events in the life of an algal zooid. . . . In such wise the autotrophic zooid of highly differentiated anisokont habit may be visualised as passing on to the initiation of the series of the great marine group of the Phæophyceæ." Strange that an old Oxford teacher should have employed for his exposition a medium "complex beyond the possibilities of human computation."

Yet if the reader can summon up courage to face the repellent language of this tract he will find suggestions of extraordinary interest. The superiority of the botanist over the zoologist is emphasised; even "a tree is in many respects more entitled to respectful admiration than a man," unless, we presume, he be a botanist.

Human Personality and its Survival of Bodily Death. By Frederic W. H. Myers. Edited and abridged by S. B. and L. H. M. Pp. xiii + 307. (London: Longmans, Green, and Co., 1919.) Price 6*s*. 6*d*. net.

THE original two-volume work, published in 1903, is abridged by condensing the text and omitting the greater part of the appendices. The illustrative cases which are published form part of the text, and are nearly always quoted in full.

The Nature of the Katmai Volcanic Gases and Encrustations.

THE fumarole activity following and continuing after the great Katmai eruption of June, 1912, has provided south-western Alaska with the first among the natural wonders of the world. The volcanic gases force their way to the surface over an area of more than fifty square miles. This area is covered with volcanic ash and pumice, largely distributed by an enormous flow of mud following the explosion of the Novarupta volcano, but preceding the outburst of Katmai ten miles to the eastward. The relatively coarse ash and pumice from Novarupta were not ejected to any considerable distance, but, falling locally, quickly melted the snow on the mountains, and, with the rainfall accompanying the eruption, slid down into the adjacent valleys, forming a viscous mass which poured down the Bering Sea slope of the peninsular axis for a distance of more than fifteen miles.

As the mud drained away, unlike the more fluid water,

FIG. 1.—Fractured sections of the Great Mud Flow. Note the conglomerate nature of the fragments and the irregular cleavage planes. Sometimes, however, the cleavage is quite regular, as shown in Fig. 2.

it left a very large residue adhering to the valley floor. Subjected to heat from below, the mud dried, caked, and was eventually baked. The contracting, hardening mass split and cracked according to the strains and stresses set up by the irregularities of the valley floor beneath. The Katmai volcanic ash lies conformably on top of this mud-flow. Apparently the order of the sixty-hour eruption of June, 1912, was:—(1) Novarupta explosion, followed by the great flow of mud; (2) Katmai eruption; and (3) the upthrusting of the lava plug of Novarupta. No ash covers this plug. It was the last major event to happen.

Photo] [*J. W. Shipley.*

FIG. 2.—Cross-section of horizontal tunnel about fifteen feet below the surface of the mud-flow. Note the cleavage planes of the mud above the vent. One hundred feet from this is another horizontal tunnel seventy-five feet below the surface, and large enough to drive a team and wagon through. These have most probably been formed by the solvent action of superheated steam and hydrofluoric acid.

The mud-flow occupies the floor of the Valley of Ten Thousand Smokes described in this journal by Dr. Griggs ("The Eruption of Katmai," NATURE, August 22, 1918, vol. ci., p. 497). The volcanic gases force their way upward through this superincumbent detrital material, using the existing cracks and fissures, and dissolving out new channels where openings were not already available. As chemist of the 1917 Katmai Expedition, it fell to my lot to examine these gases and the encrustations deposited around the fumaroles.

The gases contain some of the strongest disintegrating agents known. Hydrofluoric acid and hydrochloric acid, together with superheated steam, proved to be the most common constituents of the outpouring gases, frequently issuing at a temperature above 400° C. Many fumaroles were so impregnated with these acids that it was impossible to breathe the vapours. The surface of the mud-flow surrounding some of the more acid vents was covered with ferrous chloride and impregnated with free hydrochloric acid. The presence of hydrofluoric acid in the emanations was accompanied by a deposit of amorphous silica around the vents, almost completely closing the orifices and forcing the gases to issue through cracks in the hot, baked silica. These deposits, sometimes 98 per cent. of pure silica and altogether anhydrous, formed dykes several feet high around the hotter vents.

This association of hydrofluoric acid and silica is not accidental. Hydrofluoric acid decomposes silicates, setting free the silicon as gaseous silicon tetrafluoride, and this in turn is decomposed in the presence of water, forming SiO_2 and free acid. The majority of the samples of encrustants brought back gave a qualitative test for fluorine, while quantitative results ran as high as 7 per cent.

Realgar and orpiment were found in conjunction with deposits of sulphur. Hæmatite in the form of "Venetian red" and small crystals of pyrites embedded in a matrix largely silica were common secondary reaction products of the volcanic gases. Hydrogen sulphide was almost ubiquitous.

Hygroscopic iron and aluminium salts formed in the throats of vents protected from the weather and at a temperature above 100° C. Unfortunately, these were highly deliquescent, and lost their crystalline form on exposure to the air.

The throats of several vents near Novarupta were lined with quantities of ammonium chloride crystals, almost 99 per cent. pure.

One of the most interesting deposits was a tarry substance found in the proximity of the ammonium chloride fumaroles, which proved on analysis to contain hydrocarbons of an asphaltic character.

Many of the fumaroles contained ammonium compounds in the issuing gases, strikingly indicated by the growth of algæ. Wherever blue-green algæ were

Photo] [*J. W. Shipley.*

FIG. 3.—The surface of the mud is very deeply eroded by watercourses, and these are frequently hard to distinguish from the fissures. These gullies are in a very active area on the northern slope of Trident Volcano.

observed growing, there the issuing gases or encrustants contained ammonia; while, conversely, an active area not supporting algæ proved to have no trace of ammonia in its emanations or encrustants.

In connection with the presence of hydrofluoric acid, the deposits of sulphates, such as alum, are very significant. Potassium alum, appearing as lichen-like growths after every rainfall, covered the surface of the ash over many of the areas of activity. Sulphuric acid is a strong disintegrating agent, and its presence in the emanations gives a key to the formation of hydrofluoric and hydrochloric acids, for sulphuric acid acting on fluorides and chlorides sets free the more volatile halogen acids.

The volcanic ash and pumice which constitute the mud-flow have been highly altered by the passage of the volcanic gases. Analysis shows that in the vicinity of the vents the ash has lost a portion of its silica content, while the iron, calcium, and magnesium have been relatively concentrated. Sometimes the ash and pumice are completely disintegrated. Superheated steam containing halogen acids is a disintegrating agent that even rhyolite cannot withstand. The presence of so many large vents, tunnels, and channels in the mud-flow may well be attributed to the action of the volcanic gases.

Photo] [*J. W. Shipley.*

Fig. 4.—A typical volcanic vent. The gases were escaping from another hole some distance away along the horizontal tunnel. Note the thickness of the encrustants covering the tunnel. They consisted of silica, sulphur, fluorides, and compounds of iron.

The nature of the emanations, and the continuous evolution of heat and gases for seven years, with little indication of any diminution in volume, indicate direct magmatic origin for the phenomena of this valley. The extrusion of semi-fluid lava from Novarupta and in the bottom of the Katmai crater may signify a similar approach of the magma to the surface in the Valley of Ten Thousand Smokes.

The Control of Scientific and Industrial Research.

Announcement is made in Nature of January 29 of the appointment of Mr. R. L. Frink to be director of research of the Glass Research Association, which has recently been formed as one of the Industrial Research Associations of the Department of Scientific and Industrial Research. The appointment raises a question which has intimate relations with scientific interests and progress, and it should not be permitted to pass without protest.

It has always been urged in the columns of Nature, and accepted as a cardinal principle by men of science generally, that scientific research can only be rightly understood and sympathetically promoted by a director who has himself taken part in it. The essential qualification, therefore, of a director of research of each of the industrial research associations should be proved capacity for research; for without such aptitude the work undertaken is bound to be narrow, and the scientific aspects upon which progress ultimately depends to be neglected. This point of view, however, seems to have received secondary consideration only in the recent appointment; for what the secretary of the Glass Research Association says as to the qualifications of the director of research is: "Mr. Frink has a lifelong experience of the American glass trade and glass research, is well known to the foremost English glass manufacturers, and his appointment is welcomed by the British glass industry."

It is scarcely too much to say that this appointment has been received with intense astonishment by all scientific men connected with the glass industry, and by many glass manufacturers as well. In the glass industry, more, perhaps, than in any other, it was naturally expected that a director of research would be a man of distinguished eminence whose work was of proved scientific value; yet practically no such evidence is forthcoming in the case of Mr. Frink.

A scientific friend in America, who is recognised as one of the first authorities upon scientific matters connected with glass, tells me that Mr. Frink is not known as a research man or in research circles, but that he is highly spoken of by practical glass-makers "as a man of long experience in the window-glass trade who is accustomed to be called in as 'first aid' for furnace troubles, colour troubles, and like technical difficulties. This trade he has pursued for some years with success, and his reputation in this domain is among the best. He maintains a so-called laboratory and has a number of technical assistants, and, I fancy, has gathered together a considerable amount of rough-and-ready wisdom which has found extensive application in an industry where research laboratories have hardly been thought of until recently."

It seems quite possible that the Glass Research Association has secured the services of a very able, practical man, but in making the appointment the council of the association has negatived the policy elaborated with such care in the article published in Nature of November 13 last: "The ideal director for this association is not an individual research worker whose glory is to work in splendid isolation, but is he who will bring *expert knowledge of the methods of scientific research* to bear upon these complex problems, who possesses such personality as to attract promising young research workers to his side . . . and to co-ordinate the efforts being made through the various laboratories, institutions, and works to which specific research and experimental work will be allotted." (Italics are mine.)

If the writer of that article, the temporary secretary of the association, had been a scientific man, he would have realised that our greatest investigators rarely "work in splendid isolation," but that only a man who has proved his capacity as an investigator can lead and co-ordinate research. It is certain that British scientific men will not submit to control and direction from the practical man; thus a definite breach is opened between science and an important branch of industry.

It has not been sufficiently clearly realised that scientific and industrial research is passing out of the control of the recognised scientific and technical societies and institutions and of the universities into the hands of the Department of Scientific and Industrial Research, and, in accordance with Government policy, the secretary of this Department is an administrator without practical knowledge of science, industry, or research. The associations which are formed under the ægis of the Department are governed by councils upon which organised science is unrepresented, but to which the Department may nominate scientific men. To the council of the Glass Research Association the Department has nominated two scientific representatives, one of whom is in India. On the executive committee science is not represented; and when this appointment was discussed between that body and the secretary of the Department, the scientific aspects of the case can have received no consideration. As the Department controls funds for research which are vastly greater than those at the disposal of the Royal Society and all the other societies and universities put together, the outlook for science is a poor one unless scientific men are prepared to take united action with the view of securing a proper share in the control of research.

MORRIS W. TRAVERS.

The Predicted Shift of the Fraunhofer Lines.

MAY I submit the following two propositions for the consideration of relativists?

(1) An occurrence takes place at a point S. Light-signals are dispatched from S at the beginning of the occurrence to two observers A and A′, and signals are again dispatched at the conclusion of the occurrence. By means of these A and A′ measure the time of the occurrence to be dt and dt' respectively. Then

$$\sqrt{g_{44}}.dt=\sqrt{g'_{44}}.dt',$$

where g_{44} and g'_{44} are the values of Einstein's 44 potential at A and A′.

(2) An occurrence takes place at S, and is measured by an observer there to take the time dt. Another occurrence takes place at S′, and is measured by an observer there to take time dt'. By means of light-signals dispatched from S and S′ at the beginning and conclusion of each occurrence, an observer A measures the times of each occurrence to be equal. Then

$$\sqrt{g_{44}}.dt=\sqrt{g'_{44}}.dt',$$

where g_{44} and g'_{44} are the values of Einstein's 44 potential at S and S′.

Prop. (1) seems to be a correct inference from Einstein's theory, and prop. (2) is deduced by applying (1) to the occurrence at S as measured by S and A, and then to the occurrence at S′ as measured by S′ and A.

If these propositions are sound, how does the Einstein theory predict the displacement of the solar lines? For it seems to me that the criterion for "similarity" of two radiating mechanisms in different parts of a gravitational field is that the invariant space-time elements corresponding to one oscillation of each should be equal. For two mechanisms at rest in the field this condition reduces to $\sqrt{g_{44}}.dt=\sqrt{g'_{44}}.dt'$.

JAMES RICE.

University of Liverpool.

EINSTEIN's prediction of a shift of the Fraunhofer lines to the red can be analysed into two assertions:—(1) That the period of vibration of an atom at rest on the sun differs from that of a similar terrestrial atom; and (2) that this difference is preserved unchanged by the light-waves travelling from the solar atom to the earth, so that it is revealed by a comparison made in a terrestrial laboratory. It is the second assertion that is challenged by Mr. Rice; and, so far as I can make out, the same objection was at the root of the criticisms formerly made by Sir Joseph Larmor. Since criticism centres entirely round the second assertion, I will deal with it solely. I may state, however, that although I regard the first assertion as highly probable, I do not regard it as proved with complete rigour; and had the criticism been directed against this, I should have been much less willing to take sides in the controversy.

The interval ds between two events is a quantity having an absolute significance independent of co-ordinate systems; and when the two events take place at the same place, $ds=\sqrt{g_{44}}.dt$. Mr. Rice's first proposition states that if we have two light-pulses travelling from the sun to the earth, the interval ds between their passages through any point is the same all the way along the track. The statement has a certain appearance of plausibility, but I cannot see any definite argument in favour of it. Space-time round the sun is non-Euclidean; the geodesics have, accordingly, defined but rather complicated tracks, and there need be no constancy of interval between points on neighbouring geodesics. The rule deduced from Einstein's theory for comparing the passage of two light-pulses at the points A and A′ respectively is not $ds=ds'$, but $dt=dt'$, *provided the co-ordinates used are such that the velocity of light does not change with* t.

If we found that the velocity of light changed secularly, we should at once condemn our time-reckoning as non-uniform; accordingly, the proviso is satisfied in practice. With the co-ordinates most commonly adopted the velocity of light is $1-2m/r$, which depends on the position r, but not on the time t. Then if t_1 and t_2 are the times of the two pulses at r, t'_1, t'_2 the times at r', since the mean velocity of the first pulse $(t'_1-t_1)/(r'-r)$ has to be the same as the mean velocity $(t'_2-t_2)/(r'-r)$ of the second pulse, over the same course but at a later time, it follows at once that $t'_2-t'_1$ is equal to t_2-t_1, which proves the statement made. The time between the two light-pulses is preserved unchanged on the journey from the sun to the earth.

In his letter (NATURE, January 22, p. 530) Sir Joseph Larmor describes this condition, that the velocity of light (or the formula for ds) shall not contain the time explicitly, as "a reasonable assumption." I cannot see that any assumption is involved; nor can I agree that it is of "an absolute type." The well-known expression

$$ds^2=-(1-2m/r)^{-1}dr^2-r^2d\theta^2-r^2\sin^2\theta d\phi^2+(1-2m/r)dt^2 \quad . \quad . \quad . \quad (A)$$

is, in the first place, simply a particular integral of Einstein's differential law of gravitation. It can be shown that it is an appropriate solution for the case of an isolated particle. But there is a fourfold infinity of other solutions applicable to the same case; so there can be nothing absolute about this solution, or about the co-ordinates r, θ, ϕ, t which it defines. It is, in fact, often more convenient to write $r=r'+m$, and use r' instead of r as our radial co-ordinate. Whether we use (A) or any other expression, we have to find out from the expression itself the meaning of the co-ordinates introduced. In the limiting case $m=0$, the above expression agrees with the formula for polar co-ordinates and time in a Euclidean world; hence it is usual to call r the distance from the sun and t the time. But there can be no exact identification of variables in a non-Euclidean world with quantities the definition of which presupposes a Euclidean world; and the only exact definition of r and t is that they are mathematical intermediary quantities which satisfy equation (A). The variable t is in no sense an absolute time; it is specifically associated with the sun, which in equation (A) is regarded as the only mass in the universe worth considering.

Without troubling about the approximate identification of t with our common notion of time, our results may be stated in the following form:—At a point in the laboratory (r=const.), dt_1 for a light vibration from a solar atom differs from dt_2 for a terrestrial atom. It follows from the formula (A) that ds_1 and ds_2 will differ in the same ratio, since we are now concerned only with the relation of dt and ds on the earth. The intermediary quantity t is thus eliminated; and the difference in the light received from solar and terrestrial sources is an absolute one, which it is hoped the spectroscope will detect.

A. S. EDDINGTON.

The Straight Path.

IN my book, "A Theory of Time and Space," I directed attention to the fact that in the simple four-dimensional time-space theory there are three types of plane in addition to three types of line.

On p. 360 I stated the following results:

"If A, B, C be the corners of a general triangle all whose sides are segments of one kind, then:

"(1) If the triangle lies in a separation plane, the sum of the lengths of any two sides is greater than that of the third side.

"(2) If the triangle lies in an optical plane, the sum of the lengths of a certain two sides is equal to that of the third side.

"(3) If the triangle lies in an acceleration plane, the sum of the lengths of a certain two sides is less than that of the third side."

These results were published in 1914, and, in spite of the fact that they were printed in italics, so that he who runs might read (that is to say, provided anyone should run on the occasion of reading my book), yet I still find writers continually making statements to the effect that the straight line in this geometry is the shortest distance between its extremities.

As a matter of fact, what I call a "separation line" lies in all three types of plane, and is, consequently, neither a minimum nor a maximum, while an "inertia line" can only lie in acceleration planes, and can easily be seen to be a maximum in the mathematical sense. Further, a triangle cannot have all its sides formed of segments of "optical lines."

I have long contended that the usual method of approach to what is generally called the "theory of relativity" is quite inadequate, and this is a further illustration of my contention.

Not only are our ordinary ideas as to space and time disturbed, but also our ideas of simultaneousness and our notions of "straight lines" in the resulting four-dimensional geometry.

From the midst of this wreckage a logical theory has to be constructed, and the difficulty is to find any firm basis at all.

In the course of my own work I succeeded in finding what appears to be such a basis in the relations of *before* and *after*.

On this basis I found it possible to construct a theory of time and space (apart from gravitation) which led to the same equations as those of Einstein, but of such a nature as to be independent of the particular observer, and therefore truly physical and devoid of the subjectivity which seems to cling to Einstein's theory.

These relations are, in fact, what might be described as *physical invariants*, and, with the help of certain postulates concerning them, they serve as a basis for a system of geometry.

If this investigation had been published in the German language it would doubtless have attracted more attention on the part of British physicists, who might then have added the ideas of *before* and *after* to their store of fundamental physical concepts. Instead of this, however, I have seen no mention of them at all in recent discussions on the so-called relativity theory. It is true, of course, that no analysis of Einstein's recent work has as yet been made in terms of the relations of *before* and *after*, but seeing that these have proved a sufficient basis for the simple theory corresponding to Euclidean space, and that such relations do actually hold in our experience, it does not seem unreasonable to suppose that with modified postulates they might serve as a basis for the more general theory.

With regard, however, to my statement that the straight line in the simple theory is not the shortest distance between its extremities, I can imagine some people casting doubts upon my veracity. For the benefit of those who do not believe me, I venture to give some simple arithmetical examples.

Taking v as unity, the length s of the segment of a separation line between elements the co-ordinates of which are (x_0, y_0, z_0, t_0) and (x_1, y_1, z_1, t_1) is given by the equation:

$$s^2=(x_1-x_0)^2+(y_1-y_0)^2+(z_1-z_0)^2-(t_1-t_0)^2.$$

Let A, B, C_1, C_2, C_3 be elements the co-ordinates of which are as follows:

	x	y	z	t
A	0	0	0	0
B	10	0	0	0
C_1	5	12	0	0
C_2	5	5	0	5
C_3	5	0	0	4

On substituting these values we get:

$$AB=10$$
$$AC_1=13 \qquad C_1B=13$$
$$AC_2=5 \qquad C_2B=5$$
$$AC_3=3 \qquad C_3B=3$$

Thus we have:

$$AC_1+C_1B>AB$$
$$AC_2+C_2B=AB$$
$$AC_3+C_3B<AB$$

For the case of an inertia line the length $\bar{s}$ is given by the equation:

$$\bar{s}^2=(t_1-t_0)^2-(x_1-x_0)^2-(y_1-y_0)^2-(z_1-z_0)^2.$$

As before, let A, B, C be elements the co-ordinates of which are as follows:

	x	y	z	t
A	0	0	0	0
B	0	0	0	10
C	4	0	0	5

Here AB=10, AC=3, CB=3.

Thus AC+CB<AB.

These examples should be sufficient to give an air of plausibility to my statements.

A. A. ROBB.

Cambridge, January 23.

Entente Scientific Literature in Central Europe during the War.

THE chief object of my letter, "A Tribute from Prague," published in NATURE of December 11, 1919, was to congratulate the Editor upon the jubilee number and to express my delight at again being able to obtain this invaluable journal after an interval of more than five years. I thought it worth while to state very briefly that this break was caused by political reasons.

The letter by Mr. Lawson published in NATURE of January 1 induces me, unwillingly, to enter a little into non-scientific details.

There is a decided difference between the point of view during the war of an interned distinguished foreigner enjoying the well-known hospitality of the inhabitants of the capital of the late Austro-Hungarian Empire and that of us Bohemians or Czechs whose country was, by the Government of the same Vienna, nearly converted into a desert, whose best men (even poets) were imprisoned and condemned to death for their regard for the Entente, and who, had the war lasted only half a year longer, would have experienced the same fate as 1,500,000 Slavonic, chiefly Serbian, children in Bosnia and Herzegovina, condemned to starvation. Their parents, in so far as they were not shot down, escaped from death only by eating grass and other herbs!

No Englishman can wonder that we (Austrian) Slavs fully sympathised with the contents of the following two remarkable articles, which I select from a great number:

(1) The leader, "The War and After," published in NATURE of September 10, 1914 (p. 29). Never previously had such a fine political article been published in your columns, and I would beg readers to convince themselves that its great truth, and even prophecy, were fulfilled to the last point.

(2) An article published by Sir Oliver Lodge during the early part of the war in the *Psychological Review*. Sir Oliver says that there exists a Great Justice watching over the destinies of mankind who will never allow a crime to become a law. The editor of our leading daily paper introduced this view as "strange ideas of a spiritualist," and only by this trick did it escape the watchful eye of the censor. I thank Sir Oliver for this article, which kept many of my countrymen and me firm in the days of our greatest distress.

All this was known to the Austrian Government, and it is well understood why it withheld during the whole war the circulation of periodicals which contained such articles as those referred to above.

Towards the end of the war, when everyone saw that the old Monarchy was going to pieces, the Austro-Hungarian Foreign Office—and I assure Mr. Lawson that I am by no means "unaware of the fact"—asked the Senate and professors of our University to fill a circular with the names of the Entente scientific journals which they would like to obtain. I denoted several journals—in the first place, NATURE. I know that those belonging to the "privileged nations" obtained the journals they wished, but no notice at all was taken of my desire or that of any other Bohemian scientific institution up to the very end of the Monarchy.

BOHUSLAV BRAUNER.

Chemical Laboratory, Bohemian University, Prague, January 20.

Percussion Figures in Isotropic Solids.

ALL anthropologists will be glad to see the subject of percussion figures receiving attention in the pages of NATURE (October 9 and November 20, 1919), as the figures form the basis of flint-fracture—the important factor in determining the age and origin of man. Unfortunately, the fracture cone is by no means so simple and constant in outline as one might be led to expect from what has already been advanced, and a number of factors enter into the question, such as the shape and elasticity of the percusser, the velocity of the blow, the striking angle, the perfection of surface of the percussed, its elasticity, and, above all, its varying refrangibility.

In Nature and practice we generally find that after the cone has maintained itself for a distance, the surface resolves into a cylinder in the striking plane, which is maintained for a certain varying distance; then it resolves outwards in a more conical direction, which may extend until rupture takes place; or it may even resolve again and again as before, giving rise to *step-cones*. Specimens before me show seven such steps. Further, from causes into which we cannot now enter, the well-known conchoidal ripplings may be set up. These may be very simple and concentric or the very reverse, and may be either apical or marginal; they pass into *step-cones*. Frequently the surface turns inwards, producing cylindrical fracture more or less normal to the striking plane.

Generally, with glass and flint there is another set of features in the form of stellate lines, which may be very few or numbered by hundreds. An examination of these shows the cone to be a surface of revolution, and the direction of the gyrations is shown by the steps made by every radial (some dozen of these are faintly shown in Prof. Raman's illustration in NATURE of October 9). These may increase in size until we get *step-fracture*, where the steps may be, say, 3 mm. or 4 mm. high. It may be noted in passing that these are the lines along which fracture in plate-glass takes place.

Perhaps the most remarkable thing about these steps is that they indicate right and left revolutions in relation to the cone. Sometimes the two hemicones coincide, and we get a perfect cone. At other times the fracture-waves overlap for a distance, giving rise to the mysterious *éraillure*; they may also meet in a re-entrant angle, which may become very acute, say down to 30°. This is only the beginning of the complications. Cones may be quite asymmetrical; one hemicone may be reduced to a plane. There are also *faceted cones, shell-cones* (*cones in cones*), and *cones in cups*. Then there are the phenomena of *cone capture*, and still greater complications of positive and negative hemicones, and multiple hemicones which by mutual capture produce large flat surfaces, and many others.

I suggest that the study involves something more than isotropics, seeing that in glass, silica, and many other substances new atomic or molecular re-arrangements set in which soon render them anisotropic or anisoclastic, and in one direction end in spontaneous disruption into forms which call for mathematical explanation quite as much as, and indeed more than, simple percussion figures in ideal isotropes; and, on the other hand, colloids pass into crystals where both optical and dynamical properties vary according to the lines along which the alterations take place.

W. J. LEWIS ABBOTT.

St. Leonards-on-Sea.

Change of Colour in Plumage of Captive "Sun-birds" or "Honey-suckers."

WE have had considerable success at the Zoological Gardens here in keeping in health nine varieties of "sun-birds" or, as locally known, "honey-suckers," all of Natal, South Africa. The aviaries are of simple wire-netting, in which are growing flowering shrubs and weeds. Their dimensions are 12×9×6 ft.

The food provided is Mellin's (baby) food, honey, and Swiss milk (tin) in equal proportions, and pea-flour one-quarter to the above.

The brilliant scarlet borne by certain of the varieties has changed in every case to a bright orange colour, thus causing the bird to present a great contrast to its original colour. Metallic green, which is borne by so many of the "sun-birds," is in no manner affected. Other colours of these birds are also not affected.

It would appear to be a case of change of plumage caused by the feeding, for the condition of life is almost natural.

We are not aware of such variety of colour having been observed previously. It would be of interest if any contributor to NATURE could give information of examples of similar occurrences with respect to captive wild birds, or offer an explanation of the physiological causes which are at work.

HAROLD MILLAR,
Director.

Zoological Gardens, Mitchell Park, Durban,
Natal, December 30, 1919.

MATHEMATICS IN THE UNITED STATES.

NOT very long ago (perhaps fifteen or twenty years) an English lady, spending a visit in Utrecht, met a distinguished Dutch professor of mathematics. In the course of conversation the lady asked the professor what he thought of contemporary English mathematicians and their work. The answer was not calculated to flatter our national vanity, for it was to the effect that he rarely looked at English mathematical papers, because they were so unconnected with the general progress of the science, and written in such a peculiar way that he could scarcely understand them. Incredible as it seems, this opinion was expressed when Salmon, Cayley, Sylvester, and Clifford had published all their best work. Prejudices die hard, and the professor's attitude would have been intelligible in the earlier part of the nineteenth century.

One moral of the story is that, as there are nationalities in drinks, so there are in mathematics, in spite of the growing tendency towards universal co-operation. The history of recent mathematical progress in the United States presents many points of interest. To a great extent, American mathematicians may be regarded as the grown-up pupils of Germany. From Germany they have acquired habits of thoroughness, breadth of view, and collaboration. But they have clearly passed the time of pupilage, as we see from their growing list of original and eminent writers; it is enough to refer to such men as the two Peirces and Willard Gibbs.

There are several features of the attitude of the Americans towards mathematics which deserve our careful attention. In the first place, it should be noted that the State and private benefactors encourage mathematics for its own sake, quite apart from considerations of utility. Many American professors are allowed to devote themselves to research in such things as group-theory, abstract geometry of all kinds, function-theory, and the higher arithmetic; the predominance of such subjects in American journals and transactions is quite remarkable. The Government and people of the United States appear to be fully conscious of the fact that special ability of *every* kind should be encouraged.

An excellent American institution, which might well be adopted here, is that of the sabbatical year, which gives the teacher an opportunity of bringing his knowledge up to date, or of carrying out some laborious research. As an example of what can be done in such periods of leisure, we may refer to the recently published first volume of Prof. L. E. Dickson's "History of the Theory of Numbers." With almost incredible industry, the author has personally consulted and summarised thousands of papers, notes, and memoirs; and if the work is carried out on the same scale it will fill four or five large octavo volumes, and be an indispensable guide to all who work in this field. It may be remarked here that we owe to the States many valuable works on the history of mathematics (especially from the teacher's point of view), and reprints and translations of scarce and valuable works.

Collaboration, both in the composition of books and in that of papers, is more common than with us. There are two sides to this question; in some cases the advantages of joint authorship are obvious, but those treatises which rank as masterpieces (such as Salmon's "Conic Sections" or H. Weber's "Algebra") are usually, if not always, the work of one man.

American mathematical colloquia are far more serious affairs than anything we have here. They are meetings of experts, lasting for a week or so, at which a serious programme is carried out, and carefully prepared addresses and short sets of lectures are delivered on topics of outstanding interest. In this matter we ourselves seem to vibrate between two extremes; either we have a technical meeting where papers are read (or taken as read), which seldom interest more than one or two of the audience, or we indulge in a picnic, at which a few casual notes are communicated, mainly for the sake of securing priority.

While thus directing attention to some things in which we might well imitate the States, we have no intention of carping at our own countrymen. The *general* condition of mathematics in this country is probably better now than it has been for many years, and we should be sorry to see some of the old English characteristics disappear. For instance, the view that mathematics is a gentlemanly recreation has something to be said for it, and we may avoid being needlessly solemn and serious in our study of it, however conscious we may be of its vital importance for national welfare.

G. B. M.

SHACKLETON'S LAST ANTARCTIC EXPEDITION.[1]

SIR ERNEST SHACKLETON'S book is an exciting story of a polar expedition that was a disastrous failure in almost everything it set out to do, with a difficult, but stolid and dangerous, retreat and a splendid retrievement. It is of popular rather than of scientific value. To readers of NATURE the last twenty-four pages are of the greatest interest.

The volume shows that medical and science graduates from London, Cambridge, and Aberdeen can be as tough and as useful as the most hardened seamen, and do more than ordinary and A.B. seamen's work on a full-rigged auxiliary steam sailing vessel. Also, that they can sit as tight on a dangerous and rotten piece of ice-floe for month after month, and do good scientific work in squalor and filth and in water in a frozen and thawing condition as well as any, and continue scientific observations and collecting—an example to others making observations and records under more favourable conditions. One and all also served as valuable officers in the fighting Services on their return.

The expedition was under-financed and under-equipped, and there was not enough time given to carry it out successfully. The Weddell Sea alone required two ships and a larger scientific staff, especially in meteorology and biology; there should also have been additional sub-Antarctic meteorological and biological stations or ships. But the Treasury and Parliament are hopelessly blind even now after they should have learned that it was on science that the European War was ended. Science has been found essential on the land, on the sea, and in the air in every way; in the fighting and equipment of the forces, and in the maintenance of non-combatants at home, older men and women and children. The Government was sure of a good leader, and should have given not less than 200,000*l.*, with the guarantee that equipment, ships, small stations, and a sufficient and thoroughly good scientific staff were secured, and that more time was afforded.

FIG. 1.—Landing on South Georgia. Composite drawing and photograph. From Sir Ernest Shackleton's "South." (W. Heinemann)

The Weddell Sea and South Atlantic have been shown to be huge suppliers of food and of material for the manufacture of explosives. It has been found that the meteorology of those parts is an important factor in the meteorology of the globe, especially in southern agricultural areas upon which we are largely dependent.

One omission is that there is no special acknowledgment to the British Admiralty, which had come in at the bitter end. The Admiralty, with special

[1] "South: The Story of Shackleton's Last Expedition, 1914–17." By Sir Ernest Shackleton. Pp. xxi+376. (London: William Heinemann, 1919.) Price 25s. net.

scientific experts and Sir Ernest Shackleton's own representatives, helped the explorer with official assistance to secure the vessels he finally obtained. Even before news of the loss of the *Endurance* came to hand, it had begun the organisation of a relief expedition, and secured and re-conditioned the *Discovery*, which actually sailed so far as Buenos Aires, involving the expenditure of a large sum of public money, better given earlier to the expedition.

The *Endurance* was crushed in approximately 69° S. after being beset off Caird Coast, the south-west coast of Coats Land, whence she drifted west, north-west, and north until she sank. Sir Ernest Shackleton and his party later escaped on floating ice, drifting in a track almost parallel to, but a little west of, the *Deutschland*; and, like the Swedish ship *Antarctic*, the *Endurance* was totally wrecked, and the biological collections and most of the records were unfortunately lost. With the *Deutschland* she thus confirmed the drift of the ice to the west of the Weddell Sea, as originally observed by the *Scotia* and others. She also confirmed the *Scotia's* observations regarding Coats Land and the southern part of the Weddell Sea, and refuted Sir Clement Markham's opinion that it was an open sea from which warm winds drove across by a strait to McMurdo Sound. Sir Ernest Shackleton plainly demonstrated that the reverse was the case, and that heavy and light conditions of ice existed there, calling it "the worst portion of the worst sea in the world," enough to imprison, crush, and lose his ship; but Sir Ernest Shackleton and Capt. Worsley allowed themselves to be too much entangled in it, which probably a veteran ice-master like Robertson would not have done.

Mr. Wordie usefully and ably summarises the scientific work done in the Weddell Sea, and says: "The work undertaken and accomplished by each member was as wide as possible, but it was only in keeping with the spirit of the times that more attention should be paid to work from which practical and economic results were likely to accrue."

FIG. 2.—The last of the *Endurance* before she sank. From Sir Ernest Shackleton's "South." (W. Heinemann.)

He also gives an excellent but too short summary on "Ice Nomenclature."

Mr. Clark proved the faunistic richness of the coastal Antarctic waters, but, unfortunately, all his collections were lost with the ship. Doubtless he has brought home some notes of which we shall hear more in time, for he was already well acquainted with the Weddell Sea fauna. He gives an excellent summary of South Atlantic whales and whaling, which should be particularly useful to the Colonial Office now that it is considering the commercial value of the industry to the Falkland Islands colony and its dependencies.

Mr. Hussey follows with a good summary on the meteorology, but, unfortunately, the valuable detailed tracings packed in the ship's hold were lost. Mr. Hussey's discussion shows that "January 1915 was dull and overcast, only 7 per cent. of the observations recording a clear blue sky, 71 per cent. being completely overcast." The clearest weather occurred in winter, when the sky was cloudless for nearly half the time. Some interesting results are likely to accrue when the meteorological records are worked up in detail and co-ordinated with other observations from South Atlantic and South American stations. "Temperatures on the whole were fairly high, though a sudden unexpected drop in February, after a series of heavy north-easterly gales, caused the ship to be frozen in, and effectually put an end to any hopes of landing that year. The lowest temperature experienced was in July, when 35° Fahr., *i.e.* 67° below freezing, was reached."

For determining the position in drifting pack ice, Mr. James found the theodolite a more generally useful instrument than the sextant, as the ice-floes were found quite steady in really thick pack ice, and the theodolite can be set up and levelled as well as on dry land. Mr. James shows that "the *Endurance* was carried by the ice-drift well to the west of the Weddell Sea, towards the position of the supposed Morrell Land, so that the accurate determination of longitude became a matter of moment in view of the controversy as to the existence of this land." The existence or non-existence of Morrell Land, however, has yet to be investigated more thoroughly, in spite of the assurance of Sir Ernest Shackleton and others that it does not exist. If it is a low *"cluster of islands,"* it would not have been seen at all; the party may have drifted on the floe to the west of it.

Sir Ernest Shackleton's appendix on the lists of provisions and gear in the McMurdo Sound huts is most useful and important for future expeditions.

Finally, the drift party reached Elephant Island, which was one of the places the Admiralty had planned to search. But several landings were made there a century ago, and Sir Ernest Shackleton's expedition is not the first to land there, as he quite excusably supposes. The voyage to South Georgia was a wonderful piece of seamanship and endurance, and Sir Ernest Shackleton has again shown that he can lead men. The story of the *Aurora* with MacIntosh and Stenhouse is another disaster. Spencer Smith unfortunately died while doing land work, which included, however, successful depôt laying, under MacIntosh. The absence of scurvy, on the Weddell Sea side, shows what is possible if fresh meat is mainly adhered to.

MacIntosh and Hayward lost their lives in a blizzard while attempting to cross from Hut Point to Cape Evans on thin ice, and were blown out to sea.

Capt. Stenhouse, of the *Aurora*, handled that vessel with marked ability during her ten months' drift beset in the ice. No mention is made of any systematic scientific work having been accomplished by the Ross Sea party. W. S. B.

TELEPHONING BY LIGHT.

TELEPHONY by means of light is a particular case of wireless telephony. It differs from what is generally understood as wireless telephony in no essential respect. In both cases electromagnetic waves are used, but whereas in ordinary wireless the waves are very long, in the case of light they are very short. As a consequence, telephony by light is easily directed by means of lenses or mirrors, and constitutes a secret means of communication—a state of affairs not yet attained in what is popularly known as Marconi wireless transmission. At the same time, the use of light imposes definite limits on the possible range of light telephony. An uninterrupted straight line is essential between the sending and receiving stations, and the extreme range is therefore determined by the curvature of the earth and the altitudes of the stations.

The transmission of speech by light is rendered possible by the well-known property possessed by selenium (and certain other substances) of changing its electrical conductivity when subjected to varying illumination. Selenium thus acts as a sort of electric valve controlled by light. It is capable of responding to some extent to light

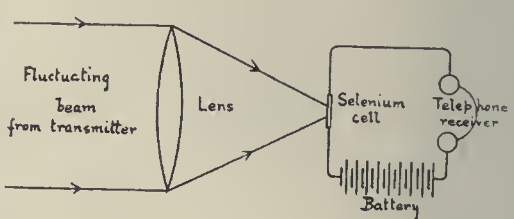

FIG 1.

fluctuations of comparatively high frequency. If a selenium cell is connected in simple circuit with a battery and a telephone receiver—as shown in Fig. 1—fluctuating currents are obtained possessing the same characteristics as the variations of the incident light, and if the latter are of audible frequency the corresponding sounds are heard in the receiver. The problem of light telephony is thus reduced to the production of a beam of light fluctuating in intensity in accordance with the vibrations constituting the speech sounds.

The construction of the first transmitter of this kind was due to Graham Bell, who in 1880 succeeded in transmitting speech by means of a beam of sunlight over a distance of about 200 yards. Telephony by light is, indeed, almost as old as ordinary telephony, and Graham Bell was the inventor of both. It is difficult to account for the difference in the rate of development of the two systems; the fact remains that ordinary telephony is now in common use, whilst telephony by light is still a novelty. Graham Bell's first photophone—as it was called—consisted of a large diaphragm, silvered so as to become a mirror. Upon this mirror a beam of light was projected and thence reflected to the distant selenium receiver. Speech sounds, falling on the diaphragm, set it in vibration, thus causing its curvature to change. The result was that the reflected beam became alternately more and less divergent, so that the amount of light incident on the selenium executed fluctuations of the original frequency and amplitude, and the speech sounds were reproduced in the telephone receiver. Other forms of transmitter are also described by Graham Bell, but it is doubtful whether they were actually successful in practice.

Little further work on the subject appears to have been done until about 1900, when Ernst Ruhmer carried out for the German Government a long series of experiments. He approached the problem from a different point of view. Instead of seeking to impose fluctuations of intensity on a beam of light from a constant source, as Graham Bell had done, he arranged to control the brightness of the source itself by means of the vibrations of speech. The sensitive or speaking arc was already known, and Ruhmer improved it for the purpose of light telephony. Briefly, the principle amounts to this. The current in an electric arc controls the brightness of the arc. Variations of current produce variations of brightness. By means of a transformer, the fluctuations of current in a microphone actuated by speech can be introduced into the arc circuit, and thus produce changes of brilliancy corresponding to the speech vibrations. Ruhmer succeeded in perfecting this system, and claims to have communicated speech over several miles by projecting the beam from the fluctuating arc, by means of a searchlight reflector, on to a distant selenium cell.

This method suffers from several disadvantages, of which the chief is that it is limited to the arc as a source of light, and rules out the use of that much more efficient source—the sun. It is difficult also to maintain the arc in the necessary sensitive condition; it requires continual adjustment. It was these considerations which caused the present writer, in working for the British Admiralty on the subject in 1916, to revert to the general method adopted by Graham Bell—namely, to interrupt the light after it had left the source. The essential point which had to be borne in mind was that the vibrations which it is possible to impart by speech to a diaphragm are of very small amplitude—a few thousandths of an inch only. In order to use these vibrations for producing large fluctuations of intensity in a beam of light, magnification is necessary. In the transmitter about to be described, it will be seen that the magnification is optical. There are many possible variations of the apparatus, but the essential features are shown in Fig. 2. Speech sounds enter the trumpet and fall upon the diaphragm of a gramophone sound-box. To the lever of this sound-box, at the place which the needle ordinarily occupies, is attached a small galvanometer mirror. The vibrations of the diaphragm cause this mirror to execute small *angular* oscillations about an axis perpendicular to the plane of the diagram. Light from a suitable source, such as an arc, or, it may be, the sun, is focussed by means of the first lens upon the vibrating mirror; thence it is reflected through the second lens. The focus of this lens coincides with the vibrating mirror, so that the emergent beam is a parallel one.

A grid consisting of equal and parallel strips alternately opaque and transparent is placed close to the first lens, and a second equal grid near the second or projecting lens. The result is that the light from each point of the source is split up into segments indicated by the unshaded portions, and the extent to which the light penetrates the second grid depends on the momentary position of the vibrating mirror. As shown in Fig. 2, about 50 per cent. of the maximum is being projected, but evidently if the mirror turns through a small angle in a clockwise direction the reflected segments will turn also, and the light penetrating the second grid will increase; a counter-clockwise movement of the vibrating mirror will, on the other hand, diminish the light projected.

Thus, in so far as the mirror copies the vibrations of speech, and provided that the amplitude is not allowed to be greater than that corresponding to the width of one space of the grids, a fluctuating beam of the desired character is ob-

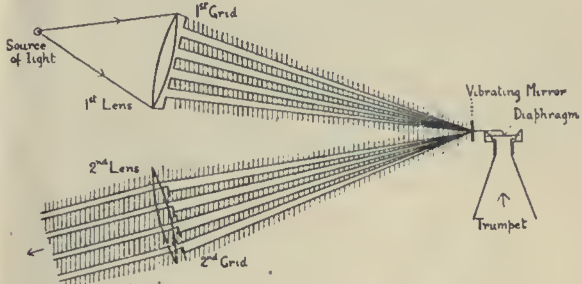

FIG. 2.

tained. It may be projected on to the receiving apparatus shown in Fig. 1 and used for the transmission of speech. By making the width of the grid spaces small in comparison with the distances between the grids and the vibrating mirror, adequate control of the light intensity is secured, even though the movements of the diaphragm are so small. It is, in fact, easy to reach the stage when the grids must be made no narrower, otherwise the amplitude of movement of the segments of light is excessive, and the frequency of interruption becomes doubled or even trebled—to the detriment of articulation in the received speech. It should be pointed out that the diagram shows only the light proceeding from a single point of the source. Actually, every source is finite in size, and in order to provide for this it is necessary to use as the vibrating mirror a *concave* reflector, the radius of curvature of which is equal to the distance between the grids and the mirror. A real image of the first grid is thus obtained on the second, and this image moves in the manner of a shutter when the mirror oscillates.

Fig. 3 is a photograph of a transmitter arranged for use with sunlight, and mounted so that it can be directed as desired. The lenses are 6 in. in diameter, and the range with sunlight, when a 6-in. collecting lens is also used, is about 8 miles. It is impossible at present to say what the ultimate limit of range may be. It depends on the apertures of the projecting and receiving optical systems, the brilliancy of the source, and the extent to which amplification by means of thermionic valves may be possible in reception. The selenium cells which the author has used were made by Dr. Fournier d'Albe, and they have given very satisfactory results, the articulation of the speech heard being extraordinarily perfect. Their special sensitivity to red light perhaps accounts for the fact that a small amount of mist between the sending and receiving stations has been found not to interfere greatly with transmission.

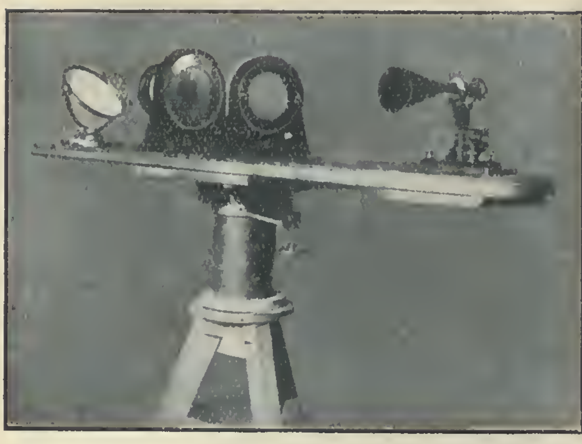

FIG. 3.

In this short article it has not been possible to give more than a brief description of essential points. Fuller details both of the photophone and of its application to the photographic recording and reproduction of sounds may be found in the Proceedings of the Physical Society of London.[1]

A. O. RANKINE.

AUSTRALIAN RAINFALL AND WHEAT YIELD.

UNTIL large schemes for the conservation of water supply with a view to irrigation have been carried out, the incidence of drought at frequent intervals is bound to have a great influence, not only on the sheep runs of the Australian Commonwealth, but also on its wheat crop. It is perhaps surprising that the relation between rainfall and wheat yield should be to a great extent directly traceable, when we consider to how many indirect influences the yield is exposed. The seed varies in such obvious characteristics as size and hardness, as well as in power of resistance to disease, partly modified by the conditions under which the crop producing the seed has been raised. There is, moreover, no constancy in the soil, which differs from place to place in composition, in aspect, elevation, and slope, from farm to farm in the amount and choice of fertilising agents, and from district to district in the dates of weather changes and precipitation. There is possible loss by barrenness of seed, by ground pests before germination, by vermin during growth, by storms, birds, insects, and disease when the grain is in the ear, and much may be shaken out when ripe if the harvest weather be very hot and dry.

In spite, however, of all these disturbing factors we find from the latest official publication on the subject strong evidence of direct correlation between the wheat yield per acre and the rainfall of the previous winter. For South Australia and the Northern Territory the correlation coefficient works out at 0·61, with a probable error of 0·07. It must be admitted that the data are far from being homogeneous, comparatively few of the stations yielding figures for the whole period. The publication is entitled "Results of Rainfall Observations made in South Australia and the Northern Territory, including all available annual rainfall totals from 829 stations for all years of record up to 1917, with maps and diagrams, also appendices presenting monthly and yearly Meteorological Elements for Adelaide and Darwin" (Green, Acting Government Printer, Melbourne, 1918), and is the fourth of a series. Previous volumes dealt with the Eastern Provinces (Queensland, New South Wales, and Victoria), and two more are contemplated to complete the set by including Western Australia and Tasmania.

There is a wealth of detail contained in the four hundred or so pages, to say nothing of the seasonal maps and diagrams. The territory covered is large, more than 900,000 square miles, and the annual rainfall varies from 4·07 in. at Mulloorina in the centre to 61·37 in. at Darwin in the Northern Territory and 45·91 in. at Stirling West in South Australia. The mean annual rainfall for the Northern Territory (four-sevenths of the whole) is 19·52 in. (thirty-seven years' average), the extremes being 30·28 in. in 1904 and 12·20 in. in 1905. For South Australia the mean is 9·39 in., and the extremes, curiously enough also in consecutive years, 15 in. in 1889 and 5·88 in. in 1888. Of forty-seven counties with a long record, twenty-eight had their driest year in 1914, and twenty-five their wettest in 1916. In quite a large number of districts, accordingly, the wheat yield per acre was lowest in 1914 and highest in 1916. The most conspicuous dry periods were 1895 to 1902 and 1911 to 1915. It may be noted that rainfall was deficient at Greenwich also for each year of the first of these periods, but not for the second.

Conditions at Adelaide, which has the longest meteorological record in the district, are very different from those at Greenwich, but there is some similarity in the rainfall. The wettest day at Adelaide in seventy-seven years was March 5, 1878, with 3·50 in., the number of daily falls

[1] Proc. Phys. Soc., vol. xxxi., p. 242, and paper read December 12, 1919.

of at least an inch being 130. The wettest day at Greenwich in seventy-eight years was July 27, 1867, with 3·67 in., and the number of daily falls of at least an inch was 113.

A much more interesting comparison, however, is afforded by the tables relating to Adelaide in the south and to Port Darwin in the north. Darwin is 11° within the Tropics and Adelaide 11° outside, but while Darwin is on the coast, Adelaide is six miles from the nearest point of the sea. The mean height of the barometer, corrected to sea-level, is 0·225 in. (or nearly 8 millibars) higher at Adelaide than at Darwin, the extreme readings being at Adelaide 29·204 in. and 30·704 in., and at Darwin 29·017 in. and 30·151 in. The temperature contrasts are striking. The mean temperature at Darwin is 82·7° F., with a monthly mean daily range of 16·8°, and at Adelaide 63·0° F., with a mean range of 19·7°. Darwin, being a tropical station, has a range of only 8° F., or rather less, between the warmest and coldest months. Adelaide, on the other hand, has a corresponding range of 22½°. Again, the highest temperatures recorded at Adelaide were 116·3° in the shade and 180·0° in the sun; at Darwin, 104·9° in the shade and 168·5° in the sun. It is therefore not surprising to find that readings of at least 100° in the shade occur much oftener at Adelaide—13·5 per annum, as against 1·6 per annum at Darwin. It is otherwise with readings of at least 90° in the shade, where the annual numbers are 43·6 at Adelaide, and 237, or nearly two days out of three, at Darwin. The lowest reading at Darwin was 55·8°, and at Adelaide 32·0°, for air temperature. Terrestrial radiation readings are not given for Darwin, but a minimum of 22·9° occurred at Adelaide. Darwin also seems to be unprovided with a sunshine recorder, but at Adelaide the annual average is 2531·5 hours, a maximum of 2829·9 hours having been measured in 1898, in which year also the sunniest month occurred, 374 hours being recorded in January.

Many other matters besides rainfall are included in the main part of the volume, as indicated in the following list of tabulations: aurora, bush fires, drought, earthquakes, floods, fog-bows, frost, hail, heat waves, high tides, meteors, mirages, mock moon, plagues and pests and live-stock diseases, heavy rainfall, thunder and lightning, volcanic dust-clouds, water-spouts, hurricanes, cyclones, heavy gales, dust-storms, etc.

W. W. B.

NOTES.

With the assistance of the Air Ministry and the co-operation of Messrs. Vickers, Ltd., Lord Northcliffe has been able to arrange, on behalf of the *Times*, for an attempted flight from Cairo to Cape Town, a distance of more than five thousand miles. This journey from one end of the continent of Africa to the other, and traversing country the nature of a large part of which is little known, is of particular interest to the scientific world in view of the fact that Dr. P. Chalmers Mitchell, secretary of the Zoological Society of London, is taking part in it as passenger and observer. The enterprise will thus not only test the practicability of the air route from Cairo to the Cape, but also doubtless lead to valuable scientific observations being made during the flight. The aeroplane left England on January 24 and arrived in Cairo on February 3. The machine is a Vickers-Vimy commercial aeroplane similar to those used for the flights across the Atlantic and to Australia, and it carries a crew of four in addition to the passenger. Dr. Chalmers Mitchell is carrying an autograph letter from the King to Lord Buxton, Governor-General of South Africa, and we hope that he will be able to deliver it in twelve days or so after a successful end to what is a pioneer effort in scientific exploration from the air.

The *Kew Bulletin* (1919, p. 399) records the appointment by the Government of South Africa of an Advisory Committee to carry out and supervise a Botanical Survey of the territories included in the Union. Dr. J. B. Pole-Evans, chief of the Division of Botany in the Department of Agriculture, will act as Director of the Survey, and he will be assisted by a small committee, including several prominent South African botanists and representatives of Government Departments interested. The objects of the survey are to continue and extend the work of the Division of Botany on the systematic study of the vegetation of the country and of the plant parasites of the indigenous vegetation; that of the Division of Veterinary Research on the relation of the vegetation to stock diseases; and that of the Forestry Department on the composition of the indigenous forests, the value of their products, and their industrial possibilities. Also to study the vegetation from the various points of view of industry, agriculture, and pastoral development; to study plant distribution and the influence of South African conditions on the structure and physiology of the native plants; and to compare and correlate the South African flora and its associated animal and plant diseases with those existing in other parts of the world under somewhat similar conditions. For the purpose of the survey the country will be divided into a convenient number of areas each under the control of a botanist, and a qualified assistant has been appointed at Kew to aid in the critical examination of the plants collected.

By a melancholy coincidence the announcement of the appointment by the Egyptian Government of an International Commission to consider the proposals for the extension of irrigation works in Egypt and the Sudan is followed by the news from Bombay of the death of Sir Michael Nethersole, who had been selected for the chairmanship of the Commission, but had felt impelled to decline the offer by reason of the claims of his work in India. Born in 1859, Sir Michael passed in 1880 from the Royal Indian Engineering College at Coopers Hill into the Public Works Department, and, rising through the grade of executive engineer, he became in 1900 Chief Engineer and Secretary to Government in the United Provinces. In this position he remained for a dozen years until his appointment as Inspector-General of Irrigation in India. He retired in 1917 with a knighthood, having been created C.S.I. in 1914. Retirement from public service, however, was only followed by professional activity of another kind, and until his death Sir Michael occupied the position of chief hydro-electric engineer to the Tata Co. at Bombay, under the auspices of which he recently completed the tunnelling work for the Andhra Valley scheme of water-power.

WE regret to announce the death on February 1, in his seventy-ninth year, of Mr. C. E. Groves, F.R.S.

DR. W. McDOUGALL, Wilde reader in mental philosophy in the University of Oxford, has been elected president of the Society for Psychical Research, in succession to the late Lord Rayleigh.

SIR DANIEL HALL, K.C.B., F.R.S., Permanent Secretary of the Board of Agriculture, has been elected a member of the Athenæum Club under the rule which empowers the annual election by the committee of a certain number of persons "of distinguished eminence in science, literature, the arts, or for public service."

SIR NORMAN MOORE, president of the Royal College of Physicians, has appointed Dr. F. W. Andrewes to be Harveian orator and Dr. R. C. Wall to be Bradshaw lecturer for this year. The council has appointed Dr. Martin Flack to be Milroy lecturer for 1921, and the Censors' Board has awarded the Oliver-Sharpey prize for 1920 to Prof. Emil Roux, of the Pasteur Institute, Paris.

PROF. E. B. TITCHENER, Cornell University, Ithaca, N.Y., informs us that the prize of 100 dollars offered for the best paper on the availability of Pearson's formulæ for psychophysics (NATURE, vol. xcii., p. 508, January 1, 1914) has been awarded to Dr. Godfrey H. Thomson, of Armstrong College, Newcastle-upon-Tyne, for a paper entitled "On the Application of Pearson's Methods of Curve-fitting to the Problems of Psychophysics."

Symons's Meteorological Magazine came to an end with the January number, which completed vol. liv. This month it will appear as the *Meteorological Magazine*, with which the *Meteorological Office Circular* will be incorporated. In order to preserve the continuity, the new magazine will be issued as No. 1, vol. lv. The editors will be Mr. Carle Salter and Mr. F. J. W. Whipple. The change is the outcome of the British Rainfall Organisation becoming part of the service of the Meteorological Office.

THE death is announced, in his fifty-second year, of Mr. Robert Hollister Chapman, who had been connected with the U.S. Geological Survey since 1880, with the exception of the period from 1909 to 1912, during which he was engaged on topographical work in Canada. Mr. Chapman made extensive explorations in the principal Western and Southern States, and was the author of maps of Death Valley and adjacent deserts and of the high Sierras. He was secretary of the American Alpine Club. His published work includes many articles and bulletins on topographical subjects, and a book entitled "Personal Explorations in the Northern Selkirks."

THE Elizabeth Thompson Science Fund has been serviceable for many years in giving aid, by small grants, to research which otherwise might not be readily undertaken. The grants are made only for scientific investigations, and must be applied to actual expenses of the research, *i.e.* they are not made to support an investigator or to meet the ordinary expenses of publication. The trustees give preference to researches involving international co-operation. The grants are not made for researches of narrow or merely local interest, nor are they available for the equipment of private laboratories or for the purchase of apparatus ordinarily to be found in scientific institutions. Applications for grants from this fund should be made to Prof. W. B. Cannon, secretary of the trustees of the fund, Harvard Medical School, Boston, Mass.

THE Secretary of State for the Colonies has appointed a Committee to consider whether the staffs of the Veterinary Departments in the various Colonies and Protectorates are adequate, and, if necessary, to recommend increases of staff; to consider whether the rates of salary offered to the veterinary staff are adequate, and, if necessary, to suggest improvements; and to make recommendations for improving the arrangements for recruiting veterinary staffs for the Colonies and Protectorates. The members of the Committee are:—Sir Herbert Read, K.C.M.G., Assistant Under-Secretary, Colonial Office; Sir J. M'Fadyean, Principal of the Royal Veterinary College, London; Sir S. Stockman, Chief Veterinary Officer, Ministry of Agriculture; the President of the Royal College of Veterinary Surgeons; Prof. O. C. Bradley, Principal of the Royal (Dick) Veterinary College, Edinburgh; Prof. J. Share-Jones, Director of Veterinary Education and Professor of Veterinary Anatomy, University of Liverpool; and Major R. D. Furse, Assistant Private Secretary (Appointments), Colonial Office. Mr. A. Cooke, of the Colonial Office, is secretary of the Committee.

IN *Folk-lore* for December last (vol. xxx., No. 4) Dr. W. Crooke discusses the cults of the mother goddesses in India, in the hope that these may throw some light on their somewhat obscure sister goddesses in the West. The cult of Mother Earth prevails widely in India. Beginning with the type of a local fertility spirit of the village, she rapidly becomes anthropomorphised, and is supposed to enjoy a periodical rest after her labours, and to be strengthened for her benign offices by a sacred marriage with a male consort and by animal sacrifice. But in the Vedas and in the later Brahmanical Hinduism goddesses play only a subordinate part. It is among the Dravidians of Southern India that the goddess cult attains its highest development. The Earth Mother is no doubt the parent in India of many of the local goddesses, but it is going too far to assume, as some writers on the mythology of the West have done, that goddess-worship in general originated in the Earth Mother culture. Even in India many of the local goddesses come from the pre-agricultural stage, the Jungle Mothers, or they are the deified spirits of women who died in some heroic way.

Little has hitherto been known about the Stone ages in Ceylon, but the first steps towards a solution of the problem have been taken in a paper by Mr. E. J. Wayland, late Assistant Mineral Surveyor to the Government of Ceylon, published in *Spolia Zeylanica* (vol. xi., part 41, 1919). In opposition to other authorities, Mr. Wayland believes that there is no evidence that the Veddas passed through a Stone-age phase in Ceylon; they are assumed to be immigrants from the Indian peninsula, and the Palæolithic age dates from a period long antecedent to their arrival in the island. The Ceylon implements fall into two groups, that of the hills and that of the lowlands. Pigmy flints are abundant, and the author believes that they were used mainly in boring bone needles. The Chellean type is represented by the hand-axe, the Mousterian by scrapers, and the Aurignacian by pointed implements with edge trimming. An important feature of this paper is the correlation of the various types with the local geological features. Mr. Wayland has given a good introductory sketch of the subject, and by means of his large collection, which, however, needs much addition, the problem of the Stone ages in Ceylon, where the material is abundant, seems to be approaching a solution.

We welcome the reappearance of *The Mariner's Mirror,* the journal of the Society for Nautical Research. Mr. T. Sheppard contributes an article on the Hull whaling trade, once of great importance, from which the present great fish and oil trades may certainly be said to have developed. Mr. C. Pickering has made a fine collection of objects connected with the business, and presented a large museum devoted to the fishing industry. Mr. Sheppard in his article describes and illustrates many interesting exhibits—"flensers" for cutting the blubber into strips; the seal picks used by men working in masses of ice; a wrought-iron gun-harpoon bent by the speed with which the whale dragged the boat after it; one of the old explosive harpoons, known as Balchim's patent; and harpoons and gun-spears, with a collection of old guns. He also reprints an interesting journal describing the wreck of the whaler *Thornton,* which was lost in 1821. The city of Hull is honourably distinguished for the zeal and enterprise shown in the preservation of relics of its former industries.

Dr. J. W. H. Harrison has tested the effect of alcohol on a Geometrid moth, *Selenia bilunaria,* and finds the resulting offspring superior in many respects (*Journal of Genetics,* vol. ix., No. 1). In broods from treated parents the development was quicker, the mortality lower, and the mean weight of the pupæ greater. This is in agreement with Prof. Pearl's studies of the effects of alcohol on fowls, and is to be interpreted as the result of elimination of the weaker germs and individuals. The offspring from a cross between a treated male and an untreated female was superior to that from the reverse mating. Contrary to expectation, it was found that treatment with alcohol did not lead to the production of germinal variations.

In a valuable discussion of phylogenetic degeneration in the ostrich (*Journal of Genetics,* vol. ix., No. 2), Prof. Duerden, who is in charge of ostrich-breeding investigations in South Africa, concludes that over its whole continental range this bird has long been undergoing progressive degenerative changes. The toes have undergone gradual reduction as in the horse, until of the original five only the third and a much reduced fourth remain. Even the third, which is the functional toe, shows signs of further reduction. Similar retrogressive tendencies are found in the structure of the wing and in many features of the plumage. These changes are looked upon as orthogenetic in nature, pursuing a continuous course independent of natural selection or adaptation, and certain to lead ultimately to the extinction of the species. In certain cases well-marked steps in variation are taken, as in the bald spot of the North African ostrich, which behaves as a Mendelian dominant character, and is believed to have originated as a mutation. On the other hand, reduction in the wing-coverts and in the scutellation of the toes is a more gradual process, occurring by a series of steps. Contrasted with this is the down of the legs, which begins to disappear when each chick is about six months old, and is thus an ontogenetic phenomenon. In all these cases it seems clear that the seat and origin of the change is in the germ-plasm. The point of view arrived at agrees in many respects with that of Whitman (see Nature of January 29, p. 566) concerning orthogenetic evolution in pigeons.

The first part of a "Flora Arabica," by Prof. Ethelbert Blatter, is issued as vol. viii., No. 1, of the Records of the Botanical Survey of India. Prof. Blatter's work on the Indian flora, and more recently on the flora of Aden, renders him especially well equipped for the systematic study of the botany of Arabia, and he has been able also to work through the rich collections at Kew and the British Museum (Natural History). He divides the area into four natural botanical regions—the extra-tropical west, the tropical west, the tropical east, and the extra-tropical east or Persian Gulf region. Part i. comprises a systematic list of thirty-eight families of dicotyledonous flowering plants, the arrangement adopted being that of Bentham and Hooker's "Genera Plantarum." The habitats and general distribution of each species are recorded, also the vernacular names and, where known, the uses of the plants. The chief elements of the flora are the Mediterranean and North African desert.

We learn from the *Geographical Journal* for January (vol. lv., No. 1) that a new topographical map of New Zealand is in course of publication. The basis of the map is a triangulation, which already existed for cadastral surveys, supplemented by a secondary triangulation. The new map is on a scale of 1/125,000, with contours at 100-ft. intervals, and hill-shading in neutral tint. Roads, water, and wooded lands are shown in colour.

The rainfall over England in 1919 was nearly everywhere in excess of the average, according to an article in *Symons's Meteorological Magazine* for January (vol. liv., No. 648). The excess was nowhere large, exceeding 10 per cent. only in scattered patches across the southern Midlands, and reaching 20 per cent. apparently only in parts of Leicestershire. North Wales had a 10 per cent. excess, but in South Wales the summer and autumn drought resulted in many places in a 10 per cent. deficiency. Parts of the east and north of Scotland, notably northern Aberdeenshire and the Orkneys, had more than the average fall, but in central and southern Scotland there was a deficiency culminating in 20 per cent. below the average in central Inverness-shire and Perthshire. Almost the whole of Ireland had less than the average rainfall, the deficiency being greatest in counties Cork, Galway, and Kerry, where it reached 20 per cent. below the mean. Taking the British Isles as a whole, the year, although by no means exceptional, was probably the driest since 1908—a result largely due to the shortage of rain in summer and autumn.

COL. J. TILHO announced some important discoveries in the Sahara in a paper read before the Royal Geographical Society on January 19. The Tibesti highlands prove to be an enormous triangular massif twice the area of Switzerland, with summits more than 10,000 ft. in height. Emi Kussi, the culminating point of the region, is the largest of a series of extinct volcanoes. This volcano has a well-formed crater, which in the past was occupied by a lake, but now has a thick deposit of sodium carbonate on the floor. The population of Tibesti is considerable, and is devoted to camel-rearing and brigandage. Col. Tilho claims to have disproved the possibility of former river connection between Lake Chad and the Nile. His explorations show an extension of the highlands formerly known to occur between the southern borders of Tripoli and Darfur. With regard to the economic development of the Sudan and the Sahara, Col. Tilho advocates an east-and-west transcontinental railway. That this would facilitate the pilgrimage to Mecca is an important consideration for great Mohammedan Powers like Britain and France.

DR. G. F. KUNZ, the well-known authority on the subject of jewelry in all its aspects, contributes to *Mineral Industry* (New York: McGraw-Hill Book Co., Inc.; London: Hill Publishing Co., Ltd., 1919, vol. xxvii., pp. 604–28) his customary chapter on the production of precious stones for the previous year. It may be remarked that this annual volume is written from the point of view of the United States. Rather more than two-thirds of this chapter is devoted to diamond, pre-eminently the precious stone. The jewelry trade is such a sensitive barometer of general trade conditions that we are not surprised to read that the incidence of heavy war expenses and the increase in taxation had sensibly checked the import of precious stones into the United States in the year 1918; the initial figures for 1919 show, however, that the setback was only temporary. We note that in the United States, just as in this country, successful attempts appear to have been made to develop the diamond-cutting industry. We are told that the output of gem material in the Rangoon district of Burma for the year 1917, which is the latest year dealt with, was of much higher value than that of the previous year, although the quantity produced was slightly less. The jade output in North Burma, which is wholly exported to China, where it is highly prized, remains as prosperous as ever. The United States does not produce much gem material, what there is being confined mainly to ruby, sapphire, turquoise, quartz, and tourmaline, although diamonds are being mined in Arkansas.

IN a paper on the factors controlling climate, which appears in the December, 1919, issue of the Journal of the Franklin Institute, Prof. W. J. Humphreys, of the United States Weather Bureau, discusses the theories which have been propounded to account for the existence in the past of "Ice ages," which, after enduring for a time, were succeeded by long periods during which the conditions were again normal. Solar variation, eccentricity of the earth's orbit, and carbon dioxide in the earth's atmosphere are shown not to be capable of affording satisfactory explanations, while the presence of volcanic dust in the atmosphere for any considerable period is proved to be capable of accounting for a fall of temperature of a few degrees Centigrade. The finest dust from Krakatoa probably reached an altitude of 40 to 80 km., and took nearly three years to fall through the isothermal layer of the atmosphere to the level of the upper clouds. If the coefficient of absorption of solar radiation by the dust is greater than its coefficient for terrestrial radiation, the value of the pyrheliometric constant will be diminished. The author shows that there is abundant evidence of this diminution after every considerable volcanic eruption.

AT the meeting of the Illuminating Engineering Society on January 27 a discussion on colour-matching by natural and artificial light took place. Mr. L. C. Martin, in opening the discussion, gave a summary of existing methods of producing artificial daylight. One of the most convenient devices has been the use of a special tinted glass transmission screen used with electric incandescent lamps to remove the excess of red and yellow rays. With the gas-filled lamp the efficiency of such units is considerably improved, 33 per cent. being claimed for a sunlight unit and 19 per cent. when light from the blue sky is imitated. A communication from Mr. M. Luckiesh, read later in the evening, showed how widely such units are being used in the United States. Mr. Martin exhibited the Sheringham daylight lamp, and explained that the overall efficiency of the blue-sky unit was not widely removed from that obtained with similar units using blue transmission screens. On the other hand, the diffusion of the light from the extensive coloured reflector surface used with the Sheringham lamp is considered a distinct advantage. Mr. Martin also showed some very striking colour changes in dyed fabrics seen successively under artificial daylight and light from a tungsten lamp. Mr. Bawtree exhibited a form of colorimeter for the analysis of colour, and Miss F. E. Baker, in showing the tintometer testing apparatus, also described some experiments on a new form of daylight lamp. A communication from Prof. Gardner, of Bradford Technical College, was also read. The production of artificial daylight is exciting keen attention, and several speakers emphasised the need for a systematic comparison of the various existing units and the establishment, if possible, of a standard of so-called "white" light.

WHILST the chemistry of gelatin has been investigated with much care, less attention has been given to that of glue. Both gelatin and glue are hydrolytic products of the collagen present in hides, but they represent different phases of the hydrolysis, and the details of the manufacture of glue have largely been kept secret. Crucial points are, first, the stage at which the process of hydrolysis must be stopped and the degree of concentration necessary in order to obtain a glue solution which will "set" to a jelly; and next, the method of drying this jelly into the finished glue. A low temperature has been considered necessary for successful drying, and also for avoiding bacterial action during the process. Hence the making of glue in warm countries, such as India, has hitherto not been found practicable. A paper by Mr. K. C. Srinivasan, of the Department of Industries, Madras ("The Manufacture of Glue in the Tropics"), describes how the foregoing points have been investigated by the Department, and the difficulties overcome. It is claimed that by a study of the chemical principles involved, and by laboratory and factory experiments, the details of manufacture have been successfully adapted to the climatic conditions prevailing even in the hottest parts of India.

MR. D. BROWNLIE gives some further exact data on the running of steam-boiler plants in *Engineering* for January 16. The subject dealt with is that of steam jets under or over the fire-bars, and out of the 250 typical steam-boiler plants examined no fewer than 93 plants, or 37 per cent., were fitted with steam jets. The makers of the various types of furnaces so fitted confess, as a rule, to a modest 1 to 3 per cent. of the steam production being used in the jets. Mr. Brownlie finds that the average steam consumption for the 93 plants is 5·6 per cent. of the total steam produced, and that the figure varied from 1 to 20 per cent. In the present article the results derived from 130 plants are considered, including 437 boilers both hand- and mechanically-fired. The averages are 6·6 per cent. for hand-firing and 6·7 per cent. for mechanical-firing. The lowest figure was 0·50 per cent., and the highest 21·4 per cent. If a given plant were taken in hand and scientific methods of control adopted, figures like 7½ to 15 per cent. of the steam production could be cut down to 3 or 4 per cent. with most types of steam-jet apparatus. Some of the apparatus in use is of crude and unscientific design, and incapable of giving good results. Mr. Brownlie estimates that a saving for the whole country of from 1,025,000 to 1,345,000 tons of coal per annum could be effected, partly by proper control and partly by getting rid of steam jets working under unsuitable conditions.

MESSRS. H. K. LEWIS AND CO., LTD., 136 Gower Street, W.C.1, have just issued a list of secondhand books (many of which are from their circulating library) in medicine and allied subjects which should be seen by all in search of books of this character at bargain prices. The reductions in many cases are very great. Messrs. Lewis have also sent us a list of the new books and new editions added to their medical and scientific circulating library during the months October to December last.

Messrs. Cassell and Co., Ltd., promise for February a book of travel by Sir Martin Conway entitled "Mountain Memories: A Pilgrimage of Romance," illustrated by the author. The new list of *Messrs. Constable and Co., Ltd.*, includes "Elementary Mathematics," H. E. J. Curzon; "Electric Welding and Welding Appliances," H. Carpmael (*Engineer* Library); "Paper-making and its Machinery," T. W. Chalmers (*Engineer* Library); "Calculation of Electrical Conductors," W. T. Taylor; "Low Grade and Waste Fuels for Power Generation," J. B. C. Kershaw; "Reinforced Concrete Diagrams," J. Williamson; "The Measurement of Steady and Fluctuating Temperatures," R. Royds; "Heat Transmission," R. Royds; "The Efficiency of Pumps and Ejectors," E. C. Bowden-Smith; "Oil-Firing for Kitchen Ranges," E. C. Bowden-Smith; "Storing," H. B. Twyford; "Public Health Chemical Analysis," R. C. Frederick and A. Forster; "Human Psychology," H. C. Warren; "Wild Creatures of Garden and Hedgerow," F. Pitt; and new editions of "The Propagation of Electric Currents in Telephone and Telegraph Conductors," Prof. J. A. Fleming; "The Theory of Electric Cables and Networks," Dr. A. Russell; and "Ship Form Resistance and Screw Propulsion," G. S. Baker.

THE February list of *Messrs. Longmans and Co.* contains announcements of many books relating to science and education. Among those not already alluded to in NATURE we notice "The Valuation of Mineral Property," Sir R. A. S. Redmayne and G. Stone; "Cement," B. Blount; "Plantation Rubber," G. S. Whitby; and "Margarine and Butter Substitutes," W. Clayton (Monographs on Industrial Chemistry); "The Principles and Designs of Printing Telegraph Systems and Mechanisms," H. H. Harrison; "Telephone Exchanges: Automatic Equipment," B. O. Anson; "Telephone Exchanges: Manual Equipment," H. S. Thompson; "Subscribers' Telephone Equipment," H. S. Thompson; "Overhead Construction," J. W. Atkinson; "Underground Construction," A. O. Gibbon; "Inland Telegraph and Submarine Cable Office Equipment," E. Lack; "Railway Telegraphs," C. W. Slingo; and "Testing of Lines, Apparatus, and Material," F. L. Henley (Manuals of Telegraph and Telephone Engineering); "Applied Naval Architecture," W. J. Lovett; "Industrial Administration," a series of lectures by B. S. Rowntree, T. H. Pear, A. E. Berriman, Dr. J. M. Legge, Prof. L. Hill, T. B. Johnstone, and St. George Heath; "Forage Crops in Denmark," H. Faber; "The Fireman's Handbook and Guide to Fuel Economy," C. F. Wade; "An Essay on Mediæval Economic Teaching," G. O'Brien; and a new edition, in two parts, of "Optical Projection: A Treatise on the Use of the Lantern in Exhibition and Scientific Demonstration," Lewis Wright, rewritten by his son, R. S. Wright, part 1, illustrated.

OUR ASTRONOMICAL COLUMN.

COMETS.—The object announced last week as comet 1920*a* appears to be a minor planet. It was so described by the discoverer, but through some telegraphic confusion was reported as a comet.

Two comets were discovered in December. The first, 1919*f*, was recorded on two plates taken on December 10 at Bergedorf, Hamburg, by Dr. Baade. It is probably identical with Holmes's comet, for which a search ephemeris had been calculated. If so, perihelion passage occurred about November 22.

Comet 1919*g* was discovered by Mr. J. F. Skjellerup at the Cape of Good Hope on December 18, and was also observed by Mr. Woodgate at the Cape Observatory. Dr. Halm sends the following provisional elements:

$$T = 1920 \text{ January } 2{\cdot}674 \text{ G.M.T.}$$
$$\omega = 276^\circ\ 35'$$
$$\Omega = 315^\circ\ 36'$$
$$i = 123^\circ\ 10'$$
$$\log q = 9{\cdot}47376$$

The elements bear some resemblance to those of the comet of 1797, also to 1808 I.

Ephemeris for Greenwich Midnight.

	R.A. h. m. s.	S. Decl. ° ′	Log r	Log Δ
Feb. 10 ...	20 31 52	4 34	0·0189	0·2869
		N. Decl.		
20 ...	20 34 28	0 7	0·0934	0·3095
March 1 ...	20 36 8	4 29	0·1541	0·3245
11 ...	20 36 42	8 43	0·2049	0·3337

The comet is now rather close to the sun, but should be visible in the morning in March.

THE MOTION OF THE MOON.—Dr. J. K. Fotheringham contributed a paper on this subject to the Royal Astronomical Society in January. He showed, as others have done, the necessity for applying an empirical term to the moon's longitude, and the impossibility of determining both that term and the value of the secular acceleration from modern observations alone. Accordingly, various periods were assumed for the empirical term, and the corresponding values of the acceleration deduced. The period 254 years is preferred, as this gives the same value 10″ for the acceleration as that deduced from ancient eclipses. Prof. Turner had found a period of about 240 years from a discussion of Chinese earthquakes and Nile floods. It was suggested that the two periods might be identical, and that the apparent oscillation in the moon's motion was really a change in the earth's period of rotation.

The observations used extend to the end of 1918, ten years later than those used by Drs. Brown and Cowell. These additional observations have considerable influence on the result.

STARS OF HIGH VELOCITY.—In most studies of stellar motions the stars with abnormally high velocities are excluded, which is doubtless a sound principle. Nevertheless, an examination of these motions is of great interest, and was undertaken by Messrs. W. S. Adams and A. H. Joy (Proc. Nat. Acad. Sci., Washington, July, 1919). The highest velocity in space found for any star is 494 km./sec. for the 9th mag. star A.G. Berlin 1366. On the average, the two components of the velocity in the galactic plane are about equal, and 2½ times the component perpendicular to the plane. Nearly a hemisphere in galactic longitude is devoid of apices, the values all lying between 131° and 322°. The centroid of the thirty-seven stars examined has a velocity exceeding 74 km./sec., almost exactly in the galactic plane. These facts seem to establish that the velocities have been generated within our own star system, and that the stars are not mere visitors from outside, as has sometimes been suggested. They are probably mostly of small mass, but this can scarcely be the case with Arcturus, the high velocity of which remains an enigma. It is noted that twenty-six out of the thirty-seven stars are of spectral types F and G.

THE ST. LOUIS MEETING OF THE AMERICAN ASSOCIATION.

THE seventy-second meeting of the American Association for the Advancement of Science was held in St. Louis, Mo., on December 29 to January 3, under the presidency of Dr. Simon Flexner, director of the Rockefeller Institute for Medical Research, New York City. The meeting was a most successful one, the attendance of scientific men reaching approximately twelve hundred. St. Louis is the fourth city of the United States in size, and is an extremely progressive centre, paying much attention to educational matters and possessing two universities, two admirable medical schools, an academy of science, the great Missouri Botanical Gardens, and an extraordinarily advanced system of institutions for secondary education. All the meetings (and there were thirty-two distinct organisations meeting at the same time, twelve of them being sections of the association) were held in the single building known as the Soldan High School. In this building there are very many large lecture-rooms with lantern and laboratory facilities, one auditorium with a seating capacity of more than two thousand, and a dining-room with about the same accommodation, and thus the necessity of meeting in distinct and sometimes widely separated buildings, as has occurred in other cities, was avoided.

The opening session was held on Monday night, December 29. Chancellor Hall, of Washington University, St. Louis, delivered an address of welcome, and the retiring president, Prof. John Merle Coulter, gave his address (published in NATURE of January 29, p. 581) on "The Evolution of Botanical Research."

On the following night a lecture, complimentary to the citizens of St. Louis, was delivered by President Simon Flexner on the general subject of the medical outlook in research. The trend of the address was optimistic, and the subjects especially mentioned were influenza, yellow fever, poliomyelitis, and cancer.

During the week addresses by chairmen of sections were delivered as follows:—Section A, "Recent Progress in Dynamics," George D. Birkhoff; Section B, "Some Aspects of Physics in War and Peace," Gordon F. Hull; Section D, "Science and Modern Engineering," Ira N. Hollis; Section E, "Geology as Taught in the United States," David White; Section H, "The Relations of Anthropology and Psychology," Ales Hrdlička; Section I, "New After-the-War Phases of Practical Pan-Americanism," John Barrett; Section K, "The Untilled Fields of Public Health," C. E. A. Winslow; Section L, "The Part Played by Heredity and Maturity as Factors Conditioning the Effects of Training," Stuart A. Courtis; and Section M, "The Organisation of Research," Henry P. Armsby.

There were also a number of symposia, which attracted much attention, as follows:—"World Standardisation" and "Education and Practical Work on the Metric Basis," under the auspices of the American Metric Association; "The Life-cycle in Insects," under the auspices of the Entomological Society of America; "The Relation of the Use of Power and Labour-saving Machinery to Agricultural Progress," under the auspices of Section M; "The Adjustment of Agricultural Teaching and Research to Changing Conditions," under the auspices of the Society for the Promotion of Agricultural Science; and "The Effects of the War upon Experimental Medicine and Physiology," under the auspices of Section K.

It was an important meeting from the point of view of association business, since the revised constitution was adopted, a copy of which has been published in the journal *Science*. The principal changes in the constitution which will be of interest to members of the British Association are the raising of the annual dues from three dollars to five dollars and of the life-membership fee from fifty dollars to a hundred dollars, the re-lettering of some of the old sections and the adding of new sections. The old Section A, *Mathematics and Astronomy*, has been divided, and A is now *Mathematics* and D *Astronomy*. The old Section H, *Anthropology and Psychology*, has been divided into two sections: H, *Anthropology*, and I, *Psychology*. *Social and Economic Science* becomes Section K; the Section of *Engineering* becomes Section M, and that of *Medical Science* Section N; *Agriculture* becomes Section O, and *Education* Section Q. The titles of the old Sections F and G, namely, *Zoology* and *Botany*, have been changed to *Zoological Sciences* and *Botanical Sciences*. Two new Sections—L, *Historical and Philological Science*, and P, *Manufactures*—have been established, although they will not be organised at present.

The work of the old office of the permanent secretary has been divided, and it has been arranged that a general secretary shall take charge of all features of organisation, while the permanent secretary shall be simply an executive officer to have charge of meetings and of the current finances of the association.

Chicago was chosen for the place of the next annual meeting during holiday week 1920–21, and a schedule of future meetings was tentatively drafted as a guide for affiliated societies in forming their plans for future meetings. This tentative programme includes Toronto or Buffalo for 1921–22, Boston for 1922–23, Cincinnati for 1923–24, and Washington for 1924–25. The Chicago meeting next year will be one of the large fourth-year meetings, that in Washington in 1924–25 being another of these specially large meetings. It is hoped that all the affiliated societies, and, in fact, all scientific men in America who can do so, will make a special effort to attend these fourth-year meetings, and that men of science from other countries also will be able to attend.

Arrangements were made for the establishment of geographical branches of the association and for the affiliation of State and city academies of science.

The newly established American Meteorological Society and the Southern Educational Society were admitted to affiliation.

A committee on international auxiliary languages was authorised to co-operate with a corresponding committee of the British Association and with the International Research Council.

The following affiliated societies met with the association:—American Mathematical Society, Mathematical Association of America, American Physical Society, American Meteorological Society, Society for Promotion of Engineering Education, Association of American Geographers, National Council of Geography Teachers, American Society of Zoologists, Entomological Society of America, American Association of Economic Entomologists, American Nature-Study Society, Botanical Society of America, American Phytopathological Society, American Pomological Society, Ecological Society of America, American Society for Horticultural Science, Association of Official Seed Analysts, Society for Promotion of Agricultural Science, American Metric Association, and Wilson Ornithological Club.

The election of officers by the general committee resulted in the selection of Dr. L. O. Howard, of Washington, as president for the coming year. The following vice-presidents (chairmen of sections) were elected: Section A—D. R. Curtis, Northwestern University; Section B—J. C. McLennan, Toronto University; Section C—S. W. Parr, University of Illinois; Section D—Joel Stebbins, University of Illinois; Section E—Charles Schuchert, Yale University; Section F—J. S. Kingsley, University of Illinois; Section G—R. H. True, Bureau of Plant Industry, Washington, D.C.; Section H—G. B. Gordon, American Museum of Natural History, New York; Section I—E. K. Strong, jun., Carnegie Institute of Technology, Pittsburgh; Section M—C. L. Mees, Rose Polytechnic Institute, Terre Haute; Section N—J. Erlanger, Washington University, St. Louis; and Section Q—C. H. Judd, University of Chicago.

The election of the chairmen of Sections K, L, O, and P was deferred for the present. Prof. E. L. Nichols, of Cornell University, was elected general secretary, and the selection of a permanent secretary to succeed Dr. Howard, who has held office for twenty-two years, was referred to the council, with power to act.

PIONEERS IN THE SCIENCE OF THE WEATHER.[1]

THE year 1919 will be memorable in the annals of meteorology. It witnessed the completion of the process of co-ordination of the national meteorological work in the operations of a single institution by the incorporation of the work of the British Rainfall Organization with the Meteorological Office. Beginning with the meteorology of the sea alone in 1854, when it was a department of the Board of Trade, in 1867, after FitzRoy's death, the Office undertook the mapping and the study of the daily sequence of weather, and on that account was placed in charge of a director with a "grant in aid" from Parliament under the control of a committee appointed by the Royal Society. In 1879, under a directive council, also appointed by the Royal Society, it became generally responsible for the publication of the national contribution of climatological data in accordance with an international scheme laid down by the Meteorological Congresses of Vienna in 1874 and Rome in 1879. In discharge of this duty it was authorised to obtain the aid of the Royal and Scottish Meteorological Societies and of the British Rainfall Organization; it was also empowered to recognise the duty of development of meteorological science by experiments and special investigations.

From the early years of the twentieth century the collection of the climatological data of private observers became more and more associated with the Office, until now, by the transfer of the British Rainfall Organization, the co-ordination is completed, and the compilation of information of all kinds about weather is recognised as a common public duty centred in the Meteorological Office.

At the same time, in the course of the year, by a decision of the War Cabinet on May 8, 1919, the Office itself has been "attached" to the Air Ministry; and, instead of deriving the public funds for its maintenance directly from Parliament through the Treasury, it will receive them through the Air Council, and the Air Minister will be responsible to Parliament for them. What modifications of procedure are involved in the change are not yet known.

Since the year marks so important an epoch in meteorological history, the anniversary meeting of the

[1] Abstract of the presidential address delivered to the Royal Meteorological Society on January 21 by Sir Napier Shaw, F.R.S.

society is an occasion on which we may commemorate those of our countrymen who have contributed to the organisation and development of meteorological science. From the time of the invention of the barometer by Torricelli in 1643, proceeding in chronological order, we find examples of the experimental investigation of the properties of air in the work of the Hon. Robert Boyle (1627), natural philosopher and philanthropist; of the design of meteorological instruments in Robert Hooke (1635), the first demonstrator of the Royal Society; of the compilation of observations at sea in the remarkable discourse on winds by William Dampier (1652), sailor and buccaneer; of meteorological theory in Edmund Halley (1656), natural philosopher and Astronomer Royal; in George Hadley (1686), a lawyer who explained the trade winds; and James Hutton (1726), a physician who developed a theory of rain.

Next come Richard Kirwan (1733), a weatherwise Irish gentleman, "consulted about the weather by half the farmers of Ireland," with ideas about the meteorology of the globe on the basis of the distribution of temperature; Charles Wells (1757), physician of St. Thomas's Hospital, who elaborated the theory of dew; John Dalton (1766), famous for his atomic theory, teacher of mathematics and natural philosopher of Manchester, who put the theory of water-vapour in the atmosphere upon a physical basis, a lifelong meteorological observer, and a student of the aurora, the height of which he measured successfully; Luke Howard (1772), a successful manufacturing chemist, an assiduous meteorologist who classified clouds, introduced automatic records of the barometer, discoursed on the climate of London, and studied the influence of the phases of the moon; Admiral Sir Francis Beaufort (1774), Hydrographer of the Navy, who devised the Beaufort scale of wind-force and the Beaufort alphabetical notation for weather at sea; Sir Edward Sabine (1788), Royal Engineer, secretary and, later, president of the Royal Society, and also general secretary of the British Association, who obtained the co-operation of those three great agencies in the magnetic survey of the British Isles, the trigonometrical survey of India, and the establishment of magnetic observatories in Toronto, St. Helena, the Cape, India, and elsewhere in the British Dominions, and of meteorological observations at all the foreign and Colonial stations of the Royal Engineers and Army Medical Department, and who lived long enough to become the first chairman of committee of the Meteorological Office; John Frederic Daniell (1790), professor of chemistry, the inventor of the Daniell cell and the Daniell dew-point hygrometer, a meteorological essayist, and a writer on artificial climates for horticulture; and, finally, William Reid (1791), major-general of the Royal Engineers, and Henry Piddington (1797), merchant seaman, author of "The Sailor's Horn Book," who made most notable contributions to the analysis of the phenomena of what the latter first called "cyclones," and are now in their various forms the familiar elements of interest in the daily charts of weather prepared by meteorological offices all over the world. William Whewell (1796), the omniscient Master of Trinity, may perhaps be added as representing anemometry, thus carrying on the story of weather science as developed by those born before the end of the eighteenth century, and so bringing the history to the middle of the nineteenth, when the society was founded.

These names and histories show from what various sources meteorology has derived its ideas, its initiative, and its support. In the future, as in the past, the science must preserve its wide outlook.

THE REDUCTION OF WAVE ACTION IN HARBOURS.

THE important question of the best means of effecting the maximum reduction of wave action in harbour areas formed the subject of four papers read before the Institution of Civil Engineers on January 13. Next to affording the readiest and safest accessibility under extremely adverse conditions of weather and tide, the exclusion of storm waves, or rather their reduction within limits of harmlessness, is the most pressing concern of the harbour engineer. Unfortunately, the conditions essential to the attainment of the former desideratum are not often conducive to the realisation of the latter. The criticism has been passed on at least one modern harbour of importance that in tempestuous weather the sea is as rough inside as outside. Where large areas have to be enclosed in order to afford the necessary accommodation for shipping, it is a matter of considerable difficulty to provide simultaneously the equally necessary degree of shelter.

Four river harbours—those at the mouths of the Tyne, the Wear, the Esk, and the Blyth, all on the north-east coast of England—were under consideration. In the first two the principle of wide encircling piers had been adopted, with an entrance width on the Tyne of 1200 ft. and on the Wear of 700 ft.; in the second two there is the contrast of a comparatively narrow way or passage from 200 ft. to 400 ft. in width between fairly, or roughly, parallel piers, with intercepting jetties, or wave-traps, at intervals in their lengths. The semicircular arms afford expanding areas of large proportions, wherein the entering waves are diffused and a large amount of their energy dissipates itself harmlessly on spending beaches flanking the entrance to the inner harbour. On the other hand, the openings provided in the overlapping sides of parallel piers deflect a certain portion of the wave from its course and pass it out again to sea. Both systems have their merits, and all the authors claimed that the desired results had been obtained by the method adopted in the particular cases. At Blyth sea-waves of 10 ft. to 12 ft. in height at the pierheads are reduced to 6 in. to 24 in. in mid-harbour, while at Sunderland the factor of wave-reduction is 65 per cent.

In forming a judgment on the respective claims, it must be borne in mind that much depends on the character of the port. Obviously, an internal wave action which might be without prejudicial effect on a large mercantile liner might be fatal to small fishing craft. It is difficult also to detach the problem from the particular conditions of site and coastal configuration. Spending beaches are no doubt admirable adjuncts to a harbour, but they are not always available, nor are the financial resources of ports always commensurate with bold and ample schemes of accommodation. With the means at his disposal, the task of the engineer is to secure the best compromise possible: an adequate degree of tranquillity combined with a serviceable entrance width. Circumstances may favour one method or the other. Even after general lines have been laid down, it will certainly be found wise to proceed tentatively and cautiously in the execution of the design. Much useful information can be gained during the progress of the work, and the exact position and width of the entrance may often be left to a late stage of the operations.

BRYSSON CUNNINGHAM.

ST. ANDREWS INSTITUTE FOR CLINICAL RESEARCH.

THE recent opening of an institute for clinical research in St. Andrews marks the beginning of a new era in the scientific development of the art of medicine. The enterprise has been initiated and brought to a happy stage of working order by Sir James Mackenzie, who is the director and controlling mind of its endeavours.

Briefly, the object of the institute is to investigate the early symptoms of disease before structural alterations in the body have had time to take place. Hitherto research has been mainly concerned with disease and its more advanced forms when structural and chemical changes can be detected by ordinary laboratory methods. But at the beginnings of disease symptoms of various kinds, often seemingly trivial, do occur. They become familiar to many general practitioners, though no serious attempt has been made to determine their cause and significance and to draw up a classification which will enable the medical man to appreciate their real meaning and thus put him into the position of being able to detect and arrest incipient disease.

For such purposes a small centre of population, where the same patients can be seen frequently and observed over long periods of time, is preferable to the larger centre with its rapidly moving population. St. Andrews should provide an ideal site, and has the further advantage of possessing a university and medical school with all that these imply. A suitable building has been secured overlooking the bay and in close proximity to the historic golf course.

The institute is affiliated to the University. Its staff consists of a director, a director of laboratory research, a trained biological chemist, a bacteriologist (to be appointed), a whole-time clinical assistant, and several part-time clinical assistants who are also practitioners in the town.

Three days a week patients are examined, and two days are given over to general discussions. The latter are wide in scope, and are freely opened to anyone who has anything to contribute. The trained logician and psychologist are especially welcome, and not infrequently join in the debate.

The institute is also educative, and aims at the training of the practitioner in the methods of research.

The institute has now been at work for some months, and is already bearing fruit. It has promoted harmony and goodwill and a keen interest in their work among its members. It provides an excellent model for the development of other centres, and shows how a spirit of co-operation can be fostered among medical men which is of mutual benefit to themselves and to their patients. The scientific results will follow.

P. T. Herring.

FISHERY INVESTIGATIONS IN SOUTH AFRICA.

THE Marine Biological Report of the Province of the Cape of Good Hope (No. 4) for the year ending June 30, 1918, has recently been received. The report is signed by Prof. J. D. F. Gilchrist, and although it appears that his department has been greatly restricted by lack of funds, it is clear that much useful work was done during the year under review. It is well known that a valuable industry in canning and exporting the local crawfish has been developed successfully at the Cape in recent years, and perhaps the most interesting feature of the report is an account of the habits of the different larval stages of this crustacean. The first larva of *Jasus lalandii* is small, somewhat opaque, and swims at the surface by its feather-like antennæ, the other appendages being folded close to the body and not used. This first stage, known as a "naupliosoma," continues for only a few hours, when it passes into the flattened "phyllosoma" stage. The larvæ in this stage are able to swim in a horizontal direction, but their natural habitat is still the surface waters. They were successfully reared, and after three or four days at most they passed into the third larval stage, in which they descend to the bottom and seek out the darkest corners. They then feed actively on the small animal and vegetable particles in the mud and sand, and are comparatively free from the attacks of their enemies. After undergoing a series of moults, which do not yet appear to have been followed in detail, the larva enters the "puerulus" stage, which has hitherto been found only close inshore.

Details of a number of experimental hauls for crawfish in different localities are given in the report, as well as an account of some marking experiments, which have thrown light upon the migrations of this crustacean. A useful list is added of the different species of lobsters and crawfishes found in South African waters, with short, popular descriptions drawn up by Mr. K. H. Barnard. Prof. H. B. Fantham contributes a short article on parasitic protozoa found in South African marine fishes, and the third and final list of Cape fishes, drawn up by the late Mr. W. Wardlaw Thompson, is included in the report. The strong recommendation of Prof. Gilchrist that the scientific fishery investigations, which have been suspended for a number of years, should now be resumed is one which will have the hearty support of all marine biologists, who know the valuable work which was formerly carried out under his direction.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Birmingham.—At the meeting of the council held on January 29, the Pro-Vice-Chancellor in the chair, Mr. C. Grant Robertson received a cordial welcome as Principal of the University.

The thanks of the council have been accorded to Mr. Arthur Serena for his generous offer to provide a sum of 5000*l.* towards the endowment of a department of Italian studies and a chair of Italian. Also to Mr. John Smith, of Edgbaston, for his offer to endow a prize for students in metallurgy in some educational establishment or establishments in Birmingham, to commemorate the contributions made by Prof. Turner to the science of metallurgy, to be known as "the Thomas Turner prize (or prizes) in metallurgy."

Lt.-Col. J. E. Dixon (Messrs. Rabone Bros.), Mr. Frank Gower (the Birmingham Aluminium Casting Co.), and Mr. Donald Hope (Messrs. Kynochs, Ltd.) have been appointed members of the Commerce Advisory Board.

Prof. John Robertson and Dr. C. J. Lewis have been appointed representatives of the University at the Congress of the Royal Sanitary Institute to be held in Birmingham in July next.

Mr. James Young has been appointed an assistant lecturer in the department of physics.

Cambridge.—The offer of a fund to endow a John Couch Adams astronomership in the University is announced. The offer was made by the late Mrs. Adams, widow of Prof. Adams, the discoverer of Neptune. The post, if established, is to be held by the director of the observatory unless he be at the same time a professor of the University, in which case it should be held by a duly qualified person of skill and experience in astronomy not necessarily a member of the University. The income of the fund is about 300*l.*

A further offer is made by the family of the late Dr. E. G. Fearnsides to endow an E. G. Fearnsides scholarship to further clinical research among the organic diseases of the nervous system. The scholarship would be held by Cambridge men for two years between the ends of their fourth and eleventh years. The award is biennial, and the income 50*l.* a year.

Mr. H. M. Fox, Mr. F. Debenham, and Mr. C. N. H. Lock have been elected fellows of Gonville and Caius College for research work in zoology, geology, and mathematics respectively.

LONDON.—Dr. Samuel Smiles has been appointed to the Daniell chair of chemistry tenable at King's College in succession to Prof. A. W. Crossley. Last year Dr. Smiles was appointed professor of organic chemistry at Armstrong College, Newcastle, and since 1913 he has been senior honorary secretary to the Chemical Society.

Dr. H. E. Roaf has been appointed to the University chair of physiology tenable at the London Hospital Medical College. From 1902 to 1905 Dr. Roaf held the Johnston Colonial fellowship in the University of Liverpool, where he has also been assistant lecturer on, and senior demonstrator of, physiology and histology and lecturer on chemical physiology. Since 1911 he has been lecturer on physiology at St. Mary's Hospital Medical School. For three years during the war he was in charge of the pathological laboratories at Cairo.

Prof. T. Swale Vincent has been appointed to the University chair of physiology tenable at the Middlesex Hospital Medical School. Prof. Vincent was formerly demonstrator of physiology in the University of Birmingham and Sharpey scholar and assistant professor of physiology at University College, London. Since 1904 he has been professor of physiology and biochemistry in the University of Manitoba.

The cordial thanks of the Senate have been voted to the general committee formed to promote the institution of degrees in commerce and the organisation of commercial education in the City of London and throughout the Empire for a gift of 50,000*l.* to be devoted to the extension of the buildings of the London School of Economics upon land provided for this purpose at a nominal rent by the London County Council.

A resolution was adopted by the Senate on January 28 expressing appreciation of the generosity of Messrs. S. B. and J. B. Joel in presenting 20,000*l.* for the endowment of a University chair of physics tenable at the Middlesex Hospital Medical School. Steps are being taken immediately for the appointment of the first incumbent of this professorship, which will bear the name of the donors.

The Franks studentship in archæology is open to a student qualified to undertake research or to prepare for the same. It is for the period of a year, and of the value of 50*l.* Full particulars are obtainable from the Academic Registrar of the University of London, South Kensington, and applications for the studentship must be received by, at latest, the first post of March 2.

The following doctorates have been conferred:—*D.Lit.*: Mr. R. E. M. Wheeler, an internal student, of University College, for a thesis entitled "Comparative Notes on Rhenish Pottery of the Roman Period." *D.Sc.* (*Engineering*): Mr. Marcel Tolkowsky, an internal student, of the Imperial College, City and Guilds College, for a thesis entitled "Diamond Grinding, Abrading, and Polishing."

MANCHESTER.—Mr. Frank Watts has been appointed lecturer in psychology in the University. Mr. Watts is the author of the recently published book, "Echo Personalities," a study of the contributions of abnormal psychology towards the solution of some problems of normal education.

OXFORD.—On February 3 Convocation resolved that Mr. E. S. Goodrich should be constituted professor of comparative embryology for so long as he holds the appointment of Aldrichian demonstrator in comparative anatomy. The resolution was proposed by the Rev. G. B. Cronshaw, Queen's College, and supported by Prof. Gilbert C. Bourne, Linacre professor of zoology and comparative anatomy.

The amended statute making the study of the Greek language optional for all students will come before Congregation on February 10. At a later date not yet fixed it will be submitted to Convocation. Opposition may be expected, as in many quarters it is not considered desirable that candidates for honours in such schools as that of "Literæ Humaniores" should be exempted from the study of Greek. If Prof. Gilbert Murray's amendment, exempting all science men, mathematicians, and passmen, had been carried, it is probable that no opposition would have been offered to the statute on the part of the advocates of Greek.

COMMDR. C. HAWKES has been appointed to succeed Prof. R. L. Weighton in the chair of engineering at Armstrong College, Newcastle-upon-Tyne.

DR. T. F. SIBLY, at present professor of geology at Armstrong College, Newcastle-upon-Tyne, has been appointed principal of the University College of Swansea.

SIR ARCHIBALD GARROD will deliver the Schorstein memorial lecture at the London Hospital Medical College on Friday, February 20, at 4 o'clock. The subject will be "Diagnosis of Disease of the Pancreas."

THE Women's Medical Association of New York City is offering the Mary Putnam Jacobi fellowship of about 200*l.* for post-graduate study in any country to any woman physician for work in any branch of medical science. Particulars are obtainable from Dr. Murrell, 86 Porchester Terrace, W.2.

THE lectures for teachers on recent developments in science arranged by the London County Council include a lecture on "Aviation" to be given by Mr. F. Handley Page at King's College, Strand, W.C.2, on Saturday, February 28, at 11 a.m. The chair will be taken by Sir Arthur Duckham, K.C.B.

A REUNION dinner of Old Centralians—the first to be held for six years—will take place on Saturday, February 21, at the Waldorf Hotel, Aldwych, W.C.2, tickets for which may be obtained from Mr. G. W. Tripp, Lyndhurst, Hayes Road, Bromley, Kent. We understand that Prof. Armstrong, Sir Alfred Keogh, and Prof. Unwin have accepted invitations to be present.

A CORRESPONDENT informs us that the New South Wales Parliament, in the session that closed in December last, passed an Act granting the University of Sydney a sum of 300,000*l.* for building purposes, the grant to consist of six annual instalments of 50,000*l.* The grant is in addition to the statutory endowment, and is called for by the rapid growth of all the departments of the University. It will allow the University to devote the whole of the McCaughey bequest to the extension of the present resources in staff and equipment, and the encouragement of research.

A SCHEME for the establishment of a University Bureau in the City of London in connection with the University of London commerce degree is described in the *Times* of January 30. It is proposed that the bureau shall assist in the suitable and wide employment of commerce degree students and graduates in all branches of trade and commerce throughout the country and assist employers in all matters affecting the training and employment of all such students and graduates. An initial sum of 50,000*l*. has been set aside for the purpose of establishing the bureau on a proper footing.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, January 22.—Sir J. J. Thomson, president, in the chair.—Prof. E. G. **Coker** and K. C. **Chakko**: The stress-strain properties of nitro-cellulose and the law of its optical behaviour. The physical properties of nitro-cellulose are studied from its behaviour in tension, whereby values of Young's modulus and Poisson's ratio are obtained and the form of the load-extension curve is determined. The optical properties of the transparent material are observed, with special reference to its behaviour under load; and it is shown, by observations with a comparison beam not stressed beyond elastic limit, that the relative retardation produced between the two components of a polarised beam is consistent with a linear optical stress law, which holds up to stresses of about twice those at the elastic limit. These results are confirmed by observations of the retardation bands produced in a polarised spectrum by a beam under uniform bending moment. The stresses and strains are deduced on the assumption of a linear stress-optical law, and stress-strain curve so obtained is found to agree with purely mechanical measurements of a tension member.—S. **Marsh**: Alternating-current electrolysis. The behaviour of platinum, gold, and nickel electrodes during the passage of an alternating current of 25 to 80 cycles per second has been examined. The electrolytes employed were dilute sulphuric acid and barium hydrate solution. Curves representing the relation between volume of gas evolved and time of passage of current are of two distinct types: (*a*) One type resembling "saturation-current" curves in radio-activity. This effect is shown clearly in the cases of platinum and gold in an acid electrolyte. (*b*) A second type in which the rate of evolution of gas falls off with time until ultimately a steady rate of evolution sets in, *decreasing* in value with *increasing* frequency of the alternating current. Two possible explanations of the phenomena are discussed: (*a*) Adsorption of hydrogen at an electrode during one half-period, followed by recombination with oxygen in the succeeding half-period. (*b*) Oxidation of the electrode by the oxygen of one half-period, followed by reduction of the oxide by the hydrogen of the succeeding half-period. Evidence is given that the oxidation theory successfully explains the effects with gold and nickel. In the case of platinum it is believed that oxidation plays a prominent *rôle*, though adsorption also may be effective in this case. It is shown that the electrodes have an initial surface activity in promoting recombination, which activity increases (*a*) with frequency of alternation, and (*b*) up to a maximum value with the time of passage of the current. If the current density is less than that corresponding to this maximum activity, then sooner or later evolution of gas ceases. If the current density is greater, then after a time gas is evolved at a steady rate.—W. H. **Eccles** and J. H. **Vincent**: The variations of wave-length of the oscillations generated by three-electrode thermionic tubes due to changes in filament current, plate voltage, grid voltage, or coupling. When electrical oscillations are sustained in a circuit comprising inductance and electrical capacity by aid of a three-electrode thermionic vacuum tube of the kind used in wireless telegraphy, the frequency of the oscillations and the wave-length of the radiation depend principally upon the values of the inductance and the electrical capacity, but also partly upon the resistance in the oscillatory circuit; upon the voltages of the various batteries in use; upon the temperature of the filament supplying the electrons; upon other properties of the vacuum tube; and upon the coupling between portions of the circuit associated with the grid and the anode. The object of the present investigation was to study experimentally the effects of altering each of the chief variables, with the view of finding the conditions most favourable for the production of continuous oscillations of constant frequency. For this purpose two circuits were sustained in oscillation at nearly the same high frequency, namely, about 120,000 vibrations per second, and the audible beat between these frequencies was observed. Then changes made in one circuit alone caused variations of frequency that were measurable by acoustic observation of the beat-note. The preliminary investigations showed that variation of the heating current of a filament was the most fertile source of erratic changes of frequency, and resulted in the discovery that increase in the filament current of one tube produced at low values of current a decrease of frequency, and at higher values an increase of frequency, while at a certain value of filament current the frequency had a stationary value. This phenomenon provides a method of setting an oscillation generator so as to produce a vibration of frequency constant to less than one part in 100,000. Provided with this knowledge, the other problems enumerated above were attacked. In an apparatus in which the inductance was eight millihenries, the electrical capacity 250 electrostatic units, and the wave-length 2750 metres, it was found that raising the voltage of the anode battery from 130 to 140 increased the wave-length by 6 metres, and raising the grid voltage by 1 increased the wave-length about 10 metres. The coupling in the circuit produced large effects by its variation.—S. D. **Carothers**: Plane strain: the direct determination of stress. It is pointed out in the first part of the paper that in plane strain the stresses, if determined directly, are usually obtained by the aid of the well-known stress function method. The problem is usually that of finding a function χ satisfying $\nabla_1^4\chi=0$ throughout the body, with suitable values of χ over the various boundaries. The most general value of χ in Cartesian co-ordinates appears to be

$$\chi = A\theta + Bx\theta + Cy.\theta + D(x^2+yY\theta),$$

where A, B, C, and D are any constants and θ is any plane harmonic function. It is shown that for any orthogonal co-ordinates the stresses derived by the stress-function method when applied to $\chi=(x^2+y^2)\theta$ can always be resolved into two distinct sets, while in the case of Cartesian co-ordinates the stresses can be split up into four distinct sets. In view of the foregoing, the present paper has for its object the determination of the various sets of stresses which might legitimately occur in a state of plane strain, expressed in the simplest possible terms, with the view of rendering the building up of a given state of stress a manageable operation. The paper sets forth the usual stress equations of equilibrium, and gives the identical relation between the strain components expressed in the various systems of co-ordinates. The various possible stress sets in rectangular and polar co-ordinates are then set forth in order, after which the solutions in orthogonal curvilinears are obtained in such a manner as generally to show their connection with those formerly given. The second part of the paper applies the results obtained to the solution of some examples.—F. **Horton** and Ann C. **Davies**: An investigation of the effects of electron collisions with platinum and with hydrogen, to ascertain whether the production of ionisation from platinum is due to occluded hydrogen. The effects of bombarding a platinum surface by electrons the velocity of which could be gradually increased have been investigated by methods in which these effects were detected when superposed on the original electron current, and also when they were measured independently. It has been found that a genuine ionisation by electron impacts is produced at a minimum electron velocity of 13·0 volts, but that up to electron velocities of 30 volts no detectable amount of radiation capable of acting photo-electrically on platinum is obtained. In order to ascertain whether the ionisation produced at a minimum electron velocity of 13·0 volts arises from the platinum or from hydrogen attached to its surface, the effects of electron collisions with hydrogen were investigated in the same apparatus. A radiation was detected from this gas at a minimum electron velocity of 10·5 volts, and a second type of radiation at a minimum electron velocity of 13·9 volts. Three types of ionisation were also detected, beginning when the electrons acquired velocities of 13·0 volts, 14·4 volts, and 16·9 volts respectively. The first of these types is the ionisation obtained in a high vacuum, and experiments described in the paper show that this is not due to hydrogen, but arises from the platinum itself. From the experiments in hydrogen it is concluded that the minimum electron velocity for the production of radiation from a hydrogen atom is 10·5 volts, the minimum electron velocity for ionisation of the atom 14·4 volts, and the minimum electron velocity for ionisation of the molecule 16·9 volts. These results are in general agreement with the deductions from Bohr's theory. The second type of radiation, beginning at an electron velocity of 13·9 volts, is attributed to the hydrogen molecule.—L. **Bairstow**, R. H. **Fowler**, and D. R. **Hartree**: The pressure distribution on the head of a shell moving at high velocities. This paper describes a first attempt to measure the pressure distribution on a body moving through a gas at velocities equal to or greater than the velocity of sound a in the gas. The body in question is a spinning shell, moving along its axis of symmetry, and the gas, air. The pressure at a given distance from the nose is communicated to a chamber in the head of the shell, and deduced from the time of burning a train of powder in this chamber, which is a quantity that can be directly observed. By a series of such observations the pressure at a given point of the head is determined as a function of the velocity ratio v/a, where v is the velocity of the shell relative to the air. Curves are obtained showing the variation of the pressure for values of v/a from 0·04 to 1·4, and for four different positions on the head of the shell.

PARIS.

Academy of Sciences, December 29, 1919.—M. Léon Guignard in the chair.—G. **Bigourdan**: The work of Lalande and his pupils at the Mazarin College.—H. **Deslandres**: Remarks on the constitution of the atom and the properties of band spectra. Completing four earlier communications on the same subject.—P. **Termier** and G. **Friedel**: The foldings and drift which have broken the Gard coal basin; probably Alpine movements of Miocene age.—A. **Blondel**: Graphical study of the working of audions with resonating circuit as sensitised receivers or as dampers.—C. **Sauvageau**: The parasitism of a red alga, *Polysiphonia fastigiata*.—F. **Carlson**: A property of polynomials of one variable.—M. **Mesnager**: Method of determination of the internal strains existing in a circular cylinder. The method employed by M. Portevin in a recent communication on the same subject, due to Heyn and Bauer, is faulty, as it only takes into account the tensions parallel to the axis of the cylinder. An outline of a more exact method is given.—J. **Amar**: A machine for cutting out brushes. This instrument has been specially designed for use by the blind.—E. **Kohn-Abrest**: Aluminium spontaneously oxidisable in the air. M. Guillet has recently described some aluminium alloys which undergo oxidation in the air. Some years ago the author found that aluminium could be volatilised in a vacuum at 1100° C., and the portion remaining unvolatilised sometimes proved to be spontaneously oxidisable. No satisfactory explanation of the phenomenon could be found.—N. R. **Dhar** and G. **Urbain**: The polarisation electromotive forces of iron in solutions of complex salts. Relation between these electromotive forces and the disappearance of the analytical characters of ferric ions. Measurements are given for ferrous and ferric salts, ferrocyanides, ferrioxalates, ferricyanides, and nitro-prussides.—E. **Wourtzel**: The dissociation constant of nitrogen peroxide.—L. **Vallery**: The estimation of arsenic in tin and in tinned articles. The arsenic is first separated by distillation as chloride and reduced to colloidal arsenic, and determined in a colorimeter. The determination of arsenic in tin by Marsh's method is liable to serious error.—A. **Meyer**: The estimation of thiophen in benzene.—A. **Kling** and D. **Florentin**: The production of carbon monoxide in flames of different gases. Carbon monoxide is mainly produced by sudden cooling of the flame; the amount is increased by contact with the mantle of an incandescent burner.—M. **Zeil**: Correlations between the Quaternary terraces, glacial recurrence, and upward movements of the earth's crust.—J. **Bourcart**: Cretacean and Lower Eocene formations and their extension in central and southern Albania.—Ph. **Glangeaud**: The reconstitution of a long lake depression which during the Oligocene period occupied the great coal cut of the Central Massif.—Ch. **Pussenot**: Glacial recurrences later than the "Néowürmien" in the massifs of the Aiguille de Polset (Tarentaise), of Mont Thabor, and of the Aiguille de Scolette (Maurienne).—W. **Kilian** and Ch. **Pussenot**: The age of the tufa-bearing human remains at Villard de Bozel (Savoie).—Ch. **Maurain**: The wind velocity in the stratosphere. There is a maximum mean wind velocity (14·55 metres per second) at a height of about 11,000 metres, falling to 8·04 metres per second at 19,000 metres altitude.—MM. **Stapfer** and **Moleski**: Remarks on snowfalls. Two cases are considered, the first when the snow has already been formed in the northern regions and the second when it is formed near where it falls. The conditions existing on the occasion of the fall of snow at Paris on November 3 are examined, and found to confirm the views expressed in earlier communications.—P. **Carles**: The blue *casse* of wine. Criticisms on a recent communication by M. Piedallu.—M. **Gard**: Biology of a new species of Euglæna (*E. limosa*).—L. **Lapicque**: Seasonal variation in the chemical composition of marine algæ. There is a great variation in the amount of soluble carbohydrate in *Laminaria flexicaulis*. These attain a maximum in August and September, and fall to a minimum at the end of the winter. The changes in ash are in the inverse direction.—MM. G. **Bertrand**, **Brocq-Rousseu**, and **Dassonville**: Comparative action of chloropicrin on the weevil and on Tribolium. The two parasites possess unequal resisting powers towards chloropicrin vapour, the Tribolium requiring longer exposure for its destruction.—M. **Caullery** and F. **Mesnil**: *Ancyroniscus Bonnieri*, a new species, parasite of *Dynamene bidentata*.—M. **Nicolle**, E. **Debains**, and E. **Césari**: The mutual precipitation of toxins and their antitoxins. Application to the titration of antidiphtheritic and antitetanic sera. The method of titration *in vitro*, for which great economy of time and money is claimed, has been proved to correspond with tests made *in vivo*.

MELBOURNE.

Royal Society of Victoria, December 11, 1919.—Mr. F. H. Wisewould, vice-president, in the chair.—F. **Chapman**: Tertiary fossils from Ooldea: Additional note. The author records a further series of fossils from this locality, collected by F. A. Cudmore, which confirms his earlier determination of their Miocene age.—Ellinor **Archer**: Longevity of cut flowers. Preliminary observations were made on Acacia blossoms and other plants. A solution of lead nitrate gave good results in preventing the vessels from being blocked, allowing the blossoms to last for weeks instead of days. Silver nitrate also acted in the same way, but not so efficiently.—E. **McLennan**: The endophytic fungus of Lolium: its development, distribution, and function. Instead of being parasitic, this fungus is now an essential part of the plant and plays an important *rôle* in the ripening of seed. In the ripe seed the remains of the hyphæ persist mainly in the resting endospermic combium (aleurone layer).—Jean **Shannon**: The structure of *Megascolex Fletcheri*, sp.nov. This is one of the few Australian earthworms which have been carefully worked out in detail.—J. T. **Jutson**: Notes on dust-whirls in sub-arid Western Australia. The author has had good opportunities of studying these and other æolian agencies. The occurrence of dust-whirls is practically confined to the summer months. Their general mode of rotation is counter-clockwise, although some are observed to take place in the opposite direction.—A. V. E. **James**: The physiography and geography of the Bulla-Sydenham area. In this paper a detailed account is given of the palæography of the Saltwater River and Deep Creek, the age and fossiliferous contents of the sedimentary rocks between Bulla and Keilor, and the occurrence of the igneous rocks in this area, including basalt and kaolin.

DIARY OF SOCIETIES.

THURSDAY, FEBRUARY 5.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. A. E. Conrady: Recent Progress in Applied Optics.

ROYAL SOCIETY, at 4.30.—J. H. Jeans, Prof. A. S. Eddington, Sir F. Dyson, Prof. A. Fowler, E. Cunningham, Prof. H. F. Newall, Prof. F. A. Lindemann, and possibly Sir J. Larmor: Discussion on the Theory of Relativity.

LINNEAN SOCIETY, at 5.—Dr. R. Ruggles Gates: The Existence of Two Fundamentally Different Types of Characters in Organisms.

ROYAL INSTITUTE OF PUBLIC HEALTH, at 5.—Dr. E. C. Morland: Climate in Tuberculosis.

CHEMICAL SOCIETY, at 8.—(Ordinary Meeting, followed by an Informal Meeting.)

ROYAL SOCIETY OF MEDICINE (Obstetrics and Gynæcology Section), at 8.—Dr. Goodall: The Origin of Tumours of the Ovary.—G. Ley: A Statistical Report of Carcinoma of the Ovary as met with in the Pathological Institute of the London Hospital between the years 1907–1919 inclusive, showing the Relative Frequency of Primary and Secondary Ovarian Carcinoma.

FRIDAY, FEBRUARY 6.

GEOPHYSICS COMMITTEE (at Royal Astronomical Society), at 5.—Sir Charles Parsons and Others: The Practicability of, and Scientific Advantages to be derived from, a Deep Boring.

ROYAL COLLEGE OF SURGEONS, at 5.—V. Z. Cope: The Surgical Aspect of Dysentery.

CONCRETE INSTITUTE (at Denison House, 296 Vauxhall Bridge Road), at 6.—H. J. G. Bamber: The Practical Testing of Cement.

INSTITUTION OF ELECTRICAL ENGINEERS (Students' Meeting) (at the City and Guilds (Engineering) College), at 7.—F. R. Housden: Electric Lifts and Cranes.

JUNIOR INSTITUTION OF ENGINEERS (at 39 Victoria Street), at 7.30.—Capt. J. Bradford: Tank Work in the Army.

TECHNICAL INSPECTION ASSOCIATION (at the Royal Society of Arts), at 7.30.—J. Waite: The Treatment of Steel.

ROYAL SOCIETY OF MEDICINE (Anæsthetics and Laryngology Sections), at 8.30.—Dr. F. S. Rood and Others: Discussion on Anæsthesia in Throat and Nose Operations.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Prof. Sir Walter Raleigh: Landor and the Classic Manner.

SATURDAY, FEBRUARY 7.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir F. W. Dyson: The Astronomical Evidence bearing on Einstein's Theory of Gravitation. II. Displacement of Solar Spectral Lines.

MONDAY, FEBRUARY 9.

ROYAL GEOGRAPHICAL SOCIETY (at Lowther Lodge), at 5.—Capt. H. Alan Lloyd: Characteristics of the Ground as seen from the Air.

ROYAL COLLEGE OF SURGEONS, at 5.—H. T. Gray: The Influence of Nerve Impulses on Gastro-intestinal Disorders.

BIOCHEMICAL SOCIETY (at Imperial College of Science and Technology, Botany Building), at 5.30.—H. Chick and E. M. Hume: Production in Monkeys of Symptoms closely Resembling Pellagra, by prolonged Feeding on a Diet of Low Protein Content.—C. C. Wood and S. B. Schryver: Demonstration of Method of Determining the Methoxyl Groups in Plant Tissues.

ROYAL SOCIETY OF MEDICINE (War Section), at 5.30.—Sir Wilmot Herringham and Others: Discussion on Gas Poisoning.

INSTITUTION OF MECHANICAL ENGINEERS (Graduates' Association), at 8.—Dr. C. C. Carpenter: Fuels.

MEDICAL SOCIETY OF LONDON, at 8.30.—Dr. H. Drinkwater: The Clinical or Naked Eye Diagnosis of Diphtheria and other Infections of the Fauces.—Dr. T. B. Hyslop: Some New Methods of Illustration.

TUESDAY, FEBRUARY 10.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. G. Elliot Smith: The Evolution of Man and the Early History of Civilisation. III. The Search for Gold.

ROYAL SOCIETY OF MEDICINE, at 5.—Prof. A. D. Waller: The Measurement of Human Emotion and of its Voluntary Control (Occasional Lecture).

INSTITUTION OF CIVIL ENGINEERS, at 5.30.—P. M. Crosthwaite: Experiments on the Horizontal Pressure of Sand.—Dr. A. R. Fulton: Overturning Moment on Retaining-Walls.

ZOOLOGICAL SOCIETY OF LONDON, at 5.30.—Dr. P. Chalmers Mitchell: Report on the Additions made to the Society's Menagerie during the months of November and December, 1919.—R. I. Pocock: Exhibition of Photographs of a Chinese Serow.—H. R. Hogg: Some Australian Opiliones.—Dr. C. F. Sonntag: Description of the Larynx and Œsophagus of a Common Macaque, exhibiting several unusual Features.—R. E. Turner and J. Waterston: A Revision of the Ichneumonid Genera Labium and Pœcilocryptus.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—Annual General Meeting.

QUEKETT MICROSCOPICAL CLUB, at 7.30.—Annual General Meeting.

WEDNESDAY, FEBRUARY 11.

ROYAL UNITED SERVICE INSTITUTION, at 3.—Col. F. C. Fuller: The Tank Corps.

ROYAL SOCIETY OF ARTS, at 4.30.—Lieut.-Comm. N. Wilkinson: Naval Camouflage.

ROYAL COLLEGE OF SURGEONS, at 5.—J. Sherren: The Late Results of the Surgical Treatment of Chronic Ulcers of the Stomach and Duodenum (Hunterian Lecture).

THURSDAY, FEBRUARY 12.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. A. E. Conrady: Recent Progress in Applied Optics.

ROYAL SOCIETY, at 4.30.—*Probable Papers*: J. W. McBain and C. S. Salmon: Colloidal Electrolytes. Soap Solutions and their Constitution.—C. C. Farr and D. B. Macleod: The Viscosity of Sulphur.—C. V. Raman and B. Banerji: Kaufman's Theory of the Impact of the Pianoforte Hammer.—Commander T. Y. Baker, R.N., and Prof. L. N. G. Filon: A Theory of the Second Order Longitudinal Spherical Aberration for a Symmetrical Optical System.—Dr. S. Chapman: A Note on Dr. Chree's Discussion of Two Magnetic Storms (Title only).—Dr. C. Chree: An Explanation of the Criticisms on Dr. Chapman's Recent Paper "An Outline of a Theory of Magnetic Storms" (Title only).—Prof. J. W. Nicholson: The Lateral Vibrations of Sharply Pointed Bars.—R. E. Slade: A New Method of Spectrophotometry in the Visible and Ultraviolet and the Absorption of Light by Silver Bromide.

BRITISH PSYCHOLOGICAL SOCIETY (Education Section) (at London Day Training College), at 6.—Dr. C. W. Kimmins: The Dreams of Children in Blind, Deaf, and Industrial Schools.

INSTITUTION OF ELECTRICAL ENGINEERS (at Institution of Civil Engineers), at 6.—Major K. Edgcumbe: The Protection of Alternating-current Distribution Systems without the Use of Special Conductors.

OIL AND COLOUR CHEMISTS' ASSOCIATION (at 2 Furnival Street), at 7.—Dr. R. S. Morrell: Colloid Chemistry of Paints and Varnishes.

OPTICAL SOCIETY, at 7.30.—J. W. French: The Surface Layer of an Optical Polishing Tool.—Mrs. C. H. Griffiths: Aberration Effects in Star Images.—R. W. Cheshire and W. Shackleton: The Testing of Heliograph Mirrors.

INSTITUTION OF AUTOMOBILE ENGINEERS (Graduate Section) (at 28 Victoria Street), at 8.—F. R. Cowell: Steering Gears.

ROYAL SOCIETY OF MEDICINE (Neurology Section), at 8.30.—Dr. Rows: Anxiety States.

FRIDAY, FEBRUARY 13.

ROYAL ASTRONOMICAL SOCIETY, at 5.

PHYSICAL SOCIETY, at 5.—Prof. C. H. Lees: Presidential Address.—Sir Arthur Schuster: Atmospheric Refraction during Total Solar Eclipses.—To be followed by the Annual General Meeting.

ROYAL COLLEGE OF SURGEONS, at 5.—W. G. Spencer: The Historical Relationship between Experiments on Animals and the Development of Surgery.

MALACOLOGICAL SOCIETY OF LONDON (at the Linnean Society), at 6.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Prof. W. M. Bayliss: The Volume of the Blood and its Significance.

SATURDAY, FEBRUARY 14.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir F. W. Dyson: The Astronomical Evidence bearing on Einstein's Theory of Gravitation. III. Deflection of Light in the Sun's Gravitational Field.

ASSET AND OBLIGATION.

WE referred in our issue of January 29 to an appeal made by University College, London, for 100,000*l.* for the extension of its engineering school. The work done there since its foundation in 1828 has been of such outstanding value that it should stimulate a ready response in the form of generous subscriptions to the amount required for the desired extension. The need is now very urgent, as the college, like others, has been compelled to refuse a large number of applications for admission by well-qualified candidates owing to lack of accommodation in the lecture rooms, drawing offices, and laboratories.

University College was the first in London to establish a school of engineering, soon after its foundation in 1826, and it has maintained its courses of study in this branch of applied science ever since as a potent and living force. It has always had the advantage of the guidance of distinguished engineers for its teaching, and they have greatly assisted the advancement of engineering by their inventions and contributions to applied science, as well as by their distinction in practical engineering affairs. Among these in its early days were three Fellows of the Royal Society—Eaton Hodgkinson, a great authority on the strength and testing of materials, notably in connection with columns, and C. B. Vignoles, also widely known on questions relating to railways, while William Pole exercised a great influence on contemporary engineering as secretary of the Institution of Civil Engineers. Other distinguished men of a somewhat later period are George Fuller, the inventor of a well-known form of slide-rule, and the eminent electrician, Fleeming-Jenkin, who for a short period was professor of civil engineering.

The advent of Prof. A. B. W. Kennedy (now emeritus professor) in 1874 marked a new epoch in its influence on contemporary thought in engineering science, since it was mainly due to his efforts that engineering laboratory training on a practical scale was initiated, and this has now become universal. Besides this notable achievement, Prof. Kennedy's activities during his fourteen years as professor there were remarkable for their extent and variety; he was famed alike for his work as an original investigator in such matters as riveted joints, marine engines, boilers, and kinematical science, and as an authority on a wide range of civil engineering practice, and still later as one of the foremost electrical engineers of his time. The keynote to his success as a teacher was mainly derived from his clear exposition of principles and their application in well-devised experiments in the laboratory. The effect of his teaching may be traced in the successful careers of his many students, of whom perhaps the best known are Sir Ernest Moir, Bart., a leading authority on harbours and tunnels, and Sir Alexander Gibb, whose firm is responsible for the construction of H.M. Dockyard at Rosyth. Municipal engineering, under the fostering care of the late Prof. Osbert Chadwick, has now become an important department. In the field of electrical science Dr. J. A. Fleming, the present professor of electrical engineering, has, for more than thirty years, had a far-reaching influence, not only by his great gifts as a teacher, but also as an investigator of rare capacity, particularly on alternating currents and on wireless telegraphy and telephony. Especially important are the services which Dr. Fleming has rendered to telephony by the invention of the thermionic valve, but these are too well known to need recapitulation to scientific readers.

The engineering school at University College is an element, and an important one, in the University of London, the largest university of the Empire, in the richest city, and probably the least well off when its size is taken into consideration. In University College alone there are more than 2200 students, without taking into account the medical students in University College Hospital. There will be many more if its buildings can be enlarged, as they must be if the University is to do its proper work.

During the war the staff and buildings of the college, like those of similar institutions, were utilised to their fullest extent in scientific work of the highest importance to the effective prosecution of the conflict, and now that it has come to a successful conclusion the men who guide public opinion are unanimous in declaring that one of the most important duties is to provide our universities with adequate means for the scientific training of our most precious asset, "brains," for the future guiding and directing of one of our greatest industries. Civic pride in the University will, we hope and believe, be sufficient to ensure that the engineering students of University College do not lack the modest range of buildings and equipment required to give them their chance in life, and for which its engineering committee now confidently appeals to the citizens of London to provide.

A very good start has been made by a contribution of 10,000*l.* from Lord Cowdray, with a promise of another 10,000*l.* when 70,000*l.* has been reached. The members of the family of the late Mr. Charles Hawksley have contributed 3000*l.* towards the extension of the hydraulic laboratory. Other gifts bring the total up to about 30,000*l.*, apart from Lord Cowdray's contingent promise. London is now offered an excellent opportunity of showing its appreciation of the asset it possesses in the engineering department of the college, and of discharging its obligations to an essential factor of modern progress. We look to men of means in the City and county of London to respond readily and generously to the appeal. Donations should be sent to H.R.H. Prince Arthur of Connaught, who is president of the Equipment and Endowment Fund, at his residence, 42 Upper Grosvenor Street, W.1.

INDUSTRIAL CHEMISTRY.

(1) *Industrial Gases.* By Dr. Harold Cecil Greenwood. (Industrial Chemistry.) Pp. xvii+371. (London: Baillière, Tindall, and Cox, 1920.) Price 12*s.* 6*d.* net.

(2) *The Condensed Chemical Dictionary: A Reference Volume for all requiring Quick Access to a Large Amount of Essential Data regarding Chemicals and other Substances used in Manufacturing and Laboratory Work.* Compiled and edited by the editorial staff of the Chemical Engineering Catalog. Pp. 525. (New York: The Chemical Catalog Co., Inc., 1919.) Price 5 dollars.

(1) A MELANCHOLY interest attaches to this book, which of itself would disarm any adverse criticism, even if such were called for. Its author, a comparatively young man, died on the eve of its publication. After a brilliant career at the University of Manchester, of which he was a Beyer Fellow, and where he graduated as a Doctor of Science, Dr. Greenwood worked as an 1851 Exhibition scholar for some years under Prof. Haber at Karlsruhe on the synthetic production of ammonia. During the war he became connected with the research laboratory of the Ministry of Munitions, and was engaged in the inquiry initiated by the Munitions Inventions Department on the industrial manufacture of synthetic nitrogen products. His services were recognised by the O.B.E. awarded to him in 1919. In a foreword to the book, Dr. J. A. Harker, under whom the author served, pays a graceful tribute to his memory.

Dr. Greenwood's published work and experience rendered him exceptionally well qualified to undertake the preparation of the book under review. We can unreservedly commend it. It is a well-written, scholarly production, judiciously put together with a conscientious determination to make it an accurate presentation of contemporary knowledge. As the author points out in his preface, its title implies a more comprehensive treatise than it actually is; many industrial gases, such as chlorine, hydrochloric acid, ammonia, acetylene, etc., find no place in it, as these are treated in other books in the same series. He confines himself to the gases of the atmosphere, hydrogen, the oxides of carbon, sulphur dioxide, nitrous oxide, and certain substances which have been used in gas-warfare, and he devotes a special section to fuel gases, on account, as he states, of the intimate connection of their methods of production with the general question of industrial gases.

The main subject of the book is introduced in a chapter on the more important fundamental physical and physico-chemical principles forming the basis of technical gas reactions, although no attempt is made to give a detailed theoretical treatment of the various generalisations to which reference is necessarily made. In this chapter the gases in general are treated comprehensively, and the numerical values of their various constants are grouped together in a series of tables. This method, no doubt, has certain advantages, as it enables rapid comparison to be made between individual gases, but when we come to their detailed study it involves a good deal of turning backwards and forwards. It would have added little to the size of the book, and would certainly have increased the convenience of handling it, if the various constants and factors had been repeated in the special accounts of the several gases. The author would seem to have been primarily concerned with the general principles of gas technology and their elucidation rather than with the minute treatment of individual gases. As might be expected from his experience, which had been latterly almost wholly directed to problems arising out of the war, such questions as the manufacture of hydrogen for aeronautical purposes and for the synthetic production of ammonia naturally receive special attention. Naturally also, he devotes much consideration to the question of gaseous equilibria and to that of heterogeneous catalytic gas reactions, without doubt among the most important matters in modern chemical technology. The entire chapter is worthy of the serious study of all engaged in the technical production of gases and in the working of processes depending upon their reactions. The superintendence of such processes is frequently left wholly to the engineer, who is often imperfectly acquainted with the physico-chemical principles on which they are based. Modern methods involving thermodynamical and thermochemical principles are becoming of so complex a character that their satisfactory working can be assured only when they are under the joint control and co-operation of both chemists and engineers.

A chemist, like the present writer, whose memory goes back some fifty years, will read this book with a special interest, and, if his scientific imagination is not dulled with age, he will experience a grateful sense of satisfaction that he has lived to see the extraordinary development it records. The whole story, indeed, reads like a romance; even Jules Verne in his wildest flights never imagined anything so astonishing as is revealed in this sober, matter-of-fact account which Dr. Greenwood has put together. Compare, for instance, the non-metallic section of an early or even of a late edition of Miller's "Inorganic Chemistry"—an excellent book in its day—with the present volume. One thus acquires an impression almost startling in its intensity of the changes which the last half-century has witnessed, even in matters of which the scientific history seems completed. The liquefaction of the so-called permanent gases; the industrial application of the Joule-Thomson effect; the manufacture of liquid air, its commercial application, and the fractional separation of its constituents; the discovery of argon and its allies—no longer the "tramps" of the chemical elements "who never did an honest day's work in their lives," but now turned to useful account—the isolation of terrestrial helium, its manufacture, and its use in aeronautics; the direct transformation of the "inert" nitrogen into products which serve to increase the food of man, and thus stave off the catastrophe which the late Sir William Crookes foreshadowed; the application of hydrogen in the production of fats: all this and more is set forth with the precision, impartiality, and unimpassioned detail of the man of science—"the matter of fact being barely stated without any prefaces, apologies, or rhetorical flourishes," to quote the words of the old statute of the Royal Society.

One closes this book with profound regret that its author's untimely death should have ended a career so full of promise.

(2) "The Condensed Chemical Dictionary," published by the Chemical Catalog Co., of New York, is a characteristic American production. To parody Thackeray's well-known phrase, it is written—or, rather, compiled—by hustlers for hustlers. It is one of those books which "Elia" would have stigmatised as "no book." It has no valid claim to be regarded as a contribution to chemical technology. It is apparently intended for the office-desk of the wholesale distributor or forwarding agent of chemical products who may wish to know something—but not too much—of the nature of the substances with which he deals; how they are made; what are their "grades" and uses; how they should be packed; what is their "fire hazard"; and what regulations the shipping and railroad companies impose on their transit. It makes ample allowance for the ignorance of clients, and does everything possible to facilitate business. Should further information be needed it is suggested that reference should be made to other works of a similar character published by the "Catalog Company."

The plan of the Dictionary may best be illustrated by an example:—

"Acetamide * (acetic acid amine), CH_3CONH_2.
Color and properties: Colorless crystals; mousy odor.
Constants: Specific gravity, 1·139; melting-point, 82° C.; boiling-point, 223° C.
Soluble in water and alcohol.
Derivation: By the interaction of ethyl acetate and ammonium hydroxide.
Method of purification: Crystallisation.
Grades: Technical.
Containers: Wooden barrels.
Uses: Organic synthesis.
Fire hazard: None.
Railroad shipping regulations: None."

The asterisk signifies that the substance is made in America.

All the entries, together occupying more than 500 pages of a large octavo volume, are arranged in this manner. The cast-iron uniformity of the plan imposed upon the compilers occasionally gets them into trouble. Thus in the case of fluorine, which the Dictionary informs us is manufactured in the States for organic synthesis, no practical container has been devised, as all ordinary substances are attacked by it. Nevertheless, a green label is directed to be attached to the vessel which holds it should it be sent by rail.

Standard works have been consulted in the compilation, and care appears to have been used in the selection of recent and accurate numerical data. A number of useful tables are given in an appendix, together with a list of definitions of physical and other units in common use, and the whole concludes with a statement of the regulations governing the transportation of dangerous articles, other than explosives, by freight and express.

THE ORIGIN OF PLANT LIFE ON LAND.

Thalassiophyta and the Subaerial Transmigration. By A. H. Church. (Botanical Memoirs, No. 3.) Pp. 95. (London: Oxford University Press, 1919.) Price 3s. 6d. net.

MR. CHURCH has produced a very serious contribution to the discussion of the sources of plant life on land. No one interested in this question can neglect his work. The statement is attributed to Weismann that the birthplace of all animal and plant life lies in the sea. Mr. Church circumscribes that thesis in his opening words, "The beginnings of botany are in the sea"; and his essay has as its object to demonstrate that the land flora originated, as the primal land-surfaces rose gradually above the ocean, from a marine flora already fixed upon its shores. He designates as "Thalassiophyta" the whole of the salt-water vegetation, and as "Xerophyta" the whole of the land flora. The former he divides again into Plankton and Benthos, pointing out that Plankton responds to the single factor of water, Benthos to the two factors of water and substratum, while Xerophyton responds to the three factors of water, substratum, and air. His main thesis is that the last was derived from the higher types of Benthos. "Processes of conduction and absorption involving roots and tracheides are initiated, and such departures superimposed on a seaweed soma." "The tetraspores of the sea become 'homosporous,' air-dried, and wind-borne" (p. 44).

Thus the evolution of a land flora was a phase of transition *in situ* rather than involving a preliminary landward migration, *via* fresh water. The successful transmigrant algæ of the first land migration combined the best and highest factors of marine equipment, as illustrated in many surviving groups. At the outset Mr. Church separates the problem of this migration from the origin of a cytological cycle, maintaining that the latter was already established before the migration took place. For these conclusions argument is produced rather than fact; indeed, there appears to be no new body of fact in the whole memoir. The author remarks incidentally that homoplasy and convergence have been much neglected. We agree; but may not they explain much of what he interprets as evidence of a direct migration?

Two serious omissions appear in the memoir. There is no reference to the important discoveries of Lower Devonian fossils in the Rhynie Chert, though the description of Rhynia was published early in 1917. Kidston and Lang give positive fact as to the structure of one of the earliest known land-plants; and secure fact is worth a vast amount of surmise and argument. Nor does Mr. Church refer to the question of transference of the tetrad-division in the course of descent to a fresh position in the life-cycle, though Svedelius had raised that question in 1916, and adduced facts very pertinent to it. Such facts, and the arguments that may be based upon them, might, if they had been taken into account, have materially affected Mr. Church's statements.

Notwithstanding such omissions, the memoir is a real contribution to morphological thought. It may be that Mr. Church has over-accentuated the directness of the origin of land-plants from marine forms. But he has carefully protected himself by saying that "no Phæophycean or Floridean passed on to higher autotrophic land-flora" (p. 42). The cautious philosopher, while sympathising with Mr. Church's general thesis, would probably prefer to give greater elasticity to it, seeing in the modern marine flora suggestions upon which to base hypotheses rather than those blunt statements of conclusion which find their place in Mr. Church's pages. However that may be, the effect of "Thalassiophyta" will be to direct attention, which was already swinging that way, more definitely towards marine rather than to fresh-water algæ, as a probable source of land vegetation. Though some of Mr. Church's conclusions may not find wide acceptance, the memoir is the most thoughtful contribution to the question in recent years, and it is full of originality and of interesting though bluff criticisms.

F. O. B.

NORMAL AND MORBID PSYCHOLOGY.

Mind and its Disorders: A Text-book for Students and Practitioners of Medicine. By Dr. W. H. B. Stoddart. Third edition. (Lewis's Practical Series.) Pp. xx+580. (London: H. K. Lewis and Co., Ltd., 1919.) Price 18s. net.

A REVIEW of the new edition of this well-known text-book is justified by extensive modifications corresponding to the author's conversion to the doctrines of Freud. The volume contains in 572 pages an account of normal and morbid psychology—including the tracing of all mental processes in psychological terms to their original elements and their correlation with their neural equivalents—of the clinical forms of all the neuroses and psychoses and their investigation and treatment, of the diseases to which the insane are specially liable, and of the legal relations of insanity.

Most modern problems in all these subjects are touched upon, and the book provides the sort of knowledge required by the student and general practitioner and a starting point from which the serious study of one of these branches might be begun.

Necessarily the accounts given are summary, and perhaps dogmatism is also necessary, but some of the matter included might give way to at least a brief statement of the other side of the case. The enunciation of the James-Lange theory of emotion at the present day without reference to any opposition except a footnote controverting deductions from Sherrington's dog is somewhat misleading.

A similar lack of proportion in what is intended to be a text-book is noticeable throughout. Undue prominence is given to observations and theories in which the author is specially interested, but which are by no means universally accepted. As a single example, three pages are devoted to the enumeration of many specific tendencies and actions as separate instincts, some of which it would be very difficult to bring within any modern definition of instinct known to the present writer. On the other hand, there is no reference to McDougall's grouping of such actions under a limited number of heads as instincts with associated emotions. The usefulness of the latter concept is sufficiently widely recognised to deserve mention.

Dr. Stoddart, in his adherence to the doctrine of Freud, shows all the devoutness of the convert. He accepts the literal truth of the whole gospel, including such generalisations as that dreams are invariably distorted wish fulfilments, and that neuroses and psychoses are without exception the results of repression of sexual impulses.

Surely the battle dreams of the war neuroses have rendered the former statement untenable except by the exercise of the most perverse ingenuity. As to the second, the employment of the usual evasion that Freud and his followers use the term "sexual" in a much wider sense than is usual renders discussion meaningless. The sexual instinct is not a phenomenal reality, but a concept; the extent to which it is useful to group observed phenomena of conduct under the term is a question, not of fact, but of opinion. However, in practice Dr. Stoddart, like other extreme exponents, refers all abnormalities of thought and conduct to the crudest anomalies of this instinct in its narrowest sense.

The reviewer accepts most of Freud's description of the manner in which thinking is distorted by "complexes" in the normal and the neuropath, in dreams and similar states. But he failed to repress a smile on comparing two statements in this book, first, that in psycho-analysis suggestion is most scrupulously avoided, and secondly, that with sufferers from anxiety neurosis, terrified by an air raid, the most superficial analysis—presumably to elicit the meaning of the terror—revealed the phallic significance in their minds of Zeppelins, aeroplanes, and bombs! It is the ill-concealed satisfaction of the psycho-analyst with this type of association that evokes them.

The description of the clinical forms of the neuroses and psychoses is excellent apart from a few examples of the disproportion and excessive dogmatism referred to. But with the author's change of views it requires more careful revision to render it consistent.

ASPECTS OF MODERN SCIENCE.

The Realities of Modern Science: An Introduction for the General Reader. By John Mills. Pp. xi+327. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1919.) Price 10*s.* 6*d.* net.

Modern Science and Materialism. By Hugh Elliot. Pp. vii+211. (London: Longmans, Green, and Co., 1919.) Price 7*s.* 6*d.* net.

(1) THE first of these works is evidently that of an enthusiastic scientific student, rather than teacher, who has found the systems of school and college instruction in physical science prevailing in America unsatisfactory. He desires, commendably enough, to see them replaced by courses based fundamentally upon the modern conceptions which have been arrived at only within the last two or three generations, not only for the few specialist, but also for general, students. This praiseworthy motive is, however, not likely to be much furthered by the book under notice. The author would have done better to write a book for science teachers and to assume throughout a knowledge equal to that obtainable from the despised college courses. As it is, it is difficult to understand for whom exactly the book is intended. In the first half the reader is assumed to be the veriest tyro in science, and there is much gilding of the philosophic pill. The beginnings of knowledge, of machinery, and of experimentation, weights and measures, the molecular theory, the "realities of science," electrons, the nucleus and energy are discussed rather desultorily. Then follow three chapters on the most obvious and elementary algebra, to which the non-mathematical reader is advised to give only cursory and mechanical reading in order to reach the second part of the book.

Then the author lets himself go. The reader is absolutely forgotten, or at least he must have had, in an interim, the advantage of several years of serious study of science sufficient to enable him to understand, if not to profit by, the particular parts of the last half-century's advances in physics, physical chemistry, and chemistry which the author reconstructs in terms of the present day. The kinetic theory of gases, the conduction of electricity through gases, liquids, and solids, the phenomena of electromagnetism, the van der Waals equation, solutions, electrolytic dissociation, chemical equilibria and their displacement, le Chatelier's theorem, Brownian movement, electronic and molecular magnitudes, with something about X-rays and radio-active substances, are the subjects which the tyro, who may not be able to comprehend an algebraic relation, is asked to assimilate in the remaining 150 pages. The aid of the merely verbal acquaintance he has made with the few ultimate conceptions of physics is not likely to fit him for the task. For these conceptions—matter, energy, radiation, the electron, the nucleus, the quantum, and so on—are the end-products of scientific philosophy, not the starting points, and cannot replace, at all events yet, the body of experimental and actual scientific knowledge out of which they have grown. It is true that they may be the "realities of modern science," but a universe reconstructed out of them *ab initio* without other guide would bear as little resemblance to reality as that created by the end-products of mythological and religious philosophy.

(2) This work is of a totally different character, and though it represents the same desire to synthesise and bring within the comprehension of the individual a vast range—in fact, in this case, the whole—of knowledge by means of a few generalised conceptions, it is written and intended for the serious student and mature thinker. The author upholds the extremest doctrines of materialistic philosophy. To him there is no real distinction between an engine and an engine-driver. In such philosophical discussions it is well to remember the mathematical adage that what is got out in the proof is no more and no less than what was put in at the enunciation. The first two chapters, on the (inanimate) universe and on matter and energy, give an excellent account of scientific materialism, as now universally accepted for the inanimate world. The rest of the book, on life and consciousness, on the fallacy of vitalism, and on materialism and idealism, seeks to extend this doctrine of the inanimate universe to the animate, with results as outrageous to common sense surely as any philosophical system ever devised.

The main, if not the only, issue of scientific interest, the difference between a complex organic compound and a living organism, or, for that matter, between the same organism alive and dead, is ignored. Living protoplasm is just a complex organic compound, so very complex that it nourishes itself by internal secretion, reproduces itself, and, gradually, throughout geological time modifies itself in constitution, so that, originally an amœba, it finishes as a man. To the chemist, who may be supposed to know something at least about chemical compounds, if not to the biologist, the view that living protoplasm is no more than a very complex compound is fantastic.

Laplace's doctrine of rigid determinism, applied to this monism of the animate and inanimate, leads the author to deduce that what he is now writing and the sentiments his words will convey to his readers could have been known and predicted a myriad years ago by a being of infinite knowledge and mathematical power from a study of the distribution of matter and energy in the original nebula. Events of great consequence to the future are frequently decided by men on the spin of a coin. Leave out the inanimate world and whether from his nebula the omniscient being could predict the fall of the coin, though the modern mathematical physicist would probably give reasons for an answer to this question totally different from Laplace's view. Leave out the question of moral judgments, and how they originate, altogether. Here is a man on the point of calling "Heads or Tails?" to decide the course of the future—but with the decision still untaken—with a certain distribution of energy and matter in his brain. We are asked to believe that this matter and energy will be differently distributed in a manner obvious to an omniscient being—that one distribution will make him call "Tails" and another "Heads." A scientific materialism that calmly accepts positive answers to such unsolved problems as these concerning free-will and the nature of life is scientific surely only in name.

F. SODDY.

OUR BOOKSHELF.

Mathematical Papers for Admission into the Royal Military Academy and the Royal Military College and Papers in Elementary Engineering for Naval Cadetships for the Years 1909–18. Edited by R. M. Milne. (London: Macmillan and Co., Ltd., 1919.) Price 7*s*.

A RECENT issue of this collection of examination papers has been reviewed in NATURE. It remains only to say that the papers added in the new issue maintain the standard of excellence already noticed. The questions are remarkably suitable for the discovery of what the candidates know.

Mesures Pratiques en Radioactivité. By Dr. W. Makower and Dr. H. Geiger. Traduit de l'Anglais by E. Philippi. Pp. vii+181. (Paris: Gauthier-Villars et Cie, 1919.) Price 8 francs.

A GOOD French translation of this well-known and admirable work.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Euclid, Newton, and Einstein.

SINCE the results of the Eclipse Expedition of May last have been made public a very great deal of general interest has been displayed in a theory which, until a few weeks ago, was known only to mathematicians and physicists. Even among these, not many could offer any adequate explanation of the new view of space and time and their mutual relations, while some regarded the whole question as a mathematical joke which led to interesting results of no practical value; and probably not a few thought that a non-Euclidean system of geometry was inadmissible in any physical theory of the universe. On the other hand, there are some who have gone so far as to advocate that non-Euclidean geometry should be taught to boys and girls in secondary schools. The published books on this subject do not come into touch with any ordinary experience, and the whole subject, consequently, has been regarded as a mathematical fiction. So far from this being so, most people have actually seen the ordinary operations of life proceeding in non-Euclidean space, though they have not realised the meaning of all they have seen. In the space behind a plane mirror objects are reversed right and left (perverted), though in all other respects they correspond precisely to the real objects in front of the mirror of which they are the images, but in the space behind a convex mirror this is not the case. The geometry of this space and the behaviour of moving bodies therein, as viewed by the external observer and as studied by an intelligent being within the image space, say, the image of the external observer, who applies to the images and their movements the same standards of measurement as the external observer applies to the real objects in his own space, introduce us to a non-Euclidean space which is the subject of common observation, and prepare the mind for the reception of many of the conclusions of the now famous theory of relativity. In the discussion of that theory two observers are supposed to be moving relatively to one another, each with his own set of measuring instruments and each living in his own world or system, and the differences between the phenomena which occur in each system as measured by the dweller in that system and by the external observer form the basis of the theory. Corresponding to these two observers we propose to consider the actual observer outside the convex mirror and his supposed intelligent image behind the mirror, and to consider how the images behind the mirror, treated as real objects, appear to behave to both observers.

In the first place, it is necessary to consider the size and shape of the objects, or, in other words, the geometry of the space. To save repetition it will be convenient to call the external observer A and his intelligent image B. The line joining the middle point of the mirror with the centre of the sphere of which the surface of the mirror is a part is the axis of the mirror, and may be supposed to be extended indefinitely outside the mirror. The image of an infinitely distant star on the axis of the mirror will be formed at a point half-way between the surface of the mirror and the centre of the sphere. This point is called the principal focus, and its distance from the mirror is the focal length, which is half the radius. It will be convenient to call this point F. A series of lines drawn from the circumference of the mirror outwards and all parallel to the axis encloses a cylindrical space to which the external objects considered are to be confined. All these lines produced indefinitely will at length meet the star on the axis of the mirror. Their images will, therefore, all converge to the principal focus F, and the whole of the infinite cylinder in the external world will correspond to a cone behind the mirror having F for its vertex and the mirror for its curved base. If an object outside moves away to infinity its image will never get beyond F, and the images of straight lines meeting the mirror and extending parallel to the axis as far as the distant star will all meet at F. We shall suppose the radius of curvature of the mirror to be very large as compared with the dimensions of the mirror itself or of the observer.

There is a very simple geometrical law connecting the distance of an object from the mirror and the distance of its image from F. This law need not concern us except to point out that as the object recedes from the mirror its image approaches F, and, as seen by the external observer, the dimensions of the image in all directions at right angles to the axis are proportional to its distance from F, but the dimensions parallel to the axis are proportional to the square of the distance from F of the image. This is the peculiar property of convex mirror space. If a cricket-ball is placed in front of the mirror at a distance equal to the focal length, its image will be half-way between the mirror and F, but the image will not be spherical. In all directions at right angles to the axis the dimensions will be reduced to one-half, but along the axis they will be reduced to one-quarter, so that the sphere will be represented by an oblate spheroid (an orange) with a polar axis one-half of the equatorial diameter. If the ball moves farther from the mirror the oblateness of the spheroid will be increased, and when the image is three-quarters of the way between the mirror and F the polar axis will be only one-quarter of the equatorial diameter of the spheroid, which will itself be only one-quarter of the diameter of the cricket-ball. If a circular hoop is placed with its plane at right angles to the axis its image will be circular, but if it is turned round so that its plane is parallel to the axis the image will be an ellipse, which will become more and more eccentric as the hoop recedes from the mirror and the image diminishes on approaching F. A top set spinning with its axis perpendicular to the axis of the mirror will appear in its image to the external observer to be elliptic, with its axes fixed in space, so that as any line of particles in the top approach parallelism to the axis of the mirror they will be squeezed together and expand again as they recede from parallelism. Midway between the mirror and F the density of the top will appear to A to be twice as great in the direction of the axis as in any direction at right angles to the axis, for the same number of particles will be squeezed into half the length.

All this has been written from the point of view of A, the external observer. But how will all these things appear to B, who is living and moving in the mirror space? Like A, the observer B may use a foot-rule for measuring length, breadth, and thickness, and a protractor for measuring angles. As A proceeds to measure the real object, B proceeds to measure the image, but as he approaches the focus his foot-rule, like himself and the image he is going to measure, gets smaller and in precisely the same proportion, so that if the image measured 6 in. in height when close to the mirror, it would always appear to measure 6 in. in height, for, as seen by A, the foot-rule would contract just as the image contracted, though B would be unconscious of the contraction. Moreover, half-way between the mirror and the focus B's foot-rule will appear to A to be only 6 in. long when held perpendicular to the axis, but when turned parallel to the axis it will appear to A to be only 3 in. long, and if it is turned round it will contract in exactly the same way as the image which it is used to measure. B, therefore, will be quite unable by means of his foot-rule to ascertain that the cricket-ball is no longer spherical, or the top or hoop no longer circular. The judgment of A and that of B will therefore be entirely discordant.

If a circle divided by radii, say 5° apart, into equal angles is held with its plane perpendicular to the axis, the image will appear to both A and B to be circular and the angles equal, but if it is turned with its plane parallel to the axis the image to A will appear an ellipse and the angles in each quadrant unequal, but B will have no means of detecting these inequalities, and he will place implicit faith in the accuracy of his protractor.

The question will naturally be asked: Cannot B see that his circle has become an ellipse? When the plane of the circle is at right angles to the axis and B looks straight at it, the image on B's retina, as it appears to A as well as to B, is circular, but when the circle is turned round and B turns round to look at it, B's retina undergoes precisely the same changes as the circle itself, and still the image occupies the same portion of B's retina as before, and therefore produces the same mental impression of a circle on B, though A recognises the ellipticity of B's retinal image (which A is supposed to see in the mirror).

If A walks straight away from the mirror to an indefinite distance, B will walk towards the focus, but as A can never reach the star, so B, walking, as he thinks, uniformly, can never reach F. In fact, his speed of walking as seen by A appears to diminish in proportion to the square of his distance from F, as all small distances measured along the axis diminish in this ratio, but B can never discover this, for he always appears to walk the same number of feet in a minute, as measured by his own diminishing foot-rule. It is true that when B's height and the length of his legs appear to A to be reduced to one-half, the length of his step appears to be reduced to one-quarter, and the angle between his legs as he walks to be reduced correspondingly; but if B tries to measure this angle, his protractor suffers the same distortion, as recognised by A, and B thinks he is walking always in precisely the same way.

It appears, then, that to B the principal focus F is infinity. He can never reach it, however long or however quickly he walks; and there is nothing in his world beyond it. All straight lines drawn from F to the mirror appear to B to be parallel, for they meet only at infinity, and he can never reach their point of meeting. They correspond to parallel lines in the Euclidean space outside the mirror. The image of a square held with its plane perpendicular to the axis will appear to both A and B to be square, but, held with two of its sides parallel to the axis, the angles of the square will appear to A to be unequal, for the two sides parallel to the axis will converge to F, and the dimensions of the square along the axis will be less than its dimensions at right angles, but neither the foot-rule nor the protractor in the hands of B will detect these irregularities. In convex mirror space straight lines which meet at F are parallel.

If two of the straight lines which appear to B to be parallel are cut by a third line, and the figure is examined by A, the two interior angles on the same side of the cutting line do not appear to be equal to two right angles, and the exterior angle does not appear to be equal to the interior and opposite angle. This is the essential feature of convex looking-glass space, but B will not agree with A on either question. To B, Euclid's propositions respecting parallel straight lines will appear to hold. He will think that he is living in Euclidean space, though A knows better, or thinks he knows.

To the external observer, then, convex looking-glass space has different properties as the focus is approached, or, in technical phrase, it is not homoloidal, and it has different properties in different directions, like a uniaxial crystal—that is, it is not isotropic, but differs from the crystal since its lack of isotropism increases as the focus is approached. The image of a metre rod nine-tenths of the distance from the mirror to the focus will appear to the external observer to measure a decimetre when at right angles to the axis, but only a centimetre when parallel to the axis.

This "distortion" of space is precisely what happens according to the theory of relativity in the neighbourhood of a gravitating body, though the distortion is very small even at the surface of the sun. In the direction of the gravitation pull space is contracted, and a foot-rule is actually shorter than when it lies at right angles to the force to the extent of about 43 parts in 10,000,000 at the sun's surface. The effect is greater the greater the intensity of gravitation, and, consequently, it increases on approaching a gravitating body.

If space is supposed to be occupied by points, and the length of a line to be measured by the number of points in it, then in space free from gravitation the points are equally distributed in all directions, but when gravity acts the points are closer together in the direction of gravity than in other directions, as soldiers in column are closer together from right to left than from front to rear, or as the images of evenly distributed points in space are more closely packed along the axis of a convex mirror than in other directions. This representation of the effect of gravity is due to Prof. Eddington. Light always goes from one point to another in the shortest possible time. This principle leads to the ordinary laws of reflection and refraction. In passing through space in the presence of gravitation it will take the path which necessitates passing through the smallest number of spatial points, and this means refraction similar to that produced when it passes into a denser medium in which its velocity is reduced. The effect on light in passing near to the sun will be the same as if the sun were surrounded by an atmosphere extending to a distance of many millions of miles, and diminishing in density as the distance from the sun is increased. This will act like a convex lens refracting the light, which will travel more slowly as it approaches the sun. A comet approaching the sun with the velocity of light would, according to the laws of Newton, travel more quickly as it approached, but its orbit would be bent towards the sun as the light is bent, but only to one-half the extent. If light from a star were passing the sun close to its limb, and behaved like a comet under the sun's attraction, it would be deflected about seven-eighths of a second of arc. On the theory of relativity it would be deflected through $1\frac{3}{4}$ seconds. It was this deflection which the Eclipse Expedition set out to measure. The behaviour of comets shows that there is no solar atmosphere to account for the refraction at distances from the sun at which the refraction was observed.

In all that has been said respecting the space behind a convex mirror the size of the mirror is supposed to be very small as compared with its radius of curvature, and the objects and images much smaller still. If a complete spherical mirror is suspended in free space the geometrical images of the stars will be distributed over a sphere of half the radius of the mirror, and this spherical surface is infinity to all the dwellers in the mirror space. The image of an object which subtends a large angle at the centre of the mirror will be bent. In Fig. 1, *ab*, *cd*, and *ef* are the images of straight

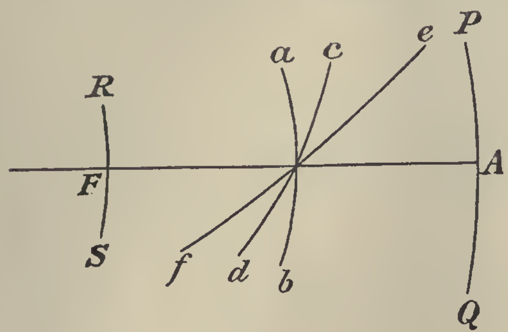

Fig. 1.

lines all passing through the same point distant half the radius from the face of the mirror. These lines are all curved and concave to the centre of the mirror, but they are straight lines in convex mirror space, and pass through the smallest number of spatial points of any line joining the extreme points. They are the paths which would be taken by rays of light in space in which the spatial points were packed as in convex mirror space. In every case the light is refracted towards the portion of space in which the point density is greatest. In the figure PQ represents the mirror, RS the focal sphere of half the radius, while the images correspond to straight lines cutting FA produced in the same point at 90°, 45°, and $22\frac{1}{2}$° respectively. It will be seen that the curvature of *ab* enables it to pass through a region in which the points are less closely packed than along the line joining *a* and *b*, which appears to the external observer to be straight. On the Einstein theory, light passing a gravitating body like the sun is refracted in the same way. In convex mirror space strings stretched between the points *a* and *b*, *c* and *d*, and *e* and *f* would take the forms shown. A person in a hurry and endeavouring to pass through a crowd will make a detour to avoid the more densely packed portions of the crowd.

According to the theory of relativity, motion and force, involving time, change the properties of space. In convex looking-glass space position and direction only are involved, so that the problem is much simpler, while many of the results are very similar.

If the two great mechanical principles of the conservation of momentum and the conservation of energy are applied to the movement of bodies in B's space a consistent system of dynamics can be constructed, and B with his measuring instruments will be quite unable to detect any divergence from Newton's laws of motion. To A, however, the laws will appear very different. For example, a body under the action of no external force moving along the axis of the mirror will move with a velocity varying as the square of its distance from F. This means that the apparent mass will vary inversely as the square of the distance of the body from F, and as the body approaches F the mass appears to increase indefinitely. This corresponds to the increase of mass according to the theory of relativity when the velocity of a body increases, becoming infinite as the velocity of light is approached. According to the theory of relativity, the mass of a body is greater in the direction of its motion than in directions at right angles to its direction of motion. In convex looking-glass space the mass is greater, when measured by the accelerative effect of a force, in the direction of the axis than in directions at right angles to the axis, and greater the nearer the focus. The reason why B cannot detect any of these changes is that all his standard units change in the same way; and, as all physical measurements ultimately reduce themselves to a comparison with standard units, if the units change a corresponding change in the quantity measured cannot be detected. We cannot, for instance, detect the variation in the weight of a body between the equator and the poles by means of standard weights and a pair of scales, though we may detect it by a spring-balance or a pendulum. It is always the looker-on, A, who sees most of the game.

Some thirty or more years ago a little *jeu d'esprit* was written by Dr. Edwin Abbott entitled "Flatland." At the time of its publication it did not attract as much attention as it deserved. Dr. Abbott pictures intelligent beings whose whole experience is confined to a plane, or other space of two dimensions, who have no faculties by which they can become conscious of anything outside that space and no means of moving off the surface on which they live. He then asks the reader, who has consciousness of the third dimension, to imagine a sphere descending upon the plane of Flatland and passing through it. How will the inhabitants regard this phenomenon? They will not see the approaching sphere and will have no conception of its solidity. They will only be conscious of the circle in which it cuts their plane. This circle, at first a point, will gradually increase in diameter, driving the inhabitants of Flatland outwards from its circumference, and this will go on until half the sphere has passed through the plane, when the circle will gradually contract to a point and then vanish, leaving the Flatlanders in undisturbed possession of their country (supposing the wound in the plane to have healed). Their experience will be that of a circular obstacle gradually expanding or growing, and then contracting, and they will attribute to *growth in time* what the external observer in three dimensions assigns to motion in the third dimension. Transfer this analogy to a movement of the fourth dimension through three-dimensional space. Assume the past and future of the universe to be all depicted in four-dimensional space and visible to any being who has consciousness of the fourth dimension. If there is motion of our three-dimensional space relative to the fourth dimension, all the changes we experience and assign to the flow of time will be due simply to this movement, the whole of the future as well as the past always existing in the fourth dimension.

The theory of relativity requires a fourth dimensional term to be introduced into its dynamical equations. This term involves time and the velocity of light. Generally, the easiest method of expressing algebraically position and motion in three-dimensional space is by reference to three directions mutually at right angles, like the edges of a cube which meet at one corner. These lines may, for example, be drawn through the observer north and south and east and west, like the reference lines on a map, while the third line is up and down. The observer's point of reference is where these three lines meet. In four-dimensional geometry there is a fourth direction at right angles to each of the three. Most of us are unable to form any clear picture of such a direction as a purely geometrical conception. To us the only figure which is at right angles to every straight line drawn through a point O is a sphere, or any number of spheres, having O as centre. As stated above, the fourth co-ordinate involves time and the velocity of light together. Imagine these spheres to be always moving inwards towards O with the velocity of light, and then to expand again from O with the same velocity, and this to take place quite uniformly, however O may move in relation to other points of observation, so that the centre of the system of contracting and expanding spheres travels with the observer, and each observer has his own system of spheres. The approaching and contracting spheres contain within them the whole future; the receding and expanding spheres contain the past. The present is the passage of a sphere through O, the observer, when that sphere is concentrated on a point. This conception of a fourth dimension is thus not that of a simple spatial dimension like the other three, but, as required in the theory of relativity, it is intimately associated with time and motion, and the observer's experience of it is simply the happening of events with the flux of time. It is very like the Flatlander's conception of the third dimension derived from the invading sphere. It will be noticed that to different observers the impressions of the present are not quite the same. We observe an event in a star. It is present to us. To an observer in the star it happened years ago.

The theory of relativity involves a change in the unit of time, according to the motion of the observer relative to the object observed. This complication did not enter into the consideration of the space behind the convex mirror, so that the dynamical problems in that space were relatively simple. According to the theory of relativity, if the observer is moving with the velocity of light, time remains unchanged. This must have been the case with the Mad Hatter. With him it was always six o'clock, and always tea-time.

W. G.

Thermionic Valves on Aircraft.

In a paper just published in the Proceedings of the Royal Society (A, vol. xcvi.) Drs. W. H. Eccles and J. H. Vincent give an account of some experiments on the small variations of wave-length introduced when changes are made either in filament temperature or plate voltage of a thermionic valve supplying oscillating energy to a wireless circuit. It may be of interest to readers of NATURE to know how this effect influenced the design of wireless aircraft generators used in the war.

In 1916, when experimenting with continuous-wave telegraphy and telephony from aircraft, I noticed a small outstanding variation of wave-length radiated from an aeroplane, which variation seemed to depend mainly on the speed of flight, and therefore, possibly, on the voltages supplied by the windmill-driven generator.

Following up this clue, I found in the Air Force Laboratory that the changes of wave-length introduced by variations of filament temperature and plate voltage were more considerable than I had thought, especially on short wave-lengths.

It was the knowledge of this fact which led to the inclusion of special regulating devices in the aircraft dynamo circuits, so that the wave-length variation, at the best of times noticeable owing to aerial sway, banking, etc., should be reduced, at any rate, to a minimum.

Popular Science.

I SHOULD like to be allowed to underline a few remarks that occur in a review entitled "Scientific Biography" in NATURE for January 29. The writer urges that science has neglected the populace and offered its wares for popular edification in a highly unedifying way. I believe this is very true. I am old enough to remember different times, and can recall with truth and gratitude the feeling of enthusiasm, and even of exaltation, which I had in early days on hearing or reading popular science lectures. I think of Huxley, Tyndall, Clifford, W. B. Carpenter, Lockyer, Roscoe, and some others. Science lectures then were aimed at showing how science did its work, and they brought into view something of the personality of the real scientific worker.

Remembering how much I had gained, I endeavoured in my turn to carry on the good work within the much-restricted range of my own powers, but in the same spirit. In time I realised two things: one, the debilitating tendency of publicity and easily won applause; the other, the invasion of the science platform by the mere entertainer and his *entrepreneur*. The work became suspect to all self-respecting people. The degenerated Press has completed the havoc.

Is it not possible to improve matters? I believe it is. No doubt some knowledge of science is more prevalent than it was, but there is yet ample room for the simple, popular lecture of the genuine kind by men who are the real workers. It is a serious tax, but I am inclined to think a justifiable one, on the time of these men to give, say once a year in some large city, a really popular account of their latest discoveries and have it printed to sell at a popular price. That, and a vocal public opinion in the world of science against comic, pyrotechnic, mystic, or other profane tickling of the groundlings, might do much in a good cause.

VICTORIAN.

Mirage Effects.

THE mirage effect noticed by Mr. Quilter and Miss Botley is very common on Woolacombe Sands, especially on hot, sunny days when the observer is looking south. The apparently wet patch keeps at a half to three-quarters of a mile's distance from the eye, but does not persist up to the southern limit of the bay, which is bounded by high ground. I cannot remember whether it is visible when the observer is facing north.

SPENCER PICKERING.

MIRAGE effects similar to those referred to in NATURE of January 29 (p. 565) have been noticed by me several times in Birmingham on tarred macadam or wood-block roads. The effect on a hot, sunny day is of a layer of water from 2 in. to 4 in. deep on the surface of the roadway, immersed in which are the feet of pedestrians and the wheels of vehicles about a hundred yards from the observer. The effect is best seen when the line of sight nearly coincides with the surface of the roadway, as, for instance, just before one breasts the summit of a slight rise, when the eye is practically level with the ground beyond the top of the rise. Stooping would produce a similar effect.

L. N. NORRIS-ROGERS.

I FIRST saw a mirage on a road in Colombo, and wondered how I was going to cross the apparent sheet of water in front of me. Since then I have seen it repeatedly in England, and instinctively look for it when the conditions are right. For the best effects these conditions are three: (*a*) Tarred roads (the reason is obvious); (*b*) bright sun; and (*c*) a slight gradient rising from the observer.

In very hot weather (*c*) may not be so necessary. At other times the mirage appears where the gradient reaches towards the level of the eyes. It is very clear, and reflections are as sharp as in water, especially of objects crossing near the further edge.

HARRY HILLMAN.

117 Colmore Row, Birmingham.

THE THEORY OF RELATIVITY.

THE meeting of the Royal Society on February 5 was devoted to a discussion on the theory of relativity. It was opened by Mr. J. H. Jeans, who said it was a better analogy to liken the new principle, not to a key of the universe, but to a ward in its lock, which gave direction to the efforts made to open it, admitting some and excluding others. In this respect it resembled the doctrine of the conservation of energy and the second law of thermodynamics. Where any of these gave a positive result it was because a process of exhaustion showed that anything else would be impossible.

The foundation of the theory may be considered to have been laid by Einstein's hypothesis, put forward in 1905, that light from any source appears to any observer to travel with the same velocity C; this hypothesis was founded on the Michelson-Morley experiment, and has since been confirmed by that of Majorana; it also explains a number of physical phenomena. It can best be visualised by the idea that to each observer the wave-surface is spherical in the four-dimension continuum. Then $x^2+y^2+z^2+(i\mathrm{C}t)^2$ (radius for the first observer) transforms into an identical expression with accented letters (radius for the second observer) by a rigid-body rotation. Such a rotation would resolve pure time into partly time, partly space, and *vice versa*. The following is an example of this: Suppose that a man lives seventy-five years, and dies 1000 miles from his birthplace; then to an observer on a rapidly receding star he might appear to have lived seventy-six years and travelled billions of miles. (In reply to Prof. Newall, who imagined paper screens to be erected at a distance of 100 light-seconds from the origin, from which a flash of light is emitted, and from which one of the observers moves while the other remains, Mr. Jeans admitted that the former would not see the reflections simultaneously, the reason being that the screens would not lie on a four-dimensional sphere to him.) This conception was preferable to that of the Lorentz contraction, which presented grave difficulties in the case of a rotating wheel, the axis of which is at rest in the æther; the rim would undergo contraction, while the spokes would remain unaltered.

Mr. Jeans used the following analogy to explain the nature of Einstein's latest theory. Imagine a race of men who had spent all their lives in caves. They would be in ignorance of the earth's rotation, and would consider gravity as a force constant in direction; however, two experiments might reveal the fact of rotation to them. If they set a ball swinging in an ellipse, by a long string, the apse of the ellipse would move; moreover, delicate measures would show that the course of rays of light was not quite straight relatively to their rotating framework. This is closely analogous to the observed progression of Mercury's perihelion and to the deflection of light-rays by the sun; in each case "we have tacitly assumed fixed axes where nothing is fixed: we have formed wrong ideas of the nature of gravitation, and our definition of a straight line is interwoven with the ideas of an untrue system of geometry."

The reason why the new law of gravitation cannot be put in simple form is that there is no *force* of gravitation; the laws of *motion* can be put in the simple form $\delta\int ds=0$. There are, however, two ways of defining ds. Einstein defines it as a line-element in a distorted space-time continuum. This necessarily involves the spectral shift to the red, and an objective curvature of space. It may also be simply defined as a conventional algebraical symbol given by Einstein's equation, but without assuming his physical interpretation; in this manner it is possible to deduce the two astronomical effects already verified, while leaving the shift of spectral lines undetermined. Decisive evidence for or against the spectral shift would be a guide as to the adoption of one or other definition of ds.

Prof. Eddington compared Euclidean space to a picture in a framework of rectangular co-ordinates, and Einstein's space to a map with curved lines of latitude and longitude. Just as the map could not accurately represent the earth's surface, unless it was made on a curved surface, so Euclidean space could not contain an accurate representation of the space-time continuum. We could look on Einstein's law of gravitation as giving instructions for the joining together of successive elements of space. The law must include all the laws of mechanics, including the conservation of energy and momentum.

Space and time could be explored in two ways—either by using clocks and measuring scales, or by observing moving particles and light-waves. The second method was both more elementary and more sensitive. An example of it was the search for the spectral shift. The reason for the shift might be briefly given thus. The time of vibration of a particle involves the factor $\left\{1-\frac{2m}{r\mathrm{C}^2}\right\}^{-\frac{1}{2}}$ which clearly increases as r diminishes, so that the vibration is slower on the sun than on the earth.

Sir F. W. Dyson spoke on the motion of the perihelion of Mercury; the observed centennial motion exceeds that calculated on the Newtonian law by 43″, which is much the largest unexplained quantity in planetary theory. Various attempts have been made to explain it. An excess of ½″ of the sun's equatorial radius over the polar would suffice; this amount is considered to be in excess of what observation will admit; the latter suggests a slight excess of the polar radius; moreover, such an equatorial excess would produce a shift of the orbit-plane of Mercury too great to be admitted. An unknown planet is excluded, since it could not fail to have been seen or photographed at some of the total eclipses when such a body has been specially looked for. A ring of small planets would have to be in the plane of Mercury's orbit, or it would produce an effect on its node and inclination. This puts the zodiacal light out of court, even if its mass were sufficient, which seems unlikely. Prof. Asaph Hall suggested that the law of attraction should be modified, the index of r being taken, not as -2, but as $-2(1+d)$, where d is a small fraction, chosen empirically so as to fit the case of Mercury. This is the law adopted in Newcomb's tables, and therefore in the Nautical Almanac. It would give a centennial shift of the moon's perigee of $135''$. (The discussion of Dr. E. W. Brown seems to establish that there is no such excess of motion in the perigee, which discredits the Hall hypothesis.)

Einstein's theory perfectly explained the excess of motion of Mercury's perihelion, without introducing any arbitrary constant, or having any other perceptible effect on the planetary or lunar motions. By the method of exhaustion it seemed to hold the field. There remained a small excess of motion in the case of the node of Venus, but it was only $2\frac{1}{2}$ times the probable error, and so was not unreasonable.

Prof. A. Fowler spoke on the attempts that had been made to detect the shift towards the red in the sun's spectral lines, and on the difficulties in the way, which arose from the effect of varying pressure, the rotation of the sun, and possible convection currents in its atmosphere. A series of cyanogen lines was selected for the test, as they were not subject to shift through pressure; care was necessary to choose isolated lines, as adjacent lines might influence the measures. The sun's rotation could be eliminated by observing opposite points of the limb. The results of the measures of Evershed, St. John, Schwarzschild, and recent Bonn observers were shown on the screen. The mean of all gave a shift towards the red of 0·003 Å. at the sun's centre and of 0·004 Å. at the limb, Einstein's predicted value being 0·008 Å. Prof. Fowler inclined to the view that the observed shift was due not to the Einstein effect, but to cooler descending convection currents at the sun's centre, and to the "limb effect" at the limb.

Mr. E. Cunningham gave the following example to show that the spectral shift need not necessarily occur on the equivalence hypothesis: Imagine two atoms each emitting light-vibrations in a non-gravitational field, the periods of vibration being the same. Referring them to a set of accelerating axes, we simulate a gravitational field. The synchronism between the two sets of waves is not destroyed; and on the equivalence hypothesis the relation of physical sequences in the simulated field is the same as in the real field. There is the qualification that the atoms must be free to fall—*i.e.* not constrained by neighbouring atoms; Mr. Cunningham doubted whether this was the case on the sun's surface. He went on to say that relativity did not necessarily imply the abandonment of the æther; a unique æther could be constructed on a mechanical basis; if it transmitted light, it must also transmit stress and energy.

Prof. A. F. Lindemann spoke of the observed average recession of 4 km./sec. in the B-stars; even those in the Orion nebula, which presumably were at rest relatively to it, showed this differential shift; he concluded that it was not a Doppler effect, and might be the Einstein one. He noted as a difficulty in the quantum theory of light that to an observer at rest the mass of a quantum would be infinite; moreover, he considered that since the mass of an electron changed with its speed, its period of vibration should also change. Speaking of Prof. Eddington's statement that a sphere of water of radius 500 million km. would fill all space, he preferred to say that to an observer on the sphere it would appear to do so, since all rays from it would be bent back to it by its attraction; but he thought there was nothing to prevent other space from existing outside it.

Prof. A. N. Whitehead showed a mathematical method by which Einstein's first two astronomical predictions might be satisfied without introducing time as the fourth dimension. The method left it uncertain whether the spectral shift would take place or not. Should the latter be finally proved not to exist, we might fall back on this method, which agreed with the facts at present observed.

A. C. D. CROMMELIN.

THE FLIGHT FROM CAIRO TO THE CAPE.

(1) AVIATION AND EXPLORATION.

THE enterprise of the *Times* in organising a flight from London to Cape Town *via* Cairo, Khartum, the Upper Nile, the interior of East Africa, Northern and Southern Rhodesia, and the Transvaal will certainly, if successful, greatly advance the theory and practice of travelling through the air from one distant part of the world to another.

The bearing of the whole question—air travel *versus* railway, ocean steamer, or road-motor transit—was well put a few days ago by Capt. Frederick Shelford in his address to the African Society. There is no real cause for rivalry or hostile competition between all four forms of rapid transport. Air travel by aeroplane or airship will for a long time to come be far more dangerous to life than road or rail transit, and a little more dangerous than sea voyages; but it will be very much quicker than all other methods. It will be impossibly expensive for the transport of goods or of many passengers. Sea travel by boat is the cheapest mode of conveyance; railways, on the whole, and especially in wild, little-developed countries, are as cheaply made as motor roads, and are much less expensive to maintain. For mails and for passengers in a great hurry, aeroplanes should have no rival, especially when meteorology is better understood, and when the great air routes of the world are duly provided with aerodromes at convenient distances.

It may seem to be stating too obvious a fact when I point out that the chief difficulty in the way to complete success on the part of aviation is the coming down safely from the air to the solid earth. No air pilot can view without grave apprehension a forced descent on an uneven or merely a slightly irregular surface. The passengers might not be more than shaken or bruised, but the delicate machine might be so injured as to be unable to resume its flight. But for this trouble about *descent* and *ascent*, the exploration of the world's land surface would now be proceeding at a tremendous rate. Soon the whole of the continents and islands would be made known in all their details.

I have always hoped myself that there may be some wonderful development in mechanics or in physics by which heavier-than-air machines might be enabled (1) to rise direct from the ground into the air *vertically*; and (2) to descend vertically and slowly, under control, making use of air-brakes in some way. The latter process may read as an impossibility, but it is not more improbable than many a feat in aviation would have sounded to the scientific theorist twenty years ago.

Then, again, I am sure we have neglected another safety apparatus: the devising of clothing that might be so inflated with air that the wearer would float to earth as gently as thistle-down.

The original mind of Dr. Chalmers Mitchell may well come back from his great air journey with new conceptions as to the future solution of these and other difficulties in aviation. Few people know as much as he does about bird-structure, and he may, when he is "up against it," be inspired to apply to the theory and practice of aviation some bright ideas—as yet overlooked—to be derived from the bird's development of the art of flying, especially the efforts made by heavy birds (cranes, storks, swans, peafowl, bustards, and large vultures) to rise into the air, to maintain themselves resting (floating) in the air, and to descend from a great height to the ground uninjured.

As to Dr. Mitchell's experiences and those of his companions on this actual journey, my impressions are: that by rising to eight or nine thousand feet they will ascend above the dangerous storms or violent winds of Central Africa; that they will nowhere run any serious danger from wild or savage men, except among the Dinkas of the Nile Valley (east of the Bahr-al-Ghazal); that they have very little to fear from any wild beast except a chance rhinoceros in East Africa; and that in seeing the desert yield to the Nile marsh-lakes, the marshes give place to mountains—even snow-mountains—and grandiose forest, the forest thinning out into parklands, the parklands passing into steppe, the steppe into desert, and the desert into the cornfields, orchards, vineyards, and gardens of South Africa, they will have had an unforgettable lesson in physical geography. I wish them the most complete success and a happy return.

H. H. Johnston.

(2) Scientific Aspects of the Route.

The expedition which started from Cairo on February 6 should be memorable as the first use of long-distance aeroplane flight for scientific and geographical research. Thanks to the enterprise of the *Times*, a Vickers' "Vimy" aeroplane is traversing Africa from Egypt to the Cape, with Dr. Chalmers Mitchell as scientific observer and Capts. Cockerell and Broome as pilots. The expedition will test the value of long aerial journeys for scientific purposes, and as it is under a man of such width of knowledge and scientific imagination as Dr. Chalmers Mitchell, we may be confident that the opportunity will be used to the best advantage.

The expedition is to travel leisurely, at moderate elevations, and never flying at night, so as to enable Dr. Chalmers Mitchell to obtain a clear survey of the country traversed. The route is from the aerodrome at Heliopolis, near Cairo, up the Nile, past Assuan, to Wadi Halfa, and thence, along the railway line, across the Dongola bend of the Nile, to the river again past Atbara to Khartum; then up the White Nile past Mongalla and Gondokoro and over the Nile rapids to Nimule. Thence the most direct route would be to leave the river and cross the Fatiko country to Lake Kiogo, and there rejoin the Nile, following it to its outflow from the Victoria Nyanza at the Ripon Falls. The expedition will fly over the lake to Kisumu, at the end of the Uganda Railway, skirt the irregular eastern coastlands to Mwanza, on the southern shore of the Victoria Nyanza, and cross "German" East Africa to Abercorn at the southern end of Tanganyika. Thence the route will be above north-eastern Rhodesia to the mining fields of the African Broken Hill, and along the railway past the Victoria Falls on the Zambezi to Wankie coalfield and Bulawayo; it will continue in sight of the railway another 182 miles southward to Palapye, where it will bend eastward across the northern Transvaal to Pretoria, and by following the railway past Johannesburg, Bloemfontein, and Beaufort West end its journey, of 5206 miles by the route projected, at Cape Town.

This journey must naturally be direct, long distances must be covered daily, and deviations to follow up interesting clues may be inadmissible, for the main object of this flight is to demonstrate the practicability of the aeroplane in the next stage of African research and development. The prospects are promising, for a bird's-eye view from a moderate elevation would reveal much of interest and practical value regarding the geography, geology, and botany of those parts of Africa composed of arid plains like the East African Nyika. One difficulty with their investigation is that, owing to the covering of scrub, travellers by foot or on horseback may march for days and see nothing beyond a few hundred yards beside the route, while any useful plane table survey is impossible. A view from above would, however, show all the essential features; the valuable areas are on the volcanic rocks or on limestones, both of which produce good soils and often maintain permanent wells, whereas the metamorphic rocks, which form the foundation of the country, yield a barren sandy soil and may have no permanent water.

The contrasts between the types of country on these three kinds of rock are so striking that an aeroplane observer would soon learn to distinguish them and thus discover potential oases on lava or limestone in the wastes of sandy scrub. In such countries travel to a physiographer is often as exasperating as the sudden interruptions of view along a railway by lines of obstructive trees, cuttings, and tunnels, which led Ruskin to renounce railway travel, on the ground that he would as soon thus hasten a journey across interesting country as an epicure would compress his meal into a single pill. Moreover, the traverse of these arid plains in the dry season is hazardous, as a caravan strong enough for necessary transport and defence is liable to disaster by failure to find water; whereas an accompanying aeroplane scout would at once discover any remaining waterholes, which might be concealed from a caravan passing a short distance from them. Aeroplane guidance might thus enable an expedition to cross an area which otherwise it would be foolhardy to enter.

The motor-car is no doubt of great service on these plains in dry weather, but its use is attended with the serious danger that a sudden fall of rain may convert the country into a sea of mud, in which the motor is immovable. A premature rainstorm before the normal rainy season may leave a party dependent on motor transport as completely isolated in the desert as a shipwrecked party on an oceanic island.

African geography is in a stage when bird's-eye views may be very instructive. For example, south-west of Lake Stefanie different explorers have reported lines of hills and scarps the interpretation of which is at present uncertain; but to an aeroplane observer surveying the country, especially when helped by the long shadows of early morning or late afternoon, these lines would appear in such diagrammatic outline as to give him an insight into their relations, which would cost a traveller on foot an arduous season's campaign. Similarly, there is much difference of opinion as to the connection between Lake Nyasa and the southern end of the Rift Valley in central "German" East Africa near Kilimatinde; the Ruaha Valley overlaps with a relief line to the north-west of it, but no connection between them has been recognised. An aeroplane survey of this region under suitable illumination would demonstrate the structural relations between the chief features in the relief of the area with a speed, an ease, and an economy which no other method could approach. Again, in the area which the *Times* expedition will skirt in going from Tanganyika to the mines at Broken Hill, the structural geography is complex, including valleys and scarps of different dates and plateaux of sandstone of various undetermined ages. The traverse of this district is arduous, and comprehensive views across it are difficult to obtain. But a survey or looking down on it, especially if able to hover over it at leisure and see it from different angles and under various conditions of illumination, would probably contribute greatly to the solution of its leading tectonic problems.

Dr. Chalmers Mitchell's traverse, being an experimental journey, will probably be unable to make many deviations for scientific study, but it is following a route of exceptional interest, and we may expect light from him on some East African physiographic problems, such as the controversy as to whether the Lower Nile Valley is a down-folded basin or a down-faulted trough, or as to the relations of the young valley which the Nile is excavating north of Khartum to the older river which drained that area. His survey of the northern face of the plateau north of Uganda, seen from a distance which will blot out the minor irregularities, may throw light on its origin; and during his flight from Nimule to the Victoria Nyanza he may discover some line of depression continuing the tectonic subsidence north-east of the Albert Nyanza towards Lake Rudolf. In addition to work of this character, enabling Africa to be studied like a great relief model, the value of the aeroplane in scientific work will probably be mainly as a means of rapid transport to centres for study or help in emergencies.

The cost of aeroplane transport may seem large when compared with railway rates of a penny per ton-mile; but it is insignificant in comparison with that of a caravan across a foodless territory, when each porter can carry so little in addition to his food that the cost of the carriage of goods from Mombasa to Uganda was reckoned at 300*l.* a ton. The aeroplane will doubtless enable the arid areas in East Africa to be investigated at a much cheaper rate than any other available method.

In the political administration of Africa, Dr. Chalmers Mitchell's mission may lead to ultimate economy in many districts. Thus, in northern British East Africa, garrisons are so isolated, and so liable to sudden calls to control the nomads or to resist Abyssinian raids, that they must be maintained at costly strength; but a periodic aeroplane inspection of the desert lands on the borders of British East Africa would reveal the whereabouts of the tribes and discover whether there were any concentrations of men and camels which threatened mischief; and thus it would add greatly to the efficiency of the frontier guard.

From its bearing on African administration, on an accelerated postal service, on quicker and cheaper transport of officials and investigators, as well as for its direct observations, the journey of Dr. Chalmers Mitchell and his companions may mark the beginning of a new epoch in African travel.

J. W. GREGORY.

(3) CIVIL AVIATION.

THE lecture by Major-Gen. Sir F. H. Sykes on "Imperial Air Routes," which was delivered before the Royal Geographical Society on February 2, will be eagerly read by all interested in the future of civil aviation. Sir F. H. Sykes spoke upon the great advantages to be gained by the establishment of a complete system of aerial routes linking up the widespread portions of the Empire, with Egypt as the "Clapham Junction" of the India, Australia, and Cape routes. The last route was discussed at some length, and an account given of the work which has been done in establishing a chain of aerodromes from Cairo to Cape Town. The great usefulness of the aeroplane as a means of reaching outlying places near the route which have at present no rapid means of conveyance was commented upon.

The main outline of the lecture is summed up as follows:—

"It is not enough to believe—as I firmly do—that aerial transport being right is bound eventually to succeed. The seasoned tree can stand alone; the shooting sapling must be stayed. Some of the requirements of aviation on an Imperial basis are:—

"(1) The maintenance of a highly efficient fighting force.

"(2) The expansion of commercial aviation to promote British trade and to supplement the fighting force when necessary by a reserve of *personnel* and material, knowledge and experience.

"(3) The co-ordination and co-operation of aerial communication throughout the Empire, and its relations to other countries.

"(4) The organisation of routes, aerodromes, ground communication, and meteorological services on an Imperial basis.

"(5) The energetic promotion of research and the encouragement of design.

"(6) Money to assist the institution of experimental mail services.

"(7) The encouragement of land survey, forest patrol, and other work in which aircraft can be utilised.

"This year will, I hope, go down to history as marking the birth of a sound, virile, and truly Imperial air policy."

As a practical commentary on the lecture comes the projected *Times* flight by a Vickers' "Vimy" aeroplane from Cairo to the Cape, referred to last week, over the route described by Sir F. H. Sykes. The machine left Cairo at 9.45 a.m. on February 6, and reached Khartum on February 8, leaving there on February 10. Should the flight along the African continent prove a success, the feat will be the third great triumph for this type of aeroplane, the present machine being practically identical with those which accomplished the Atlantic and Australian flights. The crew consists of two pilots, one mechanic, and a rigger, while the well-known zoologist, Dr. P. Chalmers Mitchell, is passenger and scientific observer. The object of the flight is primarily to determine the possibilities of the new route, but it is also to be regarded as the first attempt at exploration from the air, as much of the country to be crossed is at present unsurveyed. The result of this experiment will be awaited with interest. If success is achieved, a new proof of the commercial possibilities of the aeroplane will have been established—a proof that should convince the most sceptical.

THE DEVELOPMENT OF SPITSBERGEN.[1]

IN view of the increased public interest in Spitsbergen on account of the revival of mining activity and the recent political settlement, Dr. R. N. Rudmose Brown's new book upon the country is particularly opportune. It is further welcome because it provides the only modern work in English dealing with Spitsbergen in its general aspects; for Sir Martin Conway's "No Man's Land" is an historical volume, narrating the discovery and the early history of whaling and hunting in the archipelago and the adjacent seas. The only other recent general works are those of Holmsen in the Norwegian, and of Cholnoky, curiously enough, in the Magyar language.

Whatever its mining possibilities are (and scepticism has recently arisen), the situation of Spitsbergen as the most easily accessible polar land, along with its wonderful climate, will inevitably lead to its becoming a favourite European playground. In summer, Spitsbergen has a climate, especially in its central and western regions, which is a good deal more tolerable than the average British spring; and, apart from the drawback of polar darkness, its winter climate is said to compare quite well with that of Canada. It has glorious mountain, fiord, and glacier scenery, and the study of its spectacular physical features and natural history will afford exhaustless attractions for scientific travellers.

Dr. Rudmose Brown's book first deals pleasantly with the discovery, physical features, climate, and natural history of the Spitsbergen Archipelago, the geology, however, being deferred to the chapter describing its mineral wealth. The succeeding chapters trace the history, exploration, and economic development of the country. Spitsbergen history may be divided naturally in order of time into the whaling, hunting, exploratory, and economic periods. The whaling industry has been extinct for a century or more. Hunting and trapping have recently revived, after a period of exhaustion, in response to the high prices now obtainable for furs. Dr. Brown records and deplores the unfair and ultimately disastrous poisoning methods practised by some Norwegian hunters. The Norwegian Government, it is hoped, may now be able to deal adequately with this and other crying abuses.

The mining development of Spitsbergen dates from 1904, although coal and other minerals had been found much earlier. The only large-scale mining has been in the excellent Tertiary coal of Advent Bay, which was opened up by an American company, but is now carried on by Norwegians. In 1912 40,000 tons were raised, but in 1919 it is believed that this total will have been more than doubled. While British companies claim areas more than three times as large as those of all other nationalities combined, the war unfortunately stopped their development schemes, and it was only in 1918 and 1919 that they were able to resume their activities and send up prospecting expeditions.

Besides coal, iron ore of good quality is said to occur; gypsum is certainly present in enormous amount; and traces of copper, gold, molybdenum, lead, and asbestos have been found. Oil and oil-shales are possibilities. Nevertheless, Norwegian geologists, who for the last ten years have carried

[1] "Spitsbergen: An Account of Exploration, Hunting, the Minera Riches and Future Potentialities of an Arctic Archipelago." By Dr. R. N. Rudmose Brown. Pp. 319. (London: Seeley, Service, and Co., Ltd., 1920.) Price 25*s*. net.

on extensive prospecting work, especially in the western mountain ranges, are very sceptical as to

FIG. 1.—Temple Mountain from Bjona Haven. The Prince of Monaco's yacht, the *Princess Alice*, at anchor. One of the most important British estates in Spitsbergen is situated here. From "Spitsbergen."

workable mineral resources, except coal, as may be gathered from a perusal of recent correspondence in the *Mining Magazine*. A fierce but feeble answer to these letters by a representative of a British company interested in Spitsbergen fails to meet the facts brought forward by the Norwegian geologists, especially in regard to metalliferous ores. The reviewer believes that mining development in Spitsbergen will rest largely upon coal, with perhaps oil and oil-shale, obtained from the flat-lying rocks of the central tracts.

The later chapters of the book discuss certain German schemes for the exploitation of Spitsbergen, now happily brought to naught, its modern history, and its political status. Spitsbergen is no longer a No Man's Land, and the last chapter of Dr. Brown's book is therefore already outdated by the decision of the Supreme Allied Council to assign the sovereignty of Spitsbergen to Norway.

The twenty-two plates illustrating the book are excellent and doubtless contribute to its high price, but the two maps are comparatively poor. Mistakes and misprints are commendably very few. "Ordovician" is misspelt on p. 216, and

FIG. 2.—Longyear Mine, Advent Bay. Wire ropeway from the mine, coal dump, and jetty with a vessel loading alongside. From "Spitsbergen."

there is a discrepancy in the story of Klaus Thue's wintering on p. 106. A bibliography of the more important works on Spitsbergen would have enhanced the value of the book to interested readers, who will nevertheless find it the best available compendium of Spitsbergen information.

G. W. T.

THE LEAGUE OF UNIVERSITIES.

A REPRESENTATIVE body of British university men and women spent the autumn of 1918 in America as the guests of the United States. By invitation of the Government of the French Republic a similar delegation visited the universities of France last May. From the Belgian Government an invitation was received and accepted in November. The reports of these three university missions may be obtained from the Universities Bureau, 50 Russell Square, W.C.1. In each of the countries visited the representatives of the United Kingdom were received with profuse hospitality and treated with the utmost consideration by the Head of the State and his Ministers, as well as by the heads of the universities and their professors. In innumerable speeches the general objects of this university "entente" received eloquent and enthusiastic expression, stress being laid upon the necessity, in the interests of the world's peace, of bringing the intellectual leaders of the allied and associated countries into closer and permanent touch. There may be rivalry amongst the universities of the civilised world, but there can be no competition, in the sense in which commercial enterprises compete, with the risk of producing discord. All are engaged upon a common task, the making of knowledge, and the training of men and women for professions and occupations in which learning is the only trustworthy equipment.

During the last three or four years the universities of the United Kingdom have discovered that their power and influence may be greatly strengthened by taking counsel together, without any sacrifice of independence. There is the same need for conference and co-operation amongst the universities of the world. Amongst definite problems discussed was the interchange of teachers and students—the migration of those who dispense and of those who seek knowledge, adjusted to modern conditions. The reports of all three missions are in approximately similar terms. It is recognised that professors who are heads of departments have many administrative duties in addition to their duties as teachers. Their universities cannot spare them for any considerable time, nor can their duties be taken over by strangers. Heads of departments might with great advantage give short courses of lectures in foreign countries, provided the language difficulty can be overcome. Professors of highly specialised or recondite subjects, for which the demand is limited or occasional, might well distribute their services amongst several universities, spending an occasional year abroad.

With regard to migration of students, it is clearly desirable that students of languages should spend a part of their undergraduate career in foreign countries; but with this exception it is almost universally agreed that only in rare instances would it be to the advantage of a student to leave the university in which he is matriculated until after graduation. The first year's work at any one university is not easily articulated to the second year's work at any other. Nor would any university be content to part with its third-year students. For a graduate, every possible facility for migration should be afforded. Even though his new university be not so well equipped for work in the subject to which he is devoted, it is to his advantage that his experience should be enlarged. So far as British universities are concerned, post-graduate study will be encouraged by the new Ph.D. degree which all have now established. The same degree is obtainable in the U.S.A., and its equivalent, the doctorat de l'Université, in France and Belgium.

NOTES.

THE new session of Parliament was opened in state on Tuesday by the King, who was accompanied by the Queen and the Prince of Wales. Among the matters referred to in the King's Speech were a Bill to make further provision for education in Ireland, measures to stimulate and develop the production of essential foodstuffs within the United Kingdom, and to encourage and develop the fishing industry, and Bills providing against the injury to national industries from dumping and for the creation of an adequate supply of cheap electric and water power.

As successor to the late Mr. Henry Watts in the editorship of the Journal of the Chemical Society, and as the first secretary and registrar of the Institute of Chemistry, Mr. Charles Edward Groves, F.R.S., was for many years a very prominent figure in the chemical world. His scientific education was received under Hofmann at the Royal College of Chemistry, where he was contemporary with a group of young men of whom many became distinguished men of science. In October, 1862, Mr. Groves became senior assistant to Dr. John Stenhouse, F.R.S., who had established a private laboratory for research in Rodney Street, Pentonville, and there he remained as factotum until Dr. Stenhouse's death in 1880. He then became lecturer in chemistry at Guy's Hospital. The greater part of Mr. Groves's scientific work was done in the Pentonville laboratory, and was published under the joint names of Stenhouse and Groves, though, in consequence of Dr. Stenhouse's infirmity, the work was mostly done by his assistant. Mr. Groves was a good manipulator and a skilful analyst, and not only assisted in the research laboratory, but for five years also took part in the work of external assayer to the Royal Mint—an office held by Dr. Stenhouse until 1870, when it was abolished. Mr. Groves in his early days was a very active walker and climber in the Alps. For many years he spent his summer holidays in Switzerland, and will be remembered by many of the senior members of the Alpine Club. His death on February 1, at an age approaching eighty years, leaves but few survivors of the original group of students of the Royal College of Chemistry.

THE Carnegie Corporation of New York has announced its intention to give five million dollars for the use of the U.S. National Academy of Sciences and the National Research Council. It is understood that a portion of the money will be used to erect in Washington a home of suitable architectural dignity for the two beneficiary organisations. The remainder will be placed in the hands of the academy, which enjoys a Federal charter, to be used as a permanent endowment for the National Research Council. This impressive gift is a fitting supplement to Mr. Carnegie's great contributions to science and industry. The Council is a democratic organisation based upon some forty of the great scientific and engineering societies of the country, which elect delegates to its constituent divisions. It is not supported or controlled by the Government, differing in this respect from other similar organisations established since the beginning of the war in England, Italy, Japan, Canada, and Australia. The Council was organised in 1916 as a measure of national preparedness, and its efforts during the war were mostly confined to assisting the Government in the solution of pressing war-time problems involving scientific investigation. Reorganised since the war on a peace-time footing, it is now attempting to stimulate and promote scientific research in agriculture, medicine, and industry, and in every field of pure science.

SIR HENRY FOWLER has been elected president of the Institution of Automobile Engineers for the session 1920–21, and Dr. Blackwood Murray, Lt.-Col. D. J. Smith, and Mr. Geo. Watson vice-presidents.

THE National Sea Fisheries Protection Association has decided to form an organisation, to be known as the British Fisheries Guild, with the following objects:—(1) To gather and diffuse information upon all matters relating to fish and fisheries, and to collect and circulate statistics relative thereto; (2) to unite, encourage, and maintain all interests relating to fish and fisheries, and to affiliate local or other organisations with similar objects; and (3) to deal with all questions relative to fish and fisheries, whether scientific or economic in character.

AT the meeting of the Royal Anthropological Institute to be held on February 17 Mr. J. Reid Moir will exhibit and describe certain flint implements and flakes found in the Boulder Clay in pits north of Ipswich and at Claydon. Prof. J. E. Marr is of the opinion that this deposit represents part of the large sheet of Boulder Clay of the Ipswich sheet. Mr. Moir's examination of the form and technique of these implements has led him to the conclusion that they may with probability be referred to the Mousterian phase of culture.

MR. F. H. CARR has just been elected to a seat on the board of directors of the British Drug Houses, Ltd. After holding for several years the Salters' research fellowship, first at the Pharmaceutical Society's research laboratory and afterwards at the Imperial Institute, where he specialised on the active principles of drugs and became a leading authority on alkaloids, Mr. Carr was appointed chief of Messrs. Burroughs Wellcome and Co.'s Chemical Department. In 1914 he was appointed a director of Boots Pure Drug Co., from which position he resigned at the end of the war.

A RADIO Research Board has been established by the Department of Scientific and Industrial Research to co-ordinate and develop researches into wireless telegraphy and telephony at present being undertaken by Government Departments. The members of the Board are:—Admiral of the Fleet Sir Henry B. Jackson, G.C.B., F.R.S., chairman; Comdr. J. S. Salmond, R.N., Lt.-Col. A. G. T. Cusins, C.M.G., Wing-Comdr. A. D. Warrington Morris, C.M.G., Mr. E. H. Shaughnessy, and Prof. J. E. Petavel, F.R.S.—representing the Admiralty, War Office, Air Ministry, Post Office, and Department of Scientific and Industrial Research respectively—and Sir Ernest Rutherford, F.R.S.

ELEANOR ANNE ORMEROD, the distinguished student of economic entomology, lived at Torrington House, St. Albans, from 1887 until her death in 1901, and it was during her residence there that she achieved the final success of her great project to convince the general agricultural public that an accurate knowledge of the life-history of injurious insects was worth having, because it provided the only sure foundation for preventive and curative measures. To commemorate her residence in the county, the Hertfordshire Natural History Society has lately put up a tablet at the gate of Torrington House on Holywell Hill, which will help to keep alive the memory of Miss Ormerod's splendid record of unselfish work.

INFLUENZA is still far from assuming anything approaching an alarming epidemic, although the Registrar-General's return for the week ended January 24 showed a slight increase. In London the deaths were 24, which is rather more than in any week since the commencement of last autumn, but the deaths in the week ended January 31 are nine fewer than in the preceding week. The deaths for the ninety-six great towns of England and Wales, including London, in the week ended January 24 were 85, also the highest in any week since last autumn, but the following week shows a decrease of 19. Both December and January were remarkably mild, which, guided by the weather associated with previous epidemics, is scarcely in favour of lessening an outbreak. So far as can be judged at present, the general health over England and Wales seems highly satisfactory.

JANUARY was very mild over the British Isles with the exception of the first week, when the mean for the United Kingdom generally was nearly 2° F. below the normal. The weekly weather reports issued by the Meteorological Office show that the mean temperature for the second week was, taking the British Isles as a whole, 4° above the normal, and in the third week the excess was 2·3°, whilst for the closing week the excess for the whole kingdom was 1·6°, a deficiency of temperature occurring in Ireland. In each week the rainfall was in excess of the normal over England. The Greenwich records show that the mean temperature was continuously above the average after the first week. The mean for the month was 42·1°, which is 3·6° above the normal for the last thirty-five years; the mean maximum was 4·9° in excess, and the mean minimum 2·1° in excess. There were fourteen days with the thermometer at 50° or above, and on four days the temperature was 55° or above. So far as London is concerned, January was warmer in 1916, when at Greenwich the mean temperature for the month was 3° warmer than January this year; the January mean for 1916 was 45·3°, whilst for 1917 it was 35·3°. In Canada January was abnormally cold, the contrast with the British Isles resembling greatly the winter of 1898–99. For the nine weeks of winter from November 30 to the end of January there was an excess of temperature, and also of rainfall, over the British Isles. The controlling factor was the frequent passage of disturbances from the Atlantic, the centres of which, for the most part, travelled in proximity to Scotland.

THE twelfth annual report of the National Museum of Wales for 1918–19 is a record of steady progress. Considerable advance has been made in the formation of the Welsh portrait and topographical collections, which will in the near future be extensively used for educational purposes and for circulation. The most important accession to the zoological department was the collection of British Lepidoptera and birds' eggs presented by Mr. A. F. Griffith, of Brighton. Specimens, models, and drawings are being collected with the view of forming a Welsh Naval and Military Historical Record, including aviation, which will not be confined to recent years, but will embrace naval and military incidents connected with Wales or in which Welshmen have taken a conspicuous part. The importance of the museum for education in Wales is shown by the use of the collections for special studies in different branches of natural science, and by visits paid by parties of mining students to Cardiff for the purpose. The museum officials do good service in answering inquiries on scientific questions and by identifying specimens submitted for examination.

THE Syndics of the Cambridge University Press have issued a new Catalogue, to which is prefixed an interesting note on the progress of printing in Cambridge. The first printer, John Siberch, settled there in 1521, and eight books have been found bearing his imprint. The modern history of the Press may be said to have begun in 1698, when, thanks to the labours of Richard Bentley, a great revival of typography took place. Additions were made to the buildings, new presses set up, beautiful types imported from Holland, and a body of Curatores Præli Typographici, of whom the Press Syndics of the present day are the successors, was appointed. One of the most famous English printers, John Baskerville, entered into an agreement with the University in 1761. Early in the nineteenth century stereotype plates, the invention of the third Earl Stanhope, were successfully used. In 1824 part of the surplus of the fund for erecting a statue of William Pitt was devoted to the new Press buildings; J. W. Parker (1836–54) was the first to introduce steam-power; and since then under the control of the Clay family—John Clay, the late printer, died in 1916—and of the present printer, Mr. J. B. Peace, the work of the Press has rapidly extended its operations, the result of which is fully illustrated in the new Book Catalogue.

IN the "Historical Collections of the Essex Institute" (vol. lvi., part i., January, 1920) Mr. F. B. C. Bradlee gives an interesting account of the maritime history of Newburyport, Massachusetts. Many famous vessels sailed from this old Essex County city, among the best known of which was the *Dreadnought*, built in 1853, and afterwards celebrated for making the shortest passage across the Atlantic ever accomplished by a sailing vessel—nine days and seventeen hours from Sandy Hook to Queenstown. She was named by sailors the "Wild Boat of the Atlantic," and was a semi-clipper, possessing the merit of being able to bear driving as long as her sails and spars would stand. Mr. Bradlee, in opposition to what he calls "a small coterie in New York," claims to have proved the correctness of the records of this famous voyage of the *Dreadnought* in 1859, and gives a full account of later ships sailing from Newburyport.

IN the issue of the Annals of the Natal Museum for May, 1919 (vol. iv., part 1), a valuable paper is contributed by Mr. Claude Fuller entitled "The Wing Venation and Respiratory System of Certain South African Termites," illustrated by eight folding plates. The author's observations on the development of the wing-veins have been directed towards an investigation of the conclusions of Comstock and Needham. One of the main points wherein he differs from the American authors is in the origin of the wing tracheæ. It is remarked that the tracheæ of the wing-sac develop from two or three buds, arising from the spiracular trunk tracheæ of the meso- and metathorax, and not upon the dorsal and ventral longitudinal trunks, as enunciated in the general scheme of Comstock and Needham. In a recent book by Comstock, "The Wings of Insects" (1918), which apparently was issued while Mr. Fuller's paper was in the press, an article is contributed by Chapman on the basal connections of the wing tracheæ, and it appears that these recent observations are more in accord with those of Mr. Fuller than the earlier American work. It is evident, however, that the origin of the wing tracheæ in termites is less primitive than in some other insects. The remainder of the paper deals with the spiracles and the tracheal system as a whole, together with a study of the venation in the completed wings of various species and of the wide range of variation exhibited therein.

IT is well known that when America was discovered maize was widely cultivated by the aborigines, but the wild source of the plant has remained obscure. Various views concerning its origin have been entertained, one being the theory of Mr. Collins, based on breeding experiments and morphological comparisons, that maize arose as a hybrid between the Mexican teosinte (Euchlæna) and some unknown grass belonging to the Andropogoneæ. Mr. Y. Kuwada in an interesting paper (Journ. Coll. Sci. Imp. Univ. Tokyo, vol. xxxix., art. 10) has studied the chromosomes of maize and its relatives, and brings cytological evidence in support of Mr. Collins's hypothesis. Maize, as well as Euchlæna and Andropogon, is found to have ten pairs of chromosomes, but those of Euchlæna are longer than those of Andropogon, while in maize they are found to be of different lengths, a pair frequently being composed of a longer and a shorter chromosome. From this it is concluded that maize is hybrid in origin, the two types of chromosomes being traceable as in certain experimentally produced animal hybrids. Some races and individuals of sugar-maize are found to have eleven or twelve pairs of chromosomes, which is attributed to cross-segmentation of one or two pairs. It would appear that in the origin of the many known varieties of maize, a considerable number of which were grown by the natives in different parts of the American continent, hybridisation and mutation may have gone hand in hand.

The United States Department of Agriculture is publishing a folio atlas of American agriculture. Part ix., section i., deals with rural population, and contains thirty black-and-white maps and diagrams based on the census returns of 1910. Among the most interesting maps are two showing respectively the increase and decrease in rural population between 1900 and 1910. Increase was mainly in the Pennsylvania mining district, in the cotton belt, in the newly developing agricultural regions of the west, and around cities. Decrease was most marked in the maize and winter wheat region. It is explained by the consolidation of many small farms into a few large ones in order to secure the full benefit of the use of machinery and large-scale production. The decrease in population in these districts is mainly a measure of their productiveness. Of much interest, too, are the maps showing the distribution of native white, foreign, and negro stocks. For this purpose all people are classed as foreign who either were born abroad or one or both of whose parents were born abroad. A series of maps shows the distribution of foreign population by countries of origin. In both urban and rural populations the Germans are the principal nationality of foreign stock, and the Irish the second. Except in the case of Norwegians, Danes, and Swedes, the foreign element is more noticeable in the urban than in the rural population. A map illustrating the percentage of the rural population unable to speak English shows a high proportion in the west and north, particularly in Wyoming, North Dakota, and Minneapolis, where the Russian and Scandinavian elements are marked, and in Pennsylvania, with its comparatively recent influx of Slavs, Hungarians, Germans, and Italians.

A good geographic account of the Mackenzie River basin has been drawn up by Messrs. C. Camsell and Wyatt Malcolm for the Geological Survey of Canada (Memoir 108, 1919). It has an eminently practical bearing, and should guide those seeking new agricultural lands or new fields for industry in the North-West.

M. L. de Launay furnishes an important review of the mineral resources of Alsace-Lorraine in the *Revue Scientifique* (November 15, 1919, p. 673). It is interesting to note that this article arose from a lecture given in the recovered town of Metz, which lies at the south end of the great field of oolitic iron-ore. Sketch-maps are given of this field and of the potassium and petroleum areas in the Rhine-vale.

The importance of algæ in the formation of limestone is further emphasised by the publication of Mr. W. H. Twenhofel's paper on "Pre-Cambrian and Carboniferous Algal Deposits" (*Amer. Journ. Sci.*, vol. xlviii., p. 339, November, 1919). In the massive cases here described it is held that the calcium carbonate does not enter into the tissues of the plant, but is deposited, as in so many recent travertines, by the lessening, through the activity of organisms, of the capacity of the water to retain the salt in solution. The deposits are thus of the nature of laminated encrustations.

The Monthly Bulletin of the Hawaiian Volcano Observatory, which is always noteworthy for its unique illustrations, gives (in vol. vii., No. 8, August, 1919) a fine picture of a lava-rush in a cave, photographed in June, 1919. The work of observation has been rendered far more interesting for readers of Nature since the publication of the views of the great topographic model, in which the situation of the scientific station is clearly shown (Nature of August 7, 1919, vol. ciii., p. 456). Mr. E. S. Shepherd gives a number of analyses of the gases collected from Kilauea in Bulletin No. 7, 1919, showing a "surprisingly high" amount of water.

The appearance of a memoir of 300 pages on "The Geology of the Country around Lichfield" (Mem. Geol. Survey, England and Wales, 1919, price 9s.) makes us once more wish that some relic of the Colby-Portlock plan, hazarded in Ireland in 1840, had been allowed to remain in our Geological Survey organisations. The scheme of the Irish Ordnance Survey was undoubtedly too ambitious for the limitations of public finance, and we now possess adequate unofficial descriptions, from the Victorian county histories down to the compact and clever Cambridge geographies, of the greater part of England. The Lichfield country is fully treated in this memoir from a geological point of view, in continuation of the important modern descriptions of the details of our British coalfields; but we should hail some expansion of Mr. G. Barrow's twelve lines on the "distribution of the population." The broad agricultural landscape, controlled by Triassic strata, that is so well seen from the tower of Tamworth, is bounded on the east and west by busy coalfields. The Roman highway leading to the west undulates upwards to the bleak moor of Cannock, a "chase" long after the days when a king's daughter held Tamworth Hill against the Danes. English history is epitomised in the buildings on this hill, now so well preserved as the municipal museum; and the changes in the density of population, from the making of the Watling Street down to the development of the coal-mines, are largely concerned with geology, and deserve a chapter to themselves.

Both botanists and geologists will welcome the second part of the memoir on the remarkable petrified plants from the silicified peat-bed in the Old Red Sandstone of Rhynie, Aberdeenshire, by Dr. R. Kidston and Prof. W. H. Lang, just published in the Transactions of the Royal Society of Edinburgh (vol. lii., No. 24, with 10 plates). The genus Rhynia and a new allied genus Hornea are described in detail and referred to a new family, Rhyniaceæ, of the class Psilophytales. These, and the other vascular Cryptogams preserved with them, are the most ancient plants of which the internal structure and external appearance are adequately known. Rhynia and Hornea have neither leaves nor roots, each consisting merely of an underground rhizome, with long, unicellular rhizoids, and a round aerial stem, dichotomously branched, with sporangia at the ends. They are the simplest known undoubted Pteridophyta, and fundamentally more primitive, not only than all existing land-plants, but also than most of the plants of the Upper Devonian and Carboniferous floras. Their geological age is not later than that of the Middle Old Red Sandstone of Scotland, and an apparently related genus, Sporogonites, occurs in the Lower Devonian of Norway. Several interesting comparisons are made with existing Cryptogams, but the authors wisely defer general conclusions until they have studied more of the associated plants.

The Report of the Department of Mines of the State of Mysore for the year 1917–18 gives a detailed account of the results of the year's mining operations. Naturally, gold-mining in the Kolar goldfield still forms the preponderating part of the industry; it is satisfactory to find that, in spite of the shortage of skilled labour and the difficulty of obtaining supplies owing to war conditions, there was but little falling-off in the output, the production, amounting to 536,558·72 oz. of fine gold, being only 17,680·71 oz. below that of the previous year. The number of accidents shows an appreciable diminution, and it is interesting to note that the dangerous effects of the rock-bursts, to which this field is liable, have been somewhat prevented by the new methods of supporting the hanging wall by means of packs of waste rock. Of the other minerals produced manganese-ore is the most important; the output of this was 31,331 tons as against 20,674 tons in the previous year. Chrome-ore, magnesite, and asbestos are also produced in small quantities, whilst workings for mica, antimony-ore, corundum, galena, and kaolin are proceeding on what can, for the present, be described as a purely experimental scale.

Amongst the reports on the mineral resources of the United States recently issued by the Geological Survey of that country one of the most interesting deals with the cement production in 1917. It is there pointed out that the United States produced 93,000,000 barrels in that year, as against a production in Europe of 72,000,000 barrels. An interesting account is also given of the development of concrete shipbuilding. The pioneer concrete ship was a small boat built in France in 1849, followed in 1887 by a small vessel built in Holland. In America the first serious attempt was commenced about 1912, when a number of concrete barges were constructed, until in 1918 the *Faith*, a sea-going vessel of 5000 tons, was launched at San Francisco. It is stated that the percentage of dead-weight to full-load displacement for vessels of 3500-tons dead-weight capacity works out at 52 for concrete, 53 for wood, and 68·6 for steel, so that the capacity of the concrete ship is considerably less than that of the steel ship, although this drawback is to some extent offset by the lower first cost of the concrete ship. Much attention is being paid to this problem in the United States, the design of the steel reinforcement and the production of cement of low specific gravity being in particular closely studied. The report, though brief, contains much information of value to those interested in this modern application of reinforced concrete.

The annual volume of the Journal of the Scottish Meteorological Society recently published contains papers of considerable interest which should be read by meteorologists on both sides of the Tweed. In the first article Lt.-Col. Gold discusses the relation of meteorology to aviation, and directs attention to the new calls which flying has made on the meteorologist. Thus, for example, visibility and cloud-height, to which little attention was directed in the daily weather service a few years ago, are now of great importance, and provision must be made for such observations in any modern system of reporting to a central office. In another paper Dr. E. M. Wedderburn, who did much to advance the usefulness of meteorology to gunners during the war, states the nature of some of the problems met with in this branch of the subject and of the solutions adopted. In the old days gunners were content to use surface meteorological conditions only in working out their corrections. The introduction of the "ballistic wind" and "ballistic temperature," which take account of the changes of the meteorological elements at all heights traversed by the shell, marks a great step forward. A note by Capt. C. K. M. Douglas shows what valuable information concerning the formation of haloes and similar manifestations may be obtained by flying among the clouds which give rise to the phenomena; while an article by Capt. T. B. Franklin on meteorology and agriculture will appeal to a different class of reader.

The February issue of *Conquest*, the new popular science monthly, gives, amongst other articles of interest, a *résumé* of the first two of Prof. W. H. Bragg's Royal Institution lectures to children on sound and an article by Dr. Rosenhain on glass. In the latter, which is well illustrated, it is pointed out how serious the consequences of our former neglect of the scientific side of glass-making might have been if we had not set about repairing this fault in the early years of the war. The author describes some of the difficulties which have to be overcome before glass suitable for scientific instruments can be produced. Impurities from the melting-pots and enclosed air-bubbles account chiefly for the large percentage of rejected glass, which may reach 80 per cent. Before the war glass for chemical laboratory use was entirely imported. Our own glass manufacturers have risen to the occasion, and it is to be desired that they should in the future be able to retain a position in the industry.

It has been known for many years that by treating a photographic plate with a weak solution of a soluble iodide development may be accelerated. In the January issue of the Journal of the Royal Photographic Society S. E. Sheppard and G. Meyer (of the Eastman Kodak Co.) describe some results of their investigations of this action. It seems that the iodide has little or no effect on the action of developers that produce a visible result very soon after their application, but that developers like glycin and hydroquinone, which are slow to produce a visible effect, are much accelerated by it in the early stages of development. With hydroquinone the whole course of development is changed. Ferrous oxalate is not affected by it. The authors suggest that the process of development takes place by the formation of a complex of silver haloid and developer (which then breaks up into metallic silver and oxidation products of the developer), and that the small proportion of silver iodide produced facilitates the formation of this complex. It is well established that silver iodide has a far stronger mordanting action on dyes than silver bromide. Unfortunately for the practical application of the process, the iodide treatment seems always to produce fog.

The Journal of the British Science Guild for January contains an appeal to members to co-operate more fully in the work of the journal, which is extending its scope. A feature of interest in the present issue of the journal is the series of short editorial notes on topical events, forming a useful supplement to the more detailed accounts of reports, etc., following. A short account is given of the last British Scientific Products Exhibition, and Sir Richard Gregory's address on "Science in Industry," delivered before the Circle of Scientific, Technical, and Trade Journalists at its meeting on the opening day of the exhibition, is reproduced. The report of the Microscope Committee, originally published in the Journal in 1916, is now presented in its revised form. The newly formed Parliamentary Committee, in conjunction with the Agricultural Committee, was instrumental in presenting a memorandum on the Forestry Act, stress being laid on the inclusion, amongst the seven suggested Commissioners, of at least one member having adequate technical and scientific knowledge of the subject. In view of the contemplated legislative measures in regard to deep-sea fisheries, the need for a comprehensive scientific survey of the industry, in order that knowledge may precede legislation, is again pointed out.

The President of the Board of Education, we note in the Journal of the British Science Guild for January, does not see his way to adopt at once the suggestion of the guild for a consultative committee to advise the Board on matters affecting the relationship of universities and higher technical education to industry, but offers hope that the request may be complied with later. The suggestion conveyed to the Foreign Office that scientific *attachés* should be added to British Embassies and Legations was met by the counter-proposal that technical associations should make their own arrangements to obtain information on foreign developments. The Department of Overseas Trade has issued a circular requesting early intimation of visits to foreign countries by representatives of British firms, in order that consular officers and other officers abroad may be notified. In view of the extensive and valuable work recorded, the appeal being made by the guild for new members and additional funds should meet with generous response. The address of the guild is now 6 John Street, Adelphi, W.C.2.

The Cammellaird-Fullagar marine oil-engine, constructed by Messrs. Cammell Laird and Co., of Birkenhead, forms the subject of an illustrated article in *Engineering* for January 30. This engine is of the two-cycle type, with two opposed pistons working in the same cylinder, which is open at both ends, and the cycle takes place between the pistons. There are two vertical cylinders in each unit, arranged side by side, and two cranks at 180°. The top piston in each cylinder is connected by inclined rods to the bottom piston of the other cylinder. There are great advantages in this arrangement, among which may be mentioned the saving in space, which is reduced greatly as compared with an ordinary marine four-cycle engine. The opposed piston type has been tried for steam, gas, and petrol engines, and has so far been found wanting. For oil-engines it has several attractive features. There is no cylinder head, and the liner is a single tube free to expand at both ends. Scavenging is simple and effective, since the sweeping-out air enters at the end opposite to that through which the exhaust leaves, and no valves are required to control the scavenging. The piston speed can, in effect, be doubled, due to the compression taking place between the approaching pistons, and thus reducing the most important heat losses during this stroke of the cycle. The turning moment is improved, and stresses are not taken up by the engine framing, but confined to the moving parts of the engine. The test-bed results for the engine under notice are good, and the performances under seagoing conditions will be watched with the greatest interest.

The latest catalogue (No. 185) of Messrs. W. Heffer and Sons, Ltd., Cambridge, contains the titles of nearly two thousand works, ranging over the subjects of agriculture and husbandry, anthropology and ethnology, botany, chemistry, geology, mineralogy and palæontology, biology, physiology, anatomy and medicine, mathematics and physics, astronomy, and engineering. Some of the volumes were formerly the property of Sir William Crookes and Sir Frank Crisp. In addition to the books referred to, there are for disposal a number of portraits of scientific men.

OUR ASTRONOMICAL COLUMN.

Large Fireball on February 4.—In the early evening at 6h. 14m. a splendid meteor was seen from various parts of the country. Among the observers were several persons who have gained experience in recording meteors, so that the real path derived from their data may be regarded as fairly accurate. The fireball was seen at a low altitude in the southern or south-eastern sky, and it moved very slowly in a very long horizontal flight, distributing sparks as it sailed along, and finally breaking up into fragments.

The radiant was at 145°+8°, and the height of the object from 55 to 44 miles, length of luminous course 275 miles, and velocity 18 miles per second.

The recent fireball was a brilliantly conspicuous object, though the full moon had just risen, and many people mistook it at first for a rocket-like firework on account of its vividness, slow motion, and final burst into spark fragments.

RELATIVE MASSES OF BINARY STARS.—Any increase in our knowledge of the masses of the stars is of great value from a physical point of view, since it throws light on the correlation of mass with spectral type. Mr. G. van Biesbroeck, in *Popular Astronomy* for January, states that photographs of binary stars are now being taken with the Yerkes refractor to determine the motion of each star of the pair, as referred to the background of faint stars, and so obtain the relative masses. Photographs of Castor were taken in the years 1916 to 1919, and give the annual motion of the bright component in R.A. −0·0167s., and for the faint component −0·0118s. Assuming Boss's value for the motion of the centre of gravity, viz. −0·0135s., it results that the faint star is 1·9 times as massive as the bright one. The weakest point is the assumption of the motion of the centre of gravity. Boss assumed equal masses; but since a value identical with his was published in Monthly Notices R.A.S. for 1907 on the assumption that the faint star is six times as massive as the bright one, it would seem that the value −0·0135s. is close to the truth.

The systems of Procyon and ζ Cancri are also being investigated. It is hoped in the former case to fill up the gap in the orbit in the region where the faint star is too near to the primary to observe.

LONG-PERIOD VARIABLES.—Several years ago the Rev. T. E. R. Phillips proposed a division of these variables into Groups I. and II., which differ in the relation to each other of the first and second harmonics, when the magnitude variation is developed in a Fourier's series. Prof. Turner and Miss Blagg contributed a paper to the Monthly Notices R.A.S. for November on the star W Cygni, analysis of the light-curve of which suggested that this star is in the act of passing from Group II. to Group I. A further paper by Prof. Turner was read at the January meeting of the Royal Astronomical Society, in which he examined the observations of several stars of Group II., for which Prof. Chandler gave a secular change of period. The analysis indicates in every case a diminution of period, but seems to show that this takes place by sudden jumps, not by a steady, continuous process, such as Chandler's formula implies. It is suggested that the period decreases to a minimum value, after which the star passes into Group I., and its period then increases again.

It was formerly the idea that these red variables were near the end of their career as suns, but from a study of their proper motions, which seem to be very small, it is inferred that they are giants, near the commencement of their career. From the case of our sun, which is an incipient dwarf star, with a sun-spot variation period much longer than that of any known variable, we may conjecture that after passing into Group I. the period continually lengthens, while the amplitude diminishes and becomes practically inappreciable, except in the case of the sun, the surface of which can be studied in detail.

AUSTRALIAN SIGNPOSTS.

IN the Records of the South Australian Museum for August, 1919,[1] Mr. E. R. Waite completes a description of the Toas or direction signs of the Australian aborigines which was partly translated and arranged from the manuscript of the late Rev. J. G. Reuther, of the Lutheran Mission, by the late Sir Edward Stirling.

The description is prefaced by a summary account of the religious beliefs of the Diari and associated tribes in the district east of Lake Eyre, in South Australia. According to Mr. Reuther, these believed in a single Supreme Being called *Mura*, who was great, powerful, beautiful, omnipresent, righteous, and omniscient. *Mura* created a number of demi-gods—*Muramura*—some perfect and others imperfect, with their wives or subjects—*Mili*. The *Muramura* were the ancestors of mankind. They wandered about the country, and the legends of the natives are the records of their journeys and adventures. Native songs and invocations were addressed to them. The *Muramura* named all things, and many of the natural features of the country are ascribed to them. They named each of their camps from something noticed there, and these are the native place-names of the district.

On the death of a *Muramura* his body usually changed to a stone, which was venerated by his descendants. Sun, moon, and the constellations were also regarded as abodes of departed *Muramura*.

The Toas are thus described. They consist mostly of a piece of flattened wood (usually from 6 in. to 18 in. in length), "pointed at one end, and either coloured or plastered over with white clay, which itself may be coloured uniformly or marked with simple designs. At the upper end the clay is frequently moulded into a spherical or oval knob, and this also may be plain or variously coloured or have inserted some object typical of the locality or symbolical of a Muramura's adventure, such as a tuft of grass, twigs, feathers, hair, etc., pieces of bone, charcoal, or a model of some weapon or utensil. In a considerable number of Toas the upper end is modelled into a representation of some part of the human body, such as the hand, head, or foot, or into that of the whole or some part of a bird, fish, or other animal."

More than three hundred coloured illustrations of Toas contained in the museum collection are given. They show a surprising variety of form and ornamentation. Each Toa has a name which is a native place-name with the suffix *-ni* or *-ri*, meaning "direction towards." Four of the figures, with their explanations, are here given as examples. They are Nos. 1, 14, 66, and 187.

"1. *Dakarawitjarini* (Diari Tribe).—The word means a hard flat or plain, where Emus run to and fro, and it originates from the legend of the Muramura, Ngurakarlina, who, coming to the place, saw many of these birds running about.

"The longitudinal, vertical, and partly sinuous black stripe on the Toa represents a salt creek, the oval patch being a deep waterhole, and the lateral branches tributary creeks. Surrounding these is the plain where the Emus used to run, the white spots indicating bushes and scrub. This is the largest Toa in the collection, being over five feet in length."

"14. *Mararuni* (Wonkanguru Tribe).—To the hand

[1] "Description of Toas, or Australian Aboriginal Direction Signs." Being an Abstract from the J. G. Reuther Manuscript by the late Sir Edward Stirling, F.R.S., Hon. Curator in Ethnology, and Edgar R. Waite, Director, South Australian Museum. Pp. 105-55+plates xi-xx Public Library, Museum, and Art Gallery of South Australia. Records of the South Australian Museum. Edited by the Museum Director. Vol. i., No. 2. (Adelaide: Published by the Board of Governors, August 30, 1919.)

with four fingers, the Toa representing a four-fingered hand. The Muramura, Wutjukana, had a servant whose index and middle fingers had partly grown together, as indicated by the Toa. The Toa also has a geographical significance, for when Wutjukana came to a gorge which divided into four branches, one being deeper than the others, he said to himself, 'This place looks like the hand of the servant,' and so he gave it this name."

"66. *Witjikurawinpani* (Tirari Tribe).—To the tracks of the whirlwind in the sand. When the Muramura, Patjalina, once came, hunting, to this place, he noticed that a whirlwind had passed over it, which had effaced the tracks of animals and had swept together a litter of leaves and grass; hence he named

it thus. The white knob represents a sandhill overgrown with bushes (red dots) which adjoins Cooper's Creek. The crescent-shaped, black figure below indicates the creek itself, and the black vertical band a deep waterhole at the foot of the hill, which has been washed out by a flood. The surrounding borders of white and yellow signify soil of these colours, and the white spots trees."

"187. *Muramurawintini* (Tirari Tribe).—To the Muramura's hair. So named because on this plain the Muramura, Patjalina, tore out his hair and threw it away. The white colour represents the plain, with watercourses (red and yellow stripes), and, in accordance with the name, the Toa bears a tuft of hair."

When a native is about to remove to another camp he makes a Toa representing the locality to which he is removing and sticks its pointed end into the earth of the camp which he is leaving. Signs are made on the ground directing attention to its presence. His friends who arrive later recognise the significance of the Toa, and are thus made aware of the place to which he has gone.

The whole collection and its elucidation form a most interesting contribution to the study of Australian symbolism.

SIDNEY H. RAY.

HUMAN METABOLISM.[1]

THE first of the monographs before us deals with the prediction of basal metabolism from a knowledge of individual physical and biological constants. The usual process has been to multiply the subject's surface area, as deduced from the height and weight by du Bois's method, by the average Calorie output per square metre determined from a "standard" series, it being assumed that the metabolism per unit area in adults is approximately constant. The order of the error involved and the improvement effected by Drs. Harris and Benedict's process can be gauged by the following example. In these authors' series of 136 adult males, the mean twenty-four hours' basal output was 1631·7 Calories with a standard deviation of 204·7 Calories; the latter is 12·5 per cent. of the mean. The corresponding mean per square metre of surface was 925·5 Calories with a standard error of 74·5 Calories, about 8 per cent. of the mean.

It follows that if the distribution around the mean be assumed to be normal (actually, using a coarse unit of grouping, we find that the authors' series for women is in good agreement with a normal distribution; the series for men is somewhat less regular, but not a very improbable sample from a normal population), the assignment of 925·5 Calories per square metre as the basal metabolism of an unknown individual is subject to a standard error of ±8 per cent. But if a prediction is based upon a multiple regression equation of the first degree, the other variables used being height, weight, and age, the standard error of the prediction falls from 204·7 Calories to 101·7 Calories, or the *average* percentage is 6·2.

These remarks assume that the correlation is normal correlation. As this may not be the case, and as a complete study of the form of the regression cannot profitably be made without a larger collection of data, the authors have empirically tested the accuracies of the several methods, comparing the predictions based on their equations for samples not utilised in the calculation of the constants with those afforded by the surface rule. In nearly every case the regression equations give results closer to the truth than does the surface rule.

We may illustrate with a couple of examples taken at random from the data. A man aged twenty-nine, weighing 66 kg. and 177 cm. tall, had a basal metabolism of 1695 Calories. The surface rule would assign 1675 Calories, with a standard error of 135; the multiple regression formula gives 1664 Calories, with a standard error of 102. Here both results are good. In another case a man aged forty-three, weighing 58·5 kg. and 181 cm. tall, had a basal meta-

(2) "Human Vitality and Efficiency under Prolonged Restricted Diet." By Francis G. Benedict, Walter R. Miles, Paul Roth, and H. Monmouth Smith. Publication No. 280. Pp. xi+701. (Washington: The Carnegie Institution of Washington, 1919.)

bolism of 1331 Calories. The regression formula gives 1486 Calories ± 102; the surface rule 1620 Calories ± 130.

Neither prediction is close to the truth, but that of the regression equation is decidedly superior. On the whole, there is no doubt that the regression method is preferable, and that the tables provided by the authors are of value. In general, however, the difference is not such as to give rise to any apprehensions that the use heretofore made of the surface rule has led to practical inconvenience. Prof. Lusk recently wrote:—"For the study of metabolism processes it is certainly most fortunate that the unit of surface area eliminates the same amount of heat in the normal adult within 10 per cent. of a determined average. The reason is not clear."

This remark is not invalidated by Drs. Benedict and Harris's results, although they have provided a somewhat superior criterion. It is proper to notice this point, as our authors are a little too prone to lecture their physiological colleagues upon the real meaning of scientific "laws," and, as we think, exaggerate the importance which the surface "law" assumes in the minds of those who have employed it as a convenient working rule.

Space would have been saved and the statistical results and methods might have been brought to a sharper focus had a number of sententious generalities been omitted. An instance occurs on p. 148. The authors properly remark that surface must be less variable than mass (when Meeh's formula is used), and imply that it is a direct arithmetical consequence that heat per surface unit is less variable than heat per mass unit. This really needed further investigation. The coefficient of variation of an index is a function not only of the coefficients of variation of its constituents, but also of their correlation; the substitution for one constituent of another less variable constituent might not reduce the variability of the index were the correlation also greatly reduced. In the present case the two correlations are nearly equal, and the authors could have actually made their point more securely had they explained the theory of the matter more fully.

Were physiologists really so ill-acquainted with statistical methods as the authors hint, the remarks on p. 16 with respect to the "probable error" of the mean of a sample of four might be dangerous. But we think that British physiologists are quite alive to the importance of biometric methods, sufficiently so to congratulate Drs. Benedict and Harris upon the conclusion of a laborious task which has yielded results of appreciable value to other students of metabolism.

The second volume describes two series of experiments upon squads of college students, originally twelve in each squad. In squad A, diet providing approximately 2500 Calories and 13 grams of nitrogen was maintained for four months; in squad B, a still lower diet, yielding about 9 grams of nitrogen and 1500 Calories, was used for three weeks. The former squad lost on the average 12 per cent. of the initial body-weight, and the basal metabolism per square metre per twenty-four hours fell from 940 to 817 Calories. Squad B lost 6·5 per cent. of the average body-weight, and the basal metabolism also declined considerably. The urinary excretion of nitrogen in both series was not so variable as might have been expected, and did not decline, *pari passu*, with the diminished intake. By the end of the experiment on squad A, an average loss of 175 grams of nitrogen (based on nine men continuously observed) was inferred.

In the course of the experiments intervals of uncontrolled feeding occurred, viz. during the Thanksgiving celebrations, November 29 to December 2, 1917, and during the Christmas holidays, December 20, 1917, to January 6, 1918. On alternate Sundays the diet was usually uncontrolled. A very large number of anthropometric, physiological, and psychological measurements were made upon these men. In addition to the decline of basal metabolism above noted, both pulse-rate and blood-pressure diminished. Little objective evidence of a decrease of physical efficiency was obtained. The majority of the psychological tests pointed to a diminution of efficiency, or at least to a lack of improvement with practice. The students' college work, on the other hand, did not appear to suffer.

The value of this research, which verifies upon a relatively large scale the practicability of diminishing both the rate of metabolism and the quota of body nitrogen by a simple reduction of intake, should be appreciated by scientific clinicians, while many issues of physiological interest are raised and lines of advance suggested to the pure physiologist, especially in connection with the study of levels of nitrogenous metabolism.

As a contribution to the science and art of national dietetics, this elaborate—one might almost say over-elaborate—study is not of so much importance. It is shown that a great reduction, both of available energy and protein, may be borne for some months by healthy adults without either immediate breakdown or sign of enduring deterioration; these are facts which involuntary experiment on a vast scale had already demonstrated. The correlation between variations of nutrition and of resistance to infection, which "common sense" has postulated and which the vital statistics of Europe seem to substantiate, must engage the attention of future investigators; at present an adequate experimental technique is lacking. We do not think that Dr. Benedict and his associates have obtained any results either invalidating the general conclusions expressed by the Food (War) Committee of the Royal Society or filling up lacunæ in our knowledge of the general subject shown by that committee to exist. The experimental and statistical study of national dietetics is still in its infancy. M. G.

ISOSTATIC COMPENSATION IN THE EARTH'S CRUST.

TWO articles on isostasy by the late Prof. Joseph Barrell, which appeared in the *American Journal of Science* for October, 1919, contain what may be regarded as his mature views on the subject. The first, entitled "The Nature and Bearings of Isostasy," was a summary of six lectures delivered by Prof. Barrell at Columbia University in 1916; it gives a general account of the theory of isostatic compensation, and of the methods of investigation which have led to the recognition of the phenomenon. The second article, "The Status of the Theory of Isostasy," was written just before the author's death; it vindicates the theory as to attacks which have been made on it by MacMillan and others, and describes the various views which are held as to the degree of perfection of isostatic balance existing in Nature. Hayford's general conclusion is maintained: that surface inequalities of contour and mass are accompanied by inverse inequalities of density beneath the surface, so that at a depth of about 120 km. equal areas have equal masses superposed; but a view different from Hayford's is taken as to the exactness of this compensation.

Hayford estimated the greatest departure from compensation as being 250 ft. above or below the level for perfect balance over an area of one square degree on the earth. Other geodesists consider that the deviation is much less than this, even when the areal extent is smaller; Sir S. G. Burrard, for instance, at the recent discussion on isostasy before the Royal Astronomical Society (*Observatory*, December, 1919), suggested that so small a body as the Great Pyramid might be compensated. Prof. Barrell, on the other hand, while admitting that the larger relief of the earth is compensated for with considerable exactness, contends that over limited areas there are large deviations—amounting to 1000 ft. over an area 200 miles in diameter (about 3°), or even more. He regards the upper part of the earth's crust as sufficiently strong to sustain uncompensated loads of this amount, the vertical magnitude of the departure being, of course, inversely proportional to its areal extent; it can thus support individual mountains or limited ranges, as well as erosion features of considerable magnitude, such as the Nile and Niger deltas. Under greater and more widely extended loads, however, the crust is supposed to bend in gentle curves involving but little crustal stress; this bending is accompanied by yielding in a lower, weaker layer, which brings about isostatic compensation.

The question at issue is largely one of fact, which can be settled by observation; *e.g.* if pendulum observations show that the Nile deposits are compensated in the crust, the result will confirm the views of the extreme isostasists, that continuous adjustment goes on when the surface load changes over a comparatively small area. The manner of this adjustment, however, has not yet been made clear, and Prof. Barrell's picture of the process is more easy to conceive. On the other hand, Sir S. G. Burrard has shown recently that the alluvium in the Gangetic trough at the foot of the Himalayas is compensated for. It is much to be regretted that Prof. Barrell's death deprives us of his interpretation of this result.

DEFENSIVE SCIENCE IN GAS WARFARE.

THE prizes and certificates gained by students at the Sir John Cass Technical Institute, Aldgate, were distributed by Lt.-Col. P. S. Lelean, professor of hygiene, Royal Army Medical College, on the evening of Tuesday, February 3, when the chair was taken by the Rev. J. F. Marr, who has succeeded Sir Thomas Elliott, K.C.B., as chairman of the governing body.

Following the distribution, Col. Lelean gave an address on "Defensive Science in Gas Warfare," in which he described the preventive measures that had been adopted to meet its onset and evolution. After referring to the initial attack on April 23, 1915, when the civilised world was aroused to just anger by the news that the Germans had broken their pledged word in respect to the use of poisons as a means of injuring the enemy, Col. Lelean dealt with the means of protection first adopted in the form of pads soaked in sodium thiosulphate, of which no fewer than 98,000 were distributed to the Front within sixty hours of the attack, 300,000 within a week, and 2,000,000 within a month—a truly notable achievement, which was rendered possible only by the combined efforts of men of science, manufacturers, and voluntary helpers.

With the recognition of gas attacks as an established adjunct of modern warfare, this temporary device was succeeded by the more efficient protective appliances which were called for by the advent of toxic, paralysing, and lachrymatory gases such as carbonyl chloride, hydrocyanic acid, and chloropicrin, which culminated first in the adoption of the "P" helmet, of which nearly 27,000,000 were issued between July, 1915, and the final withdrawal in February, 1918, in favour of the now well-known "box-respirator."

A full description was given of the great difficulties that were met with stage by stage during the development of these protective appliances, especially in respect to the need for the complete absorption of the small percentages of the poison gases concerned, together with the fundamental requirements of comparative ease of breathing and exhalation.

Col. Lelean paid a special tribute to the outstanding services of Sir William Horrocks and to the late Col. E. F. Harrison in this connection; also to the many scientific helpers with whom they were associated, and particularly to the gallantry and devotion to duty of the small band of scientific workers who had served under him and upon whom had devolved the practical testing of the efficiency of the many devices which were experimented with in a "lethal chamber" before their issue to the fighting forces could be justified.

In speaking of the helpful war-work contributed by the staff of the Sir John Cass Technical Institute, Col. Lelean expressed the view that it was to such institutes that the nation looked in its hour of scientific need, and had not looked in vain; and that it is to such institutes also that, with an ever-increasing appeal, we shall have to look for victory in the future strife of industrial competition, which can be won only by superior technical skill.

VISUAL TESTS FOR MOTOR-DRIVERS.

THE Council of British Ophthalmologists, realising the importance of submitting chauffeurs and other drivers of motor vehicles to some visual tests, appointed a committee to consider the question. Its report is divided into five parts:—(1) The existing conditions under which licences are at present granted; (2) the number of accidents occasioned annually in London by mechanically propelled vehicles; (3) the various kinds of visual defects in motor-drivers from which accidents may arise; (4) proposed scheme of visual testing for licences; and (5) summary of recommendations. The subject is complicated by the following facts. There are two licensing authorities, the county or borough councils and the police authorities. The requirements vary according to the type of vehicle, *e.g.* private cars, commercial cars, omnibuses, taxi-cabs, and tramcars. The total number of applicants for licences makes it impracticable to submit every one to a satisfactory sight test. The council's chief recommendations are:—

"That special sight-test certificates for drivers of motor vehicles be instituted, and granted to applicants whose sight has been tested by ophthalmic surgeons appointed for the purpose, these certificates to be of three grades: Grade A, certifying the holder's visual capacity to drive any kind of motor vehicle; Grade B, certifying the holder's visual capacity to drive any kind of motor vehicle other than a motor-omnibus or tramcar; and Grade C, certifying the holder's visual capacity to drive a motor-tramcar.

"*For Grade A Certificate.*—(1) Every applicant, in addition to manifesting his ability to steer a motor-car satisfactorily in daylight, should be required, in a trial trip at night, to show himself capable of driving in dim light and under varying degrees of illumination. (2) In an examination by an ophthalmic surgeon he should show: (*a*) Visual acuity of 6/9 in one eye and 6/24 in the other eye without the aid of glasses; (*b*) a full field of vision in each eye; (*c*) no manifest squint; and (*d*) no double vision.

"*For Grade B Certificate.*—(1) Every applicant, in addition to manifesting his ability to steer a motor-car satisfactorily in daylight, should be required, in a trial trip at night, to show himself capable of driving in dim light and under varying degrees of illumination. (2) In an examination by an ophthalmic surgeon he should show: (*a*) Visual acuity of 6/9 in one eye and 6/24 in the other eye, with glasses if necessary; (*b*) a full field of vision in each eye; and (*c*) no double vision.

"*For Grade C Certificate.*—(1) Every applicant should be required in a trial trip to show himself capable of driving a motor-tramcar by day and by night under varying degrees of illumination. (2) In an examination by an ophthalmic surgeon he should reach the same visual standards as for a Grade A certificate."

The council has clearly taken great pains to consider the subject in all its manifold bearings. The recommendations appear to be adequate and reasonable, and there is evidence that the authorities are favourably disposed to them.

INERTNESS OF INDUSTRIAL EXPLOSIVES.

FROM Western Australia we have received an interesting report on investigations into the development of inertness in industrial explosives of the nitro-compound class by Mr. E. A. Mann, Chief Inspector of Explosives, and his colleague, Mr. T. N. Kirton (Perth, W.A.: Government Printers). These investigations were started in 1912 in consequence of repeated complaints from the mines that the explosives supplied failed to do the work expected of them. That these complaints were not without foundation was soon ascertained by obtaining samples of the explosive under suspicion and testing their velocities of detonation. The method employed was the well-known D'Autriche system, by which the velocity is calculated in relation to the meeting point of detonations of "cordeau détonant" or T.N.T. fuse initiated at either end by detonators embedded at a fixed distance from one another in the sample under test. The results were startling, and in some instances almost incredible had they not been confirmed by excellent photographs. One of the most striking cases is perhaps that of a gelignite cartridge both ends of which were shattered by the detonators attached to the T.N.T. fuse, while the main body of the cartridge remained intact. This is, of course, an extreme case, but in several instances the velocity of detonation was found to be as low as a few hundred m.p.s. as compared with about 2300 m.p.s. on arrival in the country. Another significant feature is that these inert samples have invariably increased in density from about 1·60 on arrival to about 1·69.

Although a certain degree of after-gelatinisation, with consequent reduction of sensitiveness to detonation, is a recognised phenomenon even in this country, it has not been sufficient to have any practical effect in our temperate climate; but as a result of this report it cannot be denied that, so far as our Oversea Possessions are concerned, the matter is of considerable importance, and deserves the consideration which we understand our leading manufacturers are giving to it. From concurrent observations which the writers of the report have made in regard to the alteration in the viscosity of the nitro-cotton when extracted with amyl acetate, they are disposed to attribute the phenomenon to a change in the molecular structure of this ingredient, and the further investigations they promise will be interesting.

FLOW OF WATER THROUGH A PIPE.

A PAPER entitled "The Orifice as a Means of Measuring the Flow of Water through a Pipe" describes experiments made by Messrs. Davis and Jordan, of the Engineering Experiment Station of the University of Illinois (Bulletin 109), to determine the practicability of measuring the flow of water in a pipe line by means of the pressure drop across a circular orifice in a thin plate diaphragm inserted at a pipe joint. The experiments, which covered a range of pipe diameters ranging from 4 in. to 12 in., show that as a temporary measuring device, or where the loss of head produced by the diaphragm is not serious, the method is capable of useful application. Measuring the upstream head at a point 0·8 of the pipe diameter from the diaphragm, and the downstream head at a point 0·4 pipe diameter from the diaphragm, the discharge is proportional to the square root of the difference of these heads. For a given pipe, the discharge coefficient varies slightly with the diameter of the orifice and with the velocity of flow. So long as the ratio of the diameters is between 2 and 8, the variation is, however, small. For measurements in which an error of 2 per cent. is not serious, the discharge may be taken as given by:—

$$Q = AK\sqrt{h} \text{ cub. ft. per sec.}$$

where A is the area of the pipe in sq. ft.

,, h is the difference of head on the two sides of the orifice.

$$,, \quad K = \sqrt{\frac{2g}{2.64\left(\frac{D}{d}\right)^4 - 1}}.$$

Tables showing the accurate values of K for different diameters of pipe and of orifice are given in the original paper. The device would appear to be of value for field service, as being capable of easy and inexpensive application, since in a flanged pipe system the diaphragm may be inserted at a joint with little or no disturbance of the existing piping.

APPLICATIONS OF AMPLIFYING ELECTRIC VALVES.

M. L. BLOCH communicates an interesting paper on the industrial applications of the amplifying valves used in radio communication to the *Revue Scientifique* of January 10. When the vacuum is almost perfect these valves can be used to increase the amplitudes of high-frequency oscillations at least a thousandfold. Their great advantage is that they act as if devoid of inertia, and so completely solve the problem of a telephonic relay. They are already in use in long-distance telephony. For alternating currents of low frequency the vacuum in the valves does not need to be nearly so high. If argon is used a vacuum of 3 cm. suffices, and currents as large as five amperes can pass through the valve. The valves can be usefully employed for charging accumulators from alternating-current circuits. Another important application is for measuring very small currents and pressures. The currents are magnified a thousand times, and then they actuate direct-reading instruments. By their use the messages sent from the powerful American radio stations at Annapolis and New Brunswick can be recorded on a Morse ribbon in Paris. They were much used in "earth-telegraphy" during the war. Two conductors were fixed in the ground about 50 metres apart, and a source of high-frequency current and a microphone were connected between the conductors. The receiving circuit was similar, but contained an amplifying valve and a telephone. Messages could easily be sent in this way. This method proved of great value when the ordinary lines were cut by the enemy. The valves also made "direction finding" and communication between aeroplanes easy. When used as generators they give currents the frequencies of which can be varied from a tenth to millions per second. They are of great value, therefore, for calibrating wave-meters. It is also possible by their use to maintain the oscillations of mechanical vibrators by suitable arrangements. They introduce the equivalent of negative friction or negative damping into the circuits.

THE FUTURE OF TROPICAL AUSTRALIA.

THE possibilities of settlement in tropical Australia are discussed in great detail by Mr. Griffith Taylor in the *Geographical Review for* August (vol. viii., No. 2). Taking tropical Australia to be bounded by the southern tropic, Mr. Taylor gives it an area equal to barely 40 per cent. of the total area of Australia and about one-thirtieth of the total population. Analysing carefully the climatic and vegetational factors, he concludes that it is mainly a pastoral land except in eastern Queensland, where tropical crops and wheat do well. The coastal lands of the Gulf of Carpentaria are also fit for agriculture. Mr. Taylor sees little hope of tropical Australia becoming a prosperous and productive land if the White Australia policy is maintained. Chinese are chiefly restricted to tropical lands with an abundant rainfall. The hot, dry climate of the greater part of tropical Australia is best suited to the natives of India. Even if white settlement proved to be possible by a slow process of acclimatisation, it would only be at the cost of many lives, and at best would take a very long time. But, assuming that political difficulties will eventually be overcome, Mr. Taylor tries to estimate the future population that tropical Australia could support provided transport facilities are introduced. One district in the interior of Western Australia and the Northern Territory, with an area of about 150,000 square miles, is suited for any population. The remainder of the area under consideration, according to his estimate, could support a total population of about 1,400,000, with a density varying from 8 per square mile in the east of Queensland to 1 per square mile or less in the more arid parts of Western Australia and the inland regions of the Northern Territory. Mr. Taylor's paper is a valuable contribution to the study of Australian problems.

PLANT-LICE IN THE TROPICS.

A RECENT publication of the Scientific Institute of Buitenzorg contains a well-worked-out monograph by P. Van der Goot of the aphides of Java. The author attributes the comparative scarcity of plant-lice in the tropics, as compared with temperate regions, to the attacks of insect enemies such as Syrphidæ, Coccinellidæ, and mining wasps, and also to the occurrence of violent rainstorms, drought, and other unfavourable climatic conditions. The tobacco plant and sugar-cane are the only cultivated plants seriously injured by aphides in Java. In Europe there is always a longer or shorter period of lowered temperature during which the functions of plants are more or less in abeyance. This unfavourable period is generally passed through by aphides in the form of eggs laid in autumn by sexually developed females. If, however, the temperature is artificially kept up, the sexually developed females persist, together with the eggs, and propagation takes place in the regular manner, *i.e.* by means of parthenogenetic, viviparous females. In the tropics there is no considerable lowering of temperature; there is, however, generally a rainy and a dry season. In the latter, though there is often a failure of nutriment, there is never found a rest-form in the condition of sexually produced eggs. Even in mountain regions, where in the dry season the temperature may fall to freezing point, the author has never found sexually developed aphides. Propagation of these insects in the tropics, says Van der Goot, takes place invariably by means of parthenogenesis. He has never observed in Java a regular migration of aphides; whether such a phenomenon ever occurs he is unable to conjecture. The production of winged forms does not always depend on the drying-up of plant-food, for some species acquire wings in the middle, and others at the end, of the dry season.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BIRMINGHAM.—The board of management of the Brewing School has given the sum of 20,000*l*. for the endowment of a chair of brewing, to be known as the Adrian Brown chair, in memory of the late Prof. Adrian Brown, F.R.S., the first professor of brewing in the University.

A sum of more than 2000*l*. has been subscribed for the endowment of a lectureship in social philosophy as a permanent memorial in honour of Prof. J. H. Muirhead.

LIVERPOOL.—The council of the University has appointed Mr. G. E. Scholes to the recently established chair of engineering-thermodynamics of heat engines. Mr. Scholes studied in the engineering department of Owens College, Manchester, and has held important teaching posts in engineering subjects at Manchester and Liverpool Universities and in the Army engineering schools. During his career in the Army, which he joined in 1915, Mr. Scholes did valuable work as a captain-instructor in petrol and other engines at one of the R.E. schools. Also as experimental officer he successfully devised important technical improvements relating to aircraft defence. The chief of these was a device in connection with sound-locators, which Mr. Scholes designed and constructed. This invention was adopted and standardised, the inventor being awarded a grant from the Inventions Award Committee.

MANCHESTER.—Mr. Frank Watts, who has been appointed assistant to the director of the Department of Industrial Administration at the College of Technology, will devote especial attention to a study of vocational selection and training, and assist in working out a set of tests of industrial fatigue.

THE Regional Association, the president of which is Prof. Patrick Geddes, will hold a conference on regional survey during the Easter vacation (April 6–13) at the Outlook Tower, Edinburgh. Residence is being arranged in University Hall, so that the advantages of communal life may be enjoyed during the week.

THE Seale-Hayne Agricultural College at Newton Abbot, in Devon, commenced last month its first series of regular courses in agriculture with a very satisfactory complement of students. The courses given comprise a three-year diploma in agriculture, a two-year certificate in agriculture and horticulture, and short courses upon various subjects of agricultural importance, such as poultry-keeping, dairying, etc.

THE election to the Sorby research fellowship of the Royal Society and the University of Sheffield will take place after Easter. The appointment will be for five years, and the value of the fellowship is approximately 500*l.* per annum. The person elected will be expected to pursue his investigations at the University of Sheffield, if possible. A copy of the regulations governing the fellowship is obtainable from the Royal Society, the secretaries of which will receive applications for the fellowship itself up to April 20.

A COURSE of five public lectures is to be given at 5 o'clock on successive Wednesdays, beginning on February 25, at the Imperial College of Science and Technology, South Kensington, by Sir Richard Glazebrook, the University of London Zaharoff professor of aviation. The subjects will be:—"Aeronautical Research," "Stability and its Investigation," "Instruments and Methods of Full Scale Research," "Strength of Construction," and "The Airscrew: Its Design and Efficiency." Application for tickets of admission should be made to the Registrar of the college.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, January 29.—Sir J. J. Thomson, president, in the chair.—Prof. W. **Bateson** and Caroline **Pellew**: The genetics of "rogues" among culinary peas (*Pisum sativum*). In a previous communication (Proc. R.S., lxxxix., 1915) the authors showed that certain intermediates between types and rogues in peas had a peculiar genetic behaviour. Families raised by self-fertilisation from them consist of a small minority of type-like plants and a majority of rogues. Preliminary experiment showed that the type-like plants come from seeds contained in the *lower* pods. Investigations of the past four years, consisting chiefly of reciprocal crosses made from successive flowers, have confirmed this conclusion, and proved further that the ratio of type-like to rogue-like gametes is different on the female and male sides. On the female side the ratio is about equal for the first ten flowers, after which the proportion of rogues increases. On the male side, taking the type-like gametes as unity, the proportion of rogue-like for the first six flowers in succession is as follows:—4·6, 4·9, 7, 10, 12·3, and 29·5. From self-fertilisations the proportion found for the first six flowers is 15, 11, 13, 15, 54, and more than 100. There is thus a gradational change in successive flowers. This gradual elision of the type-characters must be brought about by a process similar to that which operates more rapidly in the case of F_1 plants bred between type and rogue. These, though containing the type, breed rogues only, the type being excluded in the base of the plant.—L. T. **Hogben**: Studies of synapsis. I.: Oogenesis in the Hymenoptera. The more salient conclusions arrived at are as follows:—(1) Sex determination in ♀ agamically produced: In Cynips and Rhodites (agamic forms) there is reduction of the chromosomes in the young oocyte. The somatic number of chromosomes in Rhodites is 18, as believed by Henking. The chromosomes of the young oocyte counted by Schleip are double (bivalent). Henking's belief in the doubling of chromosomes in segmentation is confirmed. Both polar bodies are probably formed as the result of homotypic division. (2) The maturation prophases: A diploteric and pachyteric stage with the biciploid number of filaments follows synapsis in all cases in the young oocyte. At this stage nurse-cells are differentiated. In Cynips, Rhodites, and Orthopelma the *diploid* number reappears after a "diffuse" stage. These univalents pair end to end, as described by Heynes in Copidcsoma. There are thus two chromosome conjugations in the parasitic Hymenoptera, as described in Lepidosiren by Agar, but not hitherto confirmed in other animals by other work. An abortive spindle followed by an atypical formation of polar bodies appears to be general in the Hymenoptera. (3) Secondary nuclei and the oosoma: Secondary nuclei were observed in the oogenesis of Synergus, Formica, and Lasius. They appear to arise from chromidia ejected from the germinal vesicle at the time when the latter undergoes diminished staining capacity. The "oosoma" arises in Synergus as a cloud of cytoplasmic granules. It is not nuclear in origin.—H. **Onslow**: A periodic structure in many insect scales, and the cause of their iridescent colours. The cause of iridescence in insects, etc., still remains unexplained. The minute structure of many iridescent bodies was investigated, because the most eminent physical authorities differed fundamentally as to the cause of their colour. The great variety of structures described and illustrated shows that each object must be judged on its own merits, because no general theory will explain all cases. The principal type of colour-producing structure found in butterflies has not hitherto been described. It consists of transparent plates of chitin separated by films of air. These plates are at right angles to the scale-surface, and only a few half-wave-lengths in thickness. Their height, shape, and colour together control the colour-tone and saturation. Some butterflies have plates of chitin apparently parallel to the plane of the wing; others, again, show structures the colour of which cannot be explained. Reasons are given showing that the monochromatic transmission and reflection colours in beetles' scales are probably not entirely due to "gratings," as was proposed by Michelson. The chief objections to metallic reflection in the case of scales are not met with in the wings of scaleless beetles. Here the colour-producing layer is so near the surface that it would be difficult for any other adequate structure to exist. In certain beetles the colour is produced by a thick layer of doubly refractive rods, such that sections tangential to the surface still retain their colour. The wing chitin of golden "tortoise beetles" appears metallic at all depths when moistened, but loses colour when dry. In other insects and some ticks the colour returns on wetting, apparently because there is a thin film, which by adsorbing water becomes transparent, and can cause interference. Iridescence in dragon-flies, the eyes of flies, plants, and certain hairs, such as the golden mole, is also discussed.

Mineralogical Society, January 20.—Dr. A. E. H. Tutton, past president, in the chair.—Dr. E. S. **Simpson**: Gearksutite at Gingin, Western Australia. This mineral, which occurs in Cretaceous greensand, is considered to have a composition corresponding to the formula $CaF_2.AlF(OH)_2.H_2O$, and to have originated from the interaction *in situ* of fluorapatite, gibbsite, and carbonated water.—C. E. **Barrs**: Fibroferrite from Cyprus. Analysis of material from Skouriotissa, Cyprus, gave the following result. Fe_2O_3, 31·36; SO_3, 30·95; H_2O (by difference), 37·01; insoluble, 0·68.—Dr. G. T. **Prior**: The classification of meteorites. For purposes of the classification of meteorites, the significance is pointed out of the chemical composition of the nickel-iron and the magnesium silicates. In the case of meteoric irons, the structural features, as revealed by etching, are shown to be closely related to the content of nickel. In meteoric stones the proportion of magnesia to ferrous oxide in the magnesium silicates varies directly with the proportion of iron to nickel in the nickel-iron. On these principles the four classes of meteorites, viz. irons, stony-irons, chondrites, and achondrites, can be divided into interrelated groups.

The three groups of chondrites are distinguished as enstatite-chondrites, bronzite-chondrites, and hypersthene-chondrites, according to the chemical composition of the pyroxene. The achondrites are divided into corresponding groups of enstatite-achondrites, bronzite (-augite)-achondrites, and hypersthene-achondrites, while a fourth group is added richer in lime (and mostly also in alumina) than the chondrites. To avoid confusion owing to Brezina's misuse of the term chladnite, the enstatite-achondrites, comprising Aubres, Bustee, and Bishopville, are called aubrites; while for the hypersthene-achondrites (Shalka, etc.) a reversion is made to Tschermak's original name of diogenite.—A. F. **Hallimond**: Torbernite. In continuation of the author's previous work, a series of weighings was made on Gunnislake material held over various concentrations of sulphuric acid. Dehydration did not occur at the pressure required, and only took place slowly over strong acid in a period of many months. It is clear that this mineral cannot be identical with ordinary torbernite. The refractive index agrees with that found for an abnormal torbernite by N. L. Bowen. Normal torbernite has the density 3·22 and mean index 1·585, while for artificial meta-torbernite and for the Gunnislake mineral the density is 3·68 and the index 1·624. An approximate reading yielded for Gunnislake crystals $c:a=2{\cdot}28:1$. The basal planes of the two forms are of the same dimension, and the volume-change due to the addition of $4H_2O$ is borne by an increase in the vertical axis. The density of the water of crystallisation is 1·2, a value common in hydrated salts, while the refractive power is equal to that for liquid water.

CAMBRIDGE.

Philosophical Society, January 26.—Sir Joseph **Larmor**: Gravitation and light.—E. **Landau**: Note on Mr. Hardy's extension of a theorem of Mr. Polya.—L. J. **Rogers**: A Gaussian series of six elements.

MANCHESTER.

Literary and Philosophical Society, January 20.—Sir Henry A. Miers, president, in the chair.—Prof. W. M. **Calder**: Geography and history in the Mediterranean. The author described the relation of the Mediterranean to the series of great plains lying to its north and south, and to the mountain systems known as "the roof of the world." The influence of the sea and land routes on the trade and growth of neighbouring countries was discussed. The great importance of Aleppo as the railway junction of the future for London, Berlin, Calcutta, Cairo, and Cape Town was pointed out. "Rail power" may one day restore the Levant to its ancient position as the centre of communications of the Old World.

Literary and Philosophical Society (Chemical Section), January 30.—Mr. R. H. Clayton in the chair.—Dr. R. S. **Willows**: Recent work on colloids. A definite amount of energy is associated with definite colloidal areas. Adsorption was defined and sols described. Surface tension and some technical applications were discussed by the author.

PARIS.

Academy of Sciences, January 5.—M. Henri Deslandres in the chair.—A. **Lacroix**: The systematic classification of grained rocks containing plagioclase and felspars.—C. **Moureu**, C. **Dufraisse**, P. **Robin**, and J. **Pougnet**: The stabilisation of acrolein. Preservative action of phenolic bodies. Phenols all possess the property of stabilising pure acrolein, and certain polyphenols (pyrocatechol, hydroquinone, and pyrogallol) are especially active.—A. **de Gramont**: The direct arc-spectra of metals of low melting point. The metals examined were lead, zinc, cadmium, tin, antimony, bismuth, aluminium, and magnesium. In some cases spectrographs were obtained showing three spectra of the same metal (spark, direct arc, and carbon arc) on the same plate, and reproductions of these for lead and tin are given.—P. **Humbert**: The calculations of G. H. Darwin on the stability of the pyriform figure. G. H. Darwin and Liapounov came to opposite conclusions on the stability of the pyriform figure of equilibrium of a fluid in rotation. The method used by Darwin, due to Poincaré, is exact, but the development of the series was not carried to a sufficient number of terms, and the results are inexact, or at least doubtful.—A. **Véronnet**: The formation of an isolated star in an indefinite homogeneous nebula.—J. **Andrade**: The experimental control of doubly damped pendular vibrations.—G. A. **Hemsalech**: The emission of positive luminous particles by the alkali metals at high temperatures.—A. **de Gramont**: Observation on the preceding communication.—J. B. **Senderens**: The catalytic hydrogenation of lactose. A repetition of the experiments of Ipatiew on the reduction of lactose in water-alcohol solution by hydrogen at high pressures (74 atmospheres) at 130° C. in presence of nickel and nickel oxide. The main product of the reaction is dulcite, but there is a secondary reaction depending on the activity of the nickel catalyst. A new sugar, lactosite, $C_{12}H_{24}O_{11}+H_2O$, is formed, and corresponds to the melibiotite obtained as a syrup by Scheibler and Mittelmeier. On inversion, lactosite gives sorbite and galactose.—E. **de Loisy**: A commercial method for the synthetic production of alcohol or ether, starting with coal-gas. The velocity of absorption of ethylene from coal-gas by sulphuric acid is increased by the addition of a catalyst, and the same acid can be used in succession for the removal of ethylene, other unsaturated hydrocarbons, moisture, and, finally, for the preparation of ammonium sulphate.—N. J. **Lebedeff**: The Carboniferous in the Caucasus chain.—Ch. **Picquenard**: The fossil flora of the coal basins of Quimper and Kergogne.—Ch. **Gorceix**: Some considerations on the surfaces of equal density at the interior of the earth.—E. **Licent**: The ascophore form of *Clasterosporium fungorum*.—G. **Mangenot**: The evolution of the chondriome and plasts in the Fucaceæ.—P. **Noguès**: Hovering flight produced by a horizontal wind of invariable direction and velocity.—MM. **Constantin** and **Soula**: A new method of graphical recording in physiology, using a microphone and electromagnetic style. A directly recording sphygmograph.—Mlle. M. **Gauthier**: The "trypanosome" of the trout. The first trypanosome was discovered by Valentin in 1841 in the blood of a trout, but no further work on this particular parasite appears to have been done since that date. Additional observations on this organism show that it should not be included in the genus Trypanosoma properly so-called, but in the genus Trypanoplasma, created by Laveran and Mesnil in 1901.—T. **Kabéshima**: Experimental therapy on germ-carriers.—F. **d'Herelle**: The process of defence against the intestinal bacilli and the ætiology of diseases of intestinal origin.—P. **Courmont** and A. **Rochaix**: The bacterial flora of sewage effluents purified by the method known as *boues activées*. The reduction in bacteria by this process is considerable, and the species remaining in the effluent are all aerobic, and include no known pathogenic form.—F. **Bordas**: The preparation and conservation of vaccinal pulp. Reply to some criticisms by P. Achalme and Mme. Phisalix.

January 12.—M. Henri Deslandres in the chair.—G. **Bigourdan**: The observatories of Lalande at the

Palais-Royal and at the Collége de France.—L. **Maquenne** and E. **Demoussy**: The distribution and migration of copper in the tissues of green plants. Twenty-seven species of plants were examined, and copper was found in all parts of the plants, this metal tending to accumulate at points where the percentage of water is at a maximum. The increase of copper is not the consequence of a physico-chemical phenomenon, as is the case with silica and calcium carbonate, but follows a process analogous with that governing the nutrition of the plant.—A. **Blondel**: A method for the measurement of atmospheric transparency.—L. **Pomey**: Fermat's numbers.—M. **Pauthenier**: The absolute retardations in Kerr's phenomenon.—P. **Braesco**: The expansion of copper-antimony alloys. There is a sharp maximum in the increase of length for the alloy containing 38·6 per cent. of antimony, a composition corresponding with the compound Cu_3Sb; no indication of the existence of any other definite compound is given by the expansion curves.—N. H. **Dhar** and G. **Urbain**: The polarisation e.m.f. and the constitution of complex cobaltic compounds.—E. **Wourtzel**: The existence of nitrous anhydride in the gaseous state. The contraction produced on mixing known quantities of NO and O_2 was measured, keeping the NO in excess. Two experiments gave a contraction corresponding with the presence of about 2·5 per cent. of N_2O_3 in the gas mixture. This is sufficient to explain the known production of nitrite when the gas is absorbed by alkaline solutions.—A. **Kling**, D. **Florentin**, and E. **Jacob**: The preparation of chlorinated methyl carbonates.—F. **Canac**: Determination of the orientation of the rows and reticular planes of a crystal.—P. **de Souza**: The Lower and Middle Carboniferous in Portugal.—J. **Savornin**: The geology of Djurdjura and Biban (Algeria).—P. **Russo**: The phosphatic Eocene and Turritelles layers of Tadla (Western Morocco).—L. **Besson**: Diminution of the transparency of the air at Paris. Systematic observations from the summit of the Tour Saint-Jacques in the centre of the city, initiated in 1895 by J. Joubert and carried on continuously under identical conditions for twenty-five years, lead to the conclusion that for the first twenty years the clearness of the atmosphere was slowing decreasing; during the period of the war this diminution became much more marked.—G. **André**: The inversion of cane-sugar during the preservation of oranges.—E. **Saillard**: The nitrogen balance in sugar manufacture. Precipitation of the albuminoid materials of the beetroot by sulphurous acid, bisulphites, and hydrosulphites. Sulphurous acid and its compounds precipitate the same polarising materials as basic lead acetate, working with normal beets; they also precipitate the same albuminoid materials from the beet-juice as copper hydrate.—M. **Lemoigne**: A specific reaction of 2 : 3-butyleneglycol and of acetylmethylcarbinol, products of the butyleneglycollic fermentation. As the production of acetylmethylcarbinol serves to differentiate certain closely related groups of micro-organisms, a delicate and specific test is desirable. The culture is oxidised with a little ferric chloride and distilled; diacetyl passes into the distillate. This is treated with ammonia, hydroxylamine chloride, and a nickel salt, when the scarlet nickel dimethylglyoxim is produced. Acetylmethylcarbinol at a dilution of 1 in 1,000,000 can be readily recognised by this test.—W. **Kopaczewski** and Mme. Z. **Gruzewska**: Seric toxicity and the physical properties of colloidal gels. A relation has been established between the toxic power of gels and the sign of their electric charge. Gels with a positive electrical charge (alumina, barium carbonate, ferric arsenate, calcium phosphate, ferric oxide) have no toxic power, but an electro-negative silica gel is toxic.—A. **Krempf**: The development and relations of the orthosept and sterigmatosept in the Anthozoa.—E. **Grynfeltt** and L. **Carrère**: The muscles of the iris of the crocodile.—L. **Chopard**: Observations on the praying mantis and its parasites.—M. **Lagrange**: The compressive and decompressive operation of the eyeball.—M. **Fouassier**: The decomposition of hydrogen peroxide by micro-organisms extracted from pasteurised milk.

DIARY OF SOCIETIES.

THURSDAY, FEBRUARY 12.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. A. E. Conrady: Recent Progress in Applied Optics.

ROYAL SOCIETY, at 4.30.—J. W. McBain and C. S. Salmon: Colloidal Electrolytes. Soap Solutions and their Constitution.—C. C. Farr and D. B. Macleod: The Viscosity of Sulphur.—C. V. Raman and B. Banerji: Kaufmann's Theory of the Impact of the Pianoforte Hammer.—Commander T. Y. Baker, R.N., and Prof. L. N. G. Filon: A Theory of the Second Order Longitudinal Spherical Aberration for a Symmetrical Optical System.—Prof J. W. Nicholson: The Lateral Vibrations of Sharply Pointed Bars.—R. E. Slade: A New Method of Spectrophotometry in the Visible and Ultra-violet and the Absorption of Light by Silver Bromide.—Dr. S. Chapman: A Note on Dr. Chree's Discussion of Two Magnetic Storms (Title only).—Dr. C. Chree: An Explanation of the Criticisms on Dr. Chapman's Recent Paper: "An Outline of a Theory of Magnetic Storms" (Title only).

LONDON MATHEMATICAL SOCIETY (at Burlington House), at 5.—G. S. Le Beau: A Property of Polynomials whose Roots are Real.—The late E. K. Wakeford: Canonical Forms.—E. Landau and A. Ostrowski: A Problem of Diophantine Analysis.—G. H. Hardy and J. E. Littlewood The Zeros of Riemann's Zeta-function.

ROYAL INSTITUTE OF PUBLIC HEALTH, at 5.—Dr. D. P. Sutherland: The Work of a Tuberculosis Department.

ROYAL SOCIETY OF MEDICINE (Balneology and Climatology Section), at 5.30.—Dr. F. G. Thomson, Dr. J. C. McClure, and W. P. Kennedy: Resumed Discussion on The Merits and Defects of the British Health Resorts.

BRITISH PSYCHOLOGICAL SOCIETY (Education Section) (at London Day Training College), at 6.—Dr. C. W. Kimmins: The Dreams of Children in Blind, Deaf, and Industrial Schools.

INSTITUTION OF ELECTRICAL ENGINEERS (at Institution of Civil Engineers), at 6.—Major K. Edgcumbe: The Protection of Alternating-current Distribution Systems without the Use of Special Conductors.
OIL AND COLOUR CHEMISTS' ASSOCIATION (at 2 Furnival Street), at 7.—Dr. R. S. Morrell: Colloid Chemistry of Paints and Varnishes.
OPTICAL SOCIETY, at 7.30.—J. W. French: The Surface Layer of an Optical Polishing Tool.—Mrs. C. H. Griffiths: Aberration Effects in Star Images.—R. W. Cheshire and W. Shackleton: The Testing of Heliograph Mirrors.
INSTITUTION OF AUTOMOBILE ENGINEERS (Graduate Section) (at 28 Victoria Street), at 8.—F. R. Cowell: Steering Gears.
ROYAL SOCIETY OF MEDICINE (Neurology Section), at 8.30.—Dr. Rows: Anxiety States.
SOCIETY OF ANTIQUARIES, at 8.30.

FRIDAY, FEBRUARY 13.

ROYAL ASTRONOMICAL SOCIETY, at 5.
PHYSICAL SOCIETY, at 5.—Prof. C. H. Lees: Presidential Address.—Sir Arthur Schuster: Atmospheric Refraction during Total Solar Eclipses.—To be followed by the Annual General Meeting.
ROYAL COLLEGE OF SURGEONS, at 5.—Prof. W. G. Spencer: The Historical Relationship between Experiments on Animals and the Development of Surgery (Hunterian Lecture).
MALACOLOGICAL SOCIETY OF LONDON (at the Linnean Society), at 6.
JUNIOR INSTITUTION OF ENGINEERS (at 39 Victoria Street), at 7.30.—F. E. Henman: Gas Manufacture.
ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Prof. W. M. Bayliss: The Volume of the Blood and its Significance.

SATURDAY, FEBRUARY 14.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir F. W. Dyson: The Astronomical Evidence bearing on Einstein's Theory of Gravitation. III. Deflection of Light in the Sun's Gravitational Field.

MONDAY, FEBRUARY 16.

ROYAL COLLEGE OF SURGEONS, at 5.—Prof. W. G. Spencer: The Historical Relationship between Experiments on Animals and the Development of Surgery (Hunterian Lecture).
INSTITUTION OF ELECTRICAL ENGINEERS (Informal Meeting) (at Chartered Institute of Patent Agents), at 7.—A. B. Eason: Automatic Telephony for Private Branch Exchanges.
ARISTOTELIAN SOCIETY (at 74 Grosvenor Street, W. 1), at 8.—A. F. Shand: Impulse, Emotion, and Instinct.
ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.—P. Waterhouse: Education of the Architect.
ROYAL SOCIETY OF ARTS, at 8.—C. F. Cross: Recent Research in the Cellulose Industry (Cantor Lecture).
SURVEYORS' INSTITUTION, at 8.—Capt. W. H. Tapp: Survey on the Western Front.
ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 8.30.—H.E. the Spanish Ambassador: The Spanish Zones in Morocco.
MEDICAL SOCIETY OF LONDON, at 9.—Dr. H. R. Spencer: Tumours complicating Pregnancy, Labour, and the Puerperium (Lettsomian Lecture).

TUESDAY, FEBRUARY 17.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. E. Wilson: Magnetic Susceptibility.
ROYAL STATISTICAL SOCIETY, at 5.15.—Prof. E. H. Starling: Food Conditions in Germany during the War.
INSTITUTION OF PETROLEUM TECHNOLOGISTS (at Royal Society of Arts), at 5.30.—Dr. W. R. Ormandy: Recent Patents on Mixed Fuels.
ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN (Technical Meeting), at 7.—N. E. Luboshez: Fancy Lighting in Portraiture.
ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—J. Reid Moir: The Occurrence of Flint Implements of Man in the Glacial Chalky Boulder Clay of Suffolk.

WEDNESDAY, FEBRUARY 18.

ROYAL UNITED SERVICE INSTITUTION, at 3.—Lt.-Col. A. H. W. Haywood: The Campaign in the Cameroons.
ROYAL SOCIETY OF ARTS, at 4.30.—S. Preston: English Canals and Inland Waterways.
ROYAL COLLEGE OF SURGEONS, at 5.—Prof. W. G. Spencer: The Historical Relationship between Experiments on Animals and the Development of Surgery (Hunterian Lecture).

THE ORGANISATION OF SCIENTIFIC WORK IN INDIA.

THE reorganisation and development of scientific work in India are now under consideration, and important and far-reaching decisions on these questions will shortly be made by the Secretary of State. It has already been decided, both by the Government of India and by the Secretary of State, that large sums of money must be found at the earliest possible moment for the purpose of fostering the development of the Indian Empire by means of scientific research. The principle of State aid on a generous scale has been accepted, but the important question of the best method of utilising this form of assistance in the future development of India remains to be settled. These matters were referred to by the Viceroy on January 30 last in his speech opening the present session of the Imperial Legislative Council at Delhi. It is evident from the report of Lord Chelmsford's remarks which appeared in the *Times* of February 6 that the Government of India is now considering large schemes of expansion in regard to the scientific activities of the State.

Two policies at present hold the field: (*a*) Centralisation under a proposed Imperial Department of Industries of the Government of India in which chemists, botanists, zoologists, and so on will be formed into distinct, water-tight, graded services, each under the control of a departmental head; and (*b*) decentralisation under which the scientific workers at the various universities and research institutes will be given as free a hand as possible.

The policy of centralisation and the creation of graded scientific services have been strongly advocated by the Indian Industrial Commission, which was presided over by Sir Thomas Holland, formerly Director of the Geological Survey of India. It is favoured by a number of administrators in India who consider that some measure of official control is necessary for all scientific investigators, and it has also received the support of several of the scientific witnesses examined by the Commission. The arguments advanced by Sir Thomas Holland and his supporters in favour of centralised scientific services are set out in detail in chap. ix. of the Report of the Indian Industrial Commission, published last year (H.M. Stationery Office; Cmd. 51). The nature of these arguments will be evident from a study of the principles and the rules which they suggest should be adopted for the formation and control of the new Chemical Service. It is proposed to proceed with the creation of this service as soon as the committee now dealing with this matter in India has submitted its report.

The Industrial Commission considers that for administrative purposes the chemists now employed by the State in India, and at present distributed among the cadres of various services, should be brought together into one service to be called the Indian Chemical Service, and should be under the control, so far as their scientific work is concerned, of a senior officer styled Chief Chemist to the Government of India. The remaining members of the service would be divided into three groups—agricultural, mineral, and organic chemists—each group being under the supervision of a Deputy Chief Chemist located at a suitable centre. The junior members of the groups would be lent to Local Governments and to various Government Departments for periods normally limited to five years; they would carry out the routine duties required, in some cases including teaching, and undertake certain forms of research with the approval of the head of the service. All the members of the Chemical Service would carry on their duties on the following lines: (i) Whenever it is possible to lay down for any officer a programme of research work, such programme would not be sanctioned without the consent of the head of the service; (ii) the head of the Chemical Service would have power to inspect the scientific work of any of his transferred officers and to report thereon to the local authority; (iii) the results of scientific investigations would be reviewed by the head of the service, and would not be published without his consent. Ordinarily, such results would be given their first formal publication in the official journal of the service.

These details will enable men of science in Great Britain to understand how it is proposed that most of the future scientific work in India should be conducted. As soon as the organisation of chemists is completed, the Industrial Commission suggests that the botanists, zoologists, and entomologists working in India should be formed into similar centralised services.

The present system under which research is conducted in India may be described shortly as one of decentralisation, the work being carried out at the various university colleges and at a number of independent research institutes under the control of the Government of India, the Local Governments, the Indian States, and trusts, of which latter the Indian Institute of Science at Bangalore is the chief example. A large number of the most successful investigators working in the universities and at the various research institutes do not favour centralisation in separate scientific services, but consider that the present system should be developed and extended, and that in applied science the bond of union of the workers engaged should be the general subject investigated, such as agriculture or forestry, rather than the particular science involved. At present the investigators dealing with a many-sided subject like agriculture are collected at agricultural research institutes, and now belong to the agricultural department. A similar method of organisation obtains in forestry and at the centres of medical research like Calcutta and Bombay.

The present system has proved successful in practice, and the value of the work done in India in pure science, in tropical diseases, in agriculture, and in forestry has been widely recognised. Decentralisation, therefore, has been justified by success, and a very strong case will have to be made out before the workers at the existing institutes are re-grouped in centralised services under the control, as regards their scientific work, of the proposed Department of Industries of the Government of India.

Increased financial assistance on the part of the State would enable the present universities and research institutes to be developed and more workers secured. With such facilities, there should be the greatest possible freedom for the investigators carrying on original work. The general conditions under which the researches are conducted should be made as attractive as possible, and the policy to be adopted should be one which would secure the very best men available, and the provision of adequate means for their work. For original scientific investigators little or no official control is needed, and they should not be constantly called upon to furnish interim reports and programmes of work to an official chief, or to obtain his formal sanction before undertaking an investigation or publishing the results of their work. Such formalities waste valuable time, lead to constant friction, and are altogether foreign to the spirit which should reign in all centres of creative scientific research.

Briefly stated, the case to be decided is one between the advocates of a system of rigid centralisation and those who consider that in research work the man is everything, and that there can be no progress without freedom. Obviously, the conflict of opinion is a fundamental one, and much will depend on the wisdom and sympathies of the Secretary of State, with whom the final word lies, in deciding which policy is to prevail.

MODERN PHYSIOLOGY.

An Introduction to General Physiology: With Practical Exercises. By Prof. W. M. Bayliss. Pp. xv+238. (London: Longmans, Green, and Co., 1919.) Price 7*s.* 6*d.* net.

"THE task of physiologists is to refer, as far as they can, all phenomena of life to the laws of physics and chemistry." With this definition Prof. Bayliss presents the student with those fundamental principles of these sciences which are of primary importance in the study of physiology. It is quite remarkable how the author can compress these principles into a small compass, and at the same time give such a clear picture, not only of these parts of physics and chemistry, but also of their applications in physiology. It is essentially an introduction to the author's "Principles of General Physiology," and reference is constantly made to this larger book. The student would often welcome, at these places, a rather longer description, for he will probably not possess the larger book at this period of his science course.

The book is so full of interest that if it were a little longer the beginner would not be overwhelmed, but would gather all the more fruit. The first chapter, entitled "Life and Energy," contains those parts of physics concerned in vital phenomena, written in illustration of certain phenomena easily observed with an amœba. Brownian movement is the visualisation of the moving molecules in a liquid. Protoplasm is a liquid containing matter both in solution and in suspension, and is surrounded by a cell membrane. Surface properties are those mainly concerned, but no grasp of their complexity is possible without a knowledge of energy and its laws. A considerable section is devoted to this subject. The change of energy at the surface of the cell is the cause of extrusion of the pseudopodium. The entry into and exit of matter from the cell is connected with osmosis and the permeability of membranes. This is most lucidly explained. Electrolytic dissociation and the colloidal state are included in the chapter.

"Food—Digestion and Respiration" are dealt with in the second chapter. A short cut is made through organic chemistry so as to give a conception of sugar and amino-acids; it suffices at this stage if the student can differentiate the two classes of compounds, for the subject-matter is rather the origin and metabolism of carbon and nitrogen in Nature, and the supply of energy in the form of food. Food undergoes changes in the body as the result of enzyme action; the section on the nature of enzyme action is scarcely long enough, and reference must here be made to the "Principles." Respiration and oxidation are, in contrast, fully discussed. These two chapters are the chief ones in the book.

"Work—The Muscles and Stimulation—The Senses" are the subject-matter of chaps. iii. and iv. In the latter chapter there is a diagrammatic representation of the mechanism of the organ of Corti. Prof. Bayliss lays special stress upon a student getting a clear idea, even if it be erroneous, for it can be easily changed later, and it is far better than conflicting views which leave no impression. Chap. v. is a difficult one on "Adjustment—The Nervous System," and requires close attention to the text.

Chap. vi. is on "The Transport of Materials—The Vascular System." Here, again, we get an illuminating and fascinating description, while chap. vii., on "Growth and Reproduction," shows how the author himself has thought out his subject for explanation to the student.

Each chapter has a corresponding section on laboratory work, in which there is frequently some further explanation. The practical exercises illustrate the text, and are of varying difficulty. Many have been specially devised, while others are adaptations of existing experiments in physical chemistry or physiology. The value of experiments is very great, for science becomes a reality only in these circumstances. The average student may not appreciate the book, as it is not an "examination" manual. The time must soon come when the present system of practical examinations will be abandoned. Teachers should certify that their students have done a well-arranged course, and can do the experiments if given the proper opportunities.

Students of chemistry and physics will also find the book helpful in their work; many obscure points in their abstract information will be made clear by the descriptions here given. We agree with Prof. Bayliss that all beginners should have a course of *general* physiology, and we would fain see a return to the old system in which every science student worked through a course in physics, chemistry, and biology. The modern student has too restricted an outlook on one side or the other.

MENDELISM.

Mendelism. By Reginald Crundall Punnett. Fifth edition. Pp. xv+219+vii plates. (London: Macmillan and Co., Ltd., 1919.) Price 7*s.* 6*d.* net.

IN reviewing a new edition of a book so well known as Prof. Punnett's "Mendelism," it is unnecessary to notice more than the changes that have been made as compared with previous editions. The third edition (1911) was, in fact, a new book, and the fourth (1912) was substantially similar, with a certain amount of revision. Seven years have now passed, and although the war seriously interfered with genetic research in Europe, great progress in certain directions has been made in America, and it is to incorporate this new work that the chief changes in the present edition have been made. The first eight chapters are substantially unchanged, and comparatively little alteration has been made in the chapters on the economic aspect of genetics, on variation and evolution, and on man. To the chapter on intermediates there has been added an account of Nilsson-Ehle's theory of multiple factors as illustrated by his work on colour factors in wheat, by Davenport's work on mulattoes, and by Prof. Punnett's own work on the size-inheritance of fowls. Some special cases, such as that of doubleness in stocks, that were mentioned under various headings in previous editions are collected together into a special chapter on "Certain Complications." We note with regret that the hypothesis of "multiple allelomorphs," as illustrated by Nabours' experiments on grasshoppers and by certain characters in Drosophila—a hypothesis regarded by many as a preferable alternative to the presence-and-absence theory—is nowhere fully discussed.

The remaining changes and additions are almost entirely concerned directly or indirectly with the work of Prof. T. H. Morgan and his school on Drosophila—with the relations, that is to say, between Mendelian characters and sex, and with the theory that both Mendelian characters and sex are transmitted by chromosomes. Of the two chapters on sex, the first has been rearranged with some additions, but the revision has resulted (p. 92) in a reference to Abraxas as a case already described, while in fact it is not mentioned until p. 96. Incidentally, in this connection, it is an error to say that var. *lacticolor* has been recorded only in the south of Great Britain; the stock from which all or nearly all those now existing were derived came from Lancashire. We regret, also, that in this chapter the author has retained the notation *Ff* for female and *ff* for male, in birds and moths, when the symbols *Mm* for female and *MM* for male are so much simpler of application.

The second of the two chapters on sex, and that on the chromosome theory of heredity, are almost entirely new, and give a compact and useful summary of the outstanding facts derived from Drosophila and the hypotheses founded upon them. Since nearly all this work has been done in America, where students of genetics use the word "sex-limited" in a sense quite different from that in which it is employed in England, a few words on the use of the words "sex-limited" and "sex-linked" on the two sides of the Atlantic might have been a help to readers unfamiliar with the subject.

Although we have noted a few points in which we think the book might have been improved, we do so only because any blemishes, however small, are regrettable in a book of such general excellence. We still regard it, as we did in its earlier editions, as one of the best introductory treatises on the modern study of genetics.

L. DONCASTER.

AERONAUTICS IN ITALY.

(1) *Meteorologia Aeronautica.* By Prof. Giuseppe Crestani. Pp. xv+315. (Milano: Ulrico Hoepli, 1919.) Price 8.50 lire.

(2) *Dizionario Internazionale di Aeronavigazione e Costruzioni Aeronautiche. Italiano, Francese, Inglese, Tedesco.* By Mario Mele Dander. Pp. vii+227. (Milano: Ulrico Hoepli, 1919.) Price 6.50 lire.

(3) *L'Aviazione. Aeroplani, Idrovolanti, Eliche.* By E. Garuffa. Seconda edizione. Pp. xxiii+955. (Milano: Ulrico Hoepli, 1919.) Price 20 lire.

(1) THE introduction and development of aerial navigation have brought into existence new applications of nearly every branch of experimental study, but perhaps none have been brought into greater prominence than meteorology. The safety and success of the pilot involve the most careful study and observation of every element, since barometric pressure, temperature, wind velocity, and cloud formation all affect the navigation of the machine. Hence Prof. Crestani's book will meet a real demand on the part of those who are training as pilots. There is, however, no essential difference between aeronautical and ordinary meteorology, except that more is required of the former. The first part deals with instruments and methods of observation. It describes the principal apparatus used in an observatory, and is in no way limited to the special equipments required for aircraft. Part ii. treats of the principal aerial phenomena, including atmospheric electricity. In part iii. the author deals with weather charts, pressure areas, and the circulation of the atmosphere, while part iv. is concerned with weather prediction. As an introduction to ordinary meteorology treated popularly, the book serves its purpose quite well. Still, as we have said above, something more is required by the pilot. We should like to see more about the means of making observations with the limited equipment that can be carried on aircraft, the modifications in weather prediction dependent on change of position and altitude during a flight, measurements and studies of solar radiation considered with reference to airships, and so forth. There is certainly room for additional treatment in regard to meteorological observations which are peculiar to aeronautical work. Meanwhile, the pilot must gain this knowledge by experience, and his one duty is to learn to observe and interpret phenomena instinctively.

(2) Lieut. Dander's pocket book provides for pilots and aeronautical engineers a dictionary similar in scope and plan to that supplied for gunnery by the "Trilingual Artillery Dictionary" reviewed in NATURE of November 27 last. It possesses, however, several features which were not contained in the subject of the previous review. Thus German is included, as well as English, French, and Italian, and, what is also extremely useful, anyone who is in doubt as to where to find a particular word will see at the end an index in which words in all four languages mixed are arranged in a single, strictly alphabetical sequence. This index is in rather small print, but as it is scarcely likely to be required up in the air this does not much matter. It renders the dictionary equally useful for persons of any of the nationalities which it covers, but English readers would prefer that the *genders* should have been indicated in Italian and French as well as in German. Airships as well as 'planes are considered, and materials of construction, including the names of timber trees, are fully dealt with, though the mathematical as distinct from the technical side is practically unrepresented. There are a few examples of weird English in the work, such as "three-plane," "helicoptery," "cok pit," "vestment" (for costume), not to omit the American "airplane." On pp. 48–49 the author evidently overlooks the possibility of wanting to paint anything red or black or even brown, but these colours are in other dictionaries.

(3) If Dr. Garuffa's book is to be regarded as representative of the present state of development of aeronautical engineering in Italy, English

readers have little to gain in the matter of substantial knowledge from their Italian competitors. The standard of the book is very much on a level with the swarm of weekly illustrated popular journals which may be seen in the waiting-room of an English aircraft factory or on the table of the library at Central House or of the Royal Aeronautical Society. As an introduction to practical aeronautics, the book will provide the Italian student with an insight into the mass of detailed information which is required by aircraft mechanics and pilots. The best portion is undoubtedly the descriptive account of the different types of aeroplane and their component parts, and as the machines selected for illustration are mainly of Continental make, the book may be of use to English readers for purposes of comparison. As regards the theoretical side, the treatment is very elementary, and imperfect formulæ and calculations are indeed abundant, but most of these are not much more than replicas of what one can find in our elementary school text-books on geometry and mechanics. The misfortune of this practice is that things look like new principles which are as old as the hills. But we in England cannot say much when one of our own weekly journals has devoted a glowing paragraph to the announcement that an American professor has discovered that two similarly electrified bodies can overcome gravity and repel each other.

In the sections dealing with pressures on component parts of aeroplanes, considerable prominence is given to Eiffel's diagrams of experimental results. The main difficulty in practice is that the pressures on the various elements of an aeroplane are not mutually independent, and for this reason we should have preferred a section dealing with the wind channel and its use, since this has become an indispensable adjunct to our aircraft factories.

The so-called "stability" which figures in a few sections does not in any way represent stability proper as studied in this country and tested experimentally at Teddington and Farnborough.

The sections dealing with navigation describe the usual instruments found on aeroplanes, and methods which do the ordinary, easy things, such as determining the position and velocity of an aeroplane when seen from the ground, which is very different from enabling a pilot to find his way in a fog or on a dark night. A lot of algebra is expended (p. 876) over a method of finding wind velocity by making an aeroplane fly in a quadrilateral path when ruler and compass would do the whole thing at once. The section on the seaplane contains the usual theory of the metacentre; the further developments required to take account of the effects of air resistance are briefly epitomised.

On the whole, the book fairly well meets the requirements of the average pilot, mechanic, or draughtsman who is in a position to leave more theoretical considerations in the hands of scientific experts (if he can find them).

In the *Atti dei Lincei,* xxviii., (1), 7, 8, Dr. Oreste Mattirolo considers the use of wood in the longitudinal bars of an aeroplane, with special reference to the effects of growth on the strength of the timber. During the war the timber used in the construction of aeroplanes was tested and examined by the author, and the existing methods were found to be inadequate. Dr. Mattirolo directs especial attention to the effect of climatic and seasonal conditions on the growth of the rings, and to the difficulty of locating weaknesses in the structure, and he cites two cases of accidents in which the wood was sent for his inspection and the defects were discovered too late. He recommends that now the demand for aëroplanes has lessened the longitudinal beams of the wings should no longer be made of wood. It is interesting to note that similar investigations in this country have been carried out in greater detail at Farnborough and elsewhere, though a number of problems still await solution in this as in other aeronautical investigations.

In another issue of the *Atti dei Lincei* (xxviii., 1, 2), Dr. Mario Tenani refers to the influence of the density of the air on the efficiency of aeroplanes, and quotes the ordinary laws of variation of density with pressure, temperature, and altitude in support of his plea regarding the importance of a subject which has received much attention in our country both in connection with airships and in experiments with variable propellers at Farnborough.

Meteorological difficulties should not be so serious in sunny Italy as in our land of fogs, though the Italian mountains may be set against the brighter climate. At the Pisa meeting of the Italian equivalent of our British Association, a paper on weather prediction was read by Prof. Filippo Eredia, at the end of which a resolution was passed advocating the joint action of the Ministries of Agriculture, Industry, and Commerce in co-ordination with the Air Department to promote researches in weather prediction with the view of furthering the development of commercial aviation.

Papers dealing with aeronautical subjects have, however, been conspicuous by their absence from the proceedings of learned societies in this and other countries, and the *Atti dei Lincei* has been no exception to the rule. If this is a result of the war we may welcome the three papers as an augury for a better state of affairs in the future.

G. H. BRYAN.

THE RE-MAPPING OF THE WORLD.

The "Times" Survey Atlas of the World. Prepared under the direction of Dr. J. G. Bartholomew. Part i. (London: Office of the *Times*, n.d.) Price 2*s*. 6*d*. net.

THE first part of this atlas contains four maps numbered respectively 21, 60, 79, and 95. The parts of the world represented are the southern section of Scotland, Farther India, Lower Egypt (from a little above Luxor), and Mexico and Central America (from Costa Rica inclusive). Three of the maps are, and, no doubt, the majority of those in the atlas will be, drawn on the layering principle, which has the advantages of conducing to clearness and indicating the broad distribution of high grounds and low grounds at a glance. This has been done with a skill worthy of the reputation which the map-making firm responsible for it has long held for work of this class.

The layering adopted is not on a uniform scale. In the same map successive contours represent different intervals of altitude. That, however, we have even in our own Ordnance Survey maps. But there are different scales of altitude on different maps otherwise somewhat similar. On the map of the southern section of Scotland the steps in altitude are by 250 ft. up to 1000 ft., then by 500 ft. to 2000 ft., and after that by 1000 ft. The only isobath is that of 10 fathoms. On two of the other maps the only isobath is that for 100 fathoms, but whereas in Mexico the isohypses represent 100, 500, 1000, 2000, 3000, 4000, 5000, and 6000 ft., and then 8000 and 10,000 ft., in that of Farther India they are at intervals of 500 ft. up to 2000 ft., and then mark altitudes of 3000 and 6000 ft. respectively. In the map of Egypt there are no isobaths (in the main map) or isohypses. Hachures are used to indicate the margins of the plateaux on the inset map showing the environs of Cairo on the scale of 1 : 150,000.

One noteworthy feature of the maps is that they are so mounted as to be suitable for loose-leaf binding, which will have the important advantages of allowing the replacement of a map without replacing the atlas and of enabling one to detach a single map at will for close examination and frequent reference. This feature might perhaps be utilised to remedy one of the defects of the maps, the smallness of the lettering where the names are too crowded. New maps might be drawn for those who would prefer them with fewer names in a larger letter, the missing names being entered in the index with their compass bearing and distance from places that are named on the map, say from railway stations, which are very easy to find.

We are promised an index of more than 200,000 names, but are not told how the index is to be prepared. Presumably latitude and longitude are to be given, as there is no provision on the border for reference by letter and number to the degree rectangles. But if latitude and longitude are to be the means of reference, or, indeed, in any case, we hope that the maps still to be issued will have the divisions of degrees marked on the border. That is not done in the four maps of the first part, with the result that in Scotland, for example, we have an interval for latitude of one degree measuring $6\frac{3}{4}$ in. without any subdivision showing minutes. On each map also the projection used should be named.

PHYSICS FOR MEDICAL STUDENTS.

(1) *A Manual of Physics.* By Dr. J. A. Crowther. Pp. xx+537. (London: Henry Frowde and Hodder and Stoughton, 1919.) Price 16*s*. net.

(2) *Elements of Physics.* By Dr. R. A. Houstoun. Pp. viii+221. (London: Longmans, Green, and Co., 1919.) Price 6*s*. net.

STUDENTS of medicine are apt to regard physics as a subject outside the range of their medical studies, a subject imposed upon them by certain grandmotherly examining authorities, to be forgotten as soon as the examination is over. Teachers of physics have to contend not only with this attitude of mind, but also with the fact that writers of physical text-books for the most part show but little evidence of sympathy with the medical applications of their subject. The ideal text-book for medical students would be written by a trained physicist who has specialised in medical work and is imbued with the spirit of research in physics as applied to medicine. Instead of studying the common steelyard, the medical student might then find the principle of the lever illustrated in the human frame, and instead of having to wade through a chapter on terrestrial magnetism, he might be given further information on the subject of meteorological physics and the conditions determining climate. He might even learn something as to electric oscillations applied in high-frequency treatment, or as to the use of a saccharimeter. Both the volumes under review claim to meet the needs of first-year medical students; but the ideal book on physics for such students has yet to be written.

(1) Dr. Crowther has given us an excellent manual of physics suitable for beginners who have no special profession in view. He has devoted considerable space to the subject of

mechanics, and experienced teachers will agree that "a thorough grounding in this most fundamental of all the sciences is the beginning of all wisdom in physical knowledge." The treatment of the various subjects follows conventional lines, a short chapter on the discharge of electricity through gases being the only one which deals specifically with the results of modern research. The style is lucid and interesting, and the explanation of physical principles exceptionally clear. It is to be regretted that the price of 16s. net should be so high as to make it impossible for many students to purchase the volume.

(2) A smaller treatise on the elements of physics has been written by Dr. Houstoun, who has attempted to cover the same ground in less than half the number of pages. The matter is consequently somewhat compressed and the style curt. The author has been successful in including a section on simple harmonic motion, which is so important in the study of vibrations; and another on the characteristic features of wave motion, in which the difference between a stationary and a progressive wave is well brought out. The work should be useful as giving a compact systematic treatment of the whole subject.

Both books are furnished with useful collections of questions and problems, and answers are provided for the numerical examples.

H. S. Allen.

OUR BOOKSHELF.

Harmsworth's Universal Encyclopedia. Edited by J. A. Hammerton. No. 1. Pp. xix+128. (London: The Amalgamated Press, Ltd., 1920.) Price 1s. 3d.

This is, of course, a work of reference for the general reader, not the expert. The editor claims that it possesses the three necessary qualities, comprehensiveness, conciseness, and accuracy. All three are relative terms, and there is no absolute test by which his claim can be judged. But, since Mr. Hammerton is the acknowledged authority on What the Public Wants, the first claim may be conceded without further question. On the second the bare statement that A—*Afranius* occupies 128 closely printed but well-illustrated pages will enable the reader to judge for himself. On the third it is sufficient for Nature to record that the scientific articles appear all to be as completely accurate as the space allotted to them will permit, and that one of the introductory articles, by Lord Moulton on "Science and the Future," is a model expression of the obvious; originality or profundity could not be expected.

We think the production is one of which the Amalgamated Press may well be proud.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Relativity and the Displacement of Fraunhofer Lines.

In view of the uncertainty in the interpretation of Einstein's equations in the matter of the displacement of solar spectrum lines, and of the hope which has been expressed that experimental spectroscopic evidence may be forthcoming which will settle the point at issue, it may be of interest to give a brief account of the present state of the problem from the experimental point of view. There are really three questions to which answers are required:—(1) Is there any means whereby the displacements of solar lines relative to those of terrestrial origin may be disentangled from such disturbing causes as pressure, varying arc conditions, density gradients, etc.? (2) If so, what do the outstanding displacements amount to? (3) To what extent are they due to gravitation and line-of-sight motion respectively?

Upon (1) it is to be remarked that, since both gravitation and motion displacements vary directly with the wave-length, they are indistinguishable spectroscopically; moreover, the possibility of separating their sum from those due to other causes, which in general displace spectrum lines (I have enumerated some ten possible causes in a recent communication to the Royal Astronomical Society), depends upon the reputed invariability of the wave-lengths of the cyanogen bands in different parts of the arc, under pressure, under varying current densities, etc. Practically all other lines are affected by one or more of these influences, and must be ruled out of account. Further laboratory experiments are necessary before the cyanogen bands can be regarded as suitable criteria, particularly in view of a recent statement from the Bonn Laboratory that they are unsymmetrical, which for well-founded reasons brings them seriously under suspicion for astrophysical purposes.

Even if we assume for the present that the cyanogen bands are satisfactory standards, (2) presents a further difficulty in that the Mount Wilson observers find displacements varying from 0 to about one-third of that predicted by Einstein; whereas Evershed and three Continental observers find a displacement of about one-half the required amount. It is possible that the discrepancy is due to the observations being made on different dates, since at Kodaikanal, on different occasions, measures made at the pole of the sun varied from one-half to the full predicted displacement. Simultaneous solar observations at Kodaikanal and Mount Wilson are, unfortunately, impossible, and it is a pity that the Australian Solar Observatory is not yet in existence to link up the two.

If Mr. Evershed and others prove correct, the problem still remains to interpret the half-displacement observed; obviously, this can be done only if by some independent evidence the motions of the vapours are known upon that portion of the solar surface towards which the spectroscope is directed. This involves a deeper knowledge of the currents in the solar atmosphere than we at present possess. There has been a disposition to regard displacements at the polar limb as free from motion effects, but it is inevitable that there will be surface currents, and these need not be of excessive violence in order to give displacements of the order of magnitude of those observed. The problem, if we accept Mr. Evershed's data, resolves itself into choosing between (*a*) the absence of the Einstein effect, but the existence of currents of absorbing solar vapours moving away from the observer on the earth, and (*b*) the existence of the Einstein effect, together with solar currents of about the same magnitude as before, but in the opposite direction. The question thus involves an extensive knowledge of solar meteorology. There is, I fear, no immediate prospect of a rigorous solution of the problem of the displacement of the Fraunhofer lines with our present incomplete knowledge of the conditions necessary for the production of the cyanogen-band spectrum and with our present limited information regarding the circulation in the sun's atmosphere. W. G. DUFFIELD.

University College, Reading, February 8.

Statistics of Valour and Service.

IN the Weekly Edition of the *Times* for November 28, 1919, the following statistics relating to decorations awarded for services in the field are detailed:—

	V.C.	D.S.O.	M.C.	D.C.M.	M.M.
Decoration	576	8,862	36,707	24,391	114,517
1st bar ...	2	695	2,932	468	5,719
2nd bar ...	—	70	167	9	180
3rd bar ...	—	6	4	—	1

An analysis of these figures, with a consideration of the results arising from such an examination, may be not without interest.

The figures may be reclassified as follows:—

Number of Individuals who have Won Decoration

	V.C.	D.S.O.	M.C.	D.C.M.	M.M.
With 0 bar ...	574	8,167	33,775	23,923	108,798
,, 1 bar ...	2	625	2,765	459	5,539
,, 2 bars ...	—	64	163	9	179
,, 3 bars ...	—	6	4	—	1

In making this reclassification I have assumed that all the decorations were won subsequent to July, 1914. There may be exceptions—as, for instance, in the case of Capt. Leahy, V.C.—but as the number of such cases must be small, their influence may be neglected.

In analysing these statistics I shall employ a type of method which I have applied with considerable success to medical problems, chiefly of an epidemiological nature (*Science Progress*, 1914; Proc. Lond. Math. Soc., 1914; and various papers in the *Indian Journal of Medical Research*). The argument as applied to the present case is as follows: Let us assume the presence at the Front of a community of individuals, initially undecorated, who were capable of earning the decoration in question provided that opportunity offered and recognition came. Let v_x be the number of individuals who at any moment were in the grade x—that is to say, who had received the decoration with $x-1$ bars. Let $\phi_x f(t)dt$ be the probability that an individual in grade x may during the time dt pass from the grade x to the grade $x+1$. For such a passage to occur, both opportunity must offer and recognition must come. The function ϕ_x allows for variations in the probability of further attainment being dependent on the degree of anterior attainment. The function $f(t)$ is unknown; it describes the ebb and flow of the conflict. Variations in the number of individuals in the grade x are composed of influxes and effluxes. The degree of the former depends upon the number of individuals who have already attained to the grade $x-1$, and the degree of the latter upon the number of those who are in the grade x itself. Thus

$$dv_x = (\phi_{x-1}v_{x-1} - \phi_x v_x) f(t)dt.$$

Let us assume as an approximation that $\phi_x = b + cx$. Let μ_1 denote the mean grade, and μ_2 and μ_3 the second and third moments about the mean respectively. By differentiating these values according to the time, and by making use of the above differential equation, we find

$$\mu_1 = \frac{b}{c}(e^{c\theta}-1),\quad \mu_2 = \frac{b}{c}e^{c\theta}(e^{c\theta}-1),\quad \mu_3 = \frac{b}{c}e^{c\theta}(e^{c\theta}-1)(2e^{c\theta}-1),$$

where θ is written for $\int f(t)dt$; whence

$$c/b = (\mu_2 - \mu_1) \div \mu_1^2,$$

and

$$\mu_1(\mu_2 + \mu_3) = 2\mu_2^2.$$

Solving the differential equation for successive values of x, and eliminating the unknown function θ, we have, if we remember that the participating population N was initially undecorated,

$$v_x = \mathrm{N}\frac{b}{c}\left(\frac{b}{c}+1\right)\cdot\ \ \cdot\left(\frac{b}{c}+x-1\right)\frac{\left(1-\frac{\mu_1}{\mu_2}\right)^x}{x!}\left(\frac{\mu_1}{\mu_2}\right)^{b/c}.$$

In the present instance, as in very many epidemiological problems, we are ignorant of the value of N, *i.e.* of the number of individuals in the participating population. On the assumption that our hypotheses are applicable, we can, however, calculate its value by making use of the above eliminant between the moments which results from our hypotheses, and by taking advantage of the fact that, in calculating the values of moments about any selected grade, information regarding the number of individuals in that grade is unnecessary, as in each case this number is multiplied by zero. In the present instance, as we are ignorant of the number of individuals in the zero grade (*i.e.* of the number of the undecorated), we employ moments about the origin. Let us denote the second and third of these by μ'_2 and μ'_3 respectively, then by introducing the values $n_1 = \mathrm{N}\mu_1$, $n_2 = \mathrm{N}\mu'_2$, $n_3 = \mathrm{N}\mu'_3$, into the eliminant we find

$$\mathrm{N} = n_1^2(n_2 - n_1) \div \{2n_2^2 - n_1(n_2 + n_3)\}.$$

The results of these calculations are indicated in the following table:—

Number of Individuals having the Decoration

	V.C.	D.S.O.	M.C.	D.C.M.	M.M.
With 0 bar ...	574	8,158	33,769	23,925	108,789
,, 1 bar ...	2	638	2,784	460	6,555
,, 2 bars ...	—	58	152	8	169
,, 3 bars ...	—	6	6	—	3

The correspondence between calculated and actual values is good, as was in some measure to be expected, since the number of grades in the statistics in no case exceeds four, whilst the number of constants at our disposal is three. We may, however, conclude that, for particular values of these constants, our assumptions are sufficient to account for the facts, and proceed to examine the significance which attaches to these values in the light of our assumptions. The final test of the adequacy of the assumptions must clearly depend upon the reasonableness of such inferences as may obtrude themselves.

These values are as follows:—

	N	c/b	$b\int f(t)dt$
V.C.	41,763	−0·5	0·014
D.S.O. ...	215,498	+2·96	0·042
M.C.	240,477	−0·005	0·166
D.C.M. ...	1,103,730	+0·735	0·023
M.M.	1,077,444	−0·096	0·113

In the values of N we have the values of the participating populations. To recapitulate: They denote the numbers of persons at the Front who were capable of earning the decoration in question if opportunity offered and recognition came. The standard of the

V.C. stands pre-eminent. Amongst the other four we find that the populations calculated for decorations awarded to non-commissioned ranks are to those calculated for decorations awarded to officers as approximately 5 to 1.

In the values of c/b we have a measure of the amount of increase in the probability of attainment as the individual passes from grade to grade. Thus if the likelihood of winning the decoration be unity, the likelihood of obtaining a first bar is $1+c/b$, and of obtaining a second $1+2c/b$. The value of c/b is positive if the likelihood increases with the grade, and negative if it decreases. The actual values may clearly be the resultant of both positive and negative influences. For the V.C. and the M.M. these values are frankly negative, that for the M.C. is nearly zero, and those for the D.S.O. and D.C.M. are frankly positive. This would suggest that the decorations fall into two classes which are earned under different conditions. Take, for example, the effect of risk. The value $-0 \cdot 5$ for the V.C. would be accounted for if it could be shown that 50 per cent. of those who earned it died or were incapacitated in the winning. Thus the negative values of the first class of decoration can be accounted for by assuming a high degree of risk in the winning of them. Again, let us consider the questions of leadership and administrative ability. In these a positive value might indicate that although it was difficult for a soldier to get his opportunity in the first instance, once he had made his mark his opportunities for further distinguished service would be increased. The positive values found in the second class of decoration might thus be accounted for. Whether this explanation be the true one or not, it would appear that once the British soldier has got his foot on the ladder he makes good.

In the third column are tabulated values of $b\int f(t)dt$, calculated from $\log(N/v_0)$. If we assume that the ebb and flow of the conflict operate uniformly on the chance of winning each of these decorations, or that they do so within the respective classes, then the tabulated values may be taken as relative values of b, *i.e.* of the chance that an individual, potentially capable of winning the decoration, obtained it in the first instance. In this case also the factor is compounded of the chance that opportunity offers and the chance that recognition is received. Here again the V.C. stands pre-eminent. The low value for the D.C.M. is in agreement with what has been suggested in the preceding paragraph, viz. that it is relatively difficult for non-commissioned ranks to obtain a footing on the ladder. The high values for the M.C. and the M.M. would indicate that in this war of the trenches the opportunities for brave deeds were all too frequent. Taking the decorations separately, the results of this analysis are as follows:—

(1) The V.C. stands pre-eminent amongst the decorations, equally as regards the high standard which is required, the high degree of risk with which the winning is accompanied, and the difficulty of attainment even in the case of the individual who is admittedly of the required standard.

(2) The D.S.O. is an officers' decoration awarded both for deeds of valour, probably of a skilled kind, and for distinguished service of other sorts. The chance of opportunity offering and recognition being received may, in the first instance, be low, but, once obtained, there follows increasing opportunity.

(3) The M.C. is an officers' decoration in which probably the influences of both classes are combined, viz. risk and increasing opportunity. Opportunities of earning it were all too many.

(4) The D.C.M., for non-commissioned ranks, is of the same type as the D.S.O., though the chance of opportunity offering and recognition being received in the first instance is relatively less.

(5) The M.M., for non-commissioned ranks, belongs to the class of the V.C. It is characterised by the risk which the winning entails, and by the indication that the opportunities for the performance of brave deeds were many.

These, then, are the inferences which appear to me to emerge from the hypotheses which I have adopted. There may be others of which I am ignorant, but, such as they are, I venture to offer them as a tribute to the vast potentialities of the British Army, both for valour and for service—potentialities which even at the end of the great war remained to a large extent unexplored; and also as a tribute to the consistency and fairness which characterised the manner in which these decorations were awarded.

Sugar-beet Seed.

At a recent meeting of the Sigma Xi Society of the University of Colorado Dr. W. W. Robbins, botanist to the Great Western Sugar Co., read a paper on beet-seed production. Dr. Robbins related that so early as 1909 Mr. Hans Mendelson, a German in the employ of the company, undertook to grow beet-seed in Montana. In those days all the seed was imported annually from Europe, principally from Germany, Austria-Hungary, and Russia. It was held by experts that the climate and other conditions would not permit the growing of the seed in America on a commercial scale. Mr. Mendelson thought otherwise, and stated that the time might come when it would be impossible to get European seed. So he continued his experiments on a small scale; and when the war came, and the supply of seed was actually cut off, he had developed his methods to such an extent that it was possible to save the industry. In 1916 the United States was able to produce 5,211,000 lb. of seed, and in 1917, 5,546,000 lb. Furthermore, experimental work had already determined the fact that American-grown seed gave a larger tonnage and a greater amount of sugar per acre than imported seed. From this time the policy of raising American seed will be continued.

I hope that Dr. Robbins will later on tell the whole story of the sugar-beet in relation to the war. The various events are part of the significant history of human progress. But just now it is worth while to note the value to the country of such men as Mr. Mendelson, and the importance of giving them a chance to test their ideas. The public is too apt to think that scientific progress comes only through great discoveries, or requires a Darwin, a Newton, or a Kelvin. It is difficult to exaggerate our debt to the great men of science, but it remains true that the current work of the world does not rest so much on sensational discoveries as on the multitudinous minor facts determined by a host of patient workers. Even Darwin could not have done his work without the aid of such. We shall never get on a proper basis until the scientific worker—no genius, but a normal man (or woman) doing his day's work—is established as a member of the community on a par with the tailor, the baker, or the policeman.

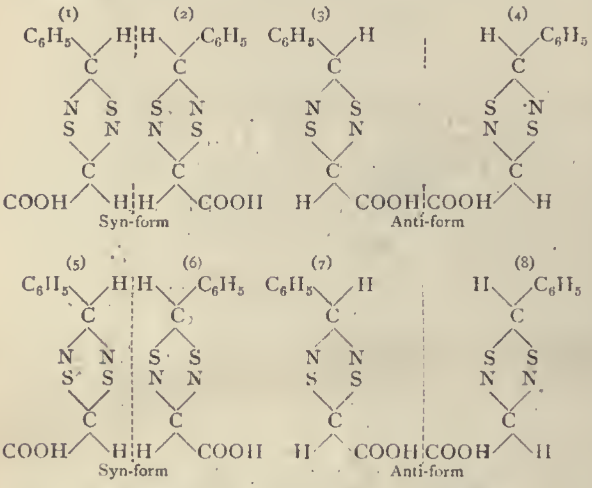
An Electronic Theory of Isomerism.

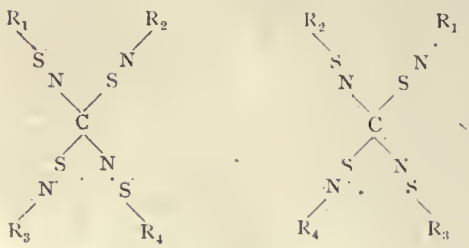
The application of the Bohr theory to organic chemistry suggests a possible explanation of the hitherto unexplained isomerism of certain organic compounds. The electrons rotating in pairs around the four carbon valencies may possess either clockwise or anti-clockwise rotation with respect to the central carbon atom (Ramsay, Proc. Roy. Soc., xcii., A, p. 451, 1915–16). On the assumption that two of these pairs of electrons rotate in a clockwise and two in an anti-clockwise direction, it is possible to deduce that eight isomerides of cinnamic acid may exist. It has long been known that four isomerides of cinnamic acid exist, whereas only two are possible on the ordinary structural formulæ.

Erlenmeyer has recently shown (*Biochem. Zeitsch.*, 1919, xcvii., pp. 198–245) that ordinary cinnamic acid can be obtained in two optically active isomerides. If the clockwise rotation of the electron gives a north-seeking character to the valency, and the anti-clockwise rotation a south-seeking character, it is possible to represent eight isomeric cinnamic acids as follows:



The formulæ are grouped in pairs, and only two of these pairs are mirror images, (5) being the mirror image of (6), and (7) of (8). None of the isomerides 1 to 4 are superposable, as can be readily seen from the solid models. (A north-seeking valency will be the mirror image of a south-seeking valency.) The new type of optical activity is due not to the asymmetry of the radicles, but to an asymmetric arrangement of the pairs of rotating electrons.

It may be that the dextro- and lævo-rotatory forms of an organic compound are not structural isomerides, but owe their optical activity to this asymmetric arrangement of the electrons:



There is thus possible a large number of such isomerides in organic chemistry which are, however, stable only in very few types of organic compounds. The case of the cinnamic acids is not an isolated one, for it appears from the work of Erlenmeyer that benzaldehyde is capable of occurring in the dextro- and lævo-forms (*Biochem. Zeitsch.*, 1914, lxiv., pp. 382–92), and also, according to Marckwald, methyl-ethyl-malonic acid occurs in optically active forms.

This theory differentiates between two kinds of valency, according to whether the rotation of the electrons with respect to the valency is clockwise or anti-clockwise, and may explain the peculiar characteristics of the physical properties of the homologous series, where those compounds containing an even number of carbon atoms appear to belong to one series, and those with an uneven number to another series.

All the isomerides which are obtained on this theory, except the optical pairs, should possess different free energies according to the arrangement of the rotating electrons. W. E. GARNER.

University College, London, February 2.

The Sociological Society.

MAY I beg the hospitality of your columns for two announcements? First, the Sociological Society is moving from the London School of Economics and Political Science to a house of its own at 65 Belgrave Road, Westminster, S.W.1. The society hopes to get installed there by the beginning of March.

The second is that the society's new house affords more accommodation than the society itself can use, and we should be glad, therefore, to hear from congruent societies or organisations which might desire to rent one or more rooms. The present housing pressure is, we understand, putting not a few societies into a considerable difficulty as regards accommodation.

As to the situation, the new house of the Sociological Society is about five minutes' walk south-east from Victoria Station. It is just over a mile in a direct line from Charing Cross, and two 'bus routes (24 and 24A) cross Belgrave Road, within a couple of minutes' walk of the house. T. J. C. FRASER DAVIES,

February 16. Secretary.

Mirage Effects.

WHILE a patient at the Red Cross Hospital for Officers, Brighton, the phenomenon described by various correspondents was observed by me on numerous occasions last autumn. It was particularly noticeable on hot, sunny days along the Marine Parade, Kemptown. From a point opposite the Hotel Bristol, the road a quarter of a mile distant, *in either direction*, appeared as if flooded by a water-cart. Indeed, the illusion was so complete that the first time I witnessed it, being confined to a spinal chair, I instructed my attendant to make a detour.

ROBERT ROSS.

3 Sudeley Terrace, Brighton.

AN excellent place to observe mirage round our coasts is Morecambe Bay on a sunny afternoon when the tide is out and a fresh breeze is blowing in from the sea. Viewed from the low shore by Hest Bank, the Furness shore is clearly reflected in detail, even the steam of trains on the Furness Railway. Also, the bay towards Carnforth appears to be full of water where there is only dry sand.

Mirage effect on an asphalted pavement may be seen on the North Road between Newcastle-upon-Tyne and Gosforth when the sun is shining warmly and at the same time a cool wind from the north-east is blowing across it. The effect is observable to anyone walking up the road and approaching a level portion or slight depression. ALBERT TARN.

Barrow Hedges, Carshalton, February 15.

UNEXPLORED PAPUA.[1]

IN an interesting book on his experiences as a magistrate in the western division of Papua, Mr. Wilfred Beaver has given a vivid description of life in a practically unknown portion of that little-known land.

The western division is the largest in the territory, and has only partly been brought under Government control. It comprises the basins of the Fly River and the rivers east and west, from the Dutch boundary to the north-western portion of the Gulf of Papua. The people on the coast about Kiwai Island appear as a black, frizzy-haired race of medium height, narrow-headed, with the arched and prominent nose called Semitic. Inland skins are lighter, and noses shorter and straighter, while towards the east there are still other variations, but nowhere in this division is there any trace of the mixed people whom Seligman has described as Papuo-Melanesians.

After short sketches of Papua in general and of the western division and its history in particular, the author takes each river system or its hinterland in turn, as forming the most convenient means of describing the natives and the districts themselves.

In Kiwai the native houses are communal, varying from 250 ft. to 450 ft. in length. The whole roof is supported on the side posts, and, being carried forward over the end of the flooring, forms a verandah. The interior is divided into family compartments, each with its own fireplace. These compartments are open in the Fly River houses, and closed in those further east. All are now giving place to smaller houses, where married men sleep with their families.

Inland from the Fly River and at the western end of the division the bush people differ from those on the coast. The excessive use of *gamada* (*Piper methysticum*), the kava of Polynesia, has had to be prohibited by a Government regulation. In all this region the population is decadent, in the bush through pulmonary disease, on the coast through raids of tribes from the west.

The eastern part of the division on the coast and inland from the Papuan Gulf has scarcely yet been brought under control. Mr. Beaver gives an account of a pacificatory visit and the genesis of a Government station at Goaribari, where the Rev. James Chalmers and his party were killed in 1901. Cannibalism in this district was common, the stronger tribes gradually eating up the weaker. Yet these people are among the best physically in the possession, and, being quick, intelligent, and imitative, are now becoming employed in increasing numbers by white planters. The whole country being a region of swamps and morasses, the natives are naturally expert canoe-makers, and sago, both here and in the Fly basin, is the staple vegetable food, with bananas and yams when the soil is suitable.

Both at Kiwai and Mawata the natives are becoming "civilised," civilisation consisting in the wearing of European clothes, the use of European tools, and the laying out of the village in two streets of pile houses, each occupied by two families. "There is a flagstaff and a small court-house, a wooden church, and a trader's store." Amusing instances are given of the mingling of old and new ideas. Women make proposals, and brothers and sisters are exchanged in marriage, while the court for native affairs deals with affiliation orders and fines of thirty shillings for "philandering" with other men's wives.

FIG. 1.—Bamu River archer in full fighting dress. The gauntlet is worn on the left arm to protect it from the bowstring. The bamboo beheading knife is carried slung around the neck. The head-carrier is carried over the left shoulder. From "Unexplored New Guinea."

It is impossible to give an adequate view of these interesting chapters within the limits of a short notice. Mingled with descriptions of scenery and personal sketches of prominent natives are interesting accounts of native arts, fishing by means of the sucker fish, and the spearing of dugong from platforms on the reef. Dress or the lack of it, pigs and cassowaries, swamps and gardens, sorcerers' magic and charms, births, marriages, and deaths, are all dealt with in a most unconventional way. A chapter on property and inheritance and Dr. Landtman's account of the religious beliefs of the Kiwai people conclude the book.

The spirit in which Mr. Beaver wrote this most picturesque book is shown when he says: "There is a mystery about Papua that seems to enhance its

[1] "Unexplored New Guinea: A Record of the Travels, Adventures, and Experiences of a Resident Magistrate amongst the Head-hunting Savages and Cannibals of the Unexplored Interior of New Guinea." By Wilfred N. Beaver. With an Introduction by Dr. A. C Haddon. Pp 320. (London: Seeley, Service, and Co., Ltd., 1920.) Price 25s. net.

fascination. What that fascination is, and why there should be any at all, is hard to say. . . . Papua is a land of disappointment, a land where nothing happens as you anticipate, where the unexpected usually happens, and the impossible is achieved."

An introductory sketch by Dr. Haddon gives a short biography of the author, who was killed at Polygon Wood, in France, in September, 1917. His death deprived ethnology of a keen and intelligent observer, and the Papuan Government of a most zealous and successful magistrate, loved by his fellow-officers, and trusted by the natives, whom he understood and with whom he sympathised.

SIDNEY H. RAY.

ALPINE PLANTS FOR ROCK-GARDENS.[1]

"PROCLAMATIONS of purpose are often confessions of failure to achieve it," is the opening sentence of the Introduction of Mr. Farrer's book. His volume is "vast," and from the nature of the subject justly so. Mr. Farrer has not only given an account of the rock-garden plants which now figure in the nurserymen's catalogues, but has also unearthed from botanical treatises a large number which no doubt will some day come into cultivation, so that his book is of more than present-day value. In addition to this, he has been at great pains to discover the correct names of the plants he records, which has entailed considerable research into botanical literature, and for this valuable labour he is deserving of high praise. He also gives some useful information as to rock-garden construction, and throughout the volumes there are good practical instructions as to the cultivation of the various plants.

But Mr. Farrer has unfortunately failed to sink either his own individuality or idiosyncrasies in the volumes before us, so that instead of presenting us with a lucid and useful account of rock plants suitable for English gardens easy to be understood, he has expressed his own ideas and opinions with an exuberance of persiflage that is very irritating. In his Introduction of eighty-four pages and throughout the book the author seems far more interested in striving to commit extravagant excesses with the English language than in conveying useful information about Alpine plants, and in consequence many of the really valuable portions of the book tend to be overlooked. With regard to his descriptions of the plants, moreover, we cannot say that his work is very helpful. After his diatribes on the wearisome jargon of botanists one does not feel that the following description of *Dianthus arenarius* is either very intelligible or informing: "Related to *D. squarrosus*, is much laxer in the habit with fewer flower stems, taller and frailer and larger, with very fringy whirligigs of white or pale pink." Nor is this seven-and-a

[1] "The English Rock-Garden." By Reginald Farrer. Vol. i., pp. lxiv+504+52 plates; Vol. ii., pp. viii+524+50 plates. (London and Edinburgh: T. C. and E. C. Jack, Ltd., 1919.) Price 3*l*. 3*s*. net two vols.

half-line sentence on *Primula Winteri* particularly illuminating: "It is unfair to say that the name of *P. Winteri* is a base and unpardonable pun, yet true it is that in midwinter always seem to emerge the crowded new rosettes of powdered, rounded, toothed leaves on their firm footstalks, and in their heart an interminable cabbage of these glorious, wide, lavender-lilac flowers with their fringed lobes and noble outline, succeeding each other for many months, in a rivalry of beauty, against the grey and mealy beauty of the robust leaves, if only the weather will allow. There is no other fault than this—which perhaps is merely due to the plant's inexperience—to be brought against this unparalleled introduction. . . ." A barren superfluity of words indeed!

Many extracts from this riot of verbiage might be made, but only one or two can be given. Of "the moonlight radiance of *Roscoea cantlioeides*," Mr. Farrer remarks: "Its nearest match is in the lucent citrons of *Meconopsis integrifolia*, but here the tone is yet blander and more serene, shining with a solemn and unearthly radiance as the blossoms, like ghostly butterflies of light, hover pale and vivid upon the background of dark pine-branches."

Then, again, when he speaks of *Aster lichiangensis* as "a bonus of the gods," or of *Anemone alpina*, almost blasphemously, as "the Great King of Glory," or of a double form of this species as "windmill-whirling," one feels tempted to relegate the book to "the dust and silence of the upper shelf."

Yet despite these adverse criticisms, which perforce bulk largely in a notice of the book, it is a real compendium of sound information and learning, though unduly biased in certain respects. On the genus Primula, for instance, which occupies nearly 100 pages, and on Saxifrage and many other genera, Mr. Farrer speaks as an authority, and we welcome his useful marshalling of information. Why he should dismiss Rhododendron in half a page because he says it "asks for a book" we fail to see. He appears to forget both here and elsewhere that only certain species in a genus are rock or Alpine plants. In a few pages ample accounts could have been given of *Rhododendron intricatum*, *R. fastigiatum*, *R. hippophaeoides*, and the few other Alpine forms, whereas he alludes to *R. praecox*, *R. dauricum*, and *R. ciliatum*, which are certainly not "rock-garden" plants in the usually accepted sense.

FIG. 1.—*Gentiana Farreri*. From "The English Rock-Garden."

The book is admirably illustrated with an excellent series of some 200 photographs. In reproducing the picture of *Gentiana Farreri*, a plant for the introduction of which gardeners will always hold Mr. Farrer's name in grateful remembrance, we cannot refrain from quoting his exuberant description: "*G. Farreri*, which sends out many flopping, slender shoots from the stock, clad in very narrow foliage, and ending each in a single huge, up-turned trumpet wide-mouthed, and of an indescribably fierce, luminous Cambridge blue within (with a clear white throat), while, without, long vandykes of periwinkle-purple alternate with swelling panels of nankeen, outlined in violet, and with a violet median line." *Non equidem invideo; miror magis!*

The publishers have also assisted to increase the reader's irritation with the book, which, in spite of its too obvious faults, has many excellent qualities, by leaving the pages uncut and untrimmed—surely an unreasonable offence in a book of this character.

A NEW COPPER-REFINING INDUSTRY IN GREAT BRITAIN.

IN the last year of the eighteenth century Great Britain produced about 75 per cent. of the world's output of copper. The Cornish miners supplied most of the ore, and the Swansea smelters extracted and refined the metal. In the United States of America only a few tons were made. In 1913 the positions were reversed. Great Britain smelted and refined barely 6 per cent. of the world's production of this metal, and all but an insignificant fraction was derived from imported ores, matte, blister copper, and precipitate or cement copper. In the same year the United States of America furnished more than 55 per cent. of the world's total, and by far the greater part of this was obtained from home supplies of ore.

Whether in peace or war, copper is, and has long been, second in importance only to iron, not only in the various types of the commercial metal, but also in its numerous alloys. The enormously greater extent to which it is now used is not, however, generally realised. In 1800 the world's production did not exceed 10,000 tons, and that was probably the high-water mark of the annual production up to that time; in 1900 it had risen to about 500,000 tons, and in 1912 to about 1,000,000 tons. Thus, in little more than a hundred years, the production had increased a hundredfold.

During the war the whole question of the future of the copper-smelting and refining industries of this country was examined and considered by the Non-Ferrous Metal Trades Committee of the Board of Trade under the chairmanship of Sir Gerard Muntz. In due course the Committee reported, but the report has not been published. The announcement is now made in a recent issue of the *Times* that a syndicate has been formed to set up a large copper refinery in Devonshire, and has chosen a site near Newton Abbot, and that it is proposed to spend nearly 10,000,000*l*. on the scheme. The chairman of the syndicate is Sir Gerard Muntz. It is stated that Mr. H. J. Wilson, who originated the scheme, at first intended to harness and utilise the water-power of the Dartmoor plateau, but so much opposition was shown in some quarters that this proposal has been abandoned, at any rate for the time being. It has been decided to utilise a large deposit of lignite, of which it is estimated that more than 800,000,000 tons are available for the generation of the electric power required. At the site chosen there are tide-water facilities. By-products will be collected and marketed. The power generated will be mainly devoted to the electrolytic refining of copper, but it is considered that it will be so cheap as to enable current to be supplied in bulk to all the towns in South Devon, as well as to the industries which may be attracted to the neighbourhood.

The lignite deposits have only been used locally to a small extent. The *Times* states that a few months before the outbreak of war a party of Germans conducted a series of experiments and acquired a considerable tract with the evident intention of developing it on a large scale.

In the years immediately preceding the war the United States of America refined electrolytically more than 90 per cent. of the world's output of crude copper. Most of this production was absorbed by the electrical industry. Great Britain, accordingly, was obliged to obtain the bulk of this type of copper from America, and in 1913 imported about 100,000 tons. In view of the great importance of the home electrical industry, it will be obvious that the proposal to establish a large electrolytic refinery in a suitable locality possesses value which it is not easy to exaggerate. It should be pointed out, however, that the refinery will have to depend mainly upon imported blister copper for its raw material, since only a small amount of this metal is smelted in Great Britain at the present time. There are no longer any considerable home deposits of copper ore, and the few smelters who do exist have found it more and more difficult to obtain smelting materials. The United States of America, by virtue of the extent of its control of its own deposits and of those in Chile, is able largely to influence the price of copper, and the policy pursued by the works there is to attract smelting materials from other countries for treatment. The Americans can afford to pay high prices for imported ores, because the remainder of this raw material is produced at home at a price which is so low that a low average selling price for the whole serves to secure an adequate profit. In Great Britain only a few copper manufacturing firms and one or two companies owning mines abroad can afford to operate smelting works under these conditions. This consideration has no doubt been given its due weight by the syndicate, but it has not been made clear upon what sources they will rely for their blister copper.

In conclusion it must be stated that in this country a small amount of electrolytic refining is carried on, and that there are a large number of manufacturers who are engaged in the furnace-refining of blister, Bessemer, and other varieties of the crude metallic copper, and in producing the "tough" and "best selected" brands of the metal. The "tough" quality is used chiefly by the engineering and shipbuilding industries, and the "best selected" for the manufacture of alloys. In the production of this class of material the works in Great Britain are, and have long been, pre-eminent. If, therefore, the plans of the syndicate are successful in providing British manufacturers with sufficient supplies of electrolytically refined metal for their purpose, the production of this commodity in Great Britain will be placed on a much more satisfactory footing than it has been for many years.

H. C. H. CARPENTER.

THE "TIMES" AFRICAN FLIGHT.

DISCOVERY OF A NEW VOLCANIC FIELD.

NEWS has been received with great disappointment that, owing to the failure of the engine, Dr. Chalmers Mitchell's trans-African flight was checked on February 11, when a descent had to be made in the bush, and then the machine was taken to Jebelein for repairs. The South African machine, the *Silver Queen*, has been irreparably smashed by a forced descent at night at Korosko. The troubles of both machines may be due to their having been unduly forced, owing to the supplies of petrol in some southern stations being apparently adequate for one machine only. The flight was resumed on February 14, and a point twenty miles from Mongalla was reached at 4 p.m. on that date. On the following day the short flight was taken to Mongalla, where Dr. Chalmers Mitchell expected to be detained for three days. In his latest message, dated February 16, he says:—

I consider the Cairo-Khartum part of the route satisfactory if relays of aeroplanes are available. The arranged landing-grounds are good and forced descents fairly practicable. The stage from Khartum to Mongalla is extremely dangerous, as the arranged aerodromes are difficult to locate and forced descents require luck and unusual skill. Bush fires destroy visibility, and render the smoke fires on the aerodromes useless as guides. The positions of the wireless station and the telegraph wires at Mongalla are extremely dangerous. The pilots, the mechanics, and the Vickers' "Vimy" machine are excellent. We hope that the worst of the trip is over, but must proceed slowly.

Dr. Chalmers Mitchell has thus successfully achieved more than one-third of the journey along Africa, and has shown how valuable aeroplane surveys may be by a discovery of first-class importance. After leaving Assuan, on approaching the section of the Nile flowing from south-west to north-east from Dosha to Korosko, he remarked many high hills with steep walls running north-east and south-west. These steep hill-fronts may indicate that both the section of the Nile above Korosko and the parallel section from Korti to Abu Hamed were determined by earth-movements, which have a wide influence in this part of Africa; for the section of the Nile flowing from Abu Hamed south-west to Korti is in line with a remarkable breach through the mountain rim of the Red Sea basin. The mountains which extend west of the Red Sea from behind Kosseir, southward past Berenice and Mersa Shab, end to the south-east in the group of Adal Qaqa (about 5925 ft.). The geology of this group is known by the monograph by Dr. J. Ball (1912), whose maps indicate the existence of faults of late Cretaceous or post-Cretaceous age, some of which trend north-west to south-east, and others from north-east to south-west. South-east of Adal Qaqa the highlands are resumed by the mountains which extend south from Gebel Elba, west of Cape Elba, through Gebel Shendil (6275 ft.) and Gebel Asotriba (7270 ft.). The Adal Qaqa and the south-eastern groups are separated by a deep depression formed by the plains of Nafab and by the broad valley of the Wadi Di-ib which discharges to the Red Sea. The divide between the Nafab and Wadi Di-ib is probably less than 2000 ft. above sea-level. The straight course of the 1000-metre contour line on the south-eastern side of the Adal Qaqa group, as shown on the 1 : 7,500,000 map of the Nile Basin by the Egyptian Survey (1906), occurs on the extension of the line of the Nile from Abu Hamed to Korti. On the continuation of this line across the Red Sea the irregularities in the front of the Arabian plateau between the coastlands of El-Gof and Medina may be due to the same tectonic cause.

The representation of the 1000-metre contour near Adal Qaqa may be untrustworthy, or its continuation on the line of the Nile from Abu Hamed to Korti may be only a coincidence. But the probability of a long north-east to south-west fracture is strengthened by the discovery by the *Times* Expedition of a group of extinct volcanoes in the Bayuda Desert, half-way between Merowe and Berber.

The discovery is quite new, since this volcanic field was unknown to so alert an observer as Mr. G. W. Grabham, the Government Geologist of the Sudan. Mr. Grabham has, however, been able to support Dr. Chalmers Mitchell's identification, as he had received some volcanic tuffs obtained by Sir Herbert Jackson about fifty miles distant from the craters seen by Dr. Chalmers Mitchell. There was apparently no evidence as to the age of these tuffs, or whether they came from modern volcanoes, but Dr. Chalmers Mitchell concludes from his observations that the eruptions were not later than the Kainozoic, and as he refers to the hills as craters they were probably formed late in that era. The great earth-movements along the Rift Valley are frequently associated with volcanic outbreaks, due to material compressed by the subsidence, being forced up the adjacent fractures. Dr. Chalmers Mitchell's discovery, therefore, suggests that one line of crustal fractures explains the bend of the Nile south-westward from Abu Hamed to Korti, the Nafab—Di-ib depression, and the Bayuda volcanic field.

Col. Lyons has shown that the course of the Nile from Berber to Korosko is comparatively young, and that above Berber, as at the Shabluka Gorge, it has re-excavated a new channel through the comparatively soft rocks which have filled up an older valley. It therefore seemed possible, from the information previously available, that the disturbances which have given the Nile its S-shaped course from Korosko to Khartum were due to earth-movements contemporary with the breach through the Red Sea rim near Berenice. This conclusion is strengthened by the discovery of the Bayuda volcanoes. The movements doubtless happened during the Kainozoic era, and Dr. Chalmers Mitchell's observations on the condition of the volcanic hills of the Bayuda will probably indicate a more precise date.

J. W. GREGORY.

THE NATIONAL RESEARCH COUNCIL OF THE UNITED STATES.

AN account has recently been published of the organisation established by the National Research Council of the United States for the carrying out of its work. Americans are proud of their organising ability, and it is very interesting to study the efforts of the men of science of America to develop their scheme of mobilising the whole strength of American science for the promotion of the national well-being and for the advance of science itself.

The National Research Council was established to deal with war problems. It was started by the men of science themselves; they recognised that although the Government had already strong scientific bureaux, there were many other workers who in the isolation of their own laboratories were almost unavailable, but eager for opportunity to help. This organisation is now being completed and put on a permanent basis. We are told that it differs from organisations for similar purposes in England, Canada, Australia, and Japan in that, while recognised by Government, it was not initiated or organised by Government, and is not supported by it. Its support is derived from funds contributed by private sources.

The machinery is somewhat elaborate. There are seven divisions devoted to special branches of science and technology. These divisions are physical science, engineering, chemistry and chemical technology, geology and geography, medical science, biology and agriculture, and anthropology and psychology. The members of each of these divisions include representatives of societies dealing with cognate subjects, other scientific workers, and representatives of firms. Attached to each division there are a very large number of committees to give attention to special problems. But in addition to this classification into seven divisions there are six "general relations" divisions—a Government division, a division for foreign relations, a division of States relations, a division of educational relations, a division of industrial relations, and a division of research information. The idea underlying these divisions may be seen from their constitution. For example, the educational division has a membership including representatives of all the principal university associations, the United States Bureau of Education, the Carnegie Foundation for the Advancement of Teaching, etc. The division for research information will, we are told, be a national centre of information concerning American research work and research workers, with all its information promptly available to institutions and individuals interested in knowing at any time what problems are under investigation in America and their status.

The National Research Council has permanent headquarters in Washington, with an executive staff of men of science giving their whole time to the work of their respective positions. Each of the divisions has a resident chairman and a small office staff in Washington.

It is not yet possible to say much as to the actual work of the new Council. From the list of subjects being studied by the numerous committees of the different divisions, it would appear that problems of wide national interest are receiving first attention. If we compare the American organisation with that of our own Research Department as shown in its annual reports, it would seem that in America the scientific worker is organised to a greater, and the industrial leader to a less, degree than in this country. There is nothing in the American scheme that quite coincides with the research associations for each large industry established by our Research Department. It is clear that both the American Department and our own will have much to learn by watching each other's development, and it is to be hoped that some degree of co-operation may be established in connection with problems of interest and importance to both nations.

The official organ of the National Research Council for the publication of accounts of research work and of committee and other reports will be the Proceedings of the National Academy of Sciences, but in addition the Council proposes to publish a Bulletin at irregular intervals. The first number of the Bulletin contains articles by Dr. G. E. Hale and other writers on different aspects of the national importance of scientific and industrial research. Dr. Hale gives an account of the origin of the Council and outlines its objects. He argues against the view that organised effort in science may hamper the individual investigator and hinder personal initiative. In his opinion, well-planned co-operation stimulates the individual and brings out his best and most original efforts. The Council will favour this type of co-operation, but is opposed to all attempts at a central control of research.

The Hon. Elihu Root writes on the need for organisation in research, and holds that science has been arranging, classifying, methodising, and simplifying everything except itself. One fears that the degree of organisation suggested by Mr. Root would almost amount to the control which Dr. Hale tells us the Council has no wish to attempt. Other articles dealing with the relation of research to industry are written by men of wide experience in large industrial concerns, and the Bulletin concludes with an account by Mr. Howe of the organisation of scientific and industrial research in the United States, the British Empire, France, Italy, Japan, and Belgium. An appendix contains a list of non-military researches undertaken by the Council covering a wide range of subjects, and especially numerous in the section of medical science.

THE SECONDARY SCHOOL CURRICULUM.[1]

THE Secondary School Examinations Council is an august body the members of which have for the most part more experience of university work and of administration than of secondary schools. The council was therefore well advised in selecting, for the investigation of the methods and standards of award of the seven approved first examinations, "panels" of experienced teachers. These have now made their reports, which are published for the information of all concerned. The conclusions reached are not so startling as to make the non-committal preface appear necessary in the eyes of a schoolmaster.

The mathematical investigators in particular have not exceeded their terms of reference, though a hint is thrown out that the present forms of compulsion may require revision. Thus "elementary mathematics should include arithmetic" seems a harmless proposition. To some examining bodies, however, "elementary mathematics" means algebra and geometry, and is not compulsory. Later there follows the sentence: "So long as mathematics is a compulsory subject for exemption purposes, the present standards for credit cannot well be raised, but they are in themselves unsatisfactory." It may be inferred that compulsory algebra is viewed with disfavour, a view which is shared by many examiners who have realised the appalling waste of time involved for half the boys and girls who try to learn algebra without attaining the power or even the need to apply it in the simplest way. Compulsory arithmetic is much more defensible, and it is a pity that the investigators have not maintained a clearer distinction between the two. In geometry it is recommended that the theorems on congruence of triangles, parallel lines, and angles round a point (*i.e.* Euc. i. 4, 8, 26; 27, 28, 29, 32; 13, 14, 15) should be omitted. We may infer that only the proofs of these theorems are indicated, and that the enunciations (*pace* Einstein) are to be assumed.

The science investigators have had to cover a wider field and to consider a greater variety of practice on the part of the different examining bodies. Thus in one examination a paper is set on "Elementary General Science," covering a very elementary treatment of heat, hydrostatics, chemistry, and botany, this paper having been recently introduced for the benefit of rural secondary schools. The "panel" is of opinion that further investigation of this general science work is particularly desirable. We may remark here that it would greatly help the movement if specimen copies of the paper referred to could be circulated among teachers and examining bodies. To quote the report: "The examination, like the syllabus in the schools up to the sixteen-year-old stage, should be suited to the capacity of the average pupil of sixteen, should cover a reasonably wide range, and should not encourage instead advanced work within a limited field. Further, it should not be confined to an abstract and academic treatment of the subject, but should require a knowledge of the applications of the sciences to everyday life. It must be remembered that at this age pupils obtain far more value from a concrete than from an abstract treatment of science, and this should be borne in mind both in drawing up a syllabus and in setting a paper. The investigators direct attention in this connection to the observations contained in paragraphs 47, 50, and 51 of the Report of the Government Committee on Science." Most teachers of science in schools will assent to this. The generation of science masters who began their science at the university is rapidly passing away. On them must partly rest the responsibility for the effort which has been made in the last thirty years to impart an appreciation of "scientific method" to boys at too early a stage. Now they are being followed by a generation of teachers who may have begun the systematic study of science at the age of twelve, and in some cases find themselves deficient in literary attainments. An undergraduate starting on geometrical optics is at a disadvantage if he has never handled lenses or prisms in such a way as to know their peculiarities; but if he has done this, and knows the meaning of the words used, he need not have been through a prolonged course of optical measurements, nor need he belong to the class of natural science students who come up "knowing how to measure every physical quantity, but with no ardent desire to measure any."

It may be remarked here that "general science" is no more than a branch of English, and that its teaching implies the demonstration to the various senses of the meaning of a number of English words. This has evidently been realised by the "panel" of geographers, whose remarks are worthy of quotation. They "are of opinion that geography should be a subject in Group I.; but they are of opinion that it should be a subject in Group III. also." Geography, in other words, is not only a branch of English, but also a branch of science. This is a bold saying, and it may possibly account for the cautious prefatory statement: "It must not be assumed that either the council or the board are at present committed to any or all of the suggestions." If geography is to belong to two groups, why not also general science? And why should not algebra find a place among the foreign languages? The insidious suggestion might lead to the collapse of all the walls of partition and to the survival of English as the one essential subject, as seen in a vision by Sir Arthur Quiller-Couch. For the investigators in English report thus: "They are of opinion that (in the interests of the language and of lucidity of expression) a reasonable standard of English should be required in all subjects of the examina-

[1] Secondary School Examinations Council. Reports of the Investigators Appointed to inquire into the Methods and Standards of Award in the Seven Approved First Examinations held in July, 1918. Group I., English, History, Geography; price 6*d*. Group II., Classics, Modern Languages; price 4*d*. Group III, Mathematics, Science; price 4*d*. (H.M. Stationery Office.

tion." Again: "No candidate should obtain a certificate who does not show a good command of English and the power of writing it intelligently." If to this were added the power of reading English intelligently, which implies a knowledge of the meaning of a number of words in common use under the headings of geography, history, and general science, and, finally, the power of doing simple arithmetic, is it not conceivable that a candidate possessing these three powers might be thought fit to continue his studies at any university of the realm?

NOTES.

BOTANISTS in Great Britain have been considering the practicability of holding an Imperial Botanical Congress in London at which botanists from the overseas Dominions might meet their colleagues at home for the discussion of matters of common interest. Many subjects are ripe for discussion, such as the methods of training botanists for service abroad, the relation between the pure science and its applications and between the botanist and the commercial men interested in industries in which botanical knowledge should play an important part, more helpful co-operation between the home and the overseas botanist, botanical surveys of overseas Dominions, and others. After careful consideration it has been decided that it would be inadvisable to hold such a congress during the present year.

M. LUCIEN POINCARÉ, Vice-Rector of the University of Paris, will be entertained at dinner by the Groupe Inter-Universitaire Franco-Britannique on Monday, February 23. The dinner is being organised in connection with the formal opening of the British Bureau of the Office National des Universités et Ecoles Françaises by M. Poincaré. The chair will be taken by M. Petit-Dutaillis, Director of the Office National. Amongst the members who have intimated their intention of being present are his Excellency the Belgian Ambassador, his Excellency the Greek Minister, the Lord Chancellor, the Earl of Reading, Viscount Burnham, the Right Hon. H. A. L. Fisher (President of the Board of Education), the American Consul-General, Mr. Austen Chamberlain, and the Lord Mayor and Lady Mayoress.

THE anniversary of Sir Francis Galton's birth, February 16, was celebrated by the Eugenics Education Society as usual this year. Prof. Arthur Keith delivered the Galton lecture, and this was preceded by a dinner at the Connaught Rooms. These annual gatherings have been held since 1914 in every year but one, when war conditions stood in the way. In his interesting lecture, which will be printed in full in the next issue of the *Eugenics Review*, Prof. Keith gave a sketch of Galton's life in so far as it affected his work, and a broad and general account of his investigations and theories. The main thought running through his address was that Galton's work had not been adequately appreciated during his life, and that his reputation would increase as time went on. In Galton's day anthropologists concentrated their attention on the individual man, whilst it was equally necessary to consider the distribution of men according to their qualities. Hence Galton's teachings made slow progress because they fell on unprepared ground, whereas in the future he would come to be recognised as one of the greatest men of science produced in England during the nineteenth century. Major Leonard Darwin was in the chair, and said that Galton always had practical aims in view and always had the courage of his opinions. If ever the *name* of eugenics came to be captured by cranks it would be because scientific men did not follow his example, and, through fear of contact with cranks, gave this important subject lukewarm support. The *science* of eugenics could never suffer in this way, because it was founded on indisputable truths. The proceedings terminated by a vote of thanks moved by Sir Robert Blair and seconded by the Dean of St. Paul's.

AT the National Conference of Manufacturers and Producers, held at Kingsway Hall on February 11, Sir Robert Hadfield, representing the Federation of British Industries, proposed a resolution appreciating the work of the Department of Scientific and Industrial Research; and strongly urging all manufacturers, either individually or collectively by trades, to organise and maintain research facilities. In the course of his remarks Sir Robert Hadfield affirmed that science and industry are now in indissoluble partnership, and that further steps should be taken to organise research more thoroughly and efficiently than has been done in the past. We must recognise that, in these days of international competition, the prosperity of every British manufacturer and trader is bound up with that of British trade as a whole, and hence research must be regarded as a national rather than as an individual matter. While admitting the necessity for, and the value of, the research work done by big firms along the lines of their special activities, Sir Robert Hadfield pointed out that there are also a number of questions affecting whole industries the solution of which can be obtained only by the co-operation of many workers investigating special branches of the subject. In these cases everything is to be gained by carrying on the work of research in combination and making its results available to the whole of the organised industry. This is what the Department of Scientific and Industrial Research enables to be better accomplished, at any rate in certain trades and lines of work.

THE third annual Silvanus Thompson memorial lecture of the Röntgen Society will be delivered by Prof. W. H. Bragg in the Barnes Hall of the Royal Society of Medicine, 1 Wimpole Street, at 8 o'clock on Tuesday, March 2. The subject will be "Analysis by X-rays." Admission will be free.

PROF. A. DEPAGE (University of Brussels), Drs. Pierre Duval and A. Gosset (Paris), Prof. J. M. T. Finney (Johns Hopkins University), and Dr. Charles H. Mayo (Rochester, U.S.A.) have been elected honorary fellows of the Royal College of Surgeons of England.

At the recent annual general meeting of the Optical Society Mr. R. S. Whipple was elected to the presidency; Prof. F. J. Cheshire, Sir Herbert Jackson, and Mr. H. F. Purser were elected vice-presidents; Mr. I. G. Aitchison, hon. treasurer; Mr. J. H. Sutcliffe, hon. librarian; and Messrs. W. Shackleton and L. C. Martin, hon. secretaries.

The following officers and council of the Malacological Society of London for 1920 were elected at the annual meeting on February 13:—*President:* G. K. Gude. *Vice-Presidents:* H. O. N. Shaw, T. Iredale, J. R. le B. Tomlin, and A. S. Kennard. *Treasurer:* R. Bullen Newton. *Editor:* B. B. Woodward. *Secretary:* A. E. Salisbury. *Other Members of Council:* A. Reynell, C. Oldham, Major M. Connolly, H. Woods, the Rev. A. H. Cooke, and H. H. Bloomer.

The following officers and members of council of the Royal Astronomical Society were elected at the anniversary meeting on February 13:— *President:* Prof. A. Fowler. *Vice-Presidents:* Sir F. W. Dyson, Prof. A. S. Eddington, Major P. A. MacMahon, and Prof. H. F. Newall. *Treasurer:* Mr. E. B. Knobel. *Secretaries:* Dr. A. C. D. Crommelin and the Rev. T. E. R. Phillips. *Foreign Secretary:* Prof. H. H. Turner. *Council:* Prof. A. E. Conrady, Dr. J. L. E. Dreyer, Dr. J. W. L. Glaisher, Mr. J. Jackson, Dr. Harold Jeffreys, Mr. H. S. Jones, Prof. F. A. Lindemann, Mr. E. W. Maunder, Dr. W. H. Maw, Prof. J. W. Nicholson, Mr. J. H. Reynolds, and Lt.-Col. F. J. M. Stratton.

The war memorial of the Institution of Mining and Metallurgy is to be a sculptured figure, to be placed in the house of the institution, and a record of those who served in his Majesty's Forces. The full scope of the memorial cannot be decided until the council knows the extent of the response to an appeal now being made, but it is hoped that a fund of about 4000*l.* may be available. A member of the institution, Lt.-Col. Peter N. Nissen, has prepared a design for the figure, which has been accepted, as has also his offer to model the figure and friezes. These will be executed in bronze and the pedestal-base in malachite, with four silver-alloy plates upon which an appropriate inscription and the roll of honour will be engraved. This work is already in progress. Members of the institution and others interested in the mining industry are invited to contribute to the war memorial fund. Subscriptions should be sent to the secretary of the institution, 1 Finsbury Circus, London, E.C.2.

The report printed in Nature of January 8, presented by the Joint Committee of the British Medical Association and the British Science Guild, regarding awards for medical discovery is published in the Journal of the British Science Guild for January. Advances in medical treatment of great value to humanity frequently convey no additional remuneration to the discoverers, and may even involve monetary loss, and it is suggested that rewards should suffice to meet this latter contingency. The principle was accepted by Parliament in the case of Jenner in 1802 and 1807, but the 60,000*l.* annually disbursed by the Government under the Medical Research Committee subsidises only investigations in progress, and not discoveries already made. Honours, medals, and prizes bestowed by H.M. the King or public bodies are acts of grace falling outside the consideration of the committee, which deals with pecuniary reward. It is accordingly recommended that Parliament should provide an annual sum of not less than 20,000*l.*, enabling pensions amounting to between 500*l.* and 1000*l.* a year to be awarded as compensation for losses incurred in achieving medical discoveries.

The annual general meeting of the Institute of Metals will be held in the building of the Institution of Mechanical Engineers, Westminster, on Thursday and Friday, March 11 and 12, under the presidency of Prof. H. C. H. Carpenter. The president-designate is Engineer Vice-Admiral Sir George Goodwin, K.C.B. The following are among the communications to be submitted:—Fifth Report to the Corrosion Research Committee, Dr. G. D. Bengough, R. M. Jones, and Ruth Pirret; The Action on Aluminium of Hard Industrial Waters, Dr. R. Seligman and Percy Williams; Zinc Alloys with Aluminium and Copper, Dr. W. Rosenhain, J. L. Haughton, and Kathleen Bingham; Tin-Phosphorus Alloys, A. C. Vivian; Effect of Hydrogen on Copper, W. C. Hothersall and E. L. Rhead; Influence of Cold Rolling on the Physical Properties of Copper, F. Johnson; Study of Thermal Electromotive Force as an Aid to the Investigation of the Constitution of Alloy Systems, J. L. Haughton; and Idiomorphic Crystals of Electro-deposited Copper, W. E. Hughes. On June 10 (not on May 5, as previously announced) Prof. Carl A. F. Benedicks, of Stockholm, Sweden, will deliver the tenth May lecture, his subject being "Recent Progress in Thermo-electricity."

By the death of Dr. Vincent Arthur Smith at Oxford on February 6 India has lost an eminent historian, archæologist, and numismatist. Born in Dublin in 1848, Dr. Smith was educated at Trinity College in that city, and passed thence into the Bengal Civil Service in 1871, being posted to the United Provinces of Agra and Oudh. He served in this Province until 1900, passing through all the grades of the Service, his last appointments being those of Magistrate-Collector, District Judge, Commissioner, and Secretary to Government. During his service he paid much attention to the local history, archæology, and numismatics, and contributed numerous papers on these subjects to the Journal of the Asiatic Society of Bengal and to the *Indian Antiquary*. On his retirement he devoted his life to historical literature, and wrote a series of valuable works. In "The Early History of India" Dr. Smith for the first time evoked order from chaos, and established the chronology, hitherto uncertain, on a firm basis. This was followed by "The History of Fine Art in India and Ceylon," biographies of Asoka, the Buddhist Emperor, and of Akbar, the Great Mogul, and the Oxford "History of India," from the earliest period down to the present day, which appeared only a few months before his death. In numismatics he investigated the series of Gupta coins, and catalogued the collection of Indian coins in the

Calcutta Museum. Dr. Smith leaves many friends, to whom he was always ready to impart his wide stores of learning, and the charm of his personality will be to them a lasting memory.

AN account of the mammals collected in Eastern Cuba during 1917 by Dr. H. E. Anthony appears in the Bulletin of the American Museum of Natural History (vol. xli., art. xx.). Though but a brief preliminary survey of the material collected, this contribution is one of very considerable interest. It forms, indeed, the complement to Dr. Anthony's recent memoir on the indigenous mammals of Porto Rico, living and extinct. Two species of that extinct and extremely primitive insectivore Nesophontes were found, and one of these is new to science. This he has named *Nesophontes longirostris*. The other species, *N. micrus*, bears a close resemblance to *N. edithae* of Porto Rico. Of the Hutias (Capromys), which occur also in Jamaica and Porto Rico, two species were obtained, and several species of bats. All the remains found were from caves, and it would seem that they were deposited in the form of "castings" from the barn-owl. This is a point of some interest, since it helps to explain the great accumulations of small mammal bones found in similar situations in other parts of the world.

THE Archives of the Cambridge Forestry Association for 1919 is a brief pamphlet recording the progress of this society since its foundation in October last. The members are mainly past and present students of the School of Forestry, who meet together to promote research and to render assistance in various ways to this important teaching centre. The secretary invites contributions of apparatus, specimens, books, and periodicals to the museum, which is worthy of support, as it already contains a remarkably fine collection of foreign and home timbers, as well as many instructive objects and photographs, illustrating the uses of wood and the diseases, defects, and abnormalities of trees. The income of the school is very meagre, amounting in 1919 to only 576*l.* 13*s.*, a sum insufficient to pay salaries and incidental expenses, there being an actual deficit of 123*l.* 1*s.* 4*d.* From this it is evident that there are no funds available for the purchase of apparatus or specimens. The lists of desiderata and of recent additions to the collection given in the pamphlet ought to stimulate donations to the School of Forestry at Cambridge. The other contents consist chiefly of short notes on various objects in the museum, with an account at some length of experiments on the swelling and shrinkage of wood which have been carried out recently by Mr. Herbert Stone. Forestry has lately attracted a great number of students to the universities where the subject is taught, and societies similar to that at Cambridge have been founded during the past year also at Oxford and Edinburgh.

THE folding and faulting that characterise the Rocky Mountain belt in Alberta are well shown in the small coloured sections accompanying Memoir 112 of the Geological Survey of Canada (1919) by Mr. J. S. Stewart. The contrast between the region uplifted in Early Eocene times by the "Laramide revolution" and the level or undulating Cretaceous strata to the east is as marked as that between the Juras and the Paris basin. The Oligocene beds in this eastern region represent the river-outwash from the Laramide surface of denudation, and subaerial action in succeeding ages has dissected the country to depths of 2000 ft.

DR. CHARLES SCHUCHERT (Bull. Geol. Soc. America, vol. xxix., p. 245, 1918) reviews the stratigraphical position of the American Morrison and the East African Tendaguru formations, which are rich in Dinosaurs. He retains the former in the Jurassic, while suggesting a break in the latter, the lower Dinosaur zone in East Africa being Early Jurassic, and the two main later zones bridging the time from Jurassic to Cretaceous. The discovery of great sauropod Dinosaurs in the south of the late German colony in East Africa dates only from Fraas's work in 1907, and the importance of the deposits is greatly enhanced by the evidence as to age given by the intercalation of strata with marine molluscs. A recent communication to Dr. Schuchert from Prof. Branca in Berlin is mentioned, and may be welcomed as one of the signs of a *rapprochement* between scientific workers.

BULLETIN 688 of the United States Geological Survey, on "The Oilfields of Allen County, Kentucky," contains a neat little coloured geological map on the scale of 1/1,000,000 of a very much wider and a very interesting area of oil-producing country in Kentucky and Tennessee, west of the Alleghany range. The folded strata of the great range are included at the south-east angle. The authors, Messrs. Shaw and Mather, describe the occurrences of what are known as oil "sands"—that is, oil accumulations in a variety of rocks in strata of Silurian, Devonian, and Carboniferous age—and believe the original source to have been mainly decaying vegetation. The country dealt with in detail is mainly a gently undulating plainland, with lakelets in sink-holes caused by the solution of the underlying St. Louis limestone, an important stratum of Lower Carboniferous age. The prospector, whose zeal for the discovery of anticlines is now known even on the Stock Exchange, is warned of the occurrence of "pseudo-anticlines" (which, by the way, are true anticlines for the geologist), due to local features of surface-slip and solution.

THERE is something fascinating in looking across the Hudson from the higher platforms of New York City, and seeing in the uplands of New Jersey the foothills of a country that "needs no embellishment, for in the woods, the streams, the waterfalls, and mountain outlooks Nature has provided the best." We quote from the Report of the Department of Conservation and Development of New Jersey for 1918 (published 1919), which presents a model record of local government and local watchfulness. The director, Mr. Alfred Gaskill, may well be proud of his Department, which has, perhaps, its nearest counterpart in our islands in the Department of Agriculture and Technical Instruction for Ireland. One of Mr. Gaskill's Boards proposes the reservation of a mountain-park, where summer camps and children's playgrounds can flourish along thirty-six miles of practically uninhabited country; the geological division conducts soil surveys in lands where profitable patches require indication; it also presides over matters of water-supply, and, curiously enough, over the State Museum, with its permanent and loan educational collections; and the forestry division furnishes admirable illustrations of trees in relation to highways, and of the necessity for maintaining its reserves. It is characteristic, and due to climatic conditions, that the Fire Warden's report should be a considerable feature in this attractive little volume. The use of glauconitic marl as a source of potash is now in the hands of the Spilsbury Engineering Co., of New York, which proposes to produce 100 tons a day of a chemical extract the nature of which is not specified.

From Freiburg-im-Breisgau, the picturesque Rhine town that so often suffered in return for the savagery of German air-raids, there comes once more the *Berichte* of the local *naturforschende Gesellschaft* (Bd. xxii., Heft 1, 1919), which in happier years maintained our scientific knowledge of the Rhinelands. This part is devoted to a fourfold disquisition ("Vier Kapitel") by Prof. W. Deecke on petrographic subjects, the first section being on "Konglomeratbildung." A number of points commonly overlooked in teaching are shrewdly emphasised, such as the necessity for a hollow of erosion or of sinking for the accumulation of a big pebbly mass, and for some form of almost contemporaneous cementation if the conglomerate is ultimately to be preserved. In the section on the "Diagenesis" of sediments Prof. Deecke points out that under varying conditions subaqueous sediments are preserved from remote ages as loose material (the sands with bucklered ganoids of Dorpat are an instance), or as consolidated and resisting rocks. The influence of heat and pressure on gels in the interstices between the grains leads to firm cementation, as when iron hydrates pass into magnetite, and garnet develops from calcium carbonate, quartz, and kaolin by removal of water from the mixture. Next, the mystic words of Suess, "Sal" and "Sima," are critically discussed; the author remarks that there is a "good form" even among geologists (do we not know it in university circles?), which maintains the use of such terms beyond their true importance. Dr. Holtedahl's essay on these magmas was referred to in Nature of January 29, p. 574. Lastly, we have an excellent review of fossil reef-formation, in which the tendency of similar conditions to produce similar groupings of animal types is excellently impressed upon us.

English mining engineers may be interested to find that the flotation process is beginning to attract attention in France, as is shown by a lengthy article on the subject in the *Revue générale des Sciences* for January 15, though it must be admitted that the information therein given is far from being either up-to-date or quite trustworthy. It seems curious that so recent an article should make no mention of Sulman's important contribution to the theory of flotation read before a meeting of the Institution of Mining and Metallurgy in November last, the French author being apparently quite unaware of it. It is strange to read two months after the publication of so exhaustive a treatment of the subject that "the time still appears far distant when a theory capable of explaining the observed phenomena can be established." Whilst his knowledge of the theory of the process is thus defective, the author of the article in question commits not a few errors in regard to its technology. It is scarcely correct to say that flotation is applicable only to ores carrying sulphides, and English readers will be interested to learn that the Murex process is stated to have been devised by an inventor of that name!

The Canadian Department of Mines has issued the statistics of the mineral production of Canada for 1918 in two reports, one devoted to coal and coke, the other to the metals. The former is, perhaps, the more interesting in view of the immense importance to the whole world of coal output at the present moment. It is pointed out that the term "coal production" is used in a perfectly definite sense, namely, the total of coal sold *plus* coal used by the producers, and this must not be lost sight of in comparing Canadian production with that of other countries, *e.g.* Britain, which latter includes coal lost or unsaleable and coal put into stock. The Canadian production was 13,373,148 statute tons, as compared with 12,541,749 tons in 1917; there were employed 25,419 men, whose average earnings for the year were 1294 dollars (or 270*l.* at par), equal to 2.46 dollars or 10*s.* 3*d.* per ton. It should be specially noted that the output per man was 526 tons for the year—a figure that contrasts most favourably with the British figures. The colliery consumption and coal supplied to workmen amounted to 9·6 per cent. of the production. Of the more important metals, the copper production was 118,769,434 lb., the highest ever attained; the production of lead was 51,398,002 lb., the highest since 1906; of nickel, 92,507,293 lb., the highest ever recorded; the silver production was 21,383,979 oz., a falling-off of 3·7 per cent. as compared with 1917; and the gold production was 699,681 oz., or 5·3 per cent. below that of 1917.

Mauritius meteorological, magnetical, and seismological records are issued in the monthly and annual reports of the Royal Alfred Observatory, under the directorship of Mr. A. Walter. The annual report for 1918 and the monthly reports to August, 1919, have been received. Continuous photographic registration is made of atmospheric pressure, temperature of the air and evaporation, and automatic registration of direction and velocity of wind, of rainfall, and of bright sunshine. The photographic registrations have been checked at regular intervals by eye observations, and daily observations are made of terrestrial radiation and of thermometers ranging from 3 in. to 118 in. below the surface soil. Monthly, quarterly, and yearly departures from the normal are given for the several elements. In 1918 the temperature of the air was below the normal in all months except December. The defect was marked in July, August, and September. During 1918 a daily journal of the weather over the Indian Ocean was kept by means of observations obtained from ships' log-books. The logs of sixty voyages were copied. So far as is known, there were five cyclones in the South Indian Ocean during the year 1918. The daily records of observations published each month are of considerable value in adding to our knowledge of the physics of the globe. Epochs of diurnal range are regularly shown by the several instruments. The velocity of the wind at the Mauritius Observatory is seen to increase very regularly at the midday hours and to fall off during the night, the range frequently being shown even on days when the normal trade winds are interrupted. The seismograms record sixty-seven earthquakes during 1918.

THE January number of the "Abstracts of Papers" issued by the Institution of Civil Engineers contains 235 pages, twelve of which are devoted to name and subject indexes. The abstracts, of which there are 387, are classified under the six heads: Measurement, Materials, Structures, Distribution of Energy, Appliances, and Specialised Practice. Each head is, as a rule, subdivided into sections. It is impossible to read through the abstracts without realising the importance to the future of the engineering profession in this country of a knowledge of the progress which is taking place in the practice of engineering throughout the world. From the number of abstracts devoted to it, the question of fuel economy appears to have been taken up with vigour in America and in Germany. In the former country the use and advantages of pulverised low-grade coal have been investigated, and it appears that 75 to 80 per cent. efficiencies can be obtained with it in boilers of all sizes. In Germany the utilisation of the waste heat from iron and steel furnaces to generate steam in boilers is being strongly advocated as the best form of economy.

THE reviewer of part i. of "The *Daily Telegraph* Victory Atlas of the World," in NATURE of November 13, 1919, remarked, towards the end of a favourable notice: "The changes due to the Peace Treaty are incorporated, but a mistake is made in the area of the Slesvig plebiscite." The publishers of the map, Messrs. Geographia, Ltd., wrote at the time to say that the boundary shown on their map was correct. The reviewer's comment, as stated in our issue of December 25, p. 419, was based upon the abstract of the Treaty of Versailles, and the recent publication of the Treaty has enabled him to compare its wording with the large-scale map of Slesvig. He now writes to acknowledge the correctness of Messrs. Geographia's map in this respect, and to apologise for his mistake. We on our part much regret that, on a point of fact, a review in our columns should have contained a statement which now proves to be in error, and that, in consequence, the accuracy of a particular frontier line on Messrs. Geographia's production was wrongly questioned.

MESSRS. W. HEFFER AND SONS, LTD., Cambridge, have in the press "The Theory of Direct-current Dynamos and Motors: A Text-book for University Students of Electrical Engineering," by J. Case, which has been written to fill the gap between books of general electrical engineering and the specialised ones dealing with designs. The aim has been to furnish the student with a fairly comprehensive study of the principles and theories underlying the design of direct-current dynamos and motors, and the work will contain many worked examples; also exercises for the student. The notation adopted is that of the International Electrotechnical Commission.

MR. C. BAKER's classified list (No. 68) of second-hand scientific instruments includes in one of its sections a number of microscopes and accessories which should be of particular interest at the present time to students and other workers. There are also sections on surveying and astronomical instruments, spectroscopes and projection apparatus, and other instruments.

MR. L. T. HOGBEN wishes to direct attention to an omission in the abstract of his Royal Society paper, "Studies in Synapsis," i., reprinted in NATURE of February 12 (p. 649). He does not conclude that abortive spindles characterise the Hymenoptera in general, but only the Hymenoptera parasitica.

OUR ASTRONOMICAL COLUMN.

MERCURY AS AN EVENING STAR.—This planet will reach its greatest easterly elongation (18° 11′) on March 3, and set at about that date rather more than an hour and three-quarters after the sun. This will be the most favourable period of the year for viewing Mercury in the evenings. The intending observer should look towards the east-by-south region of the horizon, and when the atmosphere is clear the planet will be seen about an hour after sunset at a low altitude. It will set on February 26 at 7.5 p.m., on March 4 at 7.31 p.m., and on March 11 at 7.23 p.m.

CENTENARY OF THE ROYAL ASTRONOMICAL SOCIETY.—At the annual general meeting of this society held on February 13, the president, Prof. A. Fowler, gave an address on the foundation of the society just a century before. The four men who were most influential in its formation were the Rev. William Pearson, Mr. Francis Baily, Sir John F. W. Herschel, and Mr. Charles Babbage. The two latter both lived until 1871, and there are no fewer than fifteen surviving fellows whose fellowships overlapped with theirs. One of these, Mr. Inwards, said that he remembered speaking to Sir John Herschel at a meeting of the society. There was at first a good deal of opposition to the new society on the part of the Royal Society, and the Duke of Somerset, who was elected the first president, quickly resigned this office owing to the pressure brought to bear upon him. He was succeeded after an interval by Sir William Herschel, who was then eighty-two years of age, and died in 1822. Mr. Stephen Groombridge, well known for his Star Catalogue, was another of the original members. They were not called fellows until 1830, when the Royal Charter was granted, giving the society its present title; it was previously called the London Astronomical Society. The earliest publications of the Society were in the form of memoirs; the Monthly Notices did not commence until several years later, and were at first only small pamphlets containing ephemerides of comets and other matters of transient interest.

IS VENUS CLOUD-COVERED?—Mr. Evershed has taken many photographs of the spectrum of Venus in recent years, for the purpose (*inter alia*) of endeavouring to detect the Einstein shift, and of testing his own hypothesis that the earth has an effect on the atmospheric circulation of the sun. In the course of this work he found, to his surprise, that a much longer exposure-time was needed than was the case in photographing the spectrum of a cumulus cloud on which the sun was shining (Monthly Notices R.A.S., November). Mr. Evershed expected the time to be shorter, for the intensity of sunlight on Venus is 1·92 times as great as on the earth. Allowing for the absorption of Venus's atmosphere, he concludes that if Venus were covered with clouds similar to our cumulus clouds, the exposure-time would be less on the former than on the latter in the ratio of 1 to 1·3, whereas the contrary is the case. He concludes that the atmosphere of Venus is not cloud-laden, but that its lower strata contain much dust in suspension, veiling the surface features. This conclusion is similar to that reached by Prof. Lowell from his observations at Flagstaff.

Mr. Evershed thinks that the values of the colour-indices assigned by Prof. H. N. Russell to the sun and Venus (+0·79m. and +0·78m.) are mutually inconsistent, since they imply that no selective absorption takes place in Venus's atmosphere. Mr. Evershed finds evidence of decided selective absorption in the violet, as compared with his cloud spectra.

PROFESSIONAL METEOROLOGY.

SIX parts of the new Professional Notes of the Meteorological Office have now been issued. The first[1] deals with the relation between cloud and wind direction at Richmond, and gives tables for each month for 10h., 16h., and 22h. for fifteen years, showing the number of times each cloud amount was associated with each wind direction or with calms; it would perhaps have been clearer if percentage values had been given. Several important points come out, such as the well-known tendency of cloud to disperse at night, but it is also shown that this tendency is not the same for all winds or for all seasons. Cloud forecasting became important during the war, and will in future be of wide application; it is to be hoped, therefore, that Lieut. (now Capt.) Brunt will fulfil his intention of continuing this research. Tables also give values for Greenwich for January and July, and various differences from Richmond are apparent; Richmond had only 59 calms in 180 months, while Greenwich had 58 in 20 months, which indicates, perhaps, a difference in estimating light winds. Greenwich had more south-west and fewer south and north-west winds than Richmond, due probably to local exposure.

It would be more satisfactory to compare cloud amount with wind at cloud-level or with gradient direction, for Mr. Newnham's paper[2] on a night valley wind shows that surface winds may be shallow and more or less unrelated to upper-air phenomena. Cold air flows down valleys at night in radiation weather, and if, at so open a station as Benson, the wind at night sometimes blows "very steadily from east-by-south to east-south-east regardless of what the direction had been during the previous day," the need for caution in dealing with surface winds is obvious. But in the case of fog it is the surface wind that is of importance, as appears in Mr. Brooks's paper[3] on the fog in London on January 31, 1918, when the incidence of the fog seems to have been influenced by "shallow streams of cold air flowing down the sides of hills." The isobaric maps in this paper show a bend in the isobars over the Thames estuary which Mr. Brooks thinks is real, but possibly exaggerated "by slight inaccuracies in some of the barometer readings." Those who draw isobars know how peculiar are some of the readings, and would welcome a future Professional Note on these peculiarities.

A vast amount of information was obtained during the war on upper-air temperatures and winds, and it would be a real loss to meteorology if this were unused or lost. Lieut. Stacey and Capt. Chapman are therefore to be congratulated on having made use of some of these records. Lieut. Stacey[4] deals with upper-air temperatures at Martlesham Heath from February, 1917, to January, 1918, and sets out the information clearly on the whole, though several misprints are noticeable. Unfortunately, "no information is to hand of the type and exposure of the instruments used," which is to be regretted, especially as one would suppose such information could have been obtained; as a matter of fact, the thermometers were exposed on the wing-struts of the aeroplanes, but the type of thermometer varied from time to time, and therefore the early records are probably not strictly comparable with the late ones; but these facts are not recorded in the paper. It is very desirable that all details of meteorological war-work should be collected before it is too late to obtain them.

Capt. Chapman[5] reviews formulæ connecting increase of wind velocity with height. Many of the early ones were linear, but linear formulæ are unlikely, and were probably only intended as working guides until more observations were available. From a consideration of many observations, including 190 in north-eastern France, the author deduces the formula $V = a \log H + b$ (where V is the wind velocity, H the height, and a and b are constants), which fits most of the observations below the height at which the mean gradient velocity is reached. The whole paper deserves careful study. In another publication[6] Capt. Chapman discusses the normal curve of errors in connection with what meteorological observations should be classified as unusual or exceptional.

Meteorology has advanced rapidly in recent years, and these publications, and others, show that the advance in this country is due largely to the Meteorological Office, and it is to be hoped that its future activities may not be hampered by the proverbially unscientific attitude of Government Departments.

[1] "On the Inter-relation of Wind Direction and Cloud Amount at Richmond." By Lieut. David Brunt. (Meteorological Office, 1918.) Price 3*d*.

[2] "Notes on Examples of Katabatic Wind in the Valley of the Upper Thames at the Aerological Observatory of the Meteorological Office at Benson, Oxon." By E. V. Newnham. (Meteorological Office, 1918.) Price 3*d*.

[5] "The Variation of Wind Velocity with Height." By Capt. E. H. Chapman. (Meteorological Office, 1919.) Price 1*s*.

[6] "On the Use of the Normal Curve of Errors in Classifying Observations in Meteorology." By Capt. E. H. Chapman. (Meteorological Office, 1919. Price 6*d*.

STEAM BOILERS AND ECONOMISERS.

AS chief engineer of the Manchester Steam Users' Association Mr. C. E. Stromeyer prepares a yearly memorandum. The memorandum for the year 1918–19 deals with fuel economy and with economiser and furnace collapses. Some industries require much power and little steam for heating and boiling; others much steam and little power. If two such industries could combine, the cost of 1 h.p. could be reduced from, say, 2 lb. of coal to $\frac{1}{3}$ lb. If, for instance, a spinning mill consumes 20 tons of coal for power alone, and a sugar factory an equal quantity of coal for boiling purposes, some means ought surely to be found to bring them together, and thus satisfy both demands with a consumption of 23 tons instead of 40 tons.

In discussing the question of the safety of cast-iron economisers, Mr. Stromeyer gives a summary of all the economiser explosions—seventeen in number—reported upon by the Board of Trade since 1882. Only nine of these explosions were destructive, but, unfortunately, none of the inquiries into these mishaps have revealed their true causes. If the Board of Trade inquiries into boiler explosions are to be of value, they ought to be conducted in such a manner that the study of the reports may be of service to engineers who have to design and use the appliances. It would appear, however, that the object which Mr. Stromeyer's association had in view in drawing up the Boiler Explosions Act, 1882, has been entirely lost sight of. It was intended that every explosion should be investigated by an expert, but it was found necessary, in order to get the Bill through Parliament, to add one competent lawyer to the engineering experts. The lawyer has always been made president of the commission, with results which may be imagined. Further, there are probably very few "competent and independent engineers" who are, as required by the Act, "practically conversant with the manufacture and working of boilers," since few engineers pass through the boiler-shop, and fewer still have had to work them. But the Board of Trade has no hesitation in appointing men to make these inquiries who have never even seen the objects which they have to investigate. At a recent inquiry two investigators, both marine engineers, confessed that they knew nothing about land economisers, neither their design, material, manufacture, nor mode of working. As the Board uses a rota, the chances are that these engineers will never again be called upon to inquire into an economiser explosion, despite the knowledge they doubtless gained in the course of the inquiry. In these circumstances it is but natural that many preliminary reports, and nearly all Commissioners' reports, dismiss the cause of explosions with a non-committal remark to the effect that "the boiler burst because it could not withstand the steam pressure."

Mr. Stromeyer suggests, and we strongly support the suggestion, that the duty of investigating boiler explosions should be entrusted to an enthusiastic engineer, who would certainly go into details, and make experiments on the strengths of materials, especially upon the parts of burst boilers, which is scarcely ever done at present; he would also take steps to become acquainted with the influences of working conditions.

The memorandum contains ample evidence, extracted from Board of Trade reports, to justify Mr. Stromeyer's remarks. For example, Report No. 2470, on an economiser explosion, omits to mention certain old fractures. The two "competent and independent engineers" (selected by the Board from among its own staff), together with other engineers, refused in their evidence to admit that an open damper could have caused the failure of any of the pipes, and attributed the explosion to the old fractures. By withholding this information the report deprives the engineering profession of the means of studying the problem of economiser safety.

The fact appears to be that the investigations are carried out by the solicitor of the Board of Trade, who brings forward sworn evidence, though the swearing is not required by the Act, and without any warning to the witnesses, these may now be cross-examined both by their own side and by the Commissioner, and then very often their own sworn evidence is used against them. It is unfair to witnesses who wish to give the Commissioners every assistance, and as the whole atmosphere is now a legal one (even a Lord Advocate once appeared for an insurance company) the technical causes of explosions are scarcely inquired into.

THE BELGIAN ROYAL OBSERVATORY.

IT is pleasant to see that the Brussels Observatory is in a position to resume the publication of its memoirs (Annals of the Belgian Royal Observatory, vol. xiv., part 2). After a discussion of the division errors of the Repsold meridian circle, Prof. Stroobant contributes an interesting essay on the constitution of the ring of minor planets. Tables and diagrams are given of the distribution of the various elements; the striking grouping of the perihelia towards Jupiter's perihelion is already well known, and Newcomb gave an explanation of it from theory. The eccentricities show a similar grouping, high eccentricities being most frequent in the quadrants where the perihelia congregate; this can also be explained by the action of Jupiter. The formulæ expressing the perihelion density (N is the number of perihelia in an arc of 30°) and the eccentricity are:

$$N = 66{\cdot}75 - 31{\cdot}7 \sin (\varpi - 106{\cdot}7^\circ)$$
$$e = 0{\cdot}141 - 0{\cdot}028 \sin (\varpi - 86{\cdot}5^\circ).$$

The ascending nodes show a slight tendency to group towards Jupiter's ascending node; it would probably be easier to study the relations of nodes and inclinations if the elements were referred to the plane of Jupiter's orbit rather than to the ecliptic.

There is an interesting study of the probable total number of asteroids brighter than magnitude 20. From some very faint asteroids discovered by photography at the Lick Observatory, combined with the area of sky covered by the plates, the total 57,000 is obtained. From a study of the number of known planets of different magnitudes the empirical law is deduced that the number per magnitude doubles for a fall of one magnitude. On this basis the total number brighter than magnitude 20 is 100,000. The two estimates are in satisfactory accordance, bearing in mind the large measure of extrapolation employed in each method.

It is estimated that very few asteroids (say twenty) brighter than the 12th mag. at opposition remain to be discovered.

Taking the mean albedo as 0·108 (midway between those of Mercury and Mars) and the density the same as the moon's, the total mass is 1/22 of that of the moon, the planets brighter than magnitude 10 contributing one-third of this total, and those between magnitudes 10 and 11 another one-third.

The third memoir in the volume is on the brightness, colour, position, and parallax of Nova Aquilæ; a large-scale light curve is given extending from 1918 June 10 to November 23. From the end of June until the middle of August there were fairly regular oscillations in the curve, the period being thirteen days. Prof. Stroobant notes two cases of apparent rapid change of light. On August 29 the brightness increased 0·7 mag. in twelve minutes; on October 6 it fell 0·3 mag. in five minutes. Changes like this need verification from more than one station to make sure that they are not due to a local variation in the transparency of the air.

The position and parallax were obtained by observations with the meridian circle. Screens of muslin were placed over the object glass for the brighter stars. The thickest screen reduces the light by

3·2 mag. Two determinations of the parallax are given:

(1) 0·20″ ± 0·05″ M. Philippot.
(2) 0·06″ ± 0·07″ M. Delporte.

Both determinations appear to be improbably large, judging by the small proper motion and the values obtained for other novæ.

A. C. D. CROMMELIN.

THE LIVERPOOL MARINE BIOLOGY COMMITTEE.[1]

THE issue of the thirty-third annual report of the Liverpool Marine Biology Committee, and, as we are informed, the last of the series, is an opportune moment for the publication of a review of the important work that has been done since the formation of the committee in 1885. This report is not the swan-song of a dying enterprise, but rather the triumphant cry of those who have achieved an initial victory that gives hope for a rapid and continuous advance in the future; and, although the old L.M.B.C. ceases to exist, there is every reason to believe that its work will be carried on with increased efficiency by the newly organised staff of the oceanography department of the University of Liverpool.

In the short history of the work of the committee that is published in this report it is clear that a very substantial contribution has been made to our knowledge of the species of animals and plants that inhabit the waters of the Irish Sea, and that valuable information has also been acquired about the many characters of the sea-bottom round the Isle of Man and the north coast of Wales.

All this is necessary pioneer work, although much of it may seem dull and uninteresting when in print. The workmen must learn the use of their tools before undertaking the more serious work of production. But we see in the L.M.B.C. memoirs, of which twenty-three have already been published, in the important investigation of Prof. Herdman and his colleagues on the fluctuations of the plankton, and in the biochemical researches of Prof. Moore and others, that these valuable contributions to our scientific knowledge of the sea have outgrown the "Records" of the early years of the life of the committee.

The work of recording and describing the booty of the sea must, of course, continue; but with the ripe experience of thirty-three years, with the more complete equipment of laboratory space and apparatus, and with the new organisation of the oceanography department of the University, we may confidently look forward to further important developments in the general scientific work of the Port Erin institution.

We may tender to Prof. Herdman our cordial congratulations on his achievements in the past and our good wishes for the full success in the future of the great enterprise which is so largely due to his own personal genius and enthusiasm.

S. J. H.

APPLICATIONS OF INTERFEROMETRY.

IN a report by Prof. Carl Barus, of Brown University, recently published by the Carnegie Institution of Washington, a number of interesting applications of achromatic interferometry are described. In the first chapter a method of measuring small angles is discussed. The general theory of the subject is developed at some length, and a variety of interferometer devices, with mirror, ocular, and collimator micrometers, are instanced. As the achromatic fringes cannot (in general) be found without first finding the corresponding spectrum fringes, the second chapter is devoted to spectrum fringes. The work described in the third chapter was undertaken at the request of Prof. W. G. Cady, in the endeavour to obtain the elastic constants of small bodies. The application of the displacement method proved astonishingly easy in a case where a degree of rough handling is inevitable, but it was found that there lurked in the elastic apparatus some discrepancies, both of viscosity and hysteresis, the nature of which escaped detection after many attempts to locate its origin. The fourth chapter contains applications of the rectangular interferometer using achromatic fringes to the study of gravitation. A method for the determination of the Newtonian constant is worked out. Again, the same interferometer is associated with the horizontal pendulum for the detection of small changes in the inclination of the earth's surface. Series of observations extending between January and August are recorded. In the fifth and last chapter the author deals with the application of interferometers to the study of vibrating systems. To test the method, an examination is made of the vibration of telephonic apparatus. Interference-vibration curves have been obtained for two identical telephonic systems joined directly in series, while these forms subsided completely when the telephones were joined differentially.

RESEARCHES AT HIGH TEMPERATURES AND PRESSURES.

BY THE HON. SIR CHARLES A. PARSONS, K.C.B., F.R.S.[1]

I.

JUST ten years ago in this room Sir Richard Threlfall discussed the effects of temperature and pressure on various substances, and commenced by referring to a suggestion I made in 1904 to sink a bore-hole twelve miles deep in the earth with the object of exploring the region beneath us, about which so little is known. Last summer at Bournemouth I ventured again to direct attention to the desirability of such an exploration in the interests of science generally, and to the possibility that it might ultimately lead to some developments of practical importance and utility.

Ten years ago no experiments had been made on the behaviour of rocks under the conditions existing at great depths below the surface of the ground; but, prompted by my suggestion in 1904, and after some subsequent correspondence in regard to the possibility of the rock crushing in and closing the shaft, Prof. Frank D. Adams, of McGill University, Montreal, commenced experiments on the strength of rocks to resist the closing up of cavities under the conditions prevailing at great depths below the surface. He published the account of these experiments in the *Journal of Geology* for February, 1912.

Adams's method was to place a block of granite or limestone in a tightly fitting cylinder of nickel-steel, which was shrunk lightly around the block to ensure perfect fitting and support; hard steel rams actuated by a hydraulic press were arranged to exert a known pressure against the ends of the block. Two small holes were previously drilled in the specimen, one axial in the centre and one transverse, the diameter of the holes being 0·05 in., or one-tenth the diameter of the specimen. The temperature of the container and specimen was maintained at any desired point up to the softening point of steel. In some experiments no heat was applied, while in others the temperature

[1] Discourse delivered at the Royal Institution on Friday, January 23.

was raised to that estimated to exist at the depth below the surface of the earth corresponding to this pressure.

When no heat was applied the holes in the granite showed no alteration under a pressure equivalent to thirty miles deep, and in the case of limestone the specimen supported one-half of this pressure without alteration. Adams then raised the temperature of the container and specimen. When granite was heated to 550° C., a temperature corresponding to eleven miles below the surface, it stood a pressure equivalent to fifteen miles, and might have stood more but that the container became weakened by the heat. Limestone begins to decompose at a temperature of 450° C., but even at this temperature it withstood a pressure corresponding to ten miles.

Adams concludes that small cavities in granite will not close in under the conditions of pressure and temperature at eleven miles below the surface, however long a time is allowed to lapse, and that the cavities may persist to much greater depths, but the softening of the steel of the container precluded the carrying of his experiments to still higher temperatures and pressures.

So far as they go, these experiments are reassuring as to the permanence and safety of a pit shaft twelve miles deep sunk through granite, but it would be more satisfactory to experiment on a larger specimen than one only $\frac{1}{2}$ in. in diameter as used by Adams, and to heat the specimen electrically when submerged in graphite while keeping the container cold, the temperature being indicated by a thermo-couple in the specimen. This could be carried out in a nickel-steel container like that shown in Fig. 2.

In this connection P. W. Bridgeman in 1911 submerged a sealed glass tube containing a cavity under an external hydrostatic pressure of 24,000 atmospheres (corresponding to a depth in the earth of fifty-six miles) for three hours, and the cavity showed no change in size or form. It, however, appears that temperature will probably place a limit to the depth that could be reached before the closing in of the shaft commences to occur, for Judd, Milne, and Mallet agree in the view that the deepest origin of earthquakes is between thirty and fifty miles. This would seem to indicate that at greater depths than thirty miles the temperature and pressure are such that changes of form take place by plastic deformation, and not by sudden slips or the formation of faults, which are the chief cause of earthquakes. Again, Oldham states that beyond twenty miles deep seismic waves which are transmitted by compression and distortional vibrations change in character in this respect: that though the compressional waves are only slightly affected in velocity, on the other hand the distortional waves are reduced to one-half their velocity. This would seem to imply that the modulus of elasticity in shear has, at twenty miles depth, owing to the rise of temperature, fallen to one-half, and it seems probable that the rock also is weakening in its resistance to shear; in fact, that the rock is becoming more plastic, and that cavities would probably close up at twenty miles below the surface.

The greatest depth to which a shaft has as yet been sunk is only about $1\frac{1}{3}$ miles. The deepest single-stage shaft on the Rand is that of the Hercules East Rand Proprietary Mine. It is 4500 ft. vertically, and rectangular in section. The deepest shaft in the world is that at Morro Velho, Brazil. The bottom is 6400 ft. vertically below the surface, and it has been sunk, and is worked, in stages, two of which are about 1200 ft. vertical. The deepest shaft designed on the Rand is by the City Deep Co. It is 7000 ft. vertically, is circular of 20 ft. diameter, and is to be worked in two stages of 3500 ft. each. The most rapid sinking record was made at the Crown Mines No. 15 Shaft, where 310 ft. were sunk in a month; the shaft is circular, and of 20 ft. in diameter.

There are several interesting departures from ordinary mining practice necessary. The haulage is arranged in stages of about half a mile, principally in order to economise the weight of rope and also the power for winding. In countries where the atmosphere is dry the sides of the shaft are cooled by sprinkling water upon them, which by evaporation cools the rock. It is, however, possible to augment this effect by artificially drying and cooling the air before passing it down the mine.

When still greater depths of shaft are in contemplation further methods of cooling in addition to these would probably be found necessary; for instance, the carrying of the heat upwards by means of brine circulated in a closed ring formed of steel pipes with a rising and descending column. Though the columns might be carried the whole depth of twelve miles, the hydraulic pressure at the bottom would be about 12 tons per square inch, and entail very costly pipes of great strength to resist the pressure. A cheaper plan would be to work in stages, each ring covering a stage of from two to three miles of the shaft, the heat being transferred from the top of one brine ring to the bottom of the ring above by surface-heat exchangers and refrigerating machinery to neutralise the heat drop on transfer. These may be called heat pumps, and would be driven electrically.

As the depth of the shaft increases, the pressure of the air upon the miners will be about doubled for every three miles, but what is more serious is the increase in temperature of the air itself caused by the adiabatic compression due to gravity, by which it will be raised about 100° F. For these reasons it will be necessary to place airtight partitions across the shaft at every mile or two, and to carry on the ventilation through these by means of a pump to deliver the foul air upwards and an expander to allow the fresh air to descend. These two machines would be linked together, and the difference in their power supplied by an electric motor. (This method has been often used with water, and is equally applicable to air.)

At each partition heat exchangers and refrigerating machinery similar to those used for the brine would be placed. Another and preferable plan would be to place numerous heat exchangers between the ascending columns of air to transfer heat from one to the other. The air would, in this case, not itself act as a conveyor of heat to the surface, for which the brine columns would be depended upon, but it would enable airlocks every three miles to suffice. A further alternative and very simple method would be to convey liquid air from the surface, and allow it to escape at the part of the shaft requiring cooling. It would ensure good ventilation.

When sinking the deeper portions of the shaft, shields would probably be necessary to protect the miners from the splintering of the rock which is caused by the intense compressive stress, which splits off scales from the surface, sometimes with considerable violence.

In 1904 the estimate of the time required to sink twelve miles was eighty years, and was based on the records of that time. With improved machinery and methods the records have been so much lowered that an estimate of thirty years seems now to be reasonable.

Threlfall traced the gradual evolution of the theory of the effects of temperature and pressure on the allotropic forms of various substances. He described his apparatus and experiments designed to melt graphite under high pressure, his inference then being that under pressures up to 100 tons per square inch carbon does not follow the same law as many other substances, and does not crystallise as diamond on cooling.

An interesting discovery was made by Bridgeman in 1911 when studying the compressibility of mercury. He found that it had a remarkable power of penetrating steel containers, a power not possessed by oil or water, which caused them to burst at much lower pressures than when they were charged with oil or water. The phenomenon he attributed to the fact that mercury has the power of dissolving small percentages of iron, and will amalgamate with it when the surfaces are absolutely free from oxide.

In 1912 Bridgeman published his remarkable researches on water under pressures up to 20,000 atmospheres. He found that there are four allotropic forms of ice besides ordinary ice, which are found under various conditions of pressure and temperature with determinate regions of stability. All these forms except ordinary ice are more dense than water; one is remarkable as existing from a temperature of −18° C. under a pressure of 4500 atmospheres up to a temperature of 67° C. under a pressure of 20,000 atmospheres.

Recently a pressure of from 200 to 1000 atmospheres at a temperature between 500° and 700° C. has been applied to compel hydrogen to combine with nitrogen to form ammonia on a great commercial scale, a catalyst being necessary to promote the combination and to establish the equilibrium between the gases and their product. This action is reversible as regards temperature and pressure. On the other hand, iron just molten is an energetic catalyst in the transformation of diamond into graphite, but, contrary to expectations, as we shall see, no amount of pressure that has yet been applied appears to have caused a reversal of this action.

More than thirty years ago, having suitable apparatus at hand, I made a few experiments to try the effect of high pressures and temperatures on carbon, compounds of carbon, and some other substances.

The apparatus consisted of an 80-ton press, under which suitable containers were placed, and a turbo-generator of 24 kilowatts output at 80 volts provided the current. It had been discovered by Cheesborough that the carbon filaments for incandescent lamps became very hard and resilient when heated in a hydrocarbon atmosphere of about 4 mm. absolute pressure, and I was anxious to try what would be the result if a rod of carbon were electrically heated when submerged in a liquid hydrocarbon under high pressure. Benzine, paraffin, treacle, chloride, and bisulphide of carbon were tested under a pressure of 2200 atmospheres, or about 15 tons per square inch. The results were not successful in producing a hard coating to the rod or in increasing materially its density and hardness except in the case of tetrachloride of carbon, which slightly consolidated and hardened it; on the contrary, the carbon deposited from the liquids always appeared as soft amorphous carbon like soot. These experiments were extended by substituting, instead of the liquids mentioned, silica, alumina, and other substances and increasing the pressure to 30 tons per square inch. When the current density was sufficiently increased the rod was converted to soft graphite. Moissan in 1903 expressed the view that iron in a pasty condition was the matrix of the diamond, and that great pressure was the determining factor, which compelled a minute fraction of the carbon present to appear as diamond; he further referred to the probability of carbon being liquefied when under a pressure sufficient to prevent its volatilisation, and that from the liquid state it may pass into the crystalline form on cooling. Crookes, in his lecture delivered before the British Association at Kimberley in 1905, emphasised the same view as to the probability of the crystallisation of carbon directly from the molten state on cooling.

Though my original experiments in 1888 were not favourable to these views, it nevertheless seemed desirable to carry the investigations up to the greatest possible pressures attainable. Experiments were, consequently, resumed in 1907 with a new equipment, which consisted of a 2000-ton hydraulic press and a storage battery of 360 kilowatts output. The battery can be coupled for 2, 4, 8, 16, or 48 volts as required, and the mains and the main switch can carry currents up to 80,000 amperes to the hydraulic press, which is placed by itself in a small, strong house partly below ground, with walls of 2 ft. thickness reinforced with steel bars; the door is of steel 3 in. thick, and the roof is of light galvanised iron. The container under the press is further enclosed by 2 in. thick telescoping steel rings, raised into position by steel ropes and counter-weights. These precautions, as experience showed, were necessary, as several violent explosions occurred which cracked the steel rings and blew off the roof. A charge of iron and carbon, when confined and raised to a high temperature, may be very violent if suddenly released by the melting of the pole-pieces; also some endothermic compounds have been formed which swelled the container and allowed the contents to escape.

My experiments confirmed the conclusion at which Threlfall had independently arrived: that under pressures up to 100 tons per square inch and very intense heating by electrical current, graphite is not materially changed. But modifications in the experiments were made and other methods adopted, as will be explained, which in some respects carried the investigation to still higher pressures and temperatures; these, however, lead to the same conclusion.

I propose this evening to deal chiefly with the practical or engineering side of the subject, and to review the limits of pressure and temperature which are artificially attainable, and to make some comparison between them and the pressures and temperatures occurring in Nature.

When the blade of a knife is pressed strongly against another blade so as to make a dent in each, the pressure on the boundary surface of the metal at the notch will have averaged from 300 to 350 tons per square inch, according to the hardness of temper of the steel. The pressures on the knife-edges of a weighing machine when fully loaded are also of the same order.

When a needle is broken or a piece of piano-wire is strained to the point of breaking, the maximum tension on the metal will be at the rate of 150 tons per square inch. On the other hand, the pressures that occur in the chambers of large guns do not usually exceed 20 tons per square inch, and the tensile stress on the plates of a ship in heavy weather should not exceed 8 tons per square inch. From these simple instances some idea is gathered of the limitations imposed by materials and dimensions upon apparatus for experimenting at high pressures because of the practical difficulty of hardening and tempering steel in large masses.

When dealing with small amounts of material in each experiment the dimensions allow of the container and the ram being made of tungsten steel, which can be hardened and tempered throughout, and not only superficially, as in the case of ordinary carbon steel.

The material is hard and strong, but not brittle, and it retains these qualities up to moderate temperatures, such as 600° C., to a much greater extent than any other steel.

In one form of container or die the bore is 1½ in. in diameter, and it may be used for a limited number of times for a pressure of 200 tons per square inch. It will, however, eventually crack if this pressure is many times repeated, the cracks usually beginning near the bottom of the die.

For still higher pressures it is better to use a double re-entrant container with two rams ½ in. in diameter. Both the container and the rams are made of hardened and tempered tungsten steel, and are rendered fluid and gastight by mild steel cups on the ends of the rams.

If the charge occupies only a short length of the bore, as shown, the barrel of the container where the charge lies is supported by the shear strength of the metal above and below the zone of pressure in addition to its own strength as a tube. Under these conditions it is as strong as or stronger than the crushing strength of the rams, and pressures of 300 tons per square inch may be repeated several times without cracking.

In a container of this form seven grains of fulminate of mercury have been placed, embedded in graphite, and the pressure increased very gradually until it reached 230 tons per square inch (under this treatment fulminate does not usually detonate). The die was then heated by gas to more than 180° C., the temperature of detonation. After two failures of the experiment, owing to the leakage of the steel cups, the third was successful, and no gas escaped and the container was uninjured. The graphite was somewhat caked, but otherwise unaltered. Graphite mixed with sodium nitrate and fulminate was also exploded under the same conditions. Graphite with 15 per cent. of potassium chlorate detonated when 200 tons per square inch had been reached.

Many other reactions were tested in a similar manner in larger dies under pressures of from 40 to 200 tons. The action of concentrated sulphuric acid on sugar was accelerated by a pressure of 50 tons, but, on the whole, these experiments in dies failed to produce any interesting results.

Unfortunately, the heating of the die with its charge cannot be carried much above 500° C. without serious weakening of the steel and compelling a reduction of pressure. The electrical heating of the charge in such small dies, while keeping the die cool, presents great difficulties in electrical insulation on so small a scale to withstand intense pressure, but I think that it might be accomplished in certain instances.

It has been suggested, with the object of reaching higher pressures, that a small die might be bodily immersed in a large container. Doubtless it could be arranged, but it would be very cumbersome to work with, and would only add about 100 tons per square inch to the maximum pressure.

A better plan would be to follow the principle of the usual capped armour-piercing projectile, and to reinforce the rams and ends of the container by tightly fitting copper or bronze rings around the necks of the rams, keeping the parallel part of the noses as short as possible.

When in operation the copper rings will be flattened and squeezed against the necks and shoulders of the rams, and also against the ends of the container, and by this means the parts that ordinarily would have to bear the maximum stress will have part of this stress transferred to other parts not so heavily stressed, and, consequently, the maximum pressure in the container can by this means be raised considerably, perhaps to 450 tons per square inch.

In carrying out experiments on larger samples of material and in applying electrical heating to the charge, the container becomes too large to permit of its being made of hardened steel; therefore, nickel-

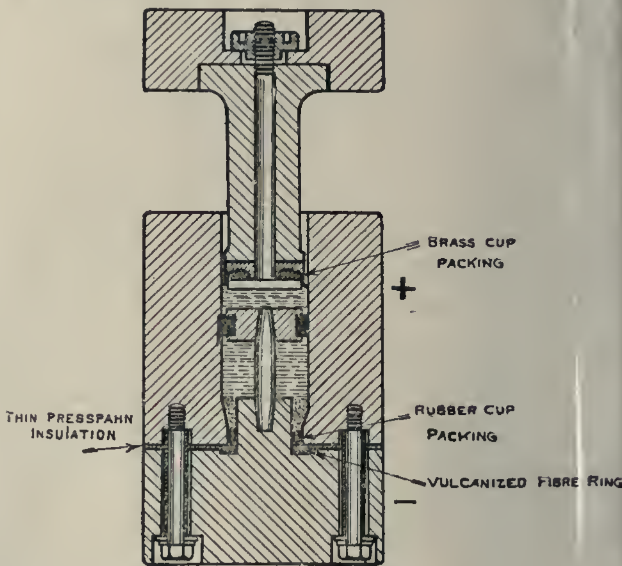

FIG. 1.—Chiefly for liquids.

steel is used, as for the barrels of guns. It is heat-treated by quenching in oil from a high temperature after rough machining. Containers (Figs. 1 and 2) with the thickness of wall equal to the diameter of the bore will stand an internal pressure of 40 tons per square inch repeated almost indefinitely without serious enlargement of the bore, but 100 tons necessitates reboring and the fitting of new packing to the ram after each experiment.

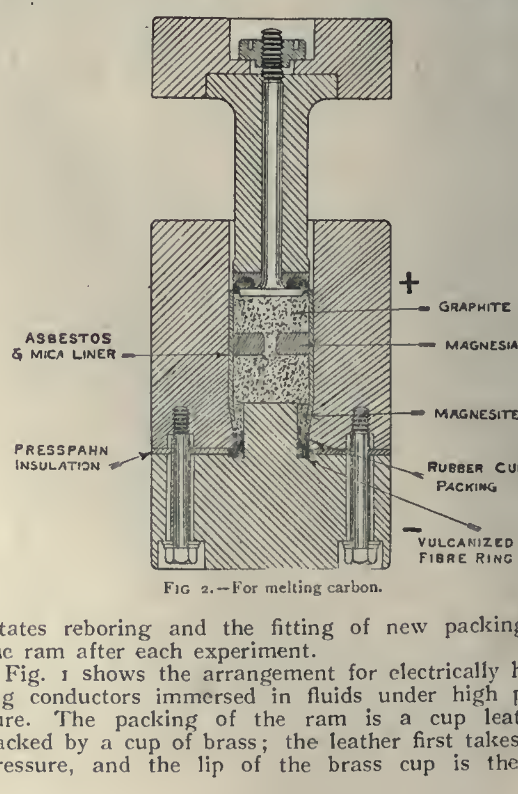

FIG 2.—For melting carbon.

Fig. 1 shows the arrangement for electrically heating conductors immersed in fluids under high pressure. The packing of the ram is a cup leather-backed by a cup of brass; the leather first takes the pressure, and the lip of the brass cup is thereby expanded tightly against the bore of the container, and remains fluid-tight even though the leather should be carbonised by the heat. The bottom pole is electrically insulated from the container by vulcanised fibre washers and a rubber cup-ring, which is protected from the heat by magnesite stemming.

The current is conveyed from the container to the top pole-piece of the conductor by pads of copper gauze, which can slide easily against the bore of the container and allow for the expansion of the conductor. Experiments on liquids with this container under 4400 atmospheres gave the same results as my former experiments under 2200 atmospheres.

Fig. 2 shows the container arranged to melt graphite under pressure by resistance heating. Here the charge is graphite, and is divided by the bridge or ring made of pressed calcined magnesia or of titanium oxide. The bore of the container is electrically insulated from the graphite by layers of asbestos, millboard, and mica.

(*To be continued.*)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Notice has been given that there will be an examination for the recently instituted diploma in psychological medicine: Part i. next October, part ii. next December.

OXFORD.—On Tuesday, February 17, the preamble of a statute providing that women may be matriculated and admitted to degrees in the University passed Congregation without a division.

The report recently issued of the Committee for Rural Economy shows a large increase in the number of students. The Michaelmas term began with 200 students, of whom 123 were working at agriculture and 77 at forestry. Lectures have been given on various subjects connected with agriculture, including courses on forest and agricultural botany, livestock, principles of cultivation, soils and manures, together with the history of agriculture and agricultural economics. Practical laboratory work has been provided, and classes have been held at the University farm.

A vote will be taken in Convocation on the question of Greek in Responsions on Tuesday, March 2. No further amendment being now possible, the statute will have to be passed or rejected as it now stands. Many will regret that the chance of an agreed statute was lost by the opposition of those who objected to the retention of the Greek language as a preliminary requirement even for the final literary and classical examinations. The defenders of Greek were willing to grant exemption to all students of natural science or mathematics, as well as to all passmen, but this concession failed to satisfy their opponents.

A COURSE of three free public lectures on Fermat's last theorem will be given by Mr. L. J. Mordell at the Birkbeck College on March 10, 17, and 24 at 5 o'clock. Tickets of admission are obtainable from the secretary of the college.

THE annual meeting of the Association of Technical Institutions will be held on Friday and Saturday, February 27 and 28, at the Cordwainers' Hall, London, E.C. The proceedings will commence at 10.30 on the Friday morning, when the president-elect, the Marquess of Crewe, will deliver his presidential address. Resolutions will be submitted dealing with pensions and salaries for teachers in technical institutions, and papers will be read by Mr. A. Mansbridge on Technical Schools and their Part in relation to Adult Education, Dr. R. S. Clay on Scholarships, and Mr. H. J. Taylor on Day Continuation Schools.

THE following scholarships will be offered for competition by the Institution of Naval Architects this year:—*Naval Architecture:* Vickers (150*l.* per annum), Hawthorn Leslie (150*l.* per annum), John Samuel White (100*l.* per annum), and Denny (75*l.* per annum). *Marine Engineering:* R. L. Scott (150*l.* per annum) and Denny (75*l.* per annum). These scholarships are open to British apprentices or students, and are tenable (subject to the regulations governing each scholarship) for three years at one or all of the following educational establishments:—Glasgow University, Durham University (Armstrong College), Liverpool University, Royal Naval College (Greenwich), and City and Guilds (Engineering) College (London). Full particulars may be obtained from the Secretary, Institution of Naval Architects, 5 Adelphi Terrace, London, W.C.2.

AN inaugural lecture on "The Universities and the Training of Teachers," delivered at Oxford last October by Mr. F. J. R. Hendy, the Director of Training in the University, has been published by the Clarendon Press in pamphlet form. Mr. Hendy deals briefly with the conditions of the new Education Act and the qualities which will be required for those who are to carry out its provisions for senior elementary, secondary, and continuation schools. In particular, he dwells on the necessity for teachers of a wider and less specialised knowledge, men and women who can take all but the highest work in two, or even three, kindred subjects. The valuable influence of the form-master is something which has tended to disappear from secondary education in recent years, and it should be one of the duties of the training colleges to restore it, at the same time avoiding the danger of superficiality by dividing the subjects of study vertically rather than horizontally, so that, instead of going half-way in two or three honours subjects, a student should go the whole way in a section of each. Some suggestive remarks are made on the subjects of method and psychology, words frequently used, but often misused; also on the immense growth of the administrative side of educational work and the comparatively small expansion of the professional or teaching side. The University Press has done a good service in putting this lecture within the reach of all concerned with the supply of men and women for the teaching profession.

SOCIETIES AND ACADEMIES.

LONDON.

Geological Society, February 4.—Mr. G. W. Lamplugh, president, in the chair.—J. A. **Douglas**: Geological sections through the Andes of Peru and Bolivia: ii., from the Port of Mollendo to the Inambari River. The paper gives a description of a geological section across the Andes of southern Peru, from the port of Mollendo to the Inambari River, a tributary of the Madre de Dios. The deflection of the Pacific coast-line of South America north of Arica towards the north-west brings to light a zone of ancient granite and gneiss comparable with the rocks of the coastal Cordillera of Chile. These rocks are shown to be of "alkaline" type, and are contrasted with the "calcic" granodiorites forming the batholitic core of the western Cordillera. It is suggested that their formation preceded the uplift of the folded chains. The Jurassic zone of northern Chile has been almost entirely stripped from the underlying plutonic core, but its continuation has been proved at more than one locality, and in the inter-Andean region strongly folded fossiliferous beds of Bajocian age are found beneath an unconformable Cretaceous series. The batholitic core is shown to comprise at least three distinct phases of plutonic intrusion, represented by granodiorites, diorites, and adamellites. The volcanic cones of the western Cordillera have given rise to an extensive series of lavas and tuffs comparable with the Mauri River series of Bolivia. Cretaceous limestones here take the place of the red gypsiferous sandstones farther south, and are transgressive on to Devonian rocks. The latter contain abundant fossils of Lower Hamilton age. The post-Cretaceous line of dioritic intrusion, formerly described as running through Coro Coro and Comanche, once more appears on the line of section. The Permo-Carboniferous fauna of Bolivia has not been discovered in the district here described.

Optical Society, February 12.—F. G. **Smith**: A ray plotter. Describes a novel instrument for the tracing of a ray through a refracting surface.—J. W. **French**: The surface layer of an optical polishing tool. Suggests a glass layer on the polishing tool as an effective cause of polishing.—Mrs. C. H. **Griffiths**: Diffraction patterns in the presence of spherical aberrations. Photographs in the various planes of the diffraction pattern for an artificial star were taken and measured, with spherical aberration of varying amounts present. These photographs were examined afterwards with the view of determining the relative intensities of light in the different zones of the ring interference and diffraction patterns both at the focus and otherwise.

DUBLIN.

Royal Irish Academy, January 12.—The Most Rev. and Right Hon. J. H. Bernard, president, in the chair.—J. A. **McClelland** and A. **Gilmour**: Further observations of the electric charge on rain. Different sections of the paper deal with the charge on non-thunderstorm rain, thunderstorm rain, snow, and hail. There is also a section dealing with the size of raindrops. The results agree with earlier observations as regards the great excess of positive charge on non-thunderstorm rain. In the case of thunderstorm rain, while the charge per cubic centimetre is greater, the excess of positive over negative is not marked. Raindrops are seldom greater in volume than 5×10^{-3} c.c.; they are usually less than 1×10^{-3} c.c. Raindrops less than a certain size ($0{\cdot}08\times10^{-3}$ c.c.) are, as previously found, always negatively charged. As a rule, drops of this size give little rainfall, but on a few occasions precipitation of this type was quite considerable.—W. B. **Wright**: Minor periodicity in glacial retreat. The terminal moraines of the Killarney and Kenmare district show a marked periodicity in their arrangement, occurring at fairly regular intervals of half a mile to a mile from one another. These moraines are themselves composite, and break up locally into smaller moraines. The smaller moraines are presumed to mark annual retreat stages, as in the neighbourhood of Stockholm—a presumption which gains support from the occurrence of an esker with seasonal mounds between two of the major stages at Kenmare. On this basis the major stages mark a 20- to 40-year periodicity, which is comparable with the climatic periodicity established by Brückner. A much longer periodicity of 500 or 600 years, in which an epoch of linear terminal moraine formation alternates with an epoch characterised by the absence of such moraine formation, is vaguely indicated by the evidence, but not proved.

January 26.—The Most Rev. and Right. Hon. J. H. Bernard, president, in the chair.—Prof. A. **Henry** and Miss M. G. **Flood**: The Douglas firs: a botanical and sylvicultural description of the various species of Pseudotsuga. Six species and one variety were investigated. The microscopical structure of the leaves was found to be distinct and constant in each species, being correlated with the special climate in which the tree lives. The Colorado and the Oregon Douglas firs exemplify this well, the leaf-anatomy of the former showing xerophytic features, which are adaptations to the dry continental climate of the Rocky Mountains. These two distinct species (*P. glauca* and *P. Douglasii*), usually regarded as of only varietal rank, are treated very fully. The remarkable difference in the odour exhaled by these two trees led to a chemical examination of the oils distilled from their foliage by Mr. C. T. Bennett. The delicious fragrance of the Oregon species was found to be due to the presence in the leaf-oil of geraniol, pinene being absent. The strong turpentine odour of the Colorado species is associated with the presence in its leaf-oil of large percentages of pinene and bornyl acetate.

Royal Dublin Society, January 27.—Dr. F. Hackett in the chair.—Prof. J. **Wilson**: The application of the food-unit method to the fattening of cattle. Thirty years ago N. J. Fjord commenced by experiments to determine what quantities of several other feeding-stuffs were equivalent to 1 lb. of barley, and his successors in Denmark and Sweden have so developed his method that there is now scarcely a feeding-stuff the feeding value of which they cannot express in terms of barley, which they have retained as the unit. Many fattening experiments have been carried out in Britain during the last eighty or ninety years, but, having no very general purpose, they have led to no very definite result. By applying Fjord's method to these experiments, however, the relative efficiencies of the various rations can be approximately determined and suggestions made for improvement in the use of feeding-stuffs for stock of all kinds.—Prof. H. H. **Dixon** and H. H. **Poole**: Photo-synthesis and the electronic theory. The modern view of the part played by sensitisers of the photographic film suggests the hypothesis that green-leaf pigment, which acts as a sensitiser to the wave-lengths it absorbs, loses electrons under the action of the absorbed light. This would suggest a photo-electric theory for photo-synthesis. Accordingly, the photo-electric properties of leaf pigment were tested qualitatively at first by several methods. These giving no indication of photo-electric activity under the action of light active in photo-synthesis, a more refined quantitative method was employed. This showed that the number of electrons ejected, even under intense illumination, from a film of leaf pigment or from a layer of leaf-powder is negligible in the photo-synthetic process. The result supports the view that the displacement of electrons, which we should expect to be the first step in photo-synthesis, must be entirely confined within the pigment-complex of the leaf, or even within the molecules of one of the pigments, and lends no support to the hypothesis that the pigment, by emitting electrons under the action of light, is able to build up carbohydrates external to itself.

PARIS.

Academy of Sciences, January 19.—M. Henri Deslandres in the chair.—M. **Hadamard**: The elementary solution of linear hyperbolic non-analytic partial differential equations.—H. **Douvillé**: The limit between the Cretaceous and the Eocene in Aquitaine, India, and the Sudan.—C. **Deperet**: An attempt at a general chronological co-ordination of Quaternary time.—P. **Boutroux**: A family of multiform functions associated with a differential equation of the first order.—G. **Valiron**: The theorem of M. Picard and the generalisations of M. Borel.—M. **d'Ocagne**: The distribution of curvatures round a point on a surface. —J. **Villey**: Explosion motors for rarefied atmospheres. Five methods are classified by means of which a normal motor may be made more effective at high altitudes.—G. **Claude**: The advantages of the synthesis of ammonia at very high pressures. At 1000 atmospheres the number of passages of the gaseous mixture over the catalyst necessary for complete combination can be reduced to three, and, as a consequence, the volume of the part of the apparatus containing the catalyst can be reduced to at least one-tenth of that currently in use in German practice. At this pressure the ammonia formed can be liquefied out by simply cooling with water.—W. A. **Noyes**, jun.: Polarisation in iron solutions. The Nernst formula does not apply to the polarisation of iron solutions, but indicates values proportional to the experimental values.—C. **Matignon** and E. **Monnet**: The reversible oxidation of sodium nitrite. Sodium nitrite heated to about 500° C. with oxygen under pressure (175 atmospheres) is almost completely oxidised to the nitrate. The reaction is slow, but possibly a suitable catalyst may make the reaction of practical interest in the synthetic nitrate and nitrite industry.—G. **Chaudron**: The reversible reaction between steam and molybdenum.—F. **Kerforne**: Some observations on the Redonian sea of Brittany.—J. **Couégnas**: Contribution to the study of the Argentat fault between Eymoutiers and Treignac.—H. **Coupin**: The causes of the elongation of the stem of etiolated plants. Plants grown in the dark in water containing the juice extracted from green plants do not have elongated stems, but resemble seedlings grown in the light.—E. **Gain** and A. **Gain**: The thermal differences of opposite sides of a lacustral valley.—A. **Guilliermond**: The evolution of the chondriome in the plant-cell.—R. **Mirande**: Alum carmine and its use, combined with iodine green in plant histology. Alum carmine should be considered as a stain for pectic materials, and not for cellulose, as usually believed.—G. **Mangenot**: The evolution of the chondriome and plasts in Fucus.—G. **Arnaud**: The family of the Parodiellinaceæ.—A. **Marie** and L. **MacAuliffe**: The anthropometric study of 136 natives of Tunis.—J. **Pellegrin**: The sub-fossil fish strata of the Tchad low country and their signification.—J. **Legendre**: The food of the Madagascan perch.

January 26.—M. Henri Deslandres in the chair.—Y. **Delage**: An integrating Pitot tube for measuring the average velocity of variable currents. The instrument, a diagram of which is given, is based on the measurement of the water flowing from the upper end of the Pitot tube at the sea-level.—F. **Widal** and P. **Vallery-Radot**: Anaphylaxy due to antipyrin after a long phase of sensibilisation. The case described had taken antipyrin monthly for nine years before any trouble arose, then each dose of antipyrin produced definite effects, localised in the lips. After seven years without this drug, antipyrin immediately reproduced the same symptoms. The treatment by which this anaphylactic state was cured, following the method of Pagniez, is described.—J. **Andrade**: The photographic measurement of rolling resistance.—L. and E. **Bloch**: A spectroscopic arrangement for the study of the extreme ultra-violet. The prism and lenses are made of fluorspar, and air absorption is prevented by maintaining the whole apparatus in a high vacuum (0·001 mm.) by means of a Gaede pump. Spark spectra of several metals have been photographed with apparatus down to a wave-length of 1550 Ångström units.—E. **Wourtzel**: The velocity of oxidation of nitric oxide. The oxidation of nitric oxide by oxygen is a reaction of the third order, and the course of the reaction undergoes no sudden modification when half the nitric oxide is oxidised. The velocity of the reaction diminishes as the temperature rises.—C. **Matignon** and Mlle. G. **Marchal**: Some properties of sodium nitrite. Determinations of the melting point (276·9° C.), heat of solution, heat of neutralisation, heat of formation, and action on colouring matters. An aqueous solution of sodium nitrite at 100° C. in oxygen at 50 to 55 atmospheres remained unoxidised during five or six hours. Platinum black is without action as a catalyst.—A. **Kling**, D. **Florentin**, and E. **Jacob**: The properties of the chlorinated methyl carbonates. All nine possible chlorine substitution products of methyl carbonate have been prepared, and their physical properties are given in a table.—G. **du Bellay** and M. **Houdard**: The chemical properties of humus and their utilisation for the protection of combatants against asphyxiating gases. Filtration of air through about 60 cm. of earth containing humus can protect against chlorine and phosgene for several hours.—P. **da Souza**: Contribution to the lithological study of the interior of Angola.—F. **La Porte**: The beaches of Gâvre and Penthièvre (Morbihan).—E. **Mesnard**: Lunations and rainy periods.—Ch. **Dufour**: Values of the magnetic elements at the Val-Joyeux Observatory on January 1, 1920.—E. **Surgis**: Contribution to the study of the Frankeniaceæ.—A. **Vandel**: The development of the copulating apparatus in the Planaria is under the control of the genital glands.—L. **Léger**: Young fresh-water stages and biology of the marine lamprey.

Climatic Cycles and Tree-Growth. By A. E. Douglass. Pp. 127+12 plates. (Washington: Carnegie Institution of Washington.)

The Environment of Vertebrate Life in the Late Paleozoic in North America. By Prof. E. C. Case. Pp. vi+273. (Washington: Carnegie Institution of Washington.)

A Biochemic Basis for the Study of Problems of Taxonomy, Heredity, Evolution, etc. By Prof. E. T. Reichert. Part i. Pp. xi+376+34 plates. Part ii. Pp. vii+377–834. (Washington: Carnegie Institution of Washington.)

DIARY OF SOCIETIES.

THURSDAY, FEBRUARY 19.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—A. H. Smith: Illustrations of Ancient Greek and Roman Life in the British Museum.

ROYAL SOCIETY, at 4.30.—Prof. B. Moore and T. A. Webster: Studies of Photo-synthesis in Fresh-water Algæ.—Prof. W. M. Bayliss: The Properties of Colloidal Systems. IV. Reversible Gelation in Living Protoplasm.—Rev. F. J. Wyeth: The Development of the Auditory Apparatus in *Sphenodon punctatus*.

ROYAL INSTITUTE OF PUBLIC HEALTH, at 5.—Dr. S. R. Gloyne: The Problem of Immunity in Tuberculosis.

LINNEAN SOCIETY, at 5.—J. S. Huxley and D. F. Leney: Specimens of Sexually Mature Axolotls Metamorphosed into the Amblystoma Form by Feeding with Thyroid Gland, and of Urodele Larvæ Precociously Metamorphosed by Treatment with Iodine Solution.—Major H. C. Gunton: Entomologico-Meteorological Records of Ecological Facts in Life of British Lepidoptera.

INSTITUTION OF MINING AND METALLURGY (at Geological Society), at 5.30.—T. B. Stevens and C. E. Blackett: The Use of Haloid Cyanides for the Purpose of Gold Extraction.

CHILD-STUDY SOCIETY (at Royal Sanitary Institute), at 6.—Commr. B. T. Coote: Physical Education and its relation to National Ideals.

CHEMICAL SOCIETY, at 8.—S. B. Schryver and C. C. Wood: A New Method for the Estimation of Methyl Alcohol.—C. S. Gibson and Sir William J. Pope: $\beta\beta'$-Dichloroethyl Sulphide.—B. Flurscheim: The Relation between the Dissociation Constants of Acids and Bases and the Quantitative Distribution of Affinity in the Molecule.—S. Dhar: Direct Replacement of Negative Groups by Halogen in the Achromatic Series. Part I. Replacement of Nitro-group by Bromine.

SOCIETY OF ANTIQUARIES, at 8.30.

FRIDAY, FEBRUARY 20.

GEOLOGICAL SOCIETY OF LONDON, at 3.—(Anniversary Meeting.)

ROYAL COLLEGE OF SURGEONS, at 5.—Prof. G. Elliot Smith: The Evolution of the Cerebellum (Arris and Gale Lecture).

INSTITUTION OF MECHANICAL ENGINEERS (Annual General Meeting), at 6.—E. M. Bergstrom: Recent Advances in the Utilisation of Water Power (Resumed Discussion).

CONCRETE INSTITUTE (at 296 Vauxhall Bridge Road), at 6.—H. K. Dyson: Some Points in Reinforced Concrete Design.

INSTITUTION OF ELECTRICAL ENGINEERS (Students' Meeting) (at Faraday House), at 7.—A. Serner and Others: Discussion on State Ownership *v.* Private Enterprise.

JUNIOR INSTITUTION OF ENGINEERS (at Royal Society of Arts), at 7.30.—Prof. F. W. Burstall: Obscure Points in the Theory of the Internal-combustion Engine.

SOCIETY OF TROPICAL MEDICINE AND HYGIENE (at 11 Chandos Street, W.), at 8.30.—Col. W. G. King and Others: Discussion on Small-Pox.—Lt.-Col. N. H. Fairley and Capt H. R. Dew: Causes of Death from Malaria in Palestine: A Study in Cellular Pathology.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Dr. E. J. Russell: British Crop Production.

SATURDAY, FEBRUARY 21.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir J. J. Thomson: Positive Rays.

PHYSIOLOGICAL SOCIETY (at Lister Institute), at 4.

MONDAY, FEBRUARY 23.

ROYAL COLLEGE OF SURGEONS, at 5.—Prof. G. Elliot Smith: The Evolution of the Cerebellum (Arris and Gale Lecture).

ROYAL SOCIETY OF ARTS, at 8.—C. F. Cross: Recent Researches in the Cellulose Industry (Cantor Lecture).

MEDICAL SOCIETY OF LONDON, at 8.30.—Sir Charters Symonds: The Surgical Treatment of the Later Stages of Gunshot Injuries of the Chest and of Empyema.—Dr. P. M. Smith: The After-results of Certain Surgical Operations.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.30.—Jay Hambidge: Greek Design.

TUESDAY, FEBRUARY 24.

ROYAL HORTICULTURAL SOCIETY, at 3.—J. Hudson: The Cultivation of Fruits under Glass with a Minimum of Fire Heat.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. E. Wilson: Magnetic Susceptibility.

INSTITUTION OF CIVIL ENGINEERS, at 5.30.—Sir F. J. E. Spring: Restoration of a Cyclone-Damaged Breakwater End in Madras Harbour, and Coastal Sand Travel near Madras Harbour.

ZOOLOGICAL SOCIETY OF LONDON, at 5.30.—The Secretary: Report on the Additions to the Society's Menagerie during the month of January, 1920.—E. G. Boulenger: On some Lizards of the Genus Chalcides.—N. S. Lucas: Report on the Deaths in the Gardens in 1919: with Notes on Rickets and Avian Enteritis.—S. Hirst: Revision of the English Species of Red Spider (Genera Tetranychus and Oligonychus).

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN (Lantern Meeting), at 7.—Dr. C. A. Swan: Wanderings in Italy.

ILLUMINATING ENGINEERING SOCIETY (at Royal Society of Arts), at 8.—Dr. T. L. Llewellyn and Others: Discussion on Lighting Conditions in Mines, with special reference to the Eyesight of Miners.

WEDNESDAY, FEBRUARY 25.

ROYAL SOCIETY OF ARTS, at 4.30.—J. Currie: Industrial Training.

GEOLOGICAL SOCIETY OF LONDON, at 5.30.—H. C. Sargent: The Lower Carboniferous Chert Formations of Derbyshire.

BRITISH PSYCHOLOGICAL SOCIETY (Industrial Section) (at Examination Rooms of the Royal College of Physicians, 8-11 Queen's Square, W.C.), at 6.—Dr. H. M. Vernon: The Effect of Change in Hours of Work on Output.

THURSDAY, FEBRUARY 26.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—A. H. Smith: Illustrations of Ancient Greek and Roman Life in the British Museum.

ROYAL SOCIETY, at 4.30.

INSTITUTION OF ELECTRICAL ENGINEERS, RÖNTGEN SOCIETY, and ROYAL SOCIETY OF MEDICINE (Electro-Therapeutics Section) (at Royal Society of Medicine), at 5 and 8.15 (Joint Discussion on Electrical Apparatus in relation to X-rays).—Dr. R. Morton: The Efficiency of High-Tension Transformers as used for X-ray Purposes.—Major C. E. S. Phillips: The Problems of Interrupted and Fluctuating Currents.—R. S. Wright: High-Tension Transformers.

ROYAL COLLEGE OF PHYSICIANS, at 5.—Dr. A. Castellani: The Higher Fungi in relation to Human Pathology (Milroy Lecture).

CONCRETE INSTITUTE (at Vauxhall Bridge Road), at 7.30.—E. F. W. Grimshaw: Reinforced Concrete Fences and Posts.

FRIDAY, FEBRUARY 27.

ROYAL SOCIETY OF MEDICINE (Study of Disease in Children Section), at 4.30.—Dr. Mellanby and Others: Discussion on The Influence of Accessory Food Factors in Infant Feeding.

PHYSICAL SOCIETY, at 5.—T. Smith: The Balancing of Errors.—Dr. N. W. McLachlan: The Testing of Bars of Magnet Steel.—G. D. West: The Forces Acting on Heated Metal Foil Surfaces in Rarefied Gases.—Miss N. Hosali: Exhibit of Crystal Models.

WIRELESS SOCIETY OF LONDON (at Royal Society of Arts), at 8.—A. A. Campbell Swinton: Some Wireless Wonders (Presidential Address).

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—W. B. Hardy: Problems of Lubrication.

SATURDAY, FEBRUARY 28.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir J. J. Thomson: Positive Rays.

METEOROLOGY AND THE STATE.

DURING the war, meteorology, like many other branches of science, was utilised to an unexpected extent, and its importance has thereby gained recognition in far wider circles than might otherwise have been the case. The rapid development of aviation has contributed to this, for accurate forecasts and a knowledge of the conditions prevailing in the upper air are of the greatest importance to the airman, and the subject now forms a part of his course of instruction.

With the cessation of hostilities, the Meteorological Office has had to consider the reconstruction which would be necessary in its organisation to meet the larger demands made upon it, and to maintain the expansion and development of the scientific side of the subject which such increased activity demanded. In other countries the meteorological service has always been part of one of the Departments of State, but in this country its status has varied from time to time. The Meteorological Office began in 1854 as a Department of the Board of Trade for the purpose of collecting information about the meteorology of the sea, to which was added later the study of forecasting. Later, it was placed under a committee appointed by the Royal Society, which administered the funds furnished by an annual grant-in-aid. Since 1905 the Office has been under the management of a Committee appointed by the Treasury, and consisting of representatives of the Admiralty, Board of Trade, Board of Agriculture and Fisheries, and the Royal Society. Thus the Meteorological Office has for many years been a service mainly supported by State funds, but not attached to any Department, its policy being determined by the Committee responsible for its administration.

Under these conditions much valuable scientific work has been done, and, whatever the advantages of such an independent position may have been, the greatly increased utilisation of meteorological information by various Departments of State has recently brought the status of the Meteorological Office under consideration.

In the report of the Meteorological Committee for the year ending March 31, 1919, a proposal of the Air Ministry made in the spring of 1918 to take over the Office, on account of the importance of meteorology to aviation and of the use of aviation to meteorology, is presented; but no definite action was taken at the time. Later in the year a Committee of the Cabinet was in favour of transferring the meteorological service to the Department of Scientific and Industrial Research, with a view to the co-ordination of the various meteorological services then existing. Such a scheme appeared to afford a satisfactory means of meeting the requirements of the Departments, and also of maintaining the scientific research essential to advance in meteorology.

Since then it has been announced by the Under-Secretary of State for Air that the Cabinet has decided that the Meteorological Office should be attached to the Air Ministry, and the amalgamation of the staff of the Meteorological Office with that of the Meteorological Service of the Air Ministry is understood to be in course of execution. We may therefore conclude that the importance of the State Meteorological Service to the modern needs of the fighting Services, as well as to the other Departments of State, is such as to render its closer connection with them desirable, and apparently the special needs of the Air Ministry and its exceptional facilities for obtaining information from the upper regions of the atmosphere have led to its selection as the Ministry to which the Meteorological Office should be attached.

Such recognition of the importance of meteorological science, and the co-ordination of different services dealing with the subject, are to be welcomed, but men of science will wish to see the freedom for investigation and research which has been a special feature of the Office under its former committees of management fully maintained under the new conditions arising from its re-incorporation in a State Department. Some misgivings on this point seem to exist, for the council of the Royal Meteorological Society, in a resolution published elsewhere in this issue, while recognising the advantages which the Meteorological Office may gain from a closer association with the Air Ministry, suggests that there may be a tendency for certain branches of meteorology to be relegated to a subordinate position of importance if the management of the Service rests with a single Department having special interests of its own.

Here we meet the difficulty of reconciling the advantages gained from the support and resources of an influential Ministry with such restrictions as are inseparable from the administration of a large Service. The special interests and requirements of a controlling Department will naturally appeal more strongly to its administrators, and proposals for expenditure on schemes will gain more sympathy and support than others with which they are less familiar. Such considerations probably influenced the Meteorological Committee in concurring in the proposal for transference to the Department of Scientific and Industrial Research.

But, since the incorporation of the Meteorological Office in a State Department is necessary, as seems to be generally agreed, the important matter is how advance in all branches of the subject may be assured. Besides forecasts of the weather and information concerning conditions in the upper air which especially affect the Air Ministry, there are the needs of the Navy, the mercantile marine, and the shipping community in general; the interests of farmers, foresters, and fruit-growers; the requirements of water engineers, river conservancies, and many other branches of the community. The War Office has special demands of its own in connection with gunnery, sound-ranging, etc., and there are many questions coming within the scope of the Ministry of Health and other Government Departments which utilise meteorological information. For all these lines of work, scientific investigation must be carried on continuously in order to obtain fuller knowledge of the atmospheric processes which can be utilised to the advantage of the various interests which have been mentioned. To this end observatories are maintained for investigation apart from their utility as reporting stations, and it is of the utmost importance that such scientific research should be continued and afforded full freedom ot action.

With its transfer to the Air Ministry, the Meteorological Office has gained a large addition to its staff, and with its extended network of reporting stations its budgetary provision in the coming financial year will doubtless be greatly increased. The State Service is still almost the only one offering a career to a man who is attracted to the subject of meteorology, and if those of the best ability are to be obtained, it is essential that scientific research in it should be encouraged in which their powers may be utilised. No announcement has so far been made of the constitution of the Committee which continues the work of the Meteorological Committee, or of its powers and responsibilities, but it is to be hoped that science will be strongly represented on such a Committee which can advise the Air Ministry on the best policy to be pursued for the advancement of meteorological science, and will be empowered to direct the execution of such policy. By this means the Ministry will be assured that research will be carried on most efficiently and to the advantage of all branches of the subject.

THE BIRTH OF OCEANOGRAPHY.

Accounts Rendered of Work Done and Things Seen. By J. Y. Buchanan. Pp. lvii + 435 + 3 plates. (Cambridge: At the University Press, 1919.) Price 21*s.* net.

MR. J. Y. BUCHANAN has passed the allotted span of years, but we who are no longer young cannot call him old. Yet he was hard at work in a generation which has all but passed away, and his recollection reaches back to things which are but a tradition to the most of us. He is the last of that happy band who set sail from Portsmouth in the *Challenger* under Wyville Thomson just seven-and-forty years ago; he was born in another world than ours, when (as he tells us) the only railways on the Continent ran, as kings' playthings, from Paris to Versailles, from Berlin to Potsdam, from Hanover to Herrenshausen. Now in this volume, as in one before, he has "rendered his accounts" (but only partially) of the abundant work he has done and the countless things he has seen. The book contains essays both great and small, from letters to NATURE to addresses delivered to universities and learned societies, and the things of which these papers treat are both big and little, for Mr. Buchanan has kept a sharp look-out, conning everything—from the rats in a Bordighera garden (which left the oranges alone, ate the rind of lemons and left the fruit, ate the fruit of mandarins and left the rind) to the great panoramas of earth and sea which for so many years have passed before him.

Most of the papers deal (as we should expect) with matters oceanographical, such as the temperature of the sea, its colour, its saltness, or the manganese and other nodules lying in its bed. The treatment is in great measure new, or was so when the papers were written; but the themes are old—and are made all the more attractive thereby. One is reminded of Robert Boyle's "Observationes de salsedine maris," or, again, of the "Histoire Physique de la Mer"—based upon so little, because it was all there was—of that exquisite writer and gallant soldier of fortune, Louis Ferdinand, Comte de Marsilli. Even one or two names like these (and we do not forget Captain Maury, another great captain and soldier of fortune) make us hesitate a little to accept Mr. Buchanan's account of "The Birthday of Oceanography." And yet perhaps he is not very far wrong to persuade us that that science was born, a little to the westward of Teneriffe, on February 15, 1873. For this was the day when the *Challenger* made her first oceanic sounding; and, immediately after, the dredge came up full of new and strange things, great corals, huge siliceous sponges, and what not more—first-fruits of the noble harvest to be gathered from the "Depths of the Sea."

In some things, and again it is no wonder, Mr. Buchanan prefers the old times to the new. He tells us of the cool comfort of an old wooden ship, its perfect fitness for the work of exploration, and how we have no ships nowadays like the *Challenger*. We are half-tempted to agree with him. He commends, even with enthusiasm, the old-fashioned hempen dredge-rope and sounding-line, and assures us that "wire is the very emblem of treachery." In later years, when wire had come into use, he says: "I never attached a thermometer to the wire without feeling that I was guilty of a form of cruelty—cruelty to instruments." This is a much harder saying—to those of us who have used nothing else; let us hope that it is the wire which has altered, and not the men.

It need scarcely be said that this book is well worth reading. It has many pages to interest even the man in the street, and has both an historical interest and something more besides for the present-day student of oceanography. In these seven-and-forty years methods have been refined, new theories and concepts formed; but we do not forget that birthday party on board the *Challenger*, nor Mr. J. Y. Buchanan, who is the last of the godfathers.

D'Arcy W. Thompson.

INDUSTRIAL PSYCHOLOGY.

Lectures on Industrial Psychology. By Bernard Muscio. Second edition, revised. (Efficiency Books.) Pp. iv+300. (London: George Routledge and Sons, Ltd.; New York: E. P. Dutton and Co., 1920.) Price 6*s*. 6*d*. net.

This book is founded on a course of five lectures which were delivered before a general audience at Sydney University, but they must have been considerably expanded when put into book form. The author does not lay claim to have made any first-hand investigations on the problems with which he deals, but the book is very far from being a mere compilation. It shows throughout a deep insight into the principles of industrial psychology, and is especially lucid on the much-debated question of scientific management.

Mr. Muscio takes in turn the various objections to this system raised by the workers themselves, and with great ingenuity tracks down the true inwardness of these objections, and discusses the manner in which they may be overcome. He maintains that the main fact to be insisted on is that the new methods prevent waste of human energy, and render it possible to obtain a given output from a much smaller expenditure of human energy than that hitherto found necessary. Labour's objection that the general introduction of scientific management would cause widespread unemployment applies equally to every improvement introduced into industry in the past. The difficulty can be largely overcome by installing the improvements gradually and absorbing the surplus workers by the simultaneous introduction of other forms of labour.

Again, Labour maintains that scientific management leads to undue speeding up. There is much truth in this assertion, but the difficulty can be overcome by the introduction of longer intervals of rest and by shortening the working day. Other objections to the system could be avoided by arranging for an adequate system of industrial education. The employer and employee must co-operate in the introduction of a scheme whereby no time study of an operation shall be made, and no bonus system adopted, without the consent of the worker.

A very interesting and important field of industrial psychology centres around vocational selection. This subject is discussed at length by the author, and concrete instances of the methods as applied to the selection of telephone girls and electric-street-car drivers are described in detail. Industrial fatigue is treated rather briefly, and is the least satisfactory part of the book, as the information adduced is largely out of date. That concerning industrial accidents is fragmentary and misleading, and no reference is made to the "safety first" campaign, and to the effects of suggestion on the avoidance of accidents. The lectures were apparently written in 1916, and the author has endeavoured to bring them up to date in this revised edition by the somewhat irritating and unsatisfactory method of appending footnotes.

H. M. V.

CRIMINOLOGY AND NERVOUSNESS.

(1) *Criminology.* By Dr. Maurice Parmelee. Pp. xiii+522. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1918.) Price 10*s*. 6*d*. net.

(2) *The Mastery of Nervousness based upon Self-Re-education.* By Dr. Robert S. Carroll. Third revised edition. Pp. 348. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1918.) Price 10*s*. 6*d*. net.

(1) Dr. Parmelee has written a very readable book on the various aspects of crime and criminals. He has disclosed nothing that is

altogether new, but he has brought together and discussed the varied factors of a large subject in a lucid and interesting way. He begins with a consideration of the evolution of crime, and then discusses in some detail the part played by environment. In part iii. the subject of the organic and the mental basis of criminality is taken up, together with the classification of criminals and the problems of juvenile and female criminality. Part iv. deals with criminal jurisprudence, and part v. with a discussion of penology. The final section comprises a study of the problems of political crime and the crimes arising from opposition to the fixity of social custom, with a chapter on prevention.

Two appendices are added, one dealing with the relation between the price of cereals and crimes against property, and the other—of revived interest at the present time—a criticism of the late Dr. Charles Goring's book, "The English Criminal," which appeared in 1913.

Dr. Goring is taken very pointedly to task for misrepresenting Lombroso "grossly and inexcusably," for his "gross misrepresentation" of the author of "Criminology," and for his ignorance of psychology—although we must confess we think several of Dr. Parmelee's beliefs, such as the physiological theory of instinct, the James-Lange theory of emotion, and his belief in the efficacy of ideomotor action, are not the most fruitful that could be applied to the elucidation of his subject. Finally, he condemns Dr. Goring's researches as carrying the statistical method too far, and concludes that, in spite of his initial disagreement with Lombroso, Dr. Goring has proved himself "more Lombrosian than Lombroso himself."

The author's aim, as he states, has been to make a more or less comprehensive survey of criminology, and that he has succeeded admirably no one who reads his book will doubt.

(2) "The Mastery of Nervousness" is a zealous book, a volume not only of medical, but also of ethical, instruction, a guide, philosopher, and friend to the nervous, but chiefly the last. The aim has not been the exposition of any narrow or restricted doctrine; there are, consequently, a freedom of style and treatment and a command of metaphorical expression which are certainly stimulating and doubtless of benefit to many.

The author points out the growing prevalence of nervousness—that is, overactive or misdirected nervous activity—and describes the influence of various factors—heredity, diet, inactivity, work, play, and others. On "Mastery through Work" he writes: "It is a profound misfortune for any young person to enter the serious years of life without having been earnestly impressed with the dignity of work, or taught to feel that ever within reach are divinely appointed duties."

Dr. Carroll lays emphasis on the importance of the early years of life. "Loss," he writes in the chapter on "Surrender," "begins in childhood. The babe is king of us all. The grim visage of the warrior softens in the presence of its cooing innocence; nobility stops and turns, and does homage; rich and poor, high and low, young and old, kneel at the cradle to welcome the bright, new, young soul."

In the same chapter is a picturesque example of sublimation or "side-tracking," which describes how a patient worked her "jim-jams" off in the garden by "vicious jabs into the soil with hoe and spade"—a species of horticultural profanity that brought back memories of France and the impressive language of the trenches, which, we know, performed an equally estimable function.

The theme of treatment is efficiency through harmony. "If we are to win the battle of personal mastery we must lay hold on a force higher than reason alone, for force of mind not governed by force of spirit does not make man good." The great necessity, the author says, is for "ultimate control of the moral idea, as the only force resolving the dissonance of jangling nerves into harmony."

PRACTICAL CHEMISTRY.

(1) *Elementary Practical Chemistry.* Part i. *General Chemistry.* By Prof. Frank Clowes and J. Bernard Coleman. Seventh edition. Pp. xvi+241. (London: J. and A. Churchill, 1920.) Price 6s.

(2) *A Treatise on Qualitative Analysis: Adapted for Use in the Laboratories of Colleges and Technical Institutes.* By Prof. Frank Clowes and J. Bernard Coleman. Ninth edition. Pp. xvi+400. (London: J. and A. Churchill, 1920.) Price 12s. 6d.

THERE are two distinct aims that may actuate the writer of a text-book on practical chemistry, whether analytical or otherwise, namely, (1) the setting forth of principles, and (2) the enumeration of facts. To a certain extent they are inseparable, for principles without facts are useless, and facts without principles are not ordered knowledge. But it is impossible to make the best of both at the same time. If the principles are burdened with too great a multiplicity of facts, they are fairly certain to be smothered by them, and facts cannot be set forth in the clearest possible way if the method of arranging them is to serve some other end as well.

(1) "Elementary Practical Chemistry" is now, for

the convenience of students, divided into two volumes, of which the "General Chemistry" is the first, leaving "Analytical Chemistry" to the second. The volume before us deals with the principles of chemistry, and gives a series of more than 300 experiments in illustration of them. The text is sufficient to show the bearing of the experiments, in addition to the instructions for the performance of them, but it is presumed that a course of lectures dealing more fully with the subject will be given concurrently with the practical work.

(2) The "Treatise on Qualitative Analysis" has, in the present edition, been "rewritten, recast, and enlarged in order to adapt it to modern methods of teaching." It is essentially a book of facts, for it treats of the detection of the rarer as well as the more common metals and acids, a considerable number of organic acids both aliphatic and aromatic, a few hydrocarbons, halogen, nitro- and other derivatives, alcohols, ethers, aldehydes, ketones, carbohydrates, glucosides, organic bases, eighteen alkaloids, and finally nineteen different gases. In addition to all this there are instructions for making stirring rods, boring corks, etc., for performing various operations, such as precipitation, filtration, washing, and drying, and as to the use of the spectroscope, a description of laboratory fittings, recovery of residues, lists of reagents, and various tables. There is also a small section which gives lists of simple salts, mixtures, and minerals suitable for practice, though these do not include organic substances, the rarer elements, or gases. Thus teachers, as well as students in all stages of their work, will find assistance in this volume.

It is curious how long a time it takes for some facts of first importance to work their way into text-books that are written for students. It has been known for more than fifty years that manganous chloride, when introduced into a flame in the ordinary manner, colours it brightly green, but scarcely any text-books note the fact. We have known students to be led astray by this omission. The authors here state definitely that the compounds of the metals Zn, Mn, Ni, and Co show no characteristic flame colorations, and in the tables a green flame is followed by the inference —Ba, Cu, B_2O_3, exactly as in almost every text-book on the subject. There is a tendency to be more "theoretical" than practical in the statement that ammonium carbonate and nitrate are decomposed by heat into gases, and "they are therefore volatilised without producing white fumes or a sublimate."

The full instructions in the tables, and the very large number of notes appended to them, are evidence of the care taken by the authors, and the many editions that have been issued show that this care is appreciated, and it is deservedly so, by those for whose use the book is intended.

C. J.

A MATHEMATICIAN'S MISCELLANY.

Pensées sur la Science, la Guerre et sur des Sujets très Variés. By Dr. Maurice Lecat. Pp. vii + 478. (Bruxelles: Maurice Lamertin, 1919.)

M. LECAT is a great reader with catholic tastes. For twenty years he has been in the habit of copying out all the passages that have struck him in the reading which occupies his leisure. He has now, at the instance of a friend, collected and arranged them in a volume of 480 pages of double columns. There are about 11,000 extracts from some 1500 authors grouped under subject headings. The first 1200 refer to various branches of science and its most distinguished exponents. The remainder, dealing with every possible subject, grave and gay, of topical or perennial interest, come under titles arranged alphabetically; we proceed in due order from Abstraction, Abus, . . . Allemagne (the longest section), to Voltaire, Voyage, Yeux, Zola. The quotations, whatever the language of their origin, are usually, but not always, translated into French. The whole is furnished with two elaborate indexes and the dignity of an appendix.

The industry that has produced the book is amazing—so amazing that it is surprising that obvious slips should have been allowed to pass in the information concerning authors. A reviewer who should take the opportunity it affords for ridicule would lack even that small portion of humanity usually allotted to his kind. But we fear that M. Lecat is too optimistic in his hope that his collection will serve as an instrument of intellectual research by providing a compendium of the best thought of mankind. In both selection and arrangement such a work inevitably bears the impress of the editor. No one man, even with the voracity of M. Lecat, can consume all literature; the portion that he can digest is infinitesimal. Though writers of at least eight languages are included, ranging from David (the son of Jesse) to Max Harden, and from Homer to the *Morning Post*, it is only natural that those who have used the French language should have the preponderance. Nor do our author's wide interests and his passionate plea for impartiality enable him to conceal from his readers that he is a Belgian, a good son of the Church, and a mathematician. Even if he had been able to avoid the exclamatory "sic!", his best efforts would still have left those whom he addresses with the impression that they are studying, not the sifted wisdom of the ages, but the opinions of M. Maurice Lecat.

However, the subsidiary claim that he makes may be heartily supported. It is a most entertaining volume to dip into for a few moments to pass the time. If it were only rather handier, and the type a little larger, it would be ideal for the bedside. As it is, perhaps the dentist's waiting-room provides for it the proper sphere of usefulness.

N. R. C.

OUR BOOKSHELF.

Penrose's Annual. Vol. xxii. of "The Process Year Book." Edited by William Gamble. Pp. x+112+plates. (London: Percy Lund, Humphries, and Co., Ltd., 1920.) Price 10*s.* 6*d.* net.

OUR special congratulations are due to the editor and publishers of this ever-welcome annual that, after an interval of three years, they have been able to resume its issue. The editor, as usual, in his "Foreword" reviews the recent advances and the present condition of the reproductive graphic arts. In the circumstances one could scarcely expect anything strikingly new, but we are told that one bright and hopeful feature of the present is that work is now being adequately paid for, and that as a consequence employers are able to give satisfying wages as well as to improve their plants. Photo-lithography is coming more and more into use. Collotype is "coming into its own again, thanks to the absence of German competition." The collotype work now being done in this country is of excellent quality, and probably greater in quantity than ever before. Half-tone and three-colour work stand pretty much where they were before the war, while rotary photogravure is coming increasingly to the front for newspaper and periodical work. It is now quite practicable to print both text and illustrations together by this last process, and there are signs that before very long type-setting may be rendered unnecessary. Two American journals have already been produced without the aid of the compositor. The volume contains articles from the pens of many contributors, and is very rich in illustrations of all kinds.

C. J.

The Occlusion of Gases by Metals: A General Discussion held by the Faraday Society, November, 1918. (Reprinted from the Transactions of the Faraday Society, vol. xiv., parts 2 and 3, 1919.) Pp. 93. (London: The Faraday Society, n.d.) Price 8*s.* 6*d.*

THIS volume contains a record of another of the valuable symposia held by the Faraday Society. The subject of the gases retained by solid metals bears on a number of technical processes, so that the papers contributed cover a wide range. Sir Robert Hadfield's introduction gives a useful summary of the knowledge of the gases in iron and steel, with a bibliography. The theoretical aspects are dealt with by Profs. Porter and McBain, the well-known case of the absorption of hydrogen by palladium receiving attention, whilst Dr. McCance's paper on balanced reactions in steel manufacture discusses the question of the equilibria in the steel furnace which determine the proportions of the various gases which will be in contact with the metal at the time of tapping. The view that the amorphous phase in solid metals is responsible for much of the dissolved gas is maintained by several of the contributors, but no evidence is adduced to prove that gases are insoluble in crystals of pure metals. The fact that the solubility of gases in molten metals increases with the temperature has often seemed remarkable, but Prof. Wilsmore points out that this is probably the normal behaviour, water being exceptional in its diminished solvent power for gases with increasing temperature. The discussion contains much that is of interest both to metallurgists and to physical chemists.

C. H. D.

Examples in Heat and Heat Engines. By T. Peel. Pp. iii+104. (Cambridge: At the University Press, 1919.) Price 5*s.* net.

THE working of exercises forms a very important part of the course work of an engineering student. Many of the exercises required for the purpose of elucidating the subject of heat and heat engines can easily be made up; on the other hand, there are many important facts which can be illustrated only by exercises containing as data observations made during experiments. Teachers and students will welcome the book before us, because, among numerous other exercises, there is a large number giving experimental data on steam, gas, and oil engines, steam boilers and turbines, refrigerators, and calorimetric work. It is true that the best data for exercise working are those obtained by the student in experiments carried out by himself. Since most heat and heat-engine tests take a rather long time to carry out, the amount of information thus accumulated in the case of any one student can have only a limited scope, and the excellent exercises contained in the book will make a very useful supplement.

The Hill of Vision: A Forecast of the Great War and of Social Revolution with the Coming of the New Race. Gathered from Automatic Writings obtained between 1909 *and* 1912, *and also, in* 1918, *through the Hand of John Alleyne under the Supervision of the Author.* By Frederick Bligh Bond. Pp. xxv+134. (London: Constable and Co., 1919.) Price 7*s.* 6*d.* net.

THIS book is a sequel to "The Gate of Remembrance," which contained an account of the automatic script giving instructions for excavations in Glastonbury. The further script now published deals with the war and after, but it cannot be said that the correspondences and verifications of predictions pointed out are particularly striking or convincing.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Organisation of Scientific Work.

I TRUST the rank and file of scientific investigators throughout the Empire will wake up to the urgent need of combined energetic action. The proposals to centralise under the control of a few official departmental heads the body of actual scientific investigators in India, thus creating a few highly paid administrative posts for senior men and effectually killing all initiative, enthusiasm, and liberty of action on the part of those actually carrying on the investigations, is perfectly in accord with what has happened in this country since, in an evil day, the Government assumed the control of scientific and industrial research. It is a proposal that appeals, naturally, to the official without knowledge of the way in which scientific discoveries originate, and anxious to secure a body of cheap and docile labour, even though it be mediocre in calibre, and to those few who hope to secure for themselves these senior lucrative administrative posts. To genuine investigators such posts, however highly paid, would be unattractive, and under such a system there seems every inducement for men of originality and scientific ability to give the service a wide berth. Whereas the crying need in India, as everywhere, is for men of high calibre and honest, independent mental outlook, anxious only to secure favourable conditions under which they may be left free to pursue their creative work, and, this being secured, careless of wealth, rank, and power save as the necessary antecedents to the essential condition.

Two assertions, which can be made without the slightest fear of contradiction, may be put into juxtaposition in order to contrast the remedy proposed with the state of things it is desired to cure. First, that of all great nations the British Empire has most signally failed in its application of scientific knowledge and methods to its national problems; and, secondly, that in the British Empire there exists a body of skilled and hard-working scientific investigators second to none, and, even under the most disheartening conditions, actually enlarging the boundaries of natural knowledge in no mean degree. As the great schemes for rectifying matters crystallise into action, with the formation of a Department of Scientific and Industrial Research at home and concrete proposals for action, as in the Indian reorganisation suggested, more and more they seem to amount to this: The men who do the work, and against whom no fault is alleged, are to be deprived even of what little satisfaction and independence genuine scientific work for its own sake affords, and are to be put under the men against whose incompetence and lack of knowledge the whole uproar originally arose. In research, where, as the leading article in NATURE of February 19 so truly says, the man is everything, that man is to be put under men who brought an Empire, as rich in scientific talent and genius as any, perilously low. The remedy, surely, is to put the incompetent machine under the charge of competent men, not *vice versa*.

Our *soi-disant* scientific representatives seem still in the stage once lived through in our ancient universities, where it was at one time deemed politic that any scientific demand, if it were to pass, should be put up and seconded by well-known opponents of science, thus, on the chance of securing a temporary advance, permanently sacrificing the whole future. That we did not in 1914–19 repeat the medical horrors of the Boer War, when more died of pestilence than at the hands of the foe, is surely due to the emancipation in the interval of the Army medical services from non-qualified misdirection. That our food control during war-time was successful, even by comparison with that of more favourably situated belligerents, was because scientific men were from the first in charge of its scientific aspects—a rare condition, due probably to so many of them belonging to the profession that exacts due and proper respect for its members. Can one imagine young medical graduates, after a prolonged and serious university training, being sent up, as our scientific graduates were sent, hauling about gas cylinders with the rank of corporal? Can one imagine a director of a medical research association a foreign business man or manufacturer unknown to the research world? Can one imagine a proposal for State aid for medical research being dismissed by an unqualified person so ignorant of the history of scientific discovery as to deem it sufficient to dub the proposal as a "floating research" in order in his own eyes to condemn it? Neither can I imagine such happening in the scientific world if its leaders were equally alive.

Ordinary people, benevolent to science and unfamiliar with affairs, often wonder why scientific men are so powerless and peculiarly unable to protect themselves and to advance their subjects to a position commensurate with their national importance. The answer is to be found, I think, in the obsolete character of their so-called representative societies. Year after year in the chief of these the councils nominate and elect themselves without any reference to their members except for formal ratification. Through sheer lack of backbone and being out of contact with the body of their members, time and again they sacrifice interests vital to the continued existence of genuine scientific research. I do not wish to advocate for scientific investigators a close corporation keeping lynx-eyed vigil over their professional interests and seeking every opportunity to enlarge and consolidate them, identical with other learned professions; for the paramount interest of a scientific investigator should be his work, and his privileges, emoluments, and status are to be regarded merely as means necessary to secure opportunity and power *to do it*. That should be the test of these schemes, and not the further subordination of the men who do the work to the organisation attempting to get the work done. But unless they band together and take action, the rank and file of research workers throughout the Empire will not even be able to retain the miserable position they occupied before the war in the national life, and their interests will continue to be sacrificed to the ambitions and love of power of the few. FREDERICK SODDY.

THE "Notes" columns of NATURE for February 19 contained a reference to a suggested conference between British botanists at home and overseas at which matters of common interest would be discussed. From some preliminary correspondence which had taken place in order to ascertain the feeling of our colleagues overseas as to the prospects of success of such a conference some interesting communications were received, especially from India, which bear on the subject of the organisation of scientific work. It was urged that this should form a subject for discussion in the event of a conference taking place, and it was evident that the writers were strongly opposed to a policy of centralisation. On the contrary, they were seeking greater freedom in their scientific work, and their communications hinted at irritating restrictions and disastrous results due to official interference—effects which would be much enhanced by such a scheme of centralisation as was indicated in the leading article in the same issue of NATURE. There may have been some waste of effort in the past, both at home and overseas, owing to insufficient co-operation between men of science working independently, but this is a matter for workers to set right among themselves, and will not be mended by an organisation conceived on the lines of a German military system. Further, it is unlikely that the best men will be attracted to work under such deadening conditions.

Care must be taken that public money is not wasted in scientific development, but the kind of official control suggested by a scheme of centralisation does not commend itself as an efficient waste-preventer. Grants of money to scientific societies or institutions might be administered by carefully selected boards of trustees, the scientific work being left to the unhampered initiative of the scientific staff under a head specially suited to the character of the work. The management of our Natural History Museum, a Government institution, is invested in trustees, who leave to the scientific staff the carrying out of the scientific work as effectively as funds and opportunity allow. Research work of the highest value to agriculture is being carried out at the Rothamsted Experimental Station, the original endowment of which has been generously supplemented by private munificence and by Government grants. Here also the management is vested in a small committee the members of which represent the various scientific sides of the work carried on. A. B. RENDLE.

British Museum (Natural History).

Gravitational Deflection of High-speed Particles.

THE investigation of the consequences of Einstein's law as regards the motion of a material particle moving through a gravitational field with a velocity comparable to that of light brings out some interesting and rather surprising effects. As Einstein's law is entirely kinematical, involving accelerations instead of forces, no account need be taken of variation of mass with velocity other than that contained in the law itself. Let m denote the mass of the attracting body (*i.e.* the sun) in astronomical units divided by the square of the velocity of light. Then the motion of a particle in the field produced by this body is determined by

$$\delta\int\sqrt{\left(1+2\frac{m}{r}\right)\left(dr^2+r^2d\theta^2\right)-\left(1-2\frac{m}{r}\right)c^2dt^2}=0,$$

the $r\theta$ plane being that of the orbit. From the Lagrangian equations corresponding to this Hamiltonian statement of the law, the energy relation

$$\frac{1}{2}\frac{d}{dt}(v^2)=-\frac{mc^2}{r^2}\left(1-4\frac{m}{r}\right)\dot{r}=3\frac{m}{r^2}v^2\dot{r}$$

is obtained. If the velocity of the moving particle is comparable to the velocity c of light, the second term in the parenthesis on the right-hand side may be omitted as negligible compared to the last term. The resulting approximate equation is easily integrated, leading to the expression

$$v^2=c^2\left\{a^2\left(1-6\frac{m}{r}\right)+2\frac{m}{r}\right\},$$

where a is the ratio of the velocity of the particle at infinity to that of light.

Consider a particle the velocity of which at infinity is negligibly small compared to that of light. Then the factor a is small, and the second term in the parenthesis which it multiplies may be omitted. This gives the energy equation of the Newtonian theory.

If, however, the particle has a high velocity, the omitted term becomes of importance. In fact, when the velocity is $1/\sqrt{3}c$, this term has the same value as the third term, but the opposite sign. Therefore, these two terms annul each other, and the velocity of the moving particle is unaffected *in magnitude* by the gravitational field. In other words, the *tangential* acceleration of the particle is zero throughout the course of its motion through the field. If it were headed directly for the attracting centre, it would move along in a straight line with constant speed just as if no field were present.

Next, consider a particle having a velocity at infinity greater than $1/\sqrt{3}c$. The velocity of this particle is actually decreased by the gravitational field. If it were aimed straight at the attracting mass, it would be slowed down just as if it were *repelled* with a force varying inversely with the square of the distance. If the velocity of the particle at infinity is equal to that of light, its velocity decreases as it approaches the centre of attraction in the same amount as that of a light-wave, for Einstein's theory makes no distinction between material particles and electromagnetic disturbances.

Consider a particle moving along the X axis with a high velocity v. Let the attracting mass m be on the Y axis, a distance R below the origin. Then the components of the particle's acceleration are

$$f_x=-\frac{mx}{r^3}\left(c^2-3v^2\right),$$

$$f_y=-\frac{mR}{r^3}\left(c^2-v^2\right).$$

If the particle's velocity is greater than $1/\sqrt{3}c$, the tangential component f_x is positive, and the particle is slowed down as it approaches the centre of the field. The normal component f_y, however, causes the particle to be deflected towards the gravitating mass for all velocities less than c. This deflecting acceleration becomes less, however, as the velocity increases, and a particle moving with the velocity of light would travel through a gravitational field in a straight line. Its velocity, however, decreases as it approaches the gravitating centre, and then increases as it recedes from this point. For velocities close to that of light the deflection is given by

$$2\frac{m}{R}\left(\frac{c^2-v^2}{v^2}\right).$$

The deflection suffered by a light-wave is of a nature quite different from that experienced by a material particle. A ray of light is not bent towards the sun by the latter's gravitational attraction, but the velocity of that portion of the wave-front closest to the sun is decreased more than that of the more remote portion. Therefore, the wave-front is swung round in exactly the same way as when light passes obliquely from a rarer to a denser refracting medium.

In conclusion, it may be noted that the two consequences of Einstein's law which are of great enough magnitude to be tested experimentally have been most conspicuously verified. The predicted shift of the Fraunhofer lines towards the red does not seem to be a necessary consequence either of Einstein's law or of the part of the theory on which this law is based, but rests on the very doubtful assumption that the system of a freely moving atom near the sun's surface is identical with that of a freely moving atom 93,000,000 miles away. If space-time had the same properties in the two regions this identity would be required by symmetry, but as the warping of space-time is quite different near the sun from what it is at the distance of the earth, does it follow that these two systems are necessarily equivalent? It does not seem to the writer that the failure to find this shift invalidates the part of Einstein's theory from which his law of gravitation is deduced, and it certainly does not contradict this law itself.

Leigh Page.

Sloane Laboratory, Yale University, New Haven, Connecticut, January 22.

Biological Science in Secondary Schools.

I should like to direct attention to a very important paragraph in the Report of the Investigators of the Secondary School Examinations Council which is not referred to in the article which appeared in Nature of February 19 (p. 669). It is the paragraph which deals with natural history and zoology.

It is quite clear from this paragraph that the Investigators wish to discourage the teaching of the animal side of biology in secondary schools—a very serious matter in itself. But when the Investigators proceed to state that "the principles of biological science can be [better] illustrated by means of botany," they are expounding a doctrine as to the teaching of a science which is bound to have most serious and harmful results.

The principles of biological science can be taught or illustrated only by persons with a competent knowledge of both botany and zoology, and a suggestion such as this, issued as the considered judgment of a body of educationists, that a knowledge of botany alone is sufficient for this purpose, will only exaggerate the present-day incompetence of the teaching of biology in many of our secondary schools, in which the teachers have had no training in zoology. This matter has already been considered by a representative meeting of zoologists in London, and steps are being taken to represent the views of zoologists to the President of the Board of Education at an early date.

Sydney J. Hickson.

Change of Colour in Captive Birds.

Mr. Harold Millar invites notes on this subject (Nature, February 5, p. 600). The case of the crossbill (*Loxia curvirostra*, Linn.) seems in point. My attention was directed to it some years ago, when I saw a number of crossbills—six or eight, if I remember aright—confined in a large cage or small aviary at Glenferness, Nairnshire. The brilliant scarlet plumage which distinguishes the adult male in a state of freedom had changed on these captives to yellowish-olive, and I was informed that this was the invariable effect of captivity. The late Lord Lilford kept a number of crossbills in his famous aviary, and has the following note in his *coloured* "Figures of Birds of the British Isles":—

"On the vexed question of the plumage of the crossbill, I can only say that every *red* bird that I ever possessed lost that brilliant colour at the first moult, and never regained it" (vol. iv., p. 76).

In all the stuffed specimens that I remember to have seen the scarlet hue had faded to the same dingy olive.

Monreith.

Volcanic Rocks in Northern Kordofan, Sudan.

In view of the discovery of the Bayuda volcanic field observed by Dr. Chalmers Mitchell during the *Times* African flight, and referred to by Prof. J. W. Gregory in Nature of February 19, some interest attaches to a specimen of a volcanic rock sent to the Mineral Department of the British Museum for identification in July, 1912, by Dr. C. G. Seligmann. The specimen was collected by Dr. Seligmann at the base of Jebel Katul, Northern Kordofan, where he found many stone implements made of the same rock.

Jebel Katul is 350 miles south-west of the volcanic field seen by Dr. Chalmers Mitchell, and is on the trend of the north-east to south-west depression indicated by Prof. Gregory as running from the coast of the Red Sea south of Adal Qaqa, and following the course of the Nile from Abu Hamed to Korti.

The rock is very fine-grained and slate-blue in colour, weathering to pale green. Examination shows it to be a riebeckite-rhyolite showing "flow structure," but too fine in grain to enable the nature of the felspar or the relative amount of quartz present to be determined. The rock is nearly allied to the riebeckite-rhyolites of Gilgil, north of Lake Naivasha, and to the riebeckite-bearing trachytes of Senafé and Fakoda, North Abyssinia, described by Dr. G. T. Prior in 1903, both of which occurrences are on the line of the Great Rift Valley.

W. Campbell Smith.

Scientific Workers and a National Federation.

Considerable misapprehension seems to have arisen with regard to the action taken by the National Union of Scientific Workers in connection with the inaugural Conference of Professional Associations on February 7, convened for the purpose of forming a National Federation of Professional, Technical, Administrative, and Supervisory Workers. I shall be glad if you will give publicity to the following statement of fact:

This union was invited to send delegates to the inaugural conference and accepted the invitation, as there were many other technical and scientific associations invited with which it was felt this union had almost identical interests. As the result of the preliminary discussion, it was found that such bodies as this would be out-voted and out-influenced in any such federation by unions with which it has little in common. With the help of other associations we moved an amendment in an attempt to prevent the new federation from taking a definite bias at its inception. This amendment was lost, whereupon we abstained from taking further part in the proceedings.

The report as it appeared in the Press stated that the resolution to form a federation was carried unanimously, the inference being that this union, which was represented at the meeting, had decided to join the federation, and many of our members, seeing this misleading statement, have assumed that this is the case. I trust that this disclaimer will reassure them and other such persons who are interested in the union.

A. G. Church,
Secretary.

COTTON GROWING IN THE BRITISH EMPIRE.

THE report to the Board of Trade of the Empire Cotton Growing Committee has just been issued (Cmd. 523, price 1*s.* 6*d.* net). Briefly, the story there told may be summed up as follows: The British cotton mills have been directly adapted to utilise the American long-staple cottons, and they produce, in consequence, the high-class goods for which they are famed. The mills may, in fact, be described as unable to use up the abundant, though much shorter, staples of India and certain other countries of the British Empire. For some years past the mills of the States have begun to work up more and still more of their home supply (of superior cottons), so that the position has thus come about that Britain must be prepared, in the near future, to dispense with a large amount of the American raw cottons hitherto regarded as essential. In what way and how soon can this feat be accomplished? Delay may mean famine to the immense community (something like 5,000,000 people) more or less dependent on the cotton mills of Lancashire.

The answer is presumed to have been given by the report before us. But the perusal of the volume leaves a somewhat confused impression, in which we seem to have been studying something closely resembling the meanderings of a great river which flows through the tropical and sub-tropical regions of the world. It engulfs many great tributaries, and is finally discharged into the ocean of British cotton manufacturing interests by six mouths or sub-committees. All this may be fine, and certainly is ingeniously elaborated, but when we read that it is intended to flow on for ever, we begin to wonder if a complex organisation of impersonal and mutable committees is likely to prove the most satisfactory course for obtaining the very-much-to-be-desired results.

The raising of funds (Imperial and Colonial, etc.); the organisation of existing resources; the institution of greater specialisation in the working up of available supplies; the establishment of improvements in handling, transporting, and marketing the raw staple; the prevention of the practices of adulteration and damping; and many other such subjects, are all dealt with in the report, but they do not seem to resolve themselves into the promulgation of a concrete scheme of increased and improved production. Nevertheless, we are assured that the British Empire can be made self-supporting in this matter, though we are not told where or how this is to be accomplished. It must be confessed that the whole history of cotton improvement is most disheartening. We read, for example, of a great scheme having been floated, some seventy years ago, to raise in Manchester a sum of 20,000,000*l.* to be expended in India, during five years, in measures calculated to forward India as a cotton-producing country. Nothing came of that great conception, though spasmodically, after intervals of neglect (due to increased American supply), Associations, Committees, and Commissions were formed, and each in its day aroused considerable interest, but all proved more or less futile. Meanwhile, two great new manufacturing centres gradually progressed into importance—namely, the United States of America and India—and now these have to be reckoned with in the future.

There are, however, in the present report two important schemes—the training of men, and the establishment of research. In both we think the contemplated methods of accomplishment are likely to prove unsatisfactory.

But let the Central Research Institution, proposed in the Committee's report, become a permanent department of expert officials (not a committee of voluntary workers), and have handed over to it a desired programme of work, then we think a definite step would be taken in the right direction. The members of that institute could be held responsible and judged by results. Their programme should be: Research, Education, and Cotton Production. House them, therefore, in a building large enough to have fully equipped laboratories for research, give them as complete a library as possible, and build them a museum and herbarium. But let there be no hair-splitting separations into research as distinct from information—no divided responsibilities. Who can be better qualified to make public the results or materials obtained than the experts concerned? Information cannot, and should not, be separated from research in the way proposed by the report.

One-half at least of all the subjects of research that have to be investigated can be undertaken better in Manchester than in Egypt—the report suggests Egypt. Establish in Manchester a College of Cotton—a Central Research Institution, as it has been called—where both experts and planters can be trained, in close and personal relationship with the great manufacturing interests. One such centre is quite sufficient, and far better than the proposed lectureships and readerships in half-a-dozen colleges or universities, where plant physiology, plant genetics, mycology, entomology, and the like might be taught. In the one, expert and practical men would be directly and immediately trained for cotton planting; in the other, general instructions would be given that might never mature into cotton planting at all. No risks of this kind should be run; general principles of education must never be allowed to take the place of specific training and definite results.

> The Indian Committee insist on the need for more detailed botanical investigation of the existing kinds of cotton in most of the cotton-growing tracts. . . . They consider selection as the first step in evolving better types, to be followed by plant-breeding, which, however, should be entrusted to selected officers who can devote personal attention and considerable time to it.

These passages we single out of the report because they denote acceptance of a most important issue. It has far too long been the habit of cotton experts to hold systematic studies up to ridicule. They have imagined that they were operating on certain species, or they have coined quasi-scientific names for equally illusory forms known to themselves but to no one else. There can be no manner of doubt that not only critical, but also even hypercritical, studies of all the species of Gossypium are imperatively necessary. The work accomplished in one country must be capable of immediate adoption in all others. This involves acceptance of definite specific standards throughout the Empire. No plot of land should, therefore, be cultivated with cotton, in the research experimental farms, without carefully prepared botanical samples being kept of the plant, of its seeds, and of its lint. These should be registered and preserved in both the herbarium and the museum, and, when found necessary, duplicates sent to all research stations, as also to the Central Research Institution. All further experiments could then contrast result after result, until definite progress had been established or the plant rejected as worthless. We require the history of each species to be worked out in the herbarium, and its habitat thereby fully established, before it can be accepted as a unit for investigation.

Then, in collaboration with a fully equipped home institution, there should be opened out branch institutions in each of the more important centres of cotton cultivation within the British Empire. Results worked out in Egypt might be quite unsuited to India, to Africa, or to the West Indies. Each important centre must discover and establish its own stocks. After the students had passed through the home college, they would be sent out to the branch college of the locality for which they were being trained, and made to study there practical cotton planting, as well as learn the local aspects of the industry. They might with advantage be also sent, for a few months, to an American college.

So much for Research and Instruction; but it is next to useless to talk of "investigation" and "education" if no rational scheme can be submitted, side by side, of immediate and direct application. In India, for example, cotton is grown exclusively by natives, each of whom owns but a very few acres. It is believed that the Government is averse to granting land (at present cultivated by the people) to be handed over to Europeans. Tea planting became a European industry because it was organised in uncultivated waste lands. It might, therefore, be recommended to the Government of India to make every effort to organise cotton plantations on such conditions as were found possible. The planter, for example, might be guaranteed against loss while given all profits, but subject after, say, twenty or thirty years to being bought out. If some such scheme could be carried through, it is highly likely that in a very few years cotton planting would be established on a sound commercial basis, and then for a certainty be greedily taken over by the people themselves. Moreover, were it made known in India that a large cotton-growing scheme had been organised by the Government, landed proprietors might be expected to send their sons to England to be trained for running home-farms. Since India is the largest cotton-growing country within the Empire, success there would give the most immediate results; but what may be said of India is doubtless more or less true of most other cotton-growing centres.

It has, however, to be demonstrated that high-class cultivation will pay in order to overcome the peasant cultivation of to-day, with its impecuniosity that precludes advancement. The planters would all be trained pupils of the college, and given the advantages arranged for on condition of carrying out the principles enjoined on them and also of using the stock supplied from the local research station; but their plantations should on no account become experimental farms. The planters should, so far as possible, be free agents. The local research stations would no doubt require experimental farms on which to raise and develop seed, and these should be provided, but every effort should at the same time be put forth to organise a European cotton-planting industry, or at all events an industry on European lines. Indian experience (see the report of the Indian Cotton Committee[1]) would seem to establish at least one great practical conclusion—namely, that there are certain very restricted areas within which the so-called long staples of India can be produced immediately. Assuming that to be correct, cotton planting on a large scale should be at once organised within these tracts as the initial step.

In America success may be described as having been due to three main causes: (*a*) There were no vested interests of native cultivators to contend against; (*b*) the cultivation was undertaken by Europeans who were mostly intelligent farmers; and (*c*) the planters finally rejected the imported stocks, brought from India and the Levant, and evolved purely American stocks. It was these American stocks that gave the world most of the prized fine long staples. The lesson to be learnt is that the three directions indicated should be kept clearly in mind through all future endeavours. We may not be able at once to disregard local vested interests, but we can take the most promising course of ultimately overcoming them—for many years to come, planting must be on European lines if success is to be attained; and finally we must evolve in each centre its own stocks from purely indigenous, or at least long-acclimatised, plants.

Disregard of the vested interests of the people is more dangerous than ignorance of the requirements of the plant. As the Indian Committee says (and very properly), the cultivator's interests are paramount. It is on that account sailing very much too near the wind to speak, as in the report, of "control of seed" and "compulsory measures against cotton pests." No one, of course, could doubt the value of the arguments set forth in these paragraphs, but in certain countries they are highly impracticable. They

[1] Report of the Indian Cotton Committee. (Published by Superintendent of Government of India Printing, 1919.) Price 2s.

could be applied in all Government farms and plantations, but what of the many millions of acres outside? No doubt it would be the most obvious solution of many pests to have a season, like the frost of winter in the United States and in the northern tracts of India, that would kill the cotton plant and the pests as well, so that next year's sowings would stand a chance of being clean. But in many parts of the cotton area of India two cotton crops are taken off the fields every year—the *uppam* and *nadam* of Madras, for example. Cotton may, in fact, be seen growing throughout the year in almost any province of India, one crop coming immediately after the other. The soil is often such that a good staple may be raised on one plot of land, and an inferior on another closely adjacent, and the seasons of their production often overlap. Obviously, while there could not be any compulsory orders that would deprive the individual of his rights, the persuasion of personal advantage, once established by the success of neighbouring large plantations, would in a few years secure all that could be desired.

The salvation of the position is thus the establishment of independent large cotton plantations, but the most serious difficulty is the discovery of the alternative crop or crops most convenient and profitable. It is not cotton growing only (like tea planting) that has to be faced, but systematic tropical agriculture with a full rotation of crops. This aspect of the problem the report has, of course, not dealt with, and has only general principles to offer.

The extension into new areas—more especially lands with rich soils that need only enhanced schemes of water supply to bring them into bearing—is most fascinating, but, as the Indian Committee points out, better results may be looked for from an increase in the average annual yield than from new areas. That view is certainly correct, and should be faced by some practical scheme, and not by a panorama of committees.

GEORGE WATT.

INDUSTRIAL AND MEDICAL RADIOLOGY.

THE extent to which radiology has widened its scope during recent years was strikingly brought out by the exhibition of radiographs held very opportunely by the Röntgen Society at the Royal Photographic Society's galleries during January and February.

Radiology has usually been regarded as a special province of the physician and surgeon, which provides them with a routine means of quick and exact diagnosis. But radiology is spreading its wings into branches of activity far removed from medical endeavour, and the widening of its physical scope cannot fail to react beneficially on the older branch of the subject.

Simultaneously comes the awakening of the medical faculty generally to the importance and promise of physical methods and physical agencies as a means of progress in medical research. There is little doubt that within a short time every large and progressive hospital will have a physicist of standing on its staff; and in this connection we would congratulate the Middlesex Hospital on the good fortune which enables it to establish what we believe is the first medical chair of physics in this country.

In particular, as regards radiology, the physicist will find work to hand in nearly every branch with which he comes in contact. Again, nearly all the problems of equipment and design are physical in character, and need physicists to tackle them, as America has already discovered to her profit. If the physicist can further obtain the co-operation of the electrical engineer, all-round improvements should speedily follow.

(a) (b)

FIG. 1.—(a) Radiograph of hand; exposure 20 mins; January, 1896. (Campbell Swinton.) (b) Radiograph of hand; exposure 1/100 sec.; December, 1919. (Knox.)

What of progress to date? The exhibition referred to here, although confined to radiographic prints, could very fairly be regarded as representative of present-day radiography, and as such it received generous approval from both the public and the Press. Some 200 prints were hung representing work by about thirty of the leading workers.

As a radiographer rarely takes his work beyond the negative stage, for the good reason that a print shows him no more, but usually rather less, than the negative, it was gratifying to find so high a pitch of photographic technique in the majority of the exhibits. On the other hand, few exhibitors had devoted much care or thought to the mounting of their work, a feature which a photographer would never be guilty of neglecting.

About half the exhibition was devoted to medical radiography, and the extraordinary progress that has been made since the discovery of the X-rays twenty-five years ago was strikingly brought out by the juxtaposition of two prints of the human hand (Fig. 1), one taken in January, 1896, by Campbell Swinton, with an exposure of twenty minutes, and the other in December, 1919, by Knox, with a single-impulse flash occupying about 1/100 sec. In the former the bones can be seen, though only blurred; in the latter (with 1/120,000 of the exposure) every detail is brilliantly portrayed. Knox further showed a fine series of flash radiographs of the chest (Fig. 2). Detection of stones in the kidney and bladder is now relatively straightforward work, as the constituent oxalates and phosphates are dense enough to cast good shadows. Until recently gall-stones (consisting chiefly of cholesterin) were deemed impossible of detection, but the radiographer acquires astounding skill in the interpretation of faint shadows, and both Thurstan Holland and Knox showed fine examples of success in diagnosing this troublesome complaint. Fig. 3 is an example of Thurstan Holland's work in barium-meal radiography.

FIG. 2.—Flash radiograph of chest. (Knox.)

FIG. 3.—Right iliac fossa after a barium meal, showing appendix, cæcum ascending colon (with "filling defect" due to malignant growth), an transverse colon. (Thurstan Holland.)

A number of war radiographs were shown; one calling for comment was by Finzi of a bullet in the heart of a man who, it may be added, is still alive. Of interest also was the radiograph of the hand of an Egyptian mummy—a princess of the Second Dynasty (1500 B.C.)—with a scarab ring on the third finger. (Evidently an X-ray equipment will have to be added to the Egyptologist's outfit!)

Some of the most attractive prints were those of shells and rare fossils taken by Rodman; the results reminded one irresistibly of the designs which the harmonograph traces out. Henri Beclere showed a new application of the rays in the radiographing of finger-prints. The skin is first rubbed over with red lead, and the radiograph shows the surface markings and openings of the cutaneous glands in so vivid a fashion as to suggest that the method would have advantages over that normally employed by the Criminal Investigation Department.

Several examples of negative prints on radiobromide paper were exhibited, the most remarkable being that of the skeleton of a man. This radiograph, which was contained on a single sheet, 8 ft. by 4 ft., was taken by Forder with a Coolidge bulb working 8 ft. away.

The use of the X-rays for revealing the interior of plant life is comparatively recent. Considerable differences exist in the mineral content and density, and hence in the transparency, of the different parts of a plant—root, stem, leaf, flower, fruit, seed, etc. It thus happens that even the most delicate structures of plants can be laid bare without tearing the plant to pieces in order to study it. Microscopic detail is, of course, not revealed. Long-waved X-rays are required for such work, of which Knox showed some good flower illustrations.

In the case of timber the different varieties absorb X-rays to different degrees. Peculiarities in the structure and course of the fibres (such as the contortions which produce "figure") are easily discerned. The denser heart-wood is differentiated from the sap wood, the summer and spring growths of the annual rings are readily identified, and defects such as knots or grub-holes show up with astonishing clearness. Kaye and Knox showed some radiographs of aircraft timber and timber-structures taken during the war on behalf

FIG. 4.—Radiograph of aeroplane hollow "box" strut, showing badly fitting internal end-block split by screws. (Kaye and Knox.)

of the Aeronautical Inspection Department (Fig. 4). The method is particularly useful in the case of hollow or laminated components, which cannot otherwise be thoroughly inspected except by destructive tests. Bad gluing, shoddy workmanship, and a variety of timber blemishes are detectable with ease, even on the fluorescent screen.

FIG. 5.—Golf balls, showing absence of core in "floaters" and irregular core in others. (Sunic Research Laboratories.)

There appears to be considerable scope for this branch of radiography.

The radiographing of minerals is an easy means of detecting the presence of very dense elements such as uranium or tungsten. Pilon showed a good example of the method. The structure of golf balls is a somewhat unexpected subject (Batten). The "non-floaters" are wound on a core of heavier rubber; some of the cores were spherical, but others were not—to the probable detriment of accuracy in long putting or driving. Undoubtedly the standardised championship balls of the future will have to satisfy an X-ray test!

A neat method of testing the electrically heated clothing of aeroplane pilots was shown by the Sunic Research Laboratories. The heating strip is sewn within the lining of the leather garment, and any break or kink in the element can easily be "spotted" on the fluorescent screen. The same laboratories showed radiographs of outer covers of motor and aeroplane tyres, and a variety of welds in metal tubes and plates, one of these of a steel plate $\frac{1}{2}$ in. thick being of particular excellence (Fig. 6). The Cox-Cavendish Co. showed a somewhat similar collection, and Chambers and Rankine displayed examples of their curious "diffraction" and multiple image X-ray photography.

Among the most novel exhibits were those by Heilbron illustrating the X-ray examination of old paintings with the object of detecting alterations or additions made since the original work. Success in discovering any such falsifications would be

FIG. 6.—Bad weld in steel plates $\frac{1}{2}$ in. thick. (Sunic Research Laboratories.)

possible only if the paint used in the original work were denser than that used in the additions. Some of the ancient pigments used by the masters are obscure in composition, but the blacks, for example, of a more modern day are largely carbon, and very transparent. Two examples of the method were shown, both by Dutch masters of the early sixteenth century. In one, a panel of the Madonna by St. Jans, the X-rays showed that the arms (which appear in a stiff and unnatural attitude) formerly held the Child, and in the other, the "Crucifixion" by Engelbrechtsz (Fig. 7), the radiograph revealed a number of "restorations," including the painting of the portrait of a former "donatrice" over the picture of a monk. As the *Times* remarked in a recent leader, this method of detecting the presence of later additions imposed on the work of the original artists suggests a great field for the re-investigation of palimpsests and ancient manuscripts hitherto regarded as carrying only their face value. Under the trivial inscriptions of medieval monks there may be revealed older matter of priceless worth. We commend the notion to the directors of the various art galleries and museums.

Space considerations have compelled a somewhat invidious selection of exhibits for comment, and we have had to leave much interesting and clever work unnoticed. But, granting the scope and versatility of the attack, we venture to predict that the exhibition will be as nothing to a similar one held, say, in five or ten years' time. Great improvements are imperative, and will doubtless be forthcoming, in the means of registering X-rays. Photographic plates and fluorescent screens need to be improved out of recognition. A good explorer for use in radio-metallography could doubtless be evolved by means of the thermionic valve, as in wireless telegraphy.

With improved equipment radiology will acquire powers which will give it acknowledged status among the sciences, and medical radiology will find an unquestioned place in every medical curriculum. The diploma of medical radiology established last term by the University of Cambridge is a first step. An even bigger one would be the setting up of an X-ray institute in London, which, properly staffed and equipped, would lead to incalculable progress. We understand that such an institute forms part of a forthcoming memorial scheme to the late Sir James Mackenzie Davidson, which we trust will command generous support.

G. W. C. KAYE.

REAR-ADMIRAL R. E. PEARY, U.S.N.

THE death of Rear-Admiral Peary at Washington on February 19, at the age of sixty-four, removes one of the most remarkable of modern explorers. It is not so much to the crowning achievement of his life in reaching the North Pole that Peary's claim to the respect of the geographical world is due as to the manner in which he persevered, in the face of almost overpowering difficulties, with very slender resources in a cumulative effort to succeed. The really remarkable thing about Peary is that the method by which he achieved success was practically independent of modern developments in the art of travel. Before very long the North Pole will be accessible by aircraft; it is possible that it might have been attainable years ago by a steamer in an exceptionally open season, but Peary reached the Pole without mechanical help, by the exercise of the powers of human mind and body alone; and had he been a contemporary of Hudson or of Davis there seems to be no reason why his genius could not have won success in the sixteenth or seventeenth century as well as in the twentieth.

Peary's professional training was that of a land-surveyor and civil engineer, and from early youth he was accustomed to find his way through unmapped solitudes and to survey routes hitherto untrodden. He was engaged, amongst other things, on the survey of the abortive Nicaragua Canal after he had joined the civil engineering branch of the United States Navy, and his naval rank must not be taken to imply that he was in any sense a sailor. His official work lay in the construction of harbours and dockyards, and the world owes a debt to the enlightened chiefs of the United States Navy, who recognised that they were making a wise use of their powers in granting this born explorer unlimited leave for Arctic work.

Peary was led to visit Greenland for the first time in 1886 on account of his interest in Baron Nordenskiöld's journey on the inland ice, and he returned from the trip determined to continue the exploration of the ice-cap in its least-known parts. In 1891–92 he spent thirteen months in northern Greenland, establishing himself amongst the Etah Eskimo on Whale Sound, and making a 1200-mile journey with dog-sledges to the north-eastern extremity of Greenland. In 1893–95 he spent twenty-five months in travelling from the same headquarters and proved the insularity of Greenland. The result of his three years' life with the Eskimo was not only to make a thorough anthropological study of the tribe, but also to secure the personal friendship of every member of it, and to become intimately acquainted with the character of every individual, so that, in selecting travelling companions from amongst them, he knew in advance what their powers were and how far they could be trusted. He found that it was possible to live with the Eskimo as one of themselves, and so to make himself independent of the luxuries, and even of many of the supposed necessities, of civilised life without diminishing his power of travelling or of scientific study.

In 1896 and 1897 Peary made summer trips to the north-west coast of Greenland, and brought back from Cape York the famous mass of meteoric iron weighing 90 tons the existence of which had been reported by Sir John Ross nearly a century earlier. The description of the shipping of this mass of metal on a small vessel with no appliances save those which could be improvised on the spot showed how Peary, in becoming an explorer, had not ceased to be a very able civil engineer.

By this time Peary's plan for reaching the North Pole had been fully matured. He resolved to transport a picked contingent of the best of the young men of the Eskimo tribe he knew so well to the farthest north point accessible by sea, and to leave them there with their wives, families, and full equipment in an absolutely normal settlement where they would be happy and contented. From this base he was to travel north as far as the land extended by easy stages, and make a second settlement of the best natives at that point. Thence he proposed to make a continuous march over the sea ice to the Pole and back, waiting for a favourable opportunity, and spending the waiting time, whether it should be weeks or years, in studying the effects of wind and tides on the ice-movements. Lord Northcliffe presented to him the steamer *Windward*, which had done good service in the Jackson-Harmsworth expedition to Franz Josef Land, and, under the auspices of the Peary Arctic Club of Philadelphia, Peary set out on his great task in 1898. It was 1902 before he returned, having reached only 84° 17′, but, in spite of the severest hardships, he was more convinced than ever of the soundness of his method of exploration. In 1904, while recovering from his privations, Peary presided over the Eighth International Geographical Congress in Washington and New York, impressing all who attended that brilliant meeting with the confident, yet modest, assurance of his ultimate success by the methods he had worked out.

In 1905 Peary started in the new exploring ship *Roosevelt*, but had to return in 1906 with no greater success than the attainment of latitude 87° 6′, the farthest north that had been reached so far. Finally, in 1908, he went north for the seventh time, again in the *Roosevelt*, and at last, by the perfected working of his original plan, he hit the fortunate trend of ice and weather and reached the North Pole on April 6, 1909. It will be remembered how the pleasure of this triumph was marred by the pretension of Dr. F. A. Cook to have attained the Pole a year earlier; but the unfortunate controversy held at least this crumb of comfort, that Cook's claim, unfounded as it was, was to have attained success by Peary's method of travelling with trusted Eskimo.

Peary had a fine presence and a forceful diction in speech and writing, his books are amongst the most stimulating for the reading of young explorers, and his careful inductions and thoroughly reasoned plans are a model to all who have to do with the promotion of exploration. He was supported in all his efforts by his wife, who accompanied him on two of his expeditions.

H. R. M.

ROBERT ETHERIDGE.

MR. ROBERT ETHERIDGE, director of the Australian Museum, Sydney, died on January 4 last at the age of seventy-three years. He was active almost until the end, still occupied with research, and his decease is a serious loss to Australasian science. The only son of the late Mr. Robert Etheridge, palæontologist to the Geological Survey of Great Britain, and afterwards assistant-keeper of the geological department of the British Museum, Etheridge adopted the profession of his father, and made many important contributions to our knowledge of the fossils of both Australasia and Britain. Beginning his career on the first geological survey of Victoria, Australia, he returned in the early 'seventies to become palæontologist to the Geological Survey of Scotland, where he not only did important official work, but also co-operated with the late Prof. H. A. Nicholson in describing the Silurian fossils of Girvan, Ayrshire. From 1878 until 1887 he was assistant in the geological department of the British Museum, where he joined the late P. Herbert Carpenter in the authorship of the "Catalogue of the Blastoidea," which still remains the standard work on these fossils.

Colonial life, however, had special attractions for Etheridge, and in 1887 he returned finally to Australia as palæontologist to the Geological Survey of New South Wales and to the Australian Museum. He started two new serials, the Records of the Geological Survey and the Records of the Australian Museum, and published many memoirs and papers on Australian fossils. He also joined R. Logan Jack in preparing two handsome volumes on "The Geology and Palæontology of Queensland and New Guinea," which were published in 1892. In 1895 he succeeded E. P. Ramsay as director of the Australian Museum, but his new administrative duties did not damp his ardour for research, merely extending its scope. He added a deep interest in the aborigines to his earlier pursuits, and wrote, among other works, valuable memoirs on the dingo and on the sculpturing of sacred trees.

Etheridge was always absorbed in his science, and shunned ordinary social life, so that his real good nature could be appreciated only by a very small circle of intimate friends. His scientific worth, however, was widely acknowledged, and he received the Wollaston Fund from the Geological Society of London in 1877, the Clarke medal from the Royal Society of New South Wales in 1895, and the Mueller medal from the Australasian Association in 1911. His name is also associated with the Etheridge goldfield in North Queensland, a high peak on the Kosciusko tableland, and a glacier in Antarctica.

A. S. W.

NOTES.

THE report of observations of a gigantic dinosaurian reptile in the Congo region of Africa, which was made the subject of sensational articles in December last, proves, as we surmised (NATURE, December 18, p. 396), to be without foundation. Mr. Wentworth D. Gray, Acting Representative of the Smithsonian African Expedition in the Katanga, writing from Elisabethville on January 21 to the *Times* of February 23, says:—"I am authorised to contradict the statement that the members of the Smithsonian African Expedition who proceeded to this territory came here to hunt the Brontosaurus. There is no foundation for this statement. I may also state that the report of the Brontosaurus arose from a piece of practical joking in the first instance, and, as regards the prospector 'Gapelle,' this gentleman does not exist except in the imagination of a second practical joker, who ingeniously coined the name from that of Mr. L. Le Page."

THE first meeting since 1914 of the International Council for the Exploration of the Sea will be held in London on March 2. Delegates will be present from Belgium, Denmark, France, Finland, Holland, Norway, and Sweden. Russia and Germany are not represented, and France sends delegates for the first time. The German investigations, it is now known, have been resumed, and the steamer *Poseidon* has been working at sea since last September. The council, it is expected, will consider arrangements for the resumption of the pre-war investigations, and will devote special attention to tracing the effects of the restrictions on fishing during the war period on the abundance of fish in the North Sea. Proposals for the closing of certain North Sea areas against steam-trawling are, it is understood, to be considered. Arrangements are being made by the British Fishery Departments for an early beginning of an extended programme of research. The question of the inclusion of Germany has not yet been considered, but it is believed that there is a growing feeling in this country that she should be invited to participate.

THE Home Secretary, Mr. Shortt, announced in the House of Commons on February 24 that it is proposed that summer time shall begin on March 28 and end on September 27.

WE regret to announce the death, at seventy-five years of age, of Prof. J. Emerson Reynolds, F.R.S., professor of chemistry and chemical philosophy in Dublin University from 1875 to 1903.

MR. J. S. DUNKERLEY, of the University of Glasgow, and Mrs. E. W. Sexton, of Plymouth, have been appointed Ray Lankester investigators at the Marine Biological Laboratory, Plymouth.

THE lecture entitled "Some War-time Efforts in Chemical Industry at Gretna," arranged to be given by Mr. J. C. Burnham before the fellows of the Chemical Society on March 4, has been unavoidably postponed. The usual ordinary scientific meeting for the reading and discussion of papers will be held on that day.

AT the meeting of the Chemical Society held on Thursday, February 19, it was stated that the following changes in officers and council had been proposed by the council:—As secretary, Dr. H. R. Le Sueur *vice* Prof. S. Smiles. As vice-presidents, Prof. J. B. Cohen and Prof. S. Smiles *vice* Prof. A. Smithells and Prof. S. Young. As new ordinary members of council, Prof. A. J. Allmand, Dr. E. F. Armstrong, Mr. F. H. Carr, and Dr. J. T. Hewitt.

A DEPARTMENTAL Committee has been appointed by Dr. Addison to consider the present state of the law with regard to the pollution of the air by smoke and other noxious vapours, and to advise what steps are desirable and practicable to diminish the evils still arising from such pollution. The members of the Committee are:—Lord Newton (chairman), Capt. Hamilton Benn, Prof. J. B. Cohen, Mr. S. Curphey, Sir John Lithiby, Mr. J. F. MacCabe, Mrs. Gilbert Samuel, Mr. E. D. Simon, Bailie W. B. Smith, and Mr. F. J. Willis. Mr. E. C. H. Salmon, of the Ministry of Health, will be secretary, and any communication should be addressed to him at the Ministry, Whitehall, S.W.1.

THE officers and council of the Physical Society elected at the annual meeting on February 13 are as follows:—*President:* Prof. W. H. Bragg. *Vice-Presidents:* Dr. H. S. Allen, Prof. W. Eccles, Prof. A. S. Eddington, and Dr. R. S. Willows. *Secretaries:* Dr. D. Owen (Birkbeck College, Bream's Buildings, London, E.C.4) and Mr. F. E. Smith (National Physical Laboratory, Teddington). *Foreign Secretary:* Sir Arthur Schuster. *Treasurer:* Mr. W. R. Cooper (82 Victoria Street, S.W.1). *Librarian:* Dr. A. O. Rankine (Imperial College of Science and Technology). *Other Members of Council:* Mr. C. R. Darling, Prof. C. L. Fortescue, Dr. E. Griffiths, Dr. E. H. Rayner, Dr. A. Russell, Sir Ernest Rutherford, Dr. G. F. C. Searle, Mr. T. Smith, Dr. J. H. Vincent, and Mr. F. J. W. Whipple.

THE *Morning Post* of February 17 contained an article from its correspondent in Paris stating that three days previously he had witnessed five experiments at a works in the northern suburbs of the city, each of which involved the production of a ton and a half of "high-class steel." At the present time such steel is made either in crucibles or in an electric or an open-hearth furnace. The novelty of the experiments referred to consists in the fact that the steels are made in some form of "converter" of the Bessemer type. Usually this process does not give a sufficiently scientific control of the product to enable high-class steels to be made. It appears from the account given that certain "secret substances" are added which have the effect of controlling the quality of the metal produced, so that it can be used as a basis for the manufacture of high-grade alloy steels. The process is said to have been worked out by four inventors, two of whom are Belgians. The demonstration was witnessed by about a dozen metallurgical experts, who were engaged in taking samples for tests. If the claims of the inventors are substantiated the process will be one of considerable practical importance, and further details will be awaited with interest. It is stated that they have decided not to patent their method, but to operate it as a secret process.

NEWS has just been received of the death at Cairo of Mr. Henry Gribble Turner at the age of seventy-seven years. Mr. Turner joined the Madras Civil Service in 1864, and soon gained a reputation by his successful management of the wild tribes of Vizagapatam district on the east coat, a region where the practice of human sacrifice in honour of the Earth goddess had recently been discontinued. After holding for a time the office of Postmaster-General, he returned to his old district, Vizagapatam, which he administered with much credit until his retirement in 1889. It was due to Mr. Turner that, in the face of great opposition, the standard-gauge railway linking Calcutta with Madras was constructed. He was a skilled mineralogist, and discovered the Vizagapatam manganese deposits, the trade in which has so rapidly developed that the total export is now 600,000 tons annually. He also started the export of Indian magnesite, which proved most useful during the war. Another of Mr. Turner's projects was a harbour at Vizagapatam to serve the rich uplands of the interior, a scheme which is now at last to be undertaken. He failed to secure election as Member for South Somerset in 1895, and he thus escaped the fate of more than one distinguished Indian administrator who did not succeed in making his mark in the House of Commons.

THE committee of the Sheffield Museums and Mappin Art Gallery has issued a consolidated report for the last five years. Special attention is directed to an exhibition relating to infant welfare which was held in 1916. The exhibits were of a comprehensive character, and a series of descriptions was prepared by Dr. Scurfield, Medical Officer, and Dr. Lucy Naish, which is now republished. The instructions in all questions relating to the care of children are elaborate and arranged with full knowledge and much common sense. The authorities of other provincial museums might consider the advisability of reprinting the pamphlet, which is likely to be of much utility.

IN the February issue of *Man* Mr. A. C. Breton describes a remarkable picture-map from Mexico in the manuscript department of the British Museum. The museum authorities acquired the map from Mr. H. Stevens, who, in his turn, purchased it from the original finder, Col. Campos. It was found on the site of the ancient Indian city of Metlaltoynca, in a stone chest which appears to have formed the pedestal of an idol. Several remarkable statues have been found on this site, and the building depicted in the centre of the map is somewhat like the existing Castillo, a pyramid on a base with six high steps and a platform, on the summit of which are buildings. The interpretation of the figure-groups in the map is still to some degree uncertain, but its publication will doubtless lead to an elucidation of its meaning.

THE identification of two statues in the Indian Museum, Calcutta, found at Patna about a century ago, has aroused much interest among Indian archæologists. The question of the date of these statues and of the inscriptions engraved upon them is discussed in vol. v., part 4, of the Journal of the Bihar and Orissa Research Society. Dr. Vincent Smith, in one of the last articles that came from his pen, was disposed to believe that they are portraits of two kings who reigned in the fifth century B.C. This conclusion, if it be correct, revolutionises the current view of the development of Indian art, because hitherto it has been supposed that stone sculpture began in the time of Asoka, who reigned some two centuries later than the assumed date of the Patna statues. Moreover, the execution of these presupposes a long prior development of plastic art. But it must be remembered that the dates of the statues are not yet quite certain, and the question is still under discussion by archæologists.

IN *Sudan Notes and Records* (vol. ii., No. 4, October, 1919) Prof. G. A. Reisner announces the discovery for the first time in the Nile Valley of a horse cemetery. The graves were in four rows, and four complete skeletons were discovered, the horses being of a short, small breed, not unlike the Arab. Each horse was buried with its chariot trappings—they were not ridden at that period—and placed upright with the head towards the south. The regular spacing of the graves, the division into rows, the chronological order of the rows, and the uniformity of the graves in each row justify the conclusion that these horses were sacrificed at the funerals of the kings in order that the spirits of the horses might accompany the spirits of the kings into the other world. The idea is widespread, but in this special form it was hitherto unknown in Egypt. But excavations recently made at Kerma show that the sacrifice of men and animals at funerals was a well-established ancient Ethiopian custom. In fact, there seems reason to believe that horse-sacrifice was due to King Piankhy, who was a great connoisseur of horses, as is proved from his inscriptions.

PROF. C. E. A. WINSLOW, in an address to the American Association for the Advancement of Science entitled "The Untilled Fields of Public Health," expressed the opinion that the public health campaign of the future would need the collaboration of at least the seven following types of highly qualified experts: the physician, the nurse, the bacteriologist, the epidemiologist, the engineer, the statistician, and the social worker. In addition, there must be inspectors to supervise sanitary and housing conditions, and, finally, the administrator who organises and develops the work of all the rest. The latter ought to be medically trained, with subsequent specialisation in public health (*Science*, January 9, p. 23).

THE February number (vol. i., No. 5) of *Medical Science: Abstracts and Reviews*, published for the Medical Research Committee, has reached us. Reviews of current work on medical subjects appear monthly, diseases of the respiratory system and cardiovascular diseases, among others, being dealt with in this issue. In the article on the former, reference is made to the question of the production of emphysema of the lungs (a condition of permanent distension with other changes) by the playing of wind-instruments, as is stated in many text-books. Of forty-six professional players examined, in only three was there slight evidence of emphysema, so that the commonly accepted view seems to be without foundation.

WE have received the quarterly report of the Research Defence Society, dated January, 1920, when the society completed its twelfth year of active work. The society was founded to make known the value and the necessity of experiments on animals, the restrictions imposed on them in this country under the Act of 1876, the nature and the purposes of the experiments which are being made, and the discoveries which have come by the help of the experimental method; also to bring about a better understanding between the few who make these experiments and the many who profit by them. The campaign has been carried out by the circulation of pamphlets, by articles in the Press, and by public lectures. The president of the society is Lord Lamington, and the hon. secretary Mr. Stephen Paget.

MAJOR-GEN. SIR W. LEISHMAN publishes in the *Lancet* of February 14 (p. 366) the results of protective inoculation against influenza in the Army at home during 1918–19. The vaccine consisted of a mixture of three micro-organisms, the influenza bacillus, streptococci, and pneumococci. Among the inoculated, numbering 15,624, the incidence per thousand was:—Of attack, 14·1; of pulmonary complications, 1·6; and of deaths, 0·12. Among the uninoculated, numbering 45,520, the figures were 47·3, 15·3, and 2·5 respectively. At least half of the vaccinated received one dose only, and not two doses as recommended, and the vaccine used at first was considerably "weaker" than that used later. Nevertheless, the figures are decidedly favourable to the value of vaccination, particularly as a preventive of mortality from influenza.

MR. E. E. LOWE, in the *Museums Journal* (vol. xix., No. 7), utters a timely word of warning to the curators and governing bodies of local museums in regard to the haste they are displaying to be taken over by the Board of Education, as recommended by the Adult Education Committee of the Ministry of Reconstruction. If this fate ever overtakes them they will have ample time for unavailing repentance. Mr. Lowe's arguments are stated with considerable ability and force, and his views on the functions of museums are eminently sound. The modern museum, he urges, should, among other things, be educational, but he points out that it would constitute a grave error of judgment, as well as a breach of trust, to hand over museums to the local education authorities.

FROM *California Fish and Game* (vol. vi., No. 1) we learn that extensive plant is being set up at Tropico, California, for the preparation of agar-agar on a commercial scale. Experiments have been carried out which seem to show that agar-agar of a quality much superior to the imported article can be produced from the seaweeds native to the coast of southern California. If this venture is successful, it will create a new industry for the United States. In the same issue a series of figures illustrating the growth of the young of the black sea-bass or jew-fish (*Stereolepis gigas*) is given. These furnish a very striking illustration of the "recapitulation" theory, and explain how it is that the fishermen were unaware of the connection between the gaily coloured fish of a few inches long, with enormous dorsal and ventral fins, and the unicoloured giant in which these fins are relatively extremely small.

THE very handsome volumes issued in 1916–18 by the Maryland Geological Survey have now become available in Europe. They are largely a memorial to the energy of the director, William Bullock Clark, who held office for twenty-five years, dying at too early an age in 1917, and whose obituary, with a portrait, appears in vol. x., which includes his latest educational work, "The Geography of Maryland." This is now published as an amplification of the treatise already used in the State schools. Part 2 of this volume deals with water-supply, and the somewhat massive style of publication—a heritage from the traditions of the United States Geological Survey—makes one wish that the geographical part could have been issued separately bound. Mr. Clark and his staff also contribute two fully illustrated volumes on "The Upper Cretaceous Deposits of Maryland." These occur mainly on the left bank of the Chesapeake Inlet, opposite Baltimore, and are specially noted for their dicotyledonous flora. The Maryland Geological Survey, in continuation of its series of county descriptions, which recall the ambitious scheme of the Ordnance Survey of Ireland in 1837, published in 1917 its memoir on Anne Arundel County; this is written by a number of specialists, so as to present the area south of Baltimore from a geographic point of view. The co-operation of the United States Geological Survey enables this finely illustrated work to be accompanied by four large folding maps on the scale of 1/62,500 (four times that of the 1/250,000 sheets), showing the topography and political divisions, the geology, the soils, and the forestry and commercial areas.

The scientific portion of the *Central Zeitung für Optik und Meckanik* for January 1 contains the first of a series of articles by Prof. von Rohr on the principal points of optical systems and the graphical methods of determining images. The constructions given are those suitable for convex and concave systems of which the principal planes and foci are given. The industrial portion includes a reproduction of the new regulations under which optical workers of eight years' standing may attend shortened courses of instruction at the Government optical school at Jena and, after a qualifying examination, obtain the optician's diploma. A list of the optical and other instruments for which there is at present a demand in foreign countries is given. The wages paid to the various grades of workers in metal in the principal countries of the world form the subject of a further article. A list of the publications of the German Committee on Standards for Industry is provided, and the importance of the rapid adoption of the new standards throughout the country is emphasised. Coloured wall-charts have been prepared, so that the information may readily be placed before the eyes of designers, foremen, and workmen.

In a paper in the *Chemical Age* of February 14 Dr. Stephen Miall plots the atomic weights of the elements against their atomic numbers, and shows that all the elements lie upon a series of parallel lines of three different slopes. The atomic weights may be represented as $bx+a$, where x is the atomic number, a a small integer ranging from 0 to 5, and b has the value 2 for the elements from helium to nickel, 2·5 from copper to tungsten, and 3 from osmium to uranium. The first term, which contributes to the chemical character, he terms "live-weight," and the second term, which is of no influence on the chemical character, "dead-weight." Similar regularities have been previously pointed out, and, indeed, since the atomic weights for the most part conform to integral values, some such relation as the above is necessarily true. But the diagrams have a value apart from their interpretation. They suggest a novel basis for classification, and arrange the elements on parallel lines for which a and b have the same values. They may be useful to those seeking for regularities in the nuclear structure rather than in the atomic shell. Hitherto chemists have been too exclusively obsessed with the study of chemical character to the neglect of the atomic weight—an independent variable, as the study of radio-active change has made quite clear. The atomic weights, however, as the author remarks, mean something. They furnish the only present clue to the structure of the nucleus.

The Carnegie Institution of Washington has issued another section of its monumental "Index of Economic Material in Documents of the States of the United States." The section, prepared by Adelaide R. Hasse, is the first instalment of the index relating to the State of Pennsylvania. Part i. contains the titles of collected documents, mainly printed by authority of the Senate and of the House of Representatives. Part ii. is a topical analysis arranged alphabetically from A to E. Among the longer sections we find Agriculture, Canals, Climate, Coals, Coal-mining, and Education. The period covered is from 1790 to 1904. The new volume has been preceded by twelve similar quarto volumes, and will be followed by others, each devoted to a single State. The index undertakes to deal only with the printed reports of administrative officers, legislative committees, and special commissions of the States, and also with Governors' messages. References are given by volume and page to all material of economic importance contained in the reports and messages indexed. Under each sub-heading the arrangement is chronological. In the alphabetical part the compiler has introduced, in addition to subject entries, the names of persons who have exercised an important influence on the development of the economic life of the State. After each name there is reference to work done. The amount of material which had to be examined for the preparation of this volume must have been very great.

A short but useful list of books on ornithology and oology (No. 398) has just been circulated by Mr. F. Edwards, 83 High Street, Marylebone, W.1. It contains some two hundred and fifty items, including several long runs of serials such as the *Ibis*, Transactions and Journals of the Royal Microscopical Society of London, Proceedings of the Zoological Society of London, etc. The list is sent free on application.

OUR ASTRONOMICAL COLUMN.

Holmes's Comet.—Dr. Schorr reports that the cometary object 1919*f*, found on two plates taken at Bergedorf by Dr. Baade on December 10, is definitely not identical with Holmes's comet, as it failed to appear on two plates taken on December 26, on which it would have been registered if it were moving in accord with the ephemeris calculated for that comet.

Minor Planet GM.—This is the object discovered by Señor Comas Sola on January 13, and considered for a time to be a comet. As it is the brightest minor planet discovered in recent years, it is of interest to give the elements which have been deduced at the Berkeley Observatory, California.

	R.A. h. m. s.	N. Decl. ° ′	Mag.
February 28 ...	7 25 26	17 33	11
March 7 ...	7 24 54	16 44	

Nova in Lyra.—Harvard Bulletin No. 705 reports the finding of another nova on the Harvard photographs by Miss Mackie. Position for 1900·0, R.A. 18h. 49m. 3cs., N. decl. 29° 6·3′. Between December 4 and 6 it rose suddenly from mag. 16 or fainter to mag 6·5; on January 6 it had sunk to 8·5. Messrs. Adams and Joy report from Mount Wilson that its spectrum shows the striking nova characteristics.

The same message reports that these observers find remarkable changes in the spectrum of Mira Ceti, the bright helium and hydrogen lines being strengthened and widened towards the red.

TIDES IN PIPES.—In 1914 Messrs. A. A. Michelson and H. G. Gale made a preliminary investigation of the tidal changes in water-level in two pipes, each 502 ft. long, placed respectively along a meridian and a parallel, in the grounds of the Yerkes Observatory. They have now made a more refined series of observations (described in the *Astrophysical Journal* for December). The small changes of water-level are registered by photographing interference fringes produced by placing a mirror about ½ mm. below the surface of the water, and passing a beam of light from an electric lamp vertically down through the water-film, then reflecting it on emergence into a camera in which a sensitive film is moved by clockwork at the rate of 2 cm./hour. Some of the photographed curves are reproduced, and show a beautiful accord with the theoretical curves, which were carefully calculated by Prof. F. R. Moulton. The transition from spring to neap tides, and even the difference in height of alternate semi-diurnal tides, are obvious at a glance. The result shows that the pipe tides are 0·690 of what they would be on a rigid earth, so that the bodily tides in the earth's crust are 0·310 of what they would be if the earth were fluid. The earth tides appear to lag behind the impressed forces by 4°. This method avoids many of the complications that are present in the observation of ocean tides; it also appears to be capable of greater relative precision, in spite of the smallness of the quantities involved.

There appears to be a slip in the value of the rotational velocity ω (p. 350); it is printed as 2π sidl. day/solar day, but surely it should be 2π solar day/sidl. day, the mean solar day being the unit of time employed.

LUMINOSITY IN CENTIPEDES.[1]

AS Chilopoda have been traced back to the Carboniferous age by the palæontologists, these centipedes may be presumed to have understood their own interests pretty well in the struggle for existence. *Geophilus electricus* (Linn.) had already won the attention of Aldrovandi in the sixteenth century, and the specific name adopted for it by Linnæus was obviously based on its observed luminosity. The notes now under review state that among the centipedes only one great group, the Geophilimorpha, is known to exhibit the phenomenon.

With so long a history for the group in the modern period, it seems strange that biologists should still need to ask in regard to some of its species, which are by no means uncommon: Why are they luminous? Even those keen observers, Mr. and Mrs. Brade-Birks, after minute examination, with the aid of friends, and critical comparison of recent authorities, leave the subject inconclusively concluded. Microscopists will read with pleasure details of the contrivances by which they persuaded their many-legged, wriggling subjects, under just the friendliest squeeze, to sit for their portraits. As definite result of their careful study of *Geophilus carpophagus*, they "conclude that in the excretion which accompanies luminosity there are generally present: (i) the contents of the white glands, for [which they] propose the name of *protoluciferin*, (ii) mucin, (iii) acid." The expression "white glands" seems to be used rather vaguely, as applying to certain white, rounded masses on the ventral parts of the specimen, these masses being "groups of pyriform, and probably unicellular, glands intimately associated with the production of light." But it is not made clear whether whiteness is a property of individual glands or only an effect of their grouping into opaque masses.

For an understanding of the debate on the value of lighting up as displayed in this very limited section of the animal world, Dr. Shipley's brief notice may usefully be quoted. He says:—"Some members of the family Geophilidæ are phosphorescent, and secrete from certain glands on the ventral surface a luminous slime; since this is produced by both male and female, and neither of them has eyes, the secretion is regarded as a means of frightening or warding off enemies. The male Geophilus spins a web, and drops a spermatophore in the middle of it, and the female comes and fertilises herself" ("Zoology of the Invertebrata," p. 315). The present collaborators suggest that, without specialised organs of sight, the Geophilids "may be able to appreciate light by a general absorption of its waves through the surface of the body." Though this inchoate power of vision might be otherwise of service, it could scarcely help in bringing the two sexes together, and the riddle is complicated by the fact that allied species without luminosity seem to arrange their affairs very well in its absence.

In general, experience has shown that animals, other than beasts of prey, are not frightened, but attracted, from a dark environment by illumination, so that among the alternative services of *protoluciferin* suggested by the authors any scaring property may be set aside as very improbable.

The systematist is now warned by our authors that *Stigmatogaster subterraneus* should be attributed to Shaw. So lately as last December, in Nevin Foster's list of fifty-three Irish Myriapods, they sanctioned the long-standing error of assigning the species to Leach. They acknowledge themselves baffled by the specific name of *Geophilus convolvens*, on which Fabre founded his researches. This is said to be not a phosphorescent species. Otherwise one might have supposed the name evolved from the strange account which Lucas cites out of the *C.R. Acad. médicale des sciences de Metz* in 1830. This records the frightful tortures in the head of a young Frenchwoman, which after a year were suddenly terminated "par l'expulsion d'un insecte qui, jeté sur le plancher, s'agitoit avec rapidité et se rouloit en spirale." It, however, was determined to be a specimen of *Geophilus carpophagus*, Leach. Gistel in 1850, writing of the Feuerwurm *Geophilus electricus*, alludes to the story, but does not, in fact, discredit it by remarking that such a species could not penetrate the frontal cavities of a human head unless the owner of the head were asleep.

THE POSITION OF THE METEOROLOGICAL OFFICE.

AT the monthly meeting of the Royal Meteorological Society, held on February 18, Capt. C. J. P. Cave brought forward a paper on "The Status of a Meteorological Office and its Relation to the State and to the Public." It was pointed out that a Meteorological Office is a practical necessity, and, since to be at all efficient it must be subsidised from public funds, it has to be under some Government Department. The work of a Meteorological Office is, however, very wide, and concerns, not one, but almost every Government Department; and if it is to be under one without adequate safeguards, there is a great danger that many important sides of meteorology will be neglected. Safeguards are that the Director of the Meteorological Office should be directly under the Minister of the Department concerned, and on no account under other permanent officials, and that the Meteorological Office should have its separate vote and account in the Estimates. Hitherto the expenses have been controlled by the Meteorological Committee, a body on which several Government Departments as well as the Royal Society are represented; there seems to be no reason why this arrangement should not be continued. The work of the Meteorological Office concerns not only Government Departments, but also such bodies as county councils, municipal bodies, organisers of engineering undertakings, and the general public; and probably none of these know how great a use may be made of meteorological information.

The public is chiefly concerned with forecasts, and probably the mistrust of forecasts which undoubtedly exists in the public mind is due to the delay that occurs before the forecasts are available. Those that appear in the daily papers are based on observations at 6 p.m. of the previous day, but if forecasts based on the 1 a.m. or 7 a.m. observations were sent to every telegraph office in the country and posted up, and could be obtained by telephone subscribers, it would probably prove a great boon, especially to agriculturists, and do much to dispel the present mistrust of weather forecasts.

During the past year the Meteorological Office forecasts have been issued from the Air Ministry, and in the Air Estimate there appears a sum for the Meteorological Office. From this it appears as though the Office is to pass under the Air Ministry. In former times when any change was made in the status of the Office an official inquiry was held, but no such inquiry has apparently taken place as a prelude to the present change, and no public announcement of any kind has been made. There seems no reason for the change. The Meteorological Office had done work on the upper air long before the war, and it was its work which proved that long-distance night flying was a practical possibility. Meteorology must be a national Service, but the policy of handing it over to one Ministry without a separate vote and account would be disastrous, not only to meteorology as a science, but also to the State at large.

The following resolution was adopted at the meeting:—"The Royal Meteorological Society observes that in the Air Estimates for 1919–20 published last December there appears a sum of 12,000*l.* as a supplement to the grant in aid of the Meteorological Office. It would appear from this that it is intended that the finances of the Meteorological Office shall pass under the control of the Air Ministry.

"The Meteorological Office deals with a variety of problems of high scientific and practical importance, some of which have no bearings on the work of the Air Ministry, but are closely connected with the work of other Government Departments. While recognising to the full the great benefits to the meteorology of the upper air likely to accrue from a close association with the Service to which a knowledge of the upper air is so essential, and which possesses such facilities for its investigation, this society cannot but feel misgiving that there may be a tendency for other branches of meteorology to receive less than their due attention if one Government Department has the sole control of the finances and management. The society, therefore, is of opinion that the Meteorological Committee should continue to have full control of the expenditure.

"It has been the practice in the past, before any change was made in the body administering the Meteorological Office, for an inquiry to be held by a Departmental Committee. Reports of three such inquiries have been published, the last being that issued in 1904 of a Treasury Committee presided over by Sir Herbert Maxwell, Bart. The Treasury did not adopt the whole of the recommendations of this Committee, but on May 20, 1905, it issued a minute constituting the Meteorological Committee as it has since existed. The society is of the opinion that before the future constitution of the Meteorological Committee and the status of the Meteorological Office are finally settled, it is desirable that an inquiry by a representative committee should be held."

PRE-HISTORY OF MAN IN BRITAIN.

Flint Implements from the Chalky Boulder Clay of Suffolk.

MR. J. REID MOIR described to the Royal Anthropological Institute on February 17 some interesting flint implements and flakes found in two pits situated to the north of Ipswich, and in a pit at Claydon, to the north-west of that town. In each of these pits Boulder Clay of considerable thickness is exposed, and this deposit, in the opinion of Prof. J. E. Marr, who has visited the sections, is *in situ*, and represents part of the large sheet of Boulder Clay of the Ipswich district. Mr. Reid Moir found many of the specimens described *in situ* in the Boulder Clay, and the others, handed to him by workmen employed in the pits, are of such an order as to make it certain that these implements were also derived from the Boulder Clay. The specimens are in nearly every case made from flakes, and exhibit very little change of surface or signs of abrasion. The two principal types are *râcloirs* and *pointes*; primitive flake-implements and large scrapers are also represented in the series. The technique of these artefacts is in many ways comparable with that of Early Mousterian times, and it is probable that these Boulder Clay specimens are referable to this cultural phase. The implements appear to have been lying in or upon a land surface before being incorporated with the morainic material in which they are now found. One well-made and deeply ochreous flake found in the Boulder Clay appears to be of Chellean age. It exhibits reflaking along its edges, and this flaking is patinated in the peculiar manner of some of the Boulder Clay artefacts.

In the discussion which followed the reading of the paper all the speakers united in dwelling upon the importance of the contribution made by Mr. Reid Moir to the study of the pre-history of man in Britain. Prof. Arthur Keith pointed out that the conclusions which followed from the results of Mr. Reid Moir's investigations could only be described as revolutionary, and would involve a reconsideration of the evidence relating to the antiquity of Stone-age implements. Mr. Reginald Smith said that the *pointe* was considered to be the typical implement of the Mousterian stage of culture. Archæologists would have to consider the possibility of its occurrence in other periods. The peculiar patination which occurred on certain of the specimens found by Mr. Reid Moir in the Ipswich Boulder Clay occurred at Northfleet, and was usually considered to be typical of the Le Moustier period. Mr. Smith also pointed out that some thirty-five years ago Dr. Skertchley had raised the question of the occurrence of palæolithic implements below the Boulder Clay. Dr. Barnes remarked that a considerable number of flakes must be examined before it can be concluded with certainty that a particular type of implement was present. Mr. Reid Moir's collection appeared to him to present all the characteristics which one would expect to find in a group of implements belonging to the Le Moustier culture.

Mr. Kennard said that palæontologists were firmly convinced that the Boulder Clay was of late occurrence. An examination of a continuous series of examples of the fauna exhibited no traces of the variation between warm and cold types, which would have been expected to occur if the theory of alternating warm and cold periods were correct. Fauna of the cold period were always last in the series. Mr. H. Bury said that the evidence brought forward by Mr. Reid Moir made it necessary to raise the question whether Chalky Boulder Clay was always, and wherever it occurred, of the same age. The evidence from Hoxne was diametrically opposed to Mr. Reid Moir's results, and this, together with the doubts which had been expressed as to the character of the evidence obtained from Hoxne, made it desirable that the borings on that site should be repeated.

RECENT ENGLISH MARINE BIOLOGY.

Recent English papers on marine biological research include one by Dr. E. C. Jee on the hydrography of the English Channel during the years 1904–17. This forms part i. of the Fisheries Investigation Series III., the publication of which is now resumed by the Board of Agriculture and Fisheries. Periodicities in the physical properties of the Channel water are discussed, and correlations between these and the pilchard fisheries are apparently established. A most interesting "Contribution to the Quantitative Study of Plankton" is published by Dr. E. J. Allen in part i., vol. xii., of the Journal of the Marine Biological Association.

Plankton investigations, in so far as they have been quantitative, have been a series of approximations to a complete determination of the number of organisms of all kinds contained in a unit volume of sea-water. Hensen's original method consisted in the use of a net made of fine-meshed silk cloth which was lowered in the sea and hauled to the surface. Experiment and calculation gave a coefficient for each net, from which the area of cross-section of the column of water filtered could be approximately determined. It has been found latterly that the greater number of microscopic organisms in the water escaped through the meshes of the cloth, and more refined filtering methods were introduced by Lohmann.

Finally, it was thought that by centrifuging small quantities of water a complete enumeration of the organisms present might become possible, and this method did, indeed, largely increase the numbers inhabiting unit volume of sea-water. Why it should not enable the investigator to determine *all* is not easy to see, but it certainly under-estimates them, as Dr. Allen's results show. In his experiments small quantities of water (10 c.c.) were centrifuged and the contained organisms counted. From four such trials a mean of 14·45 per c.c. (or 14,450 organisms per litre) was obtained. The same water sample was then examined by inoculating ½ c.c. in a sterilised sea-water containing the culture solutions used by Allen and Nelson for the study of marine diatoms. The inoculated medium so prepared was then distributed into seventy small flasks, each containing about 20 c.c. of the liquid, and the latter were allowed to stand for several weeks. The colonies (mainly Diatoms and Flagellates) growing in the flasks were then identified and counted, giving an estimated number of at least 464 organisms per c.c. (or 464,000 per litre). Even then it is evident that the result is an under-estimate of the actual population of the water sample, for the medium is apparently selective, and organisms that appeared in the centrifuged samples did not grow (and were therefore unrecorded) in the cultures. Bacteria did grow, but were not identified and estimated. The result is therefore another, and closer, approximation to a biological value which is of extraordinary interest.

J. J.

THE RED COLOURING MATTER OF PLANT GALLS.

During recent years our knowledge concerning plant colouring matters has rapidly increased, and quite a large number of pigments have been subjected to careful and full investigation. A further interesting contribution to our knowledge in this field of research is contained in a recent paper by Dr. M. Nierenstein, in which he deals with the colouring matter of the "red-pea gall" (Trans. Chem. Soc., 1919, cxv., pp. 1328–32). The galls that were examined occur on the leaves of various British oak-trees when galled by *Dryophanta divisa*, Adler.

It has been generally assumed that the red colouring matters of these and similar galls belonged to the anthocyan class, and one of the objects of the investigation was to ascertain whether the anthocyan assumed to be present was related to quercetin. By this means it was hoped to obtain some light upon the relationship between the products present in the normal plant and those pathologically produced as the result of the formation of the galls.

The investigation resulted in the isolation of a red pigment, to which the name "dryophantin" has been given. Dr. Nierenstein concludes that this colouring matter is not an anthocyan, but a diglucoside of purpurogallin (the first derivative of purpurogallin to be found in Nature), and that, like gallotannin, it is of pathologic origin. He is of the opinion that the other so-called anthocyans obtained from plant-galls are in all probability not anthocyan colours at all, but related to "dryophantin." In view of this he proposes to classify these red pigments under the class-name "gallorubrones."

This paper is of considerable interest, particularly if further investigation confirms the presence of purpurogallin derivatives as regular constituents of these and other red galls. In respect of the conclusion implied as to the absence of pigments of the anthocyan group, the present paper is not sufficient evidence of such absence, for the process whereby the colouring matter has been isolated is such that there is a very considerable doubt whether many anthocyan pigments would survive the treatment.

IONS AND IONISATION.

The Faraday Society, though a small body, is very active. One of the most useful features of its activity is the holding of general discussions on matters of scientific and technical interest, and the publication of these discussions in its Transactions. "The Present Position of the Theory of Ionisation in Solution" was the subject of a discussion held on January 21, 1919, and the report is now issued in the form of a separate reprint (pp. 178, Faraday Society, 10 Essex Street, Strand, W.C.2, price 12*s.* 6*d.*), thus making it available to a larger public than the members of the society.

The discussion was opened by Dr. Senter, who briefly reviewed the position with regard to such outstanding problems as the hydration of ions, the deviation of strong electrolytes from the mass-action law, and the chemical activity of ions and non-ionised molecules respectively. Communications on these and other topics were afterwards read and discussed, amongst the contributors or those taking part in the discussion being Arrhenius (the originator of the theory), Acree, McBain, Bousfield, Sand, Partington, Porter, Newbery, Lindemann, Philip, and J. C. Ghosh.

Fundamental differences of opinion with regard to the main problems discussed were very marked. The evidence for the hydration of ions is by some held as final, by others as having only a limited application, and by yet others as quite inconclusive. Most attention was given to the problem of the abnormality of strong electrolytes. At extreme dilutions these electrolytes are regarded by many as behaving normally, the dissociation constant for uni-univalent electrolytes being about 0·02, but owing to the magnitude of the water-correction, and the difficulty of exactly fixing the molar conductivity for infinite dilution, this result must still be looked upon as uncertain. At ordinary dilutions the law has no application, and the most promising explanation is that elaborated by Dr. J. C. Ghosh, who proceeds on the assumption that the strong electrolytes are practically completely ionised in all dilute solutions, but that there is an electrostatic equilibrium between mobile ions, which contribute to the conductivity, etc., and inert ions, which do not. An electrical dilution law is therefore substituted for the chemical mass-action law in the case of strong electrolytes. For weak electrolytes this electrical action would only enter as a negligible disturbing factor of the mass-action law. The further development of this idea may be awaited with interest.

THE SPECIES CONCEPT AMONG FUNGI.

IN the Transactions of the British Mycological Society (vol. vi., part ii., September, 1919) Mr. W. B. Brierley protests against the practice of mycologists in describing as species the forms which are presented to them in Nature or as pathological growths, especially on cultivated plants. The description of new fungal species is based on the assumptions that the distinguishing characters are of a morphological nature, and that the essential specific characters are constant and hereditary and may be determined in one specimen of one generation. But the laboratory and field experience of the experimentalist shows that under changes in the environment the whole structure and facies of the organism may be transformed, while under identical conditions there is considerable evidence that the morphological variation of a particular fungus is definite and constant. The so-called species of the mycologist is comparable with the "ecad" of the ecologist, and is the resultant of the organism and its environment. "Ecads" indistinguishable from each other may be produced from two distinct organisms interacting with one and the same environment, or with two different environments. Two precisely similar fungi growing on a potato and a decaying tree-stump respectively may really be different species, though the systematic mycologist would consider them identical. The true organism is a physiological equilibration, a metabolic entity, the interaction of which with the environment results in the growth-form or "ecad." It follows that the morphological species concept must be given up in favour of the physiological species concept. The only exact method of determining species is by means of quantitative data derived from cultural treatment under standardised physico-chemical conditions, for this method alone reveals the physiological condition of the organism. The author suggests that even the apparently stable forms of the higher fungi, Agarics, Polypores, etc., are merely "ecads," and that two precisely similar morphological entities of, for instance, *Agaricus melleus* may conceal totally different physiological constitutions which under other conditions of growth would diverge characteristically.

Mr. Brierley also attacks another concept of mycology, namely, the "educability" of fungi, or the induction by suitable treatment of permanent modifications in their biochemical, morphological, or other properties. This concept is widely held by microbiologists, but if it implies a possibility of a change in the physiological constitution of an organism, it follows that with fuller knowledge and improved technique a rapid change of one species into another is possible. The author affirms that the condition of knowledge and the available evidence are not such as to warrant an hypothesis so subversive of the foundations of biological science. The presumed mutations may be due to the presence of mixed populations in supposed pure cultures, or merely the expression of a developmental stage previously unrecognised; further, no organism in which sexuality exists or is conceivable must be used unless its gametic constitution and genetic behaviour under all the conditions of the experiment are known.

THE UPPER LIMIT OF UNPLEASANT BEATS.

IT is well known that Helmholtz traced all discordant effects of two or more musical notes when sounded together to the presence of beats occurring between the prime tones, between the prime of one and an upper partial of the other, between the upper partials of each, or to beats occurring in some other way. Further, to produce the unpleasantness in question the beats must lie between certain limits of frequency, which limits vary with the pitch in use.

In this connection it is of interest to note that Mr. Narendranath Chatterjee, of Chittagong, India, has recently given a formula expressing the upper limiting frequency for beats for which the roughness vanishes. This formula he writes as follows:

$$B = \frac{N}{0{\cdot}7 + n + i}, \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where B is the number of beats per second for which the roughness vanishes, N is the frequency of the lower of the two tones sounded simultaneously, n is the number of the musical scale containing N and beginning with 32 per second as the fundamental of the first scale (the octave of this being the fundamental of the next scale, and so on), and, finally, i is the interval between N and the fundamental of the scale in which it is contained.

Thus N, n, and i are connected by the equation

$$N = 32 \times 2^{n-1} \times i \quad . \quad . \quad . \quad . \quad . \quad (2)$$

The results of the law compared well with Mayer's experimental values, as shown in the following table:

Frequency N of lower tone	Frequency B of beats when roughness vanishes	
	Mayer's values	Results of law
64	16	17
128	26	27
256	47	45
512	78	76
1024	135	133

RESEARCHES AT HIGH TEMPERATURES AND PRESSURES.

By the Hon. Sir Charles A. Parsons, K.C.B., F.R.S.[1]

II.

THE calories evolved in the combination of graphite and oxygen are about 0·5 per cent. less than those evolved in the combination of diamond and oxygen, indicating that graphite at ordinary temperature is, to this extent, a stable state. The bulk-pressure which has operated in some of the experiments would, however, seem to have been amply sufficient to turn the balance in favour of diamond instead of graphite. The uncertainty, on the other hand, as to the compressibilities and specific heats of the allotropic forms of carbon under high pressures and at high temperatures renders speculation of little value as to what may occur at the melting point of carbon. All we know is that, up to the pressures and temperatures reached in our experiments, no indication of a change from graphite to diamond has been produced. In one experiment very intense heating was applied for five seconds, but sufficient in amount to melt the graphite core six times over, the only result being a slight alteration in the structure of the graphite. The barrier in this experiment was calcined magnesia, and the hole in it was superficially converted to magnesium carbide. It appeared, however, desirable further to investigate the possibility of carbon losing its electrical conductivity when approaching its melting point, as alleged by Ludwig and others, and of shunting the current from itself on to the contiguous molten layers of the insulating barrier surrounding it. There had been no indication of such a change having occurred even momentarily; it rather seemed that the graphite core had been partially vaporised and condensed in the cooler parts of the charge. The experiment was repeated with rods of iron and tungsten embedded in the core, so that should the temperature of volatilisation of the metals under a pressure of 15,000 atmospheres exceed that necessary to liquefy carbon under the same pressure, the presence of these metals might produce a different result. No change, however, occurred.

Note.—The temperatures at which carbon, iron, and tungsten volatilise under a pressure of 15,000 atmospheres are unknown, but they are probably much higher than at atmospheric pressure.

This experiment also tested iron as a solvent of carbon and as a catalyst from diamond to graphite under a pressure of 100 tons, and showed that under this pressure that action was not reversed.

Fig. 3 shows the container arranged for treating powders by resistance heating with or without the addition of liquids or gases. The electric current is conveyed from the container to the upper end of the conductor by a layer of graphite which rests on the charge under treatment. The bottom end of the conductor rests on or is spigoted into a cast-iron block which rests on the bottom pole; this block is sometimes partially melted, but can be easily renewed.

The container is charged by first stemming magnesite powder by hand around the bottom pole-piece and block; then the charge is placed on the top and pressed to 5 tons per square inch; the top ram is then removed, a hole drilled through the charge, and the conductor inserted. Liquids, if used, or carbon dioxide snow may then be introduced; lastly, a layer of graphite is placed on the top, and the whole pressed to the desired pressure for the experiment.

[1] Discourse delivered at the Royal Institution on Friday, January 23. Continued from p. 681.

In one experiment several pounds of carbon dioxide snow were added to the charge, which consisted of magnesia, and was so arranged that evaporation of the heating carbon rod took place in an atmosphere of carbon dioxide and carbon monoxide under a gaseous pressure of 4400 atmospheres, the condensate resulting being soft graphite. Upwards of two hundred chemical reactions arranged to deposit carbon were tested under high pressure and central heating. After each experiment samples were taken from various parts of the charge and carefully analysed for diamond, the methods of the analyses generally following those of Moissan and Crookes. On the whole, there was no evidence that diamond had been produced by any of the chemical reactions, some of which were endothermic, such as carborundum and sodium carbonate, which produced a grey solid which detonated when struck with a hammer, and nearly caused a serious accident. In one experiment the charge was olivine and water; when molten under 10 tons per square inch the pressure was suddenly removed, and artificial pumice was formed by the expansion of water-vapour absorbed by the olivine when molten.

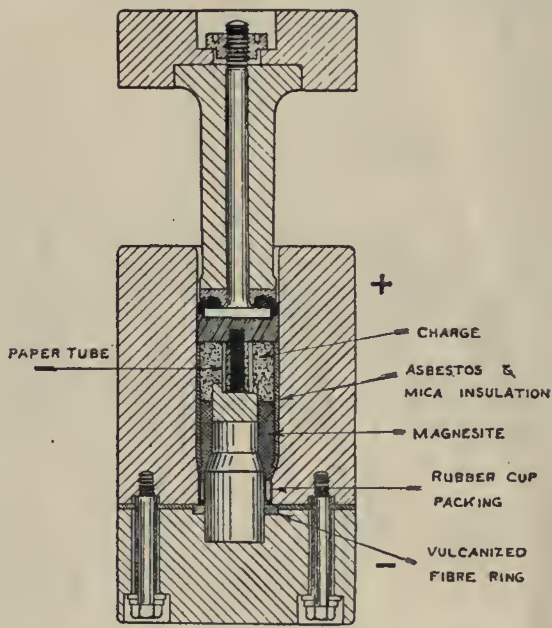

FIG. 3.—For powders with or without liquids and gases.

Having nearly reached the limits of steady pressure obtainable in steel containers under a press, experiments with impact pressures produced by steel bullets were tried, which produced much higher instantaneous pressures than are obtainable in any die.

A rifle, 0·303-in. bore, was arranged for withstanding a charge of cordite 90 per cent. in excess of the Service charge. The gun (Fig. 4) was fixed with its muzzle 6 in. from a massive block of steel, in which a hole 0·303 in. in diameter had been drilled to a depth somewhat greater than the length of the bullet, and in alignment with the bore of the gun; cylindrical bullets of steel with a copper driving band were chiefly used, shorter than the Service bullet and about one-half the weight. The substance to be compressed was placed either at the bottom of the hole, when a conical-nosed bullet of mild steel was used, or over the mouth of the hole, when a cupped-nosed bullet of tool-steel was employed. About a hundred experiments were made.

The substances tested included graphite, sugar-carbon, bisulphide of carbon, oils, etc., graphite and sodium nitrate, graphite and fulminate of mercury, finely divided iron and fine carborundum, olivine and graphite, etc. After each shot the bullet and surrounding steel were drilled out, and the chips and entrained matter analysed. Fig. 5 shows the bullet in the hole after firing.

Several experiments were also made with a bridge of arc-light carbon placed over the hole and raised

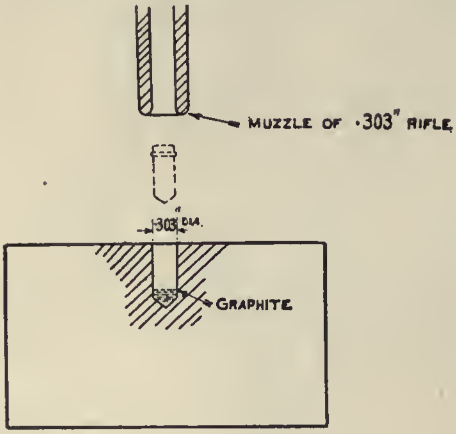

FIG. 4.

to the limit of incandescence by an electric current, and the shot fired through it into the hole at the moment the carbon commenced to vaporise, as observed in a mirror from without. Also, an arc between two carbons was arranged to play just over the hole and the shot fired through it (Fig. 6). The residues were in all cases exceedingly small, and there was no evidence of any incipient transformation of carbon in bulk into diamond that could be detected by analysis.

The pressure on impact of a steel bullet fired into

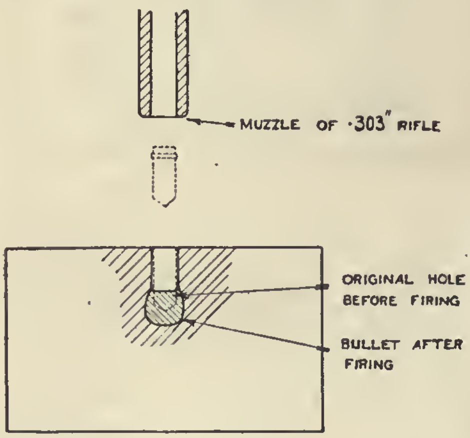

FIG. 5.

a hole in a steel block which it fits is limited by the coefficient of compressibility of steel; with a velocity of 5000 foot-seconds it is about 2000 tons per square inch. Measurements made from a section through the block and bullet (Fig. 5) showed that the mean retardation on the frontal face after the impact until it had come to rest was about 600 tons per square inch. Several experiments were made by substituting a tungsten steel block hardened and tempered, and a hole tapering gently from 0·303 in. at the mouth to 0·125 in. at the bottom. The mild steel bullet was deformed by the tapered hole, which greatly increased the velocity imparted to the nose. Progressively increased charges were used. With the 90 per cent. excess charge the block always split on the first shot, but this probably occurred after impact, and not until the full instantaneous pressure had been exerted, which was probably about 5000 tons per square inch, or about equal to that at the centre of the earth.

It would be interesting to repeat some of these experiments on a larger scale. With a projectile of 6 in. or 9 in. in diameter and a velocity of 5000 foot-seconds, the instantaneous pressure would be the same, but its duration (which is proportional to the linear dimensions) would be increased from twenty-to thirty-fold. It has been estimated that the rise in temperature due to adiabatic compression of incandescent carbon when subjected to 2000 tons per

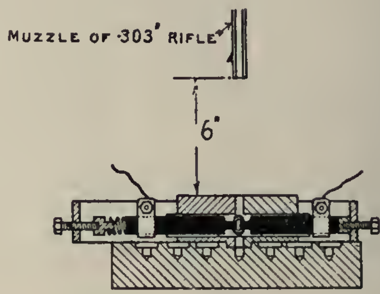

FIG. 6.

square inch is of the order of about 1000° C., so that actual melting of the carbon would probably have occurred when the shot was fired through the incandescent carbon bridge.

Another experiment was arranged which would ensure that carbon should be subjected to an extremely high temperature concurrently with a high pressure obtained by the rapid compression of the hottest possible flame, that of acetylene and oxygen, with a slight excess of the former to provide the carbon. The arrangement was as follows (Figs. 7 and 8):—A very light piston made of tool-steel was carefully fitted to the barrel of a gun of 0·9 in. bore; the piston was flat in front, lightened out behind, and fitted with a cupped copper gas-check ring, the cup facing forward; the total travel of the piston was 36 in. To the

FIG. 7.

muzzle of the gun was fitted a prolongation of the barrel formed out of a massive steel block, the joint being gastight; the end of the bore in the block was closed by a screwed-in plug made of tempered tool-steel, also with a gastight collar. A small copper pin projected from the centre of the plug to give a record of the limit of travel of the piston. The gun was loaded with 2 drams of black sporting powder, which amount had been calculated from preliminary trials. The barrel in front of the piston was filled with a mixture of acetylene and oxygen. It was estimated that this mixture would explode when the piston had travelled about half-way along the bore. When fired, the piston travelled to within $\frac{1}{8}$ in. of the end, as had been estimated, giving a total compression ratio of 288 to 1. As a result, it was found that the surfaces of the end plug, the fore end of the piston, and the circumference of the bore up to ⅜ in. from the end of the plug had been fused to a depth of about 0·01 in., and were glass-hard; the surface of the copper pin had been vaporised, and the copper sprayed over the face of the end plug and piston. The end plug, which had been hardened and tempered to a straw colour, showed signs of compression, and the bore of the block for ⅜ in. from the plug was enlarged by 0·023 in. in diameter, both indicating that a pressure above 100 tons per square inch had been reached. A little brown amorphous carbon was found in the chamber, which was easily destroyed by boiling sulphuric acid and nitre. There was no diamond residue from this. Considering the light weight of the piston and the very short duration of the exposure to heat, the effects would indicate that a very abnormal temperature had been reached, many times greater than exists in the chambers of large guns. A calculation made by Mr. Stanley Cook, based upon the ratio of compression and a final pressure of 15,000 atmospheres, indicates that a temperature of between 15,250° and 17,700° C. was reached, the exact temperature depending upon the amount of dissociation or combination existing between the elements at the time.

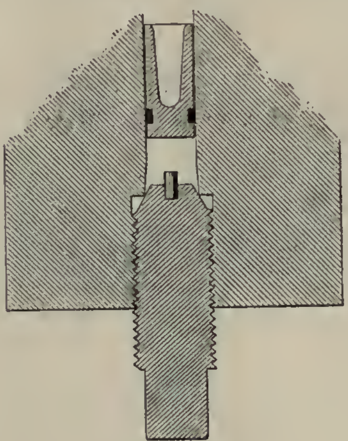

FIG. 8.

Calculation of the Temperature Reached on the Compression of Acetylene and Oxygen Experiment.
BY STANLEY S. COOK.

The temperature reached may be estimated from the final pressure, which the observed deformation of the block and plug indicates to have been in the neighbourhood of 100 tons per square inch. But it must be remembered that there is a change of molecular volume as a result of combustion. Thus the mixture, which as C_2H_2 and 5(O) has 3½ molecular volumes, would on combustion to $2CO_2$ and H_2O have only 3 molecular volumes. The final temperature deduced from the pressure will therefore depend upon the extent to which chemical combination has taken place.

The original mixture being at atmospheric pressure and at a temperature of 290° C. absolute, a pressure of 100 tons per square inch, after compression to 1/288th of its original volume, would indicate a temperature of 15,250° C. If, however, complete combustion has taken place, this pressure would correspond to a temperature greater in ratio of 3½ to 3, viz. to 17,700° C. The actual temperature must therefore have been something between these two values.

Let us for a moment consider the pressures and temperatures possible in Nature (in this I am indebted to kind assistance from Prof. Jeans). The pressure at the centre of the earth is between 4000 and 10,000 tons per square inch, according to the variation in density of the concentric layers.

Emden has estimated the probable pressure at the centre of the more massive component of the binary star S Hercules to be 360,000,000 tons per square inch.

Again, the densities of the brighter components of certain binary stars are estimated by Öpik to be about that of iron, and if we assume that their diameter is the same as that of the sun, that each has an initial velocity in space not greater than 30 miles per second, and that they directly collide, then, owing to their mutual attraction, Jeans calculates that their velocity will have increased to 450 miles per second, and that the pressures in the centre as they strike and flatten would be of the order of 1,000,000,000 tons per square inch. He also estimates that the heat equivalent of the energy would be sufficient to vaporise the whole mass 100,000 times over. This immense pressure would be maintained for many minutes, perhaps for half an hour.

Let us consider what is the greatest pressure that can be produced artificially. If the German gun which bombarded Paris were loaded with a solid steel projectile somewhat shorter and lighter than the one actually used, a muzzle velocity of about 6000 foot-seconds might be reached (many years ago Sir Andrew Noble had reached 5000 foot-seconds); and if it was fired into a tapered hole, as I have described, in a large block of steel, this would give the greatest instantaneous pressure that can be produced artificially so far as we at present know, viz. about 7000 tons per square inch: it is only about 1/150,000th part of that possible by the collision of the largest stars.

As to the temperature and conditions of matter under these intense pressures, extrapolation from known data is valueless. We have no knowledge of the coefficients of compressibility of matter under these conditions or of its specific heat. What may be the effect on the atom? And will elements under such conditions be transformed into others of higher atomic weight?

Some of us may recall that in 1888 a lecturer, after describing in this room the experiment in which oxygen at atmospheric pressure was passed in close contact with a platinum surface heated by the oxy-hydrogen burner to nearly its melting point, and then immediately cooled by contact in water, said:

"In this experiment ozone is formed by the action of a high temperature, owing to the dissociation of the oxygen molecules and their partial recombination into the more complex molecules of ozone. We may conceive it not improbable that some of the elementary bodies might be formed somewhat like the ozone in the above experiment, but at very high temperatures, by the collocation of certain dissociated constituents and with the simultaneous absorption of heat."

It seems indeed probable that the centres of the great stars and stars in collision may be the laboratories where the elements as they gradually degenerate are being continually regenerated into others of higher intrinsic energy, and where endothermic processes, such as the recombination of lead and helium into radium, may be taking place, absorbing in this process an energy 2,500,000 times that developed by the explosion of an equal weight of T.N.T.

The transformation of only a minute fraction of the mass of two colliding stars would therefore be amply sufficient to absorb the whole energy of their collision.

Emerson said many years ago, "None but the elements can themselves destroy."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

ABERDEEN.—The honorary degree of LL.D. is to be conferred on Sir J. C. Bose, founder of the Bose Research Institute, Calcutta; Prof. W. Bulloch, professor of bacteriology, London Hospital; Prof. J. Wight Duff, Armstrong College, Newcastle-upon-Tyne; Sir Daniel Hall, Permanent Secretary to the Board of Agriculture; Mr. J. H. Jeans, secretary of the Royal Society; and Sir Robert Jones, lecturer on orthopædic surgery, Liverpool University.

CAPT. JAMES W. LOW has been appointed assistant in the natural history department, University College, Dundee (University of St. Andrews).

APPLICATIONS are invited for the Radcliffe Crocker travelling scholarship in dermatology at University College Hospital Medical School. The scholarship is of the approximate value of 280*l.*, and tenable for one year. Particulars are obtainable from the Dean, University College Hospital Medical School, Gower Street, W.C.1.

THE next election—the seventh—to Beit fellowships for scientific research will take place on or about July 15 next. The latest time for receiving applications is April 19. Forms of application and information respecting the fellowships are obtainable, by letter, from the Rector, Imperial College of Science and Technology, South Kensington.

A MOVEMENT has been started to form a properly constituted Old Students' Association at King's College, London. A committee has drawn up a provisional constitution, and a general meeting has been called for March 4, at 6 p.m., at the college. It has been possible to send notices of this meeting only to those old students whose names are on the register, but it is hoped that the meeting will be made widely known, and that as many old students as possible will be present.

THE first meeting of the International Federation of University Women, which will include delegates from the women's colleges throughout the world, will meet in London in July next. The chairmen of the International Federation are Dean Virginia Gildersleeve, of Barnard College, Columbia University, U.S.A., and Prof. Winifred Cullis, of the London (Royal Free Hospital) School of Medicine for Women, University of London.

THE Chadwick Trustees announce three public lectures on "Military Hygiene in Peace and War," by Gen. Sir John Goodwin, K.C.B., in the lecture-room, Royal Society of Arts, John Street, Adelphi, W.C.2, on Mondays, March 8, 15, and 22, at 5.15 p.m. The titles of the lectures are:—Army Hygiene prior to the Recent War, Army Hygiene during the Recent War (Application of its Principles to Active Service Conditions), and The Future of Army Hygiene (Its Relation to the Hygiene of the Civil Community). All information about Chadwick public lectures may be obtained from the secretary, Mrs. Aubrey Richardson, at the offices of the Trust, 40 (6th) Queen Anne's Chambers, Westminster, S.W.1.

THE opening of the British Bureau of the Office National des Universités et Ecoles Françaises at 50 Russell Square by M. Lucien Poincaré took place on Monday, February 23, in the presence of many distinguished university men of both countries. The bureau is intended to serve as a university *liaison* office between the two countries, giving advice to British students who may wish to study abroad or French students seeking to pursue their studies in England, and so bringing British and French universities into closer touch with one another. M. Poincaré, in declaring the bureau open, said the work which would be done in Russell Square would be of the greatest use, particularly to England and France. He hoped the day would come when all Englishmen would speak French and all Frenchmen would speak English. It was too early, he thought, to say we were internationalists, using the word in its better meaning. We were rather inter-Allies. It was still necessary to struggle for civilisation. He trusted that the Office National would be a powerful factor in uniting England and France in closer bonds and for working for the good of humanity. In the evening, M. Millerand, the Prime Minister of France, in the chair, a dinner given by the Groupe Inter-Universitaire Franco-Britannique was held at the Connaught Rooms in honour of M. Poincaré and to celebrate the formal opening of the bureau. Many public men were present, and the general trend of the speeches during the evening was to emphasise the possibility of this alliance of the universities helping to cement the already established union between France and England.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 12.—Sir J. J. Thomson, president, in the chair.—J. W. **McBain** and C. S. **Salmon**: Colloidal electrolytes. Soap solutions and their constitution. For the first time a comprehensive theory of soap solutions has been set up. This has led to a definition of colloidal electrolytes, a class the members of which will probably prove more numerous than acids and bases put together. They are salts in which one of the ions has been replaced by an ionic micelle. The ionic micelle in the case of soap exhibits an equivalent conductivity equal to that of potassium ion, and double that of the palmitate ion which it has replaced. Its formula may correspond to $(P')_n . m(H_2O)$, but more probably it is $(NaP)_x(P')_n . (H_2O)_m$, where P′ is the anion of the fatty acid in question. In concentrated solutions soaps exist chiefly in colloidal form, together with sodium or potassium ion, equivalent to the ionic micelle present, whereas in dilute solution both undissociated and dissociated soaps are crystalloids of simple molecular weight. In mixtures of soaps the tendency is to form more micellæ. Addition of electrolytes, however, exerts opposing influences, dehydrating and driving back dissociation. The conception of the ionic micelle serves to explain the behaviour of solutions of dyestuffs, indicators, and proteins. A modification of the dew-point method is described, which has enabled measurements of osmotic activity and "molecular weight" to be carried out, free from the uncertainties of interpretation of the results obtained for colloids by the osmometer method, and superseding the well-known but erroneous data of Krafft.—C. C. **Farr** and D. B. **Macleod**: The viscosity of sulphur. The results are discussed of a number of experiments, under a great variety of conditions, on the viscosity of sulphur with temperatures rising and falling between 123° C. and 278° C. The method employed was that of rotating cylinders, usually with a bifilar suspension. A unifilar suspension was, however, employed in the neighbourhood of the point of minimum viscosity. Great care was taken to secure that the sulphur had actually attained the temperature indicated by the thermometer used. The effects were observed of prolonged heating, also the effects of the absorption of gases, especially NH_3 and SO_2. The relation of the viscosity to the amount of "insoluble sulphur" present is considered.—C. V.

Raman and B. **Banerji**: Kaufmann's theory of the impact of the pianoforte hammer.—Comdr. T. Y. **Baker** and Prof. L. N. G. **Filon**: A theory of the second order longitudinal spherical aberration for a symmetrical optical system. The authors obtain a formula for the longitudinal spherical aberration in a symmetrical optical system of the type

$$\Delta x = (\mathrm{A}t^3 + \mathrm{E}t^5)/(1 + \mathrm{B}t^2),$$

where Δx is the longitudinal spherical aberration on the axis, t is the slope to the axis of the emergent ray calculated by Gauss's method, and A, B, E are polynomials in the magnification of degrees 4, 3, and 6 respectively. It is shown (1) that a formula of this kind is, on the average, superior in numerical accuracy to the first two terms of the usual series of aberrations of successive order; and (2) that it removes a number of difficulties connected with convergency which occur in the methods at present in use. In particular, developments in powers of trigonometrical functions of the true inclination of the emergent ray are shown to be unsatisfactory. Certain invariant relations are obtained, connecting A, B, and E in general, and facilitating their computation. Formulæ are found enabling the functions A, B, and E to be calculated for a combination of lenses when the corresponding functions for the individual lenses are given, and a method is indicated whereby the contribution of each lens to the final image defects can be rapidly traced.—Prof. J. W. **Nicholson**: The lateral vibrations of sharply pointed bars. The paper is a sequel to one already published, which arose from a suggestion as to the formation of siliceous deposits on sponge-spicules of a certain type. The present paper deals with an exceptional case, for which the necessary analysis presents unusual features. It is that of a double rod each half of which is generated by rotation of the parabola $y = \mathrm{A}x^2$ about the axis of x. The influence of sharpness on the frequencies and nodal positions of the notes is traced numerically after the general analysis. It is shown that a limiting frequency and nodal position exist, so that the frequency is a lower limit to those producible under any conditions of support. As the rod becomes sharper all its frequencies tend to this value, while of the nodes one for each frequency tends to a definite position, and all the others to the extreme ends of the rod. The same conclusions apply to a single rod.—R. E. **Slade** and F. C. **Toy**: A new method of spectrophotometry in the visible and ultra-violet and the absorption of light by silver bromide. A new method of measuring the absorption of light by a substance has been devised. This method is independent of the relation between density and exposure of the photographic plate. The following values of the extinction coefficient of silver bromide at various wave-lengths have been determined:

λ		k	λ		k
450 $\mu\mu$	...	270	400 $\mu\mu$	...	2000
440 ,,	...	410	390 ,,	...	2790
430 ,,	...	600	380 ,,	...	3800
420 ,,	...	900	370 ,,	...	5100
410 ,,	...	1380	360 ,,	...	6700

This extinction coefficient is defined by the formula

$$\mathrm{I}_2 = \mathrm{I}_1 e^{-kd_1},$$

where I_1 and I_2 are the intensities of the light at points d centimetres apart in the absorbing medium. It is estimated that the average error of any of these values is less than 3 per cent.—Dr. S. **Chapman**: A note on Dr. Chree's discussion of two magnetic storms.—Dr. C. **Chree**: An explanation of the criticisms on Dr. Chapman's recent paper, "An Outline of a Theory of Magnetic Storms."

Linnean Society, February 5.—Dr. A. Smith Woodward, president, in the chair.—Dr. R. Ruggles **Gates**: The existence of two fundamentally different types of characters in organisms. The experimentalist point of view regarding evolution, resulting from the work in mutation and Mendelism, is frankly antagonistic to the views of palæontologists, anatomists, and others who deal with orthogenesis and the inheritance of acquired characters. While these two factors bear entirely different relations to evolutionary changes, both are necessary to account for evolution as it has taken place. The conclusion is reached that higher organisms exhibit two contrasted types of characters, which differ fundamentally (1) in their manner of origin, (2) in their relation to the structure of the organism, (3) in their relation to such phenomena as recapitulation, adaptation, and inheritance, and (4) in their relation to geographic distribution. To the first category belong cell-characters, which arise as mutations, are represented in every cell of the individual, and are usually inherited as distinct entities. To the second category belong organismal characters, which arise gradually through impact of the environment or through orthogenetic changes, may modify only localised portions of the life-cycle, and may not be incorporated in the germ-plasm from the first.

Zoological Society, February 10.—Prof. E. W. MacBride, vice-president, in the chair.—H. R. **Hogg**: Some Australian Opiliones. The genera and species described belonged to the sub-orders Palpatores and Laniatores, the Palpatores being represented by the genera Pantopsalis and Macropsalis of the family Phalangiidæ, and the Laniatores by genera of Triænobunidæ and Triænonychidæ. In the case of the Phalangiidæ the author had been able to establish that long mandibles were a male and short mandibles a female character.—Dr. C. F. **Sonntag**: Larynx and œsophagus of a common macaque, exhibiting several unusual features.—R. E. **Turner** and J. **Waterston**: A revision of the Ichneumonid genera Labium and Pœcilocryptus.

Physical Society, February 13.—Prof. C. H. Lees, president, in the chair.—Prof. C. H. **Lees**: Presidential address: The temperature of the earth's interior. In an average cubic centimetre of matter within the earth's substance the energy generated by radio-active matter is equivalent to the sum of the following quantities: (1) Heat utilised in rise of temperature, (2) loss of heat by conduction, etc., (3) change in gravitational energy, and (4) thermal stress. The only factor known with certainty is the loss by conduction, which works out to an average of 10 ergs per annum per c.c. The approximate water equivalent of the material of the earth is 0·8; therefore a rise of temperature of 1° C. requires 33,000,000 ergs. Hence, if there was nothing to take into account but the conduction loss, the temperature would fall by 1° in 3·3 million years. The discovery of radio-activity, however, showed that near the earth's surface the average amount of energy radio-actively generated is 1000 ergs per c.c. The quantity falls off rapidly as deeper rocks are reached. The present Lord Rayleigh suggests that the average may be about 10 ergs—just sufficient to balance the heat lost from the surface. If we accept this theory, we have to deal with a steady state, in which the temperature neither rises nor falls, and the calculation of the temperature at points inside the mass is simple. The equilibrium theory has been much criticised, however, and it is necessary to consider other alternatives. There are two possibilities: Either the temperature may be rising, due to the radio-energy exceeding the surface loss, or it may be falling if the balance is the other way. The geological evidence renders the first contingency highly improbable. For a rate of change of temperature of 1° per million years the change in thermal energy involved is 33 ergs per annum per c.c., while the change in gravitational energy is 20 ergs per annum per c.c. These quantities can be lumped together and regarded as one by assuming the water equivalent of the earth's substance to be 1·6 times its actual value. Thus, neglecting radio-active effects, the time taken to cool 1° would be 5·4 million years instead of 3·3 million, as calculated without taking gravitational energy into account. From the relative amounts of lead and uranium found in rocks it has been calculated that the time which must have elapsed since the formation of the crust is of the order of 1,000,000,000 years. The temperature of solidification was probably about 1300° C., so we have the data necessary to give the present rate of cooling. From this, for any assumption regarding the actual distribution of radio-active material, the temperature at points within the earth can be determined.—Sir Arthur **Schuster**: The influence of small changes of temperature on atmospheric refraction. The paper is an investigation of the possible deviation of the light from a star near the sun due to the temperature changes in the atmosphere produced by the passage of the moon's shadow across the earth during an eclipse. It is shown that while the actual displacements from this cause vary widely for slight differences in the assumed conditions, they are always negligibly small compared with the effects observed at the last solar eclipse.

Royal Meteorological Society, February 18.—Mr. R. H. Hooker, president, in the chair.—Capt. C. J. P. **Cave**: The status of a Meteorological Office and its relation to the State and to the public (see p. 705).—W. H. **Dines**: Atmospheric and terrestrial radiation. The author endeavours to follow the flow of radiant energy, other than solar, both upward and downward across any horizontal plane in the atmosphere. Certain theoretical assumptions are made to render the calculation possible, and it is shown that the curves that represent the net loss or gain of heat from strata at different heights are all more or less of the same character, whatever possible values are ascribed to the emissivity of the various strata. It is found that over Europe the air from the earth's surface up to about 8 km. is losing heat by radiation, and that from 8 km. to 12 km. it is gaining heat, losing it again at more than 12 km. The validity of the assumptions made is then discussed, and it is pointed out that the numerical values agree well with those obtained by entirely different means.—D. **Brunt**: Internal friction in the atmosphere. When a steady state of motion is assumed, any portion of the atmosphere is in equilibrium under the action of three forces: the gradient of pressure, the deflecting force at right angles to its motion, and the frictional force. The first two of these are measurable, and so the third can be evaluated. The paper gives a comparison of the frictional force calculated in this manner, with the values derived from a theoretical discussion of turbulent motion. A new derivation of the solution of the equations of motion is given. Use is made of observations at the top and base of the Eiffel Tower to derive the value of the coefficient of eddy viscosity. An additional note shows that a solution of the equation of motion is possible in cases where the coefficient of eddy conductivity varies with height.

CAMBRIDGE.

Philosophical Society, February 9.—Mr. C. T. R. Wilson, president, in the chair.—F. W. **Aston**: The mass spectra of the chemical elements. By means of a special arrangement of electric and magnetic fields it is found possible to bring positive rays of definite mass to a focus, independent to some extent of their velocity, so that the dispersion can be made much greater than hitherto without loss of intensity. In this way a mass spectrum is formed on which the values of mass can be compared, in favourable cases, to an accuracy of about one part in a thousand by comparison with known reference lines such as O (16), C (12), etc. In this way atmospheric neon is definitely proved to consist of two isotopes of mass 20 and 22. Argon gives a line exactly at 40, and if it is a mixed element the other constituents must be present in very small proportion. Chlorine gives a group of four lines exactly at 35, 36, 37, and 38, and others from which good evidence can be adduced that this element consists of at least two isotopes, Cl^{α} (35) and Cl^{β} (37), (36) and (38) being the two corresponding hydrochloric acids. Mercury is also found to be a mixture of isotopes, probably three in number, their masses not yet being accurately determined. Very interesting results are yielded by helium and hydrogen; the former appears to be a "pure" element of mass 4·00, but hydrogen is very definitely heavier than unity (O=16. H_1, H_2, and H_3 all give consistent values in approximate agreement with that accepted by chemists: 1·008 for hydrogen. When due allowance has been made for multiple charges, it is found that of more than fifty atomic and molecular masses so far determined, every one, with the exception of the three hydrogen lines, falls on a whole number within the error of experiment.—K. **Molin**: An examination of Searle's method for determining the viscosity of very viscous liquids.—H. W. **Richmond**: Note on the Diophantine equation $t^3+x^3+y^3+z^3=0$.—Prof. H. F. **Baker**: Mathematical notes: (1) The stability of rotating liquid ellipsoids; (2) the general theory of the stability of rotating masses of liquid; (3) the stability of periodic motions in general dynamics; (4) the invariance of the equations of electrodynamics in the Maxwell and in the Einstein forms; (5) a property of focal conics and of bicircular quartics; (6) the Hart circle of a spherical triangle; (7) a proof of the theorem of a double six of lines by projection from four dimensions; (8) a group of transformations of rectangular axes; (9) transformations with an absolute quadric; and (10) the reduction of homography to movement in three dimensions.

EDINBURGH.

Royal Society of Edinburgh, January 12.—Prof. F. O. Bower, president, in the chair.—Prof. W. **Peddie**: The atomic space lattice in magnetite. The question of the uniqueness of the determination by the X-ray method was discussed. It appears that the solution is probably not unique within the limits of accuracy in observation.—J. **Marshall**: An unnoticed point in the theory of Newton's rings. By consideration of the passage of light-waves through three media the author discussed the considerations under which the centre of the rings was a black spot or a bright spot. These depend upon the relative refractive indices of the three materials. It was shown that the reason why Brewster obtained a bright spot at the centre with an appearance of interference rings was because the refractive indices of his materials were approximately in geometrical progression.—A. T. **Doodson**, R. M. **Carey**, and R. **Baldwin**: Theoretical determination of the longitudinal seiches of Lake Geneva. The essential feature of this paper was the development of a mathematical method (due to J. Proudman) of successive approximations by which the nodes of seiches in irregular-shaped basins can be calculated. The method was applied to the seiches of Lake Geneva with satisfactory results.

February 2.—Sir George A. Berry, vice-president, in the chair.—Dr. C. G. **Knott** and Miss **Dallas**: Magnetic strains in nickel-steel tubes. The material was the usual commercial nickel-steel with 2·63 per cent. of nickel. The four tubes were cut down from the same bar, being all of equal length and equal width, and the bores were $\frac{1}{4}$, $\frac{1}{2}$, $\frac{3}{4}$, and 1 in. in diameter. The changes in the length of each tube in various fields were measured, as were also the corresponding changes in volume of the bore of the material and in the external form when the bores were plugged so that the tubes were in appearance solid cylinders; and from these measurements the values of the several linear dilatations in these fields were calculated. The longitudinal dilatation was always positive, attaining a value of from $3{\cdot}5\times10^{-6}$ to nearly 5×10^{-6} in field 500. The corresponding radial and tangential dilatations were negative, and ranged from $-1{\cdot}3\times10^{-6}$ to $-2{\cdot}4\times10^{-6}$. The results indicate that a spherical element becomes ellipsoidal or spheroidal, with the longest axis along the axis of the tube. If the effect is to be explained in terms of the orientation of magnetic molecules, then these molecules tend to set with their longer axes along the lines of magnetisation. In former experiments with iron and steel the longitudinal dilatation changed sign from positive to negative in fields of about 300 to 400. In nickel, again, the longitudinal dilatation was always negative and about eight or ten times larger than in the case of either iron or steel. In nickel-steel the dilatation remained positive up to the highest fields used (about 900), although in three of the tubes it passed its maximum in field 400 or 500. So far as magnetic strains are concerned, the small admixture of nickel does not impart to the alloy any nickel characteristic whatever.—Prof. W. **Peddie**: The adequacy of the Young-Helmholtz theory of colour-vision and colour-blindness. Trichromasy in normal eyes is not now theoretical, but a proved fact. Hering's theory, which is favoured by some investigators, is, as Helmholtz showed, also a trichromatic theory; and while both can account for the observed facts, the Young-Helmholtz theory is the simplest that can be formulated. Lack of recognition of its accuracy has been due to non-recognition of the fact of normal trichromasy; or to the erroneous supposition that it is tied down to any one definite view of the nature of the physical and physiological actions concerned in vision; or to the equally erroneous supposition that it can account for only one particular type of colour-blindness with merely individual variations. It can account for any type that is known, or for any at present unknown which may afterwards be found to exist, provided only that it arises from limitation of the at present known normal conditions.—Prof. W. **Peddie**: Note on the quaternionic system as the algebra of the relations of physics and relativity. The author showed that in all cases in which our observations are upon directed phenomena occurring in tridimensional space, but which are actually or merely descriptively to be regarded as influenced by the existence of that space in space of a higher order, the appropriate algebra to be used in their investigation is that of quaternions with the addition of the symbol of the space involved.

PARIS.

Academy of Sciences, February 2.—M. Henri Deslandres in the chair.—The president announced the death of Jules Boulvin, correspondant of the Academy.—C. **Moureu** and G. **Mignonac**: The dehydrogenation of the primary and secondary alcohols by catalytic oxidation. A general method of preparation of aldehydes and ketones. Finely divided silver deposited on asbestos was found to be the best catalyst, and the oxidation is carried out in stages, only about half the amount of air theoretically required for the full reaction being employed in the first stage. The results for nine alcohols are given; the yields are high—62 per cent. for formaldehyde and 70 to 95 per cent. for the higher aldehydes.—A. **Gautier**: The normal arsenic in living tissues and the traces of iodine found in air and waters. Some necessary corrections.—G. A. **Boulenger**: An extraordinary tortoise, *Testudo Loveridgii*. This tortoise is the first example of a reptile in the adult state without ribs, and is a unique case of normal osteolysis.—M. Chodat was elected a correspondant for the section of botany in succession to M. Flauhault, elected non-resident member, and M. Ch. Nicolle a correspondant in the section of medicine and surgery in succession to the late M. Lépine.—L. **de Peslouan**: A congruence between Bernoulli's numbers.—P. **Idrac**: Study of hovering flight in Upper Guinea.—M. **Romieux**: Alluvial strata of the Lot in the neighbourhood of Fumel.—L. **Brillouin**: The continuous spectrum of X-rays.—F. **Canac**: The determination of the axes of symmetry of a cubic crystal.—R. **Abrard**: A Mesoliassic fauna of Sidi Mouley Yakoub (Western Morocco).—F. **La Porte**: Atmospheric observations at Gâvre by means of free rubber balloons. The experimental results can be fairly well represented by Dines's formula with a modified numerical constant, $V=\frac{90\sqrt{F}}{(F+P)}$, where V is the ascensional velocity per minute, F the ascensional force, and P the weight of the envelope in grams.—L. **Emberger**: The evolution of the chondriome in the vascular Cryptogams.—L. **Daniel**: Antagonistic reactions and *rôle* of the pad in grafted plants.—M. **Bezssonoff**: Experimental sexuality in fungi, situated on the typical structure of the sexual plasma.—F. **Gard**: Division in *Euglena limosa*.—G. **André**: The inversion of saccharose in the juice of the orange.—E. **Hérouard**: Double monsters of the scyphistome.—C. **Gessard**: Pyocyanoid bacilli.

DIARY OF SOCIETIES.

THURSDAY, FEBRUARY 26.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—A. H. Smith: Illustrations of Ancient Greek and Roman Life in the British Museum.

ROYAL SOCIETY, at 4.30.—*Probable Papers:* L. F. Richardson: Some Measurements of Atmospheric Turbulence.—W. G. Duffield, T. H. Burnham, and A. A. Davis: The Pressure upon the Poles of Metallic Arcs, including Alloys and Composite Arcs.—J. H. Hyde: The Viscosities and Compressibilities of Liquids at High Pressure.—A. Russell: The Capacity Coefficients of Spherical Conductors.—C. Cuthbertson and Maude Cuthbertson: The Refraction and Dispersion of Carbon Dioxide, Carbon Monoxide, and Methane.—A. A. Griffith: The Phenomena of Rupture and Flow in Solids.

INSTITUTION OF ELECTRICAL ENGINEERS, RÖNTGEN SOCIETY, and ROYAL SOCIETY OF MEDICINE (Electro-Therapeutics Section) (at Royal Society of Medicine), at 5 and 8.15 (Joint Discussion on Electrical Apparatus in relation to X-rays).—Dr. R. Morton: The Efficiency of High-Tension Transformers as used for X-ray Purposes.—Major C. E. S. Phillips: The Problems of Interrupted and Fluctuating Currents.—R. S. Wright: High-Tension Transformers.

COLD STORAGE AND ICE ASSOCIATION (at Royal Society of Arts), at 5.—H. J. Deane: The Development of the Cold Storage of the Port of London Authority.

ROYAL COLLEGE OF PHYSICIANS, at 5.—Dr. A. Castellani: The Higher Fungi in relation to Human Pathology (Milroy Lecture).

ROYAL INSTITUTE OF PUBLIC HEALTH, at 5.—Dr. W. E. C. Dickson: Some Pathological Aspects of Tuberculosis.

CONCRETE INSTITUTE (at Vauxhall Bridge Road), at 7.30.—E. F. W. Grimsbaw: Reinforced-Concrete Fences and Posts.

SOCIETY OF ANTIQUARIES, at 8.30.

FRIDAY, FEBRUARY 27.

ROYAL SOCIETY OF MEDICINE (Study of Disease in Children Section), at 4.30.—Dr. Mellanby and Others: Discussion on The Influence of Accessory Food Factors (Vitamine) in Infant Feeding.

PHYSICAL SOCIETY, at 5.—T. Smith: The Balancing of Errors.—Dr. N. W. McLachlan: The Testing of Bars of Magnet Steel.—G. D. West: The Forces Acting on Heated Metal Foil Surfaces in Rarefied Gases.—Miss N. Hosali: Exhibit of Models of Crystals.

INSTITUTION OF MECHANICAL ENGINEERS (Informal Meeting), at 7.—F. W. C. Dean and Others: Discussion on The Education of the Engineer.

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—R. H. Kenyon: Defects found on Inspection of Boilers.

WIRELESS SOCIETY OF LONDON (at Royal Society of Arts), at 8.—A. A. Campbell Swinton: Some Wireless Wonders (Presidential Address).

ROYAL SOCIETY OF MEDICINE (Epidemiology and State Medicine Section), at 8.30.—Dr. M. Young: An Investigation into the Periodicity of Epidemics of Whooping Cough from 1870 to 1910 by means of the Periodogram.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—W. B. Hardy: Problems of Lubrication.

SATURDAY, FEBRUARY 28.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir J. J. Thomson: Positive Rays.

MONDAY, MARCH 1.

INSTITUTE OF CHEMISTRY OF GREAT BRITAIN AND IRELAND, at 4.30.—Annual General Meeting.

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.—General Meeting.

SOCIETY OF ENGINEERS (at Geological Society), at 5.30.—R. H. Cunningham: Some Engineering Work done by the 277th Railway Coy. (R.E.) in France and Belgium during the War.

INSTITUTION OF ELECTRICAL ENGINEERS (Informal Meeting) (at Chartered Institute of Patent Agents), at 7.—R. E. Dickinson: The Future of Labour in the Engineering Industry.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.—H. Austen Hall: The Planning of American Departmental Stores.

ROYAL SOCIETY OF ARTS, at 8.—C. F. Cross: Recent Researches in the Cellulose Industry (Cantor Lecture).

SOCIETY OF CHEMICAL INDUSTRY AND FARADAY SOCIETY (at Chemical Society), at 8.—Dr. T. M. Lowry and F. C. Hemmings: (1) The Caking of Salts and Other Crystalline Substances. (2) The Setting of Dental Cements.

ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 8.30.—Lt. E. W. P. Chinnery: The Opening of New Territories in Papua.

MEDICAL SOCIETY OF LONDON, at 9.—Dr. H. R. Spencer: Tumours complicating Pregnancy, Labour, and the Puerperium (Lettsomian Lecture).

TUESDAY, MARCH 2.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. A. Keith: British Ethnology—The Invaders of England.

ROYAL UNITED SERVICE INSTITUTION, at 3.—Anniversary Meeting.

ROYAL SOCIETY OF ARTS (Colonial Section), at 4.30.—G. F. Scott Elliot: Trade Routes for the Empire in Africa.

ROYAL COLLEGE OF PHYSICIANS, at 5.—Dr. A. Castellani: The Higher Fungi in relation to Human Pathology (Milroy Lecture).

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN (Lantern Meeting), at 7.—Miss Olive Edis: Women on Active Service during the War in France and Flanders.

RÖNTGEN SOCIETY (at Royal Society of Medicine), at 8.—Prof. W. H. Bragg: Analysis by X-rays (Silvanus Thompson Memorial Lecture).

WEDNESDAY, MARCH 3.

ROYAL SOCIETY OF ARTS, at 4.30.—W. J. Garnett: Mongolia from the Commercial Point of View.

ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 8.—Prof. B. Melvill Jones: Flying over Clouds in relation to Commercial Aviation.

INSTITUTION OF AUTOMOBILE ENGINEERS (at Institution of Mechanical Engineers), at 8.—P. J. Worsley: Gears and Gear-cutting.

SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS (at Chemical Society), at 8.—C. Ainsworth Mitchell: The Detection of Finger-prints on Documents.—C. J. Ward: Photomicrography with Simple Apparatus.—R. V. Wadsworth: The Solubilities of Theobromine.

ENTOMOLOGICAL SOCIETY, at 8.—*Probable Paper:* G. J. Arrow: Sexual Dimorphism in Coleoptera (with lantern slides.)

THURSDAY, MARCH 4.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Lt.-Col. E. Gold: The Upper Air: (1) Modern Methods of Investigation, and their Application in the War.

ROYAL SOCIETY, at 4.30.

LINNEAN SOCIETY, at 5.—Dr. A. B. Rendle, E. G. Baker, and S. L. Moore: A Contribution to the Flora of New Caledonia, based on the Collections of R. H. Compton in 1914.

ROYAL COLLEGE OF PHYSICIANS, at 5.—Dr. A. Castellani: The Higher Fungi in relation to Human Pathology (Milroy Lecture).

CHEMICAL SOCIETY, at 8.

FRIDAY, MARCH 5.

ROYAL ASTRONOMICAL SOCIETY, at 5.—(A Geophysical Discussion.) J. de Graaf Hunter and Others: The Earth's Axes and Figure.

CONCRETE INSTITUTE (at 296 Vauxhall Bridge Road), at 6.—E. S. Andrews: Some Properties of Steel.

INSTITUTION OF ELECTRICAL ENGINEERS (Students' Meeting) (at City and Guilds (Engineering) College), at 7.—Roger T. Smith: Presidential Address.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Hon. J. W. Fortescue: Military History.

SATURDAY, MARCH 6.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir J. J. Thomson: Positive Rays.
