Nature

A WEEKLY

ILLUSTRATED JOURNAL OF SCIENCE

VOLUME CIV

SEPTEMBER, 1919, to FEBRUARY, 1920

"*To the solid ground*
Of Nature trusts the mind which builds for aye."—WORDSWORTH

London
MACMILLAN AND CO., LIMITED
NEW YORK: THE MACMILLAN COMPANY

INDEX.

NAME INDEX.

Abbot (C. G.), Measures of Solar Radiation made at Mount Wilson and Calama, Chile, in 1918, 160

Abbott (W. J. Lewis), Percussion Figures in Isotropic Solids, 600

Abell (Prof. R. B.), appointed head of the Dept. of Chemistry of the Bradford Technical College, 345

Abraham (H.), E. Bloch, and L. Bloch, The Ultra-rapid Kinematograph, 459

Ackermann (A. S. E.), Power from the Sun, 500

Adames (H. B.), and J. E. Clark, Royal Meteorological Society's Phenological Returns, 437

Adams (Dr. C. E.), Determination of the Position of the Moon by Photography, 518; Photographs on Glass of the Solar Corona, 518; Tables of Mathematical Functions; The Harmonic Analysis of Tidal Observations and the Prediction of Tides, 517

Adams (J.), Presented with the Silver Medal of the Hunterian Society, 319

Adams (Prof. J.), Tests of Intelligence, 513

Adams (W. S.), and A. H. Joy, Stars of High Velocity, 612; and G. Strömberg, Spectroscopic Determination of Stellar Parallax, 511

Aitken (Dr. J.), [death], 318; [obituary article], 337; bequests by, 376

Aldridge (H. E.), Luminous Worms, 174

Alkins (W. E.), Morphogenesis of *Reticularia lineata*, 427

Allbutt (Sir T. Clifford), The New Birth of Medicine, 204

Allen (Dr. E. J.), The Quantitative Study of Plankton, 707

Allen (Dr. H. S.), A Photoelectric Theory of Colour Vision, 174; Physics for Medical Students, 658

Allen (Dr. R. W.), Practical Vaccine-Treatment for the General Practitioner, 466

Allum (Mr.), The Decimalisation of Currency, 579

Amos (A.), Recommended for Appointment to the Lectureship in Agriculture in Cambridge University, 324

Anderson (Prof. A.), The Deflection of Light during a Solar Eclipse, 394; 436; 563; The Displacement of Light Rays Passing near the Sun, 354

Andersson (Prof. J. G.), Request for a Government Grant for Scientific Researches and Collections in China, 178

Andrew, Greenwood, and Green, Defects in the Final Tests of Nickel-chromium Forgings, 485

Andrewes (Dr. F. W.), appointed Harveian Orator of the Royal College of Physicians, 608

Annandale (Dr. N.), A Loom used by the Gaodar Herdsmen of Seistan, 459; Mortality among Snails and the appearance of Blue-bottle Flies, 412; and others, The Aquatic Fauna of Seistan, 453; and others, The Fauna of the Inlé Lake, 176

Anthony (Dr. H. E.), Mammals Collected in Eastern Cuba during 1917, 672

Arber (Agnes), The Vegetative Morphology of Pistia and the Lemnaceæ, 345

Archer (Ellinor), Longevity of Cut Flowers, 619

Armstrong (Dr. E. F.), The Simple Carbohydrates and the Glucosides. Third edition, 526; and T. P. Hilditch, A Study of Catalytic Actions at Solid Surfaces. Part ii., 406

Armstrong (Prof. H. E.), Chemistry in the Making, 219; and others, Method and Substance of Science Teaching, 521

Arnold (Prof. J. O.), A New Alloy Tool-steel, 416; Resignation of the Positions of Dean of the Faculty of Metallurgy and the Professorship of Metallurgy in Sheffield University, 107; career as Professor of Metallurgy and Dean of the Faculty of Metallurgy in Sheffield University, 127

Ashworth (Dr. J. H.), appointed Professor of Zoology in Edinburgh University, 425; Zoology at the British Association, 456

Aston (Dr. F. W.), Neon, 334; The Constitution of the Elements, 393; The Mass Spectra of the Chemical Elements, 714

Atack (F. W.), assisted by L. Whinyates, The Chemists' Year Book, 1918–19, 2 vols., 112

Auric (M.), The Cycle of Eclipses, 459

Aurousseau (M.), An Interesting Form of Sub-surface Drainage, 587

Babcock (Dr. H. L.), The Turtles of New England, 23

Bacon (Major J. E.), New Sources of Aluminium, 277

Baden-Powell (Lt.-Gen. Sir Robert), The Need of Out-of-School Training and Environment as Auxiliary to Education, 522

Bahl (Karm Narayan), The Excretory System of *Pheretima posthuma*, 359

Bailey (A. M.), The Hawaian Island Reservation, 117

Baillaud (B.), Return of the Finlay Comet, 367

Bainbridge (Prof. F. A.), The Physiology of Muscular Exercise, 590

Bairstow (L.), Position and Prospects of Aviation, 246; The Scientific Development of Aviation during the War, 486; R. H. Fowler, and D. R. Hartree, Pressure Distribution on the Head of a Shell Moving at High Velocities, 618

Baker (Prof. H. F.), Mathematical Notes, 714

Baker (Commdr. T. Y.), and Prof. L. N. G. Filon, A Theory of the Second Order Longitudinal Spherical Aberration for a Symmetrical Optical System, 713

Baldit (A.), Effect produced by the Electricity of Rain on an Insulated Wire, 387

Balfour (Mr.), to be nominated as Chancellor of Cambridge University, 67; nomination for the Chancellorship of Cambridge University, 96; elected Chancellor of the University of Cambridge, 146; inaugurated Chancellor of Cambridge University, 266; The National Need for Scientific Research, 399

Ball (Dr. J.), Determination of Positions in the Libyan Desert, 574

Ballard (Dr. P. B.), The Development of Mental Tests, 513; The Measurement of Practical Ability, 513

Balls (Dr. W. Lawrence), The Equipment of Research Laboratories, 399

Bamford (Capt. A. J.), Some Observations of the Upper Air over Palestine, 366

Barbellion (W. N. P.), Enjoying Life: and other Literary Remains of, 529

Barber (Dr. C. A.), Indian Sugar-canes, 14; 578

Barcroft (J.), Time Relations in a Dream, 154
Barker (Capt. D. Wilson), Use of a Prismatic Binocular for Viewing near Objects, 532
Barlow (the late G. T.), assisted by J. W. Meares. Compiled by J. W. Meares. Hydro-electric Survey of India. Preliminary Report on the Water-power Resources of India, 363
Barnard (Edith E.), A Memorial Fellowship to, in Chicago University, 67
Barnard (J. E.), Construction and Use of Microscopes, 546
Barnes (Rev. Dr. E. W.), Address on James Watt, 75
Barnes and Morris's "Algebraic Cube," 79
Barnett (E. de Barry), appointed Lecturer in Organic Chemistry at the Sir John Cass Technical Institute, 186
Barrell (Prof. J.), [obituary], 444; The Nature and Bearings of Isostasy; The Status of the Theory of Isostasy, 645
Barrett (Sir J. W.), A Vision of the Possible: What the R.A.M.C. Might Become. An Account of some of the Medical Work in Egypt, together with a Constructive Criticism of the R.A.M.C., 21; The War Work of the Y.M.C.A. in Egypt, 560; and Lt. P. E. Deane, The Australian Army Medical Corps in Egypt, 560
Barrow (G.), Some Future Work for the Geologists' Association, 510
Barrs (C. E.), Fibroferrite from Cyprus, 649
Barter (E. G.), Radiation Pressure, 188
Bartholomew (Dr. J. G.), The *Times* Survey Atlas of the World. Part i., 658
Barus (Prof. C.), Report on Achromatic Interferometry, 677
Bateson (Prof. W.), Linkage in the Silkworm: a Correction, 315; The Progress of Mendelism, 214; and Caroline Pellew, Genetics of "Rogues" among Culinary Peas, 649
Baudouin (M.), The Fibula of a Newly-born Infant of the Polished Stone Period, and Consequences in Anatomical Philosophy, 459
Baume (G.), and M. Robert, Some Properties of Pure Nitrous Anhydride and of its Solution in Nitrogen Peroxide, 407
Bausor (H. W.), Senior Practical Chemistry, 497
Baxendell (J.), Meteorological Observations made at the Fernley Observatory, 1918, 477
Baxter and Fargher, Arsenic Compounds for Direct Intravenous Injection in Simple Aqueous Solution, 342
Bayeux (R.), The Ozogenic Power of the Solar Radiation at the Altitude of the Mont Blanc Observatory, 407
Bayliss (Prof. W. M.), awarded the Copley Medal of the Royal Society, 295: 362; An Introduction to General Physiology: With Practical Exercises, 654; Cross-Circulation as a Physiological Method, 479; Intravenous Injections of Gum Solutions in Cholera, 73; Physiology and Medicine, 389
Bazile (G.), New Methods for the Destruction of Acridians, 168
Beale (Sir William P.), re-elected President of the Mineralogical Society, 296
Beaver (W. N.), Unexplored New Guinea, 663
Bedford (the Duke of), and S. Pickering, Science and Fruit-growing: Being an Account of the Results obtained at the Woburn Experimental Fruit Farm since its Foundation in 1894, 558
Bedson (Prof. P. P.), Presidential Address to the Chemistry Section of the British Association, 37: 59
Beebe (C. W.), awarded the Elliot Medal of the U.S. National Academy of Sciences, 376
Bell (A. Graham), The Magnetic Storm of August 11–12, 1919, 7*
Bell (F. Jeffrey), Retirement from the Natural History Museum, 157
Bell (Sir Hugh), Presidential Address to the Economic Science and Statistics Section of the British Association, 37: 162
Bell (L.), The Albedo of Saturn's Rings, 138
Bell (Dr. R. J. T.), appointed Professor of Pure and Applied Mathematics in the University of Otago, 146
Bellay (G. du), and M. Houdard, The Chemical Properties of Humus and their Utilisation for the Protection of Combatants against Asphyxiating Gases, 683
Belot (E.), Vulcanicity, Natural and Artificial, 575
Benedicks (C.), The Thermo-electricity of Liquid Mercury Demonstrated by means of the Galvanometer, 187
Benedict (F. G.), W. R. Miles, P. Roth, and H. M. Smith, Human Vitality and Efficiency under Prolonged Restricted Diet, 644
Bennett (G. M.), and E. E. Turner, Organo-metallic Derivatives of Chromium, Tungsten, and Iron, 148
Benson (W. A. S.), Rudiments of Handicraft, 72
Bent (A. C.), Nearctic Diving Birds of the Order Pygopodes, 320
Bergstrand (Dr.), The Group of Helium Stars in Orion, 299
Berry (Dr. E. W.), Cretaceous Plant-remains from Tennessee, etc., 542
Bertrand (G.), Brocq-Rousseu, and Dassonville, Comparative Action of Chloropicrin on the Weevil and on Tribolium, 619; Influence of Temperature and other Physical Agents on the Insecticidal Power of Chloropicrin, 459; The Destruction of Bed-lice by Chloropicrin, 68; and M. Dassonville, Treatment of Scab in Horses by the Vapours of Chloropicrin, 88
Bertrand (L.), and A. Lanquine, Relations between Chemical Composition, Microscopic Structure, and the Ceramic Qualities of Clays, 523
Besson (L.), Diminution of the Transparency of the Air at Paris, 651
Beuzeville (W. A. W. de), Determination of the Increment of Trees by Stem Analysis: *Eucalyptus viminalis*, 587
Bichet (A.), A System of Aiming at Objects in the Air, 307
Bierry (H.), Carnivora and the Three Classes of Food, 387
Biesbroeck (G. van), Relative Masses of Binary Stars, 643
Biles (H. J. R.), awarded the Cammell Laird Scholarship by the Institution of Naval Architects, 186
Bilham (E. G.), Barometric Pressure and Underground Water-level, 366
Bintner (J.), The Symptoms and Distribution of Silver-leaf Disease, 359
Bird (W. B. M.), Work of the Salters' Institute of Industrial Chemistry, 398
Birmingham (the Bishop of), and others, The Declining Birth-rate, 157
Bissell (Dr. W. G.), [death], 357
Bjerknes (Prof. V.), Structure of the Atmosphere when Rain is Falling, 346
Black (F. A.), Planetary Rotation Periods and Group Ratios, 370
Blair (K. G.), The Australian Genus Cestrinus, Er. (fam. Tenebrionidæ), and Some Allied Genera, 407
Blair (Sir Robert), Continuation Schools, 522
Bland-Sutton (Sir John), elected First President of the Association of Surgeons of Great Britain and Ireland, 507
Blaringhem (L.), Vigour of Growth, compensating Sterility in the Hybrids of Species of Digitalis, 88
Blatter (Prof. E.), "Flora Arabica," Part i., 609
Blatterman (Capt. A. S.), The Theory and Use of Radio-direction-finding Apparatus, 137
Bliss (Major H. J. W.), Research Associations and Consulting Work and the Collection and Indexing of Information, 399
Bloch (E.), A Spectroscopic Arrangement for the Study of the Extreme Ultra-violet, 683
Bloch (L.), Industrial Applications of Amplifying Electric Valves, 647
Blondel (A.), A Solution of Heterochromatic Photometry permitting of a Physical Measurement of the Luminous Intensity, 367
Blount (B.), and J. H. Sequeira, The Colours of "Blue John" and other Varieties of Fluorite, 65
Bolduan (Dr. C. F.), and J. Koopman, Immune Sera, Fifth edition, 434
Bolton (Dr. C.), Award of the Charles Graham Gold Medal to, 344
Bolton (H.), Report on the Bristol Museum and Art Gallery, 1918–19, 574
Bond (F. B.), The Hill of Vision: A Forecast of the Great War, and of Social Revolution with the Coming of the New Race, 690
Bonde (C. v.), Some Abnormalities in the Cape Crawfish (*Jasus lalandii*), 148

Bonhote (J. L.), The Practice of Bird-liming in Lower Egypt, 444
Bonney (Prof. T. G.), Annals of the Philosophical Club of the Royal Society, written from its Minute Books, 45; The Expansion of Geology, 203
Bonnier (G.), Comparative Culture of Seedlings at High Altitudes and in the Plain, 523
Bordas (F.), Milk Contamination, 523; The Preparation and Conservation of Sera and Vaccines by Drying in an Absolute Vacuum, 307
Bose (Sir J. C.), The Response of Plants to Wireless Stimulation, 172
Boswell (Prof.), Some Recent Problems in Geo-Chemistry, 455
Bothezat (G. de), The General Theory of Blade-screws, 543
Botley (Cicely M.), Mirage Effects, 565
Bottomley (W. B.), Effect of Nitrogen-fixing Organisms and Nucleic Acid Derivatives on Plant-growth, 345
Bougault (J.), and P. Robin, The Oxidation of Benzaldoxime, 20; The Oxidation of the Hydramides, 407
Boule (Prof. M.), Vertebrate Remains in the Caverns of Grimaldi, 581
Boulenger (E. G.), Methods of Rat Destruction, 97
Boulenger (G. A.), An Extraordinary Tortoise, *Testudo Loveridgii*, 715; The Genus Saphæosaurus, 271
Boulin (Ch.), and L. J. Simon, Action of Stannic Chloride on Dimethyl Sulphate, 271
Bower (Prof. F. O.), Botany of the Living Plant, 274; elected President of the Royal Society of Edinburgh, 177; Joseph Dalton Hooker, 561; Prof. J. Graham Kerr, and Dr. W. E. Agar, Lectures on Sex and Heredity, delivered in Glasgow, 1917–18, 351
Bowie (W.), Connection of the Arcs of Primary Triangulation along the Ninety-eighth Meridian in the U.S. and in Mexico, 509
Boycott (Prof. A. E.), Sedimentation of Blood Corpuscles, 532
Boyle (J. S. W.), appointed Lecturer and Assistant in Chemistry in University College, Dundee, 87
Braae and Fischer-Petersen, Comet 1919*b*, 100, 138, 180, 361
Brabrook (Sir E.), The Anthropological Institutes of France and the United Kingdom, 476
Brade-Birks (Hilda K.), and Rev. S. Graham Brade-Birks, Luminous Chilopoda, with special reference to *Geophilus carpophagus*, Leach, 705
Brade-Birks (Rev. S. Graham), appointed Lecturer in Zoology at the South-Eastern Agricultural College, 167; Luminous Worms, 23; 93
Bradlee (F. B. C.), The Maritime History of Newburyport, Mass., 639
Braesco (P.), The Expansion of Copper-antimony Alloys, 651
Bragg (Prof. W. H.), elected President of the Physical Society, 701; to deliver the Juvenile Christmas Lectures at the Royal Institution, 318; to deliver the Silvanus Thompson Memorial Lecture of the Röntgen Society, 670; X-rays in Physical Science, 235
Bragg (Prof. W. L.), Sound-ranging, 187
Branford (B.), A New Chapter in the Science of Government, 494
Brauner (Prof. B.), A Tribute from Prague, 374; Entente Scientific Literature in Central Europe during the War, 600
Breasted (Prof. J. H.), The Origin of Civilisation, with special reference to the Nile Valley, 267
Breton (A. C.), a Remarkable Picture-map from Mexico, 702
Brierley (W. B.), Species in Relation to Fungi, 520; 708
Bright (Sir Charles), Inter-Imperial Communication, through Cable, Wireless, and Air Methods, 137
Britton (N. L.), and J. N. Rose, The Cactaceæ, 41
Brodetsky (Dr. S.), Mathematical Text-books, 109; Mathematics, Particular and General, 390
Broili (Dr. F.), appointed Professor of Geology and Palæontology in the University of Munich, 443
Brooks (C. E. P.), Incidence of Fog in London on January 31, 1918, 675
Brooks (Sir D.), The Proposed James Watt Memorial, 74
Brown (Prof. E. W.), The Secular Acceleration of the Moon, 299
Brown (Dr. R. N. Rudmose), Spitsbergen: An Account of Exploration, Hunting, the Mineral Riches and Future Potentialities of an Arctic Archipelago, 635; The Coal Export Trade from Spitsbergen, 514
Browne (F. Balfour), appointed University Lecturer in Zoology in Cambridge University, 425
Brownlee (Dr. J.), The Periodicity of Influenza Epidemics, 296
Brownlie (D.), The Performance of Colliery Steam Boiler-plants, 120; The Running of Steam-boiler Plants, 611
Brunt (D.), Internal Friction in the Atmosphere, 714; On the Inter-relation of Wind Direction and Cloud Amount at Richmond, 675
Brunton (J. D.), Gift to the Applied Science Department of Sheffield University, 67
Bryan (Prof. G. H.), Aeronautics in Italy, 656; Hodgson's Tri-lingual Artillery Dictionary, 3 vols., 332; President-elect of the Institute of Aeronautical Engineers, 340; The Neglected Study of Probabilities, 464; The Sound Emitted by Air-screws, 486; Improvement of the Efficiency of Radiators in the Heating of Rooms, 487
Bryant (Major V. S.), Science in Preparatory Schools, 514
Buchanan (J. Y.), Accounts Rendered of Work Done and Things Seen, 686
Buckman (S. S.), Jurassic Chronology: I., Lias. Supplement I., West England Strata, 586
Bugnon (P.), Use of Commercial Inks in Plant Histology, 459
Buller (Prof. A. H. R.), elected President of the Canadian Branch of the Phytopathological Society of the United States, 541
Bulloch (Prof. W.), appointed Professor of Bacteriology in London University, tenable at the London Hospital Medical College, 425
Burchall (P. R.), Elementary Survey of the Present Position of Aerial Photogrammetry, 379
Burchnall (Capt. L. L.), appointed Lecturer in Mathematics in Durham University, 385
Burd (J. S.), Experiments in the Cultivation of Barley, 446
Burley (G. W.), The Cutting Power of Lathe-turning Tools, 478
Burrows (G. J.), Volume Changes in the Process of Solution, 147
Burstall (Prof. F. W.), The Rise of Engineering Manufacture, 74
Bury (E.), Production of Alcohol from Ethylene, 416
Butler (Prof. G. M.), Handbook of Mineralogy, Blowpipe Analysis, and Geometrical Crystallography, 434
Butterfield (K. L.), The Farmer and the New Day, 592
Butterworth (S.), The Self-inductance of Single-layer Flat Coils, 366
Buxton (L. H. D.), Measurements of Skulls in Cyprus, 487

Caie (J. M.), Food Production in Scotland, 553
Calder (Prof. W. M.), Geography and History in the Mediterranean, 650
Calman (Dr. W. T.), appointed Secretary of the Ray Society, 158
Calvert (A. F.), Salt and the Salt Industry, 497
Cambage (R. H.), Acacia Seedlings. Part v., 555
Campbell (Prof. E. D.), The Solution Theory of Steel, etc., 523
Campbell (J. M. H.), C. G. Douglas, and F. G. Hobson, The Respiratory Exchange of Man during and after Muscular Exercise, 427
Campbell (Dr. Norman R.), National Representation upon International Councils, 72
Campbell (Dr. W. W.), elected an Honorary Member of the Royal Institution, 358
Camsell (C.), and W. Malcolm, The Mackenzie River Basin, 640
Cantrill (T. C.), Dr. R. L. Sherlock, and H. Dewey, Iron Ores: Sundry Unbedded Ores of Durham, East Cumberland, North Wales, Derbyshire, the Isle of Man, Bristol District and Somerset, Devon and Cornwall, 429
Caporn (A. St. Clair), Early and Late Ripening in an Oat-cross, etc., 81
Cardot (J.), Proposal to Purchase the Herbarium of Mosses of, 572
Cargill (J. T.), Gift to Glasgow University, 325

Carleton (H. M.), The Cajal Formalin-silver Nitrate Impregnation Method for the Golgi Apparatus, 406
Carothers (S. D.), Plane Strain: The Direct Determination of Stress, 617
Carpenter (Prof. G. H.), Heredity and Evolution, 81
Carpenter (Prof. H. C. H.), A New Copper-refining Industry in Great Britain, 666; The Trend of Modern Metallurgy, 243
Carpentier (Gen. H. W.), Bequests by, 167
Carpentier (J.), Colour Kinematographs of the Gaumont Establishment, 387
Carr (F. H.), elected a Director of the British Drug Houses, Ltd., 638
Carroll (Dr. R. S.), The Mastery of Nervousness based upon Self-Re-education. Third revised edition, 687
Casanowicz (I. M.), Catalogue of Examples of Ecclesiastical Art in the U.S. National Museum, 40
Cashmore (M.), Fermat's Last Theorem: Three Proofs by Elementary Algebra. Revised edition, 171
Casson (S.), Discoveries in the Balkans during the War, 487; Western Turkestan, 335
Castelnuovo (Prof. G.), Calcolo delle Probabilità, 464
Cater (G.), The Nature of Inference, 407
Cave (Capt. C. J. P.), Quotations from the Diary of Samuel Pepys on the Weather, 458; The Audibility of Thunder, 132; The Deflection of Light during a Solar Eclipse, 413; The Status of a Meteorological Office and its Relation to the State and to the Public, 705
Cave-Browne-Cave (Wing-Commdr.), Airships, 486
Chadwyck-Healey (Sir Charles), [obituary], 136
Chalmers (S. D.), [obituary], 318
Chamberlain (Austen), The Government and University Education, 75
Chamberlain (Prof. C. J.). The Living Cycads, 410
Chapman (Capt. E. H.), On the Use of the Normal Curve of Errors in Classifying Observations in Meteorology, 675; The Study of the Weather, 312; The Variation of Wind Velocity with Height, 675
Chapman (F.), An Ostracod and Shell-marl of Pleistocene Age from Boneo Swamp, Victoria, 108; Tertiary Fossils from the Ooldea Soak, South Australia, 347; Tertiary Fossils from Ooldea: Additional Note, 619
Chapman (R. H.), [obituary], 608
Chapman (Prof. R. W.), The Elements of Astronomy for Surveyors, 499
Chapman (Prof. S. J.), The Appointment of, to the Joint Permanent Secretaryship of the Board of Trade, 135
Chardonnet (M. de), The Use of Autochrome Plates instead of Hand-paintings for Clouds, 307
Charlier (C. L.), The Spiral Nebulæ, 68
Charoy (G.), and J. Durand, A Cause of Rupture of Steel Rails, and a Means of Suppressing it, 271
Chatterjee (N.), The Upper Limit of Unpleasant Beats, 708
Chatterjee (N. N.), The Nationalisation of Algebraic Equations, 187
Chavanne (G.), L. P. Clerc, and L. J. Simon, Analyses of German Aviation Petrols, 307
Cheel (E.), Three New Species of Leptospermum, 168
Cheeseman (T. F.), The Vascular Flora of Macquarie Island, 101
Chelle (L.), Detection and Estimation of Traces of Hydrocyanic and Thiocyanic Acids in a Complex Medium, 407; Detection of Hydrocyanic Acid in a Case of Poisoning, 367; Transformation of Hydrocyanic Acid into Thiocyanic Acid in the Course of Cadaveric Putrefactions, 327
Cheshire (Prof. F.), The Outlook of British Technical Optics, 530
Chevenard (P.), The Viscosity of Steels at High Temperatures, 326
Chilton (Prof. C.), A New Isopodan Genus (fam. Oniscidæ) from Lake Corangamite, Victoria, 555; Destructive Boring Crustacea in New Zealand, 78; *Orchestia tucuranna* in New Zealand, 41
Chinnery (Lieut. E. W. P.), "Dengora baiari" Initiation Ceremony of the Binandere Tribe, 386; People of the Hilly Country of New Guinea; Stonework and Goldfields in New Guinea, 488
Chofardet (P.), Observations of Borrelly's Comet, 87; Observations of Finlay's Comet made at the Besançon Observatory, 387
Chree (Dr. C.), awarded the Hughes Medal of the Royal Society, 295, 363; A Magnetic Storm Recorded at Kew Observatory, 120; The Magnetic Storm of August 11-12, 1919, 468
Christmas (W. D.), Exceptional Dryness of October, 1919, 278
Church (Major A. G.), appointed Secretary of the National Union of Scientific Workers, 444; Scientific Workers and a National Federation, 693
Church (Sir Arthur H.), The Collection of Precious Stones of the late, in the Natural History Museum, 357
Church (A. H.), Thalassiophyta and the Sub-aerial Transmigration, 624; The Building of an Autotrophic Flagellate, 594
Clark (W. B.), The Geography of Maryland, 703
Clarke (I. M.), The New Gaspé Bird Sanctuaries in Canada, 117
Claude (G.), Advantages of the Synthesis of Ammonia at very High Pressures, 683; The Industrial Employment of Extremely High Pressures, 307; The Synthesis of Ammonia at very High Pressures, 459
Clay (Prof. A. T.), American Scholars and Research Work in Asia, 64
Clements (A. J.), The Trade in Musk, 97
Clifford (F. W.), The Library of the Chemical Society: A Record of a Recent Attempt at Co-operation, 298
Clowes (Prof. F.), and J. B. Coleman, A Treatise on Qualitative Analysis: Adapted for Use in the Laboratories of Colleges and Technical Institutes, Ninth edition, 688; Elementary Practical Chemistry, Part i., General Chemistry, Seventh edition, 688
Coblentz (W. W.), and H. Kahler, Change in the Electrical Resistance of the Sulphide of Silver and of Bismuth, 478
Cockayne (Dr. L.), The Aims and Aspirations of the New Zealand Institute, 516; The Papers Presented to the New Zealand Science Congress, 516
Cockerell (Prof. T. D. A.), Sugar-beet Seed, 661
Cohn (Prof.), A Sixth Member of the Trojan Group of Planets, 100; Minor Planets, 511
Coker (Prof. E. G.), and K. C. Chakko, The Stress-strain Properties of Nitro-cellulose and the Law of its Optical Behaviour, 617
Coker (R. E.), The Habits and Economic Relations of the Guano Birds of Peru, 378
Coldstream (Lt.-Col. W. M.), The Survey of India Maps and the Modern Development of Indian Cartography, 574
Cole (Prof. G. A. J.), elected President of the Irish Geographical Association, 554; Ireland: The Outpost, 411; On Lecturing with the Lantern, 457
Cole (Dr. L. J.), and Dr. W. A. Lippincott, Relation of Plumage to Ovarian Condition, 81
Colin (H.), and Mlle. A. Chaudin, The Diastatic Inversion of Saccharose, 367
Connell (A.), appointed Professor of Surgery in Sheffield University, 385
Conrady (Prof. A. E.), Microscopical Optics, 548
Conyngham (Col. L.), Exploration in Tibet and Neighbouring Regions, 1865-79, 570
Cooper (W. R.), Retirement from the Editorship of the *Electrician*, 266
Cope (J. L.), A British Imperial Antarctic Expedition, 93
Coriat (Dr. I. H.). What is Psychoanalysis?, 22
Coronas (Rev. J.), The "Quantico" Typhoon, 79
Cortie (Rev. A. L.), A New Astronomical Model, 343; A Solar Eruption in a Giant Star, and Spectral Changes, 454
Cosserat (E.), Some Stars Possessing a Total Annual Proper Motion of more than 0.5", 68
Couch (Sir A. Quiller), The Teaching of English, 521
Coulter (Prof. J. M.), The Evolution of Botanical Research, 581
Coupin (H.), The Causes of the Elongation of the Stem of Etiolated Plants, 683

Rendle (Dr. A. B.), Organisation of Scientific Work, 691
Rey (J.), The Characteristic of a Lighthouse at the Horizon, 271
Reynolds (Prof. J. Emerson) [death], 701
Reynolds (J. H.), Fifty Years of Technical Education, 257
Riccò (Prof. A.), Heliographic Latitudes of the Solar Protuberances (1880–1918), 187; [obituary], 378
Rice (J.), The Predicted Shift of the Fraunhofer Lines, 598
Richards (Prof. T. W.), elected President of the American Academy of Arts and Sciences, 116
Richardson (L. F.), The Deflection of Light during a Solar Eclipse, 393
Richet (Prof. C.), Injections of Gum or of Plasma after Bleeding, 491; La Sélection Humaine, 351
Rideal (E. K.), Conferment of Doctorate upon, by the University of London, 185; and Prof. H. S. Taylor, Catalysis in Theory and Practice, 463
Ridewood (Dr. W. G.), Cephalodiscus, 481
Ridgeway (Sir William), A Remarkable Irish Bronze Axe, 445; The Colours of Racehorses, 334
Rigg (T.), appointed Agricultural Chemist at the Cawthorn Research Institute, 442
Rintoul and Baxter (The Misses), Report on Scottish Ornithology for 1918, 10
Roaf (Dr. H. E.), appointed Professor of Physiology at the London Hospital Medical College, 616; Pathology of Pellagra, 520
Robb (Dr. A. A.), The Straight Path, 509
Robbins (Prof. W. W.), The Botany of Crop Plants, 46
Roberts (Prof. M. M.), and Prof. J. T. Colpitts, Analytic Geometry, 390
Robertson (C. Grant), appointed Principal of Birmingham University, 425; Welcomed as Principal of Birmingham University, 615
Robertson (Dr. G. M.), appointed Professor of Psychiatry in Edinburgh University, 425
Robin (P.), The Peroxide of Benzaldoxime, 307
Robinson (Capt. J.), Directive Wireless Telegraphy as Applied to Aircraft, 487; Wireless Navigation for Aircraft, 24
Robinson (W.), Microscopical Features of Mechanical Strains in Timber, etc., 345
Robson (F.), The Seashore: Its Inhabitants and How to Know Them, 132
Rockefeller (J. D.), Gift to the General Education Board, 158; Further Gift to the Rockefeller Institute, 267; Large Gift for Education and Science, 457
Rogers (Sir Leonard), Intravenous Injections of Gum Solutions in Cholera, 73
Rohlfs (R.), A High Aeroplane Altitude, 63; A Record Aeroplane Ascent, 77
Rohr (Prof. von), Optical Systems and the Graphical Methods of Determining Images, 704
Rolleston (Dr.), The Epidemiology, Symptoms, and Treatment of Cerebro-spinal Fever, 359
Rolleston (Sir Humphry Davy), Gifts to the Royal Institution, 296
Ross (E.), The Climate of Liberia and its Effect on Man, 136
Ross (Sir E. Denison), Report of the Calcutta University Commission, 537
Ross (Prof.), National Scientific Organisation and Education, 578
Ross (Sir Ronald), Work for the National Union of Scientific Workers, 297
Ross (R.), Mirage Effects, 662
Roubaud (E.), Antagonism of Cattle and Man in the Blood Nutrition of *Anopheles maculipennis*, 88
Round (Capt. H. J.), Radio Direction and Position Finding, 576
Roussy (G.), J. Boisseau, and M. d'Œlsnitz, Traitement des Psychonévroses de Guerre, 22
Roux (Prof. E.), awarded the Oliver Sharpey Prize by the Royal College of Physicians, 608
Roux (Dr. P. B. E.), elected an Honorary Member of the Royal Institution, 358
Runner (G. H.), The Tobacco Beetle: An Important Pest in Tobacco Products, 301
Running (Prof. T. R.), Empirical Formulas, 109
Russ (Dr. S.), elected President of the Röntgen Society, 96
Russell (A.), Occurrence of Phenakite and Scheelite at Wheal Cock, St. Just, 326
Russell (Capt. A. S.), to Edit *Discovery*, 186
Russell (Dr. E. J.), Dr. Cyril G. Hopkins, 442; Farming in the New Era, 592; The Ithaca Agricultural Experimental Station, 482; War-time and Post-war Problems of Food Production, 553
Russell (Hon. G. W.), Plea for Government Support for Science in New Zealand, 516
Russell (Prof.), The Sources of Stellar Energy, 269
Rutherford (Sir Ernest), Radium and the Electron, 226; and Dr. A. H. Compton, Radio-activity and Gravitation, 412

Sabatier (Dr. P.), elected an Honorary Member of the Royal Institution, 358; and A. Mailhe, The Catalytic Reduction of the Halogen Acetic Esters, 347
Sachs (E. O.) [obituary], 63
Saha (Megh Nad), Radiation Pressure, 448
Saillard (E.), The Nitrogen Balance in Sugar Manufacture, 651
Salter (Carle), and F. J. W. Whipple, Editors of the *Meteorological Magazine* (hitherto *Symons's Meteorological Magazine*), 608
Sampson (Prof. R. A.), Newton's Views on Gravitation, etc.; The Theory of Einstein and its Observational Tests, 458
Sanford (Prof. F.), The *ignis fatuus*, 267

Sankey (G. S.), made a K.B.E., 443
Saunders (Miss), A Graded Series of Forms in Matthiola, 521
Saunders (J. T.), Hydrogen-ion Concentration and Photosynthesis, 366
Savile (Sir Henry), The Tercentenary of the Foundation of the University Chairs of Geometry and Astronomy by, 398
Schafer (Sir E. Sharpey), Developments of Physiology, 207; The Fatal Result of Section of Both Vagus Nerves, 418
Schaumasse (A.), Observations of Finlay's Comet made at the Nice Observatory, 387
Schlesinger (Dr. F.), elected Director of the Yale Observatory, 417; Two Stars with Large Parallaxes, 342
Schnittger (Dr. B.), A Large Neolithic Graveyard found by, at Gestilren, 77
Schoeller (Dr. W. R.), and A. R. Powell, The Analysis of Minerals and Ores of the Rarer Elements for Analytical Chemists, Metallurgists, and Advanced Students, 310; Villamaninite, a New Mineral, 326
Scholes (G. E.), appointed Professor of Engineering-thermodynamics of Heat Engines, 648
Schorr (Dr.), Holmes's Comet, 704
Schott (G. A.), The Scattering of X- and Y-rays by Rings of Electrons, 365
Schuchert (Dr. C.), The Stratigraphical Position of the American Morrison and the East African Tendaguru Formations, 672
Schuster (Sir Arthur), The Deflection of Light during a Solar Eclipse, 468; The Influence of Small Changes of Temperature on Atmospheric Refraction, 714
Schwarz (Prof. E. H. L.), The Kalahari Lake Scheme, 158
Scott (Dr.), Relation of the Seed-plants to the Higher Cryptogams, 521
Seares (F. H.), Absolute Magnitude as a Function of Colour, 479
Searles (E. F.), Gift to the University of California, 67
Sebileau (Dr.), appointed Professor of Laryngology in the University of Paris, 107
Senderens (J. B.), The Catalytic Hydrogenation of Lactose, 650
Senter (Dr.), and others, The Present Position of the Theory of Ionisation in Solution, 707
Sexton (Mrs. E. W.), appointed a Ray Lankester Investigator at the Marine Biological Laboratory, Plymouth, 701
Shackleton (Sir Ernest), South: The Story of Shackleton's Last Expedition, 1914–17, 602
Shah (Ikbal Ali), The Folk-life of Afghanistan, 573

TITLE INDEX.

Aberdeen University: Dr. J. Cruickshank appointed Georgina McRobert Lecturer in Pathology in, 385; Conferment of Honorary Degrees, 712
Aberystwyth, University College of Wales, B. M. Jones elected Professor of Chemistry in the, 186
Absolute Magnitude as a Function of Colour, F. H. Seares, 479
Acacia Seedlings, Part v., R. H. Cambage, 555
Acacias, Notes on, No. iv., J. H. Maiden, 586
Acalypha indica, The Dimorphic Female Flower of, L. A. Kenoyer, 297
Accipitres, A Synoptical List of the (Diurnal Birds of Prey), Parts i. and ii., H. Kirke Swann, 529
Accounts Rendered of Work Done and Things Seen, J. Y. Buchanan, 686
Acridians, New Methods for the Destruction of, G. Bazile, 168
Acrolein: The Stabilisation of, C. Moureu and C. Dufraisse, 307; C. Moureu, C. Dufraisse, P. Robin and J. Pougnet, 650; C. Moureu and A. Lepape, 326, 387
Actinium, The Genesis of, O. Hahn and L. Meitner, 575
Admiralty, Board of, Resignation of Prof. J. C. McLennan of the Post of Scientific Adviser to the, 340
Adult Education: 452; Committee of the Ministry of Reconstruction, Final Report of the, 452
Advisory Council to the Committee of the Privy Council for Scientific and Industrial Research, Sir Henry A. Miers appointed a Member of the, 178
Aerial: Photogrammetry, the Present Position of, P. R. Burchall, 379; Photography, Application of, to Hydrographic Surveys, J. Volmat, 326
Aeronavigazione e Costruzioni Aeronautiche, Dizionario Internazionale di, Italiano, Francese, Inglese, Tedesco, Lt. M. M. Dander, 656
Aeronautica, Meteorologia, Prof. G. Crestani, 656
Aeronautical Engineers, Institute of, Foundation of an, Prof. G. H. Bryan President Elect of, 340
Aeronautics: Exhibition at the Science Museum, South Kensington, 397; in Italy, Prof. G. H. Bryan, 656
Aero-Photography, the Field of Application for, P. Dautriche, 99
Aeroplane: Altitude Record, An, R. Rohlfs, 77; Flight from Cairo to Capetown, 607; to Australia, The, Capt Ross Smith, 397; High Altitude, An, R. Rohlfs, 63; Use of the, in African Exploration, Lieut. L. Walmsley, 379
Æther: and Matter: being Remarks on Inertia, and on Radiation, and on the Possible Structure of Atoms, Sir Oliver J. Lodge, 15, 82; The, *versus* Relativity, Sir Oliver J. Lodge, 543
Afforestation of Water-catchment Areas, Prof. A. Henry, 520, 554
Afghanistan, The Folk-life of, Ikbal Ali Shah, 573
Africa, Tropical, Raw Materials and Railways of, North of the Equator, M. Tilho, 68
African Rift Valley, The, Prof. J. W. Gregory, 518
Agar-agar, The Preparation of, in California, 703
Agricultural: and Horticultural Research Station, Long Ashton, Report of the, 418; Experimental Station, Ithaca, New York, Reports of the, for the Years 1914–17, 482; Research, A New Development in, 579
Agriculture: and the State, Sir Arthur Griffith-Boscawen, 181; at the British Association, Prof. A. Lauder, 553; Electricity in, Dr. J. F. Crowley, 268; Frosts and, in the United States, 95; Productive, Prof. J. H. Gehrs, 495; The Preparation of Substances important in, Prof. C. A. Peters. Third edition, 497
Aiming at Objects in the Air, A System of, A. Bichet, 307
Air: -brakes, Application of, to Aeroplanes, Capt. R. West, 486; Diminution of the Transparency of the, at Paris, L. Besson, 651; Navigation Research Section of the Air Ministry, Major H. E. Wimperis appointed Head of the, 572; obtained at High Altitudes, Proposed Analysis of, C. T. Kingzett, 540; Pollution of the, by Smoke, etc., Appointment of a Departmental Committee upon, 701; Routes, Imperial, Major-Gen. Sir F. H. Sykes, 634; -screws, The Sound emitted by, Prof. G. H. Bryan, 486

Aircraft: Research, The Need for, 589; Wireless Navigation for, Capt. J. Robinson, 24
Airships, Wing-Comdr. Cave-Browne-Cave, 486
Ajuga genevensis and *Centaurium scilloides*, Druce, var. *portense* (Brot.), Occurrence in Britain as Native Plants of, Dr. G. C. Druce, 406
Albany, The Geology of, Jutson and Simpson, 579
Alcohol: from Ethylene Gas, E. Bury, 416; its Production, Properties, Chemistry, and Industrial Applications. With Chapters on Methyl Alcohol, Fusel Oil, and Spirituous Beverages, C. Simmonds, 431; or Ether, A Commercial Method for the Synthetic Production of, starting with Coal-gas, E. de Loisy, 650; Power, Investigation Officer, Col. Sir Frederic Nathan appointed, 540
Alcohols, the Primary and Secondary, The Dehydrogenation of, by Catalytic Oxidation, C. Moureu and G. Mignonac, 715
Aldabra, etc., The Flora of, Dr. W. B. Hemsley, 118
Algal Deposits, Pre-Cambrian and Carboniferous, W. H. Twenhofel, 640
Algebra, A Linear Associative, suitable for Electro-magnetic Relations and the Theory of Relativity, W. J. Johnston, 365
Algebraic: Cube, The, 79; Equations, The Rationalisation of, N. N. Chatterjee, 187
Allen County, Kentucky, The Oilfields of, Shaw and Mather, 672
Alloys: Light Aluminium Casting, Tests of, 478; of the Duralumin Type, Heat-treatment of, 510; of Tin, Antimony, and Arsenic, Some Ternary, Dr. J. E. Stead, 448; Spherical Shell Crystals in, 448
Alpine Plants for Rock-gardens, 664
Alsace and Lorraine: Geological Survey of, E. de Margerie appointed Director of the, 157; The Mineral Resources of, L. de Launay, 640
Alternating-current Electrolysis, S. Marsh, 617
Alum Carmine and its Use, combined with Iodine Green in Plant Histology, R. Mirande, 683
Aluminium Alloys: The Tempering of certain, L. Guillet, J. Durand, and J. Galibourg, 128; The Transformation undergone by certain, L. Guillet, 459; Thermal Treatment of, M. Grard, 187; in Norway, New Sources of, L. Hawkes, 160; New Sources of, Major J. E. Bacon, 277; Spontaneously Oxidisable in the Air, E. Kohn-Abrest, 618
Aluminiumfremstilling av Norske Raastoffer, Om, Prof. V. M. Goldschmidt, 161
America of To-day, The, being Lectures delivered at the Local Lectures Summer Meeting of the University of Cambridge, 1918. Edited by Dr. G. Lapsley, 151
American: Academy of Arts and Sciences, Prof. T. W. Richards elected President of the, 116; Agriculture, An Atlas of, 640; Association, The St. Louis Meeting of the, 612; Dr. L. O. Howard appointed President of the Association, and Prof. E. L. Nichols General Secretary, 613; Books on Agriculture, 495; Embassy, Closing of the Office of Scientific Attaché at the, 40; History, Literature, and Institutions, Endowment of a Chair in, Sir George Watson, 386; Meteorological Society, Formation of an, 40; Morrison and the East African Tendaguru Formations, The Stratigraphical Position of the, Dr. C. Schuchert, 672; Scholars and Research Work in Asia, Prof. A. T. Clay, 64; Universities, 151
Americans who have produced Inventions of the First Rank, 11
p-Aminocarvacrol, Preparation of, and its Use as a Developing Agent in Photography, H. A. Lubs, 79
Amœbæ: living in Man, The, Prof. C. Dobell, 369; Parasitic, and Disease, Sir E. Ray Lankester, 369
Ammonia: Advantages of the Synthesis of, at Very High Pressures, G. Claude, 683; Nitrate of, The Extraction of, from Surplus Stocks of Explosives, Prof. Garelli, 447; The Synthesis of, at Very High Pressures, G. Claude, 459
Ammunition Chemist, Work of an, in the Field, Major E. R. Thomas, 455
Amplifying Electric Valves, Applications of, L. Bloch, 647
Anaphylaxy due to Antipyrin after a Long Phase of Sensibilisation, F. Widal and P. Vallery-Radot, 683
Andalusian Fowl, The Blue, Dr. W. A. Lippincott, 81
Anderson College of Medicine, Glasgow, Dr. J. Graham appointed Professor of Anatomy in the, 19
Andes of Peru and Bolivia, Geological Sections through the, ii., J. A. Douglas, 681
Anglo-Saxon Remains at Ravensbury Manor, Mitcham, 474
Animal Life: and Human Progress. Edited by Prof. A. Dendy, 21; Secrets of, Prof. J. Arthur Thomson, 172
"Anlage," A Protest against the Use of the Word, Dr. Th. Mortensen, 357
Anopheles maculipennis, Antagonism of Cattle and Man in the Blood Nutrition of, E. Roubaud, 88
Antarctic Whaling, Dr. S. F. Harmer, 377
Anthropological Institutes of France and the United Kingdom, The, Sir E. Brabrook, 476
Anthropology at the British Association, 487
Apples, Experiments to Ascertain the Composition of Runnings of Pressed, Misses D. Haynes and H. M. Judd, 379
Aquatic Fauna of Seistan, Dr. N. Annandale and others, 453
Aquatic Microscopy for Beginners; or, Common Objects from the Ponds and Ditches, Dr. A. C. Stokes. Fourth edition, 498
Arc-spectra of Metals of Low Melting Point, The Direct, A. de Gramont, 650
Arcs of Primary Triangulation in the U.S. and Mexico, Connection of the, W. Bowie, 509
Aristotelian Society, Proceedings of the. New Series, vol. xix; Supplementary vol. ii., 559
Armstrong College, Comdr. C. Hawkes appointed Professor of Engineering at, 616
Arsenic: Compounds for Direct Intravenous Injection in Simple Aqueous Solution, Baxter and Fargher, 342; Estimation of Small Quantities of, by Micro-titration with Iodine, H. H. Green, 477
Artillery Dictionary, Trilingual, E. S. Hodgson. 3 vols. Vol. i., English-French-Italian, 332
Asset and Obligation, 621
Association of Surgeons of Great Britain and Ireland, Formation of the, Sir John Bland Sutton elected President, 507
Astronomical: Lectures and Essays, 370; Model, A New, Rev. A. L. Cortie, 343; Observatories, Selection of Sites for, 138

ASTRONOMICAL NOTES.

Comets:
Metcalf's Comet, Miss V. Hansen and F. Fischer-Petersen, 12; Comet Notes, 43; Comets, Miss V. Hansen and F. Fischer-Petersen; Prof. Leuschner, Prof. Wolf; M. Ebell, 66; Comets, H. Vanderlinden, 80; Comet 1919*b*, Braae and Fischer-Petersen, 100; Comets, 100; Comet 1919*c*, 119; Ephemeris of Comet 1919*b*, Braae and Fischer-Petersen, 138; Comet 1919*b* (Brorsen-Metcalf), Braae and Fischer-Petersen, 180; Comets, 269; Comets, 321; Comets, Aphelia of Planets and, C. D. Perrine, 343; Comets, 361; Comets, 380; Comets, 448; New Comet 1920*a*, C. Sola, 576; Spectrum of Comet Brorsen-Metcalf, Prof. Slipher, 576; Comets, 612; Holmes's Comet, Dr. Schorr, 704
Instruments:
The Blink Microscope, R. T. A. Innes, 66; Lunar Photography with the 100-in. Reflector, F. G. Pease, 511
Meteors:
The Recent Shower of Perseids, 12; Large Meteors, 179; The Leonid Meteors, 299; Large Fireball, 321; The Leonid Meteoric Shower, 342; The December Meteoric Shower, 400; Fireball of December 25, 448; Large Fireball on January 16, 544, 576; Large Fireball on February 4, 642
Observatories:
The Selection of Sites for Astronomical Observatories, Prof. W. H. Pickering, 138
Planets:
Minor Planets, 100; The Albedo of Saturn's Rings, L. Bell, 138; The Secular Acceleration of the Moon, Prof. E. W. Brown, 299; Aphelia of Planets and

Comets, C. D. Perrine, 343; Heliocentric Grouping of Planets in December, 361; The Birth of the Moon, Prof. W. H. Pickering, 479; Minor Planets, Dr. F. Cohn, 511; Lunar Studies, Prof. W. H. Pickering, 544; The Motion of the Moon, Dr. J. K. Fotheringham, 612; Mercury as an Evening Star, 674; Is Venus Cloud-covered?, J. Evershed, 675; Minor Planet GM, 704

Stars:
A Faint Nova, Miss Mackie, 119; Stellar Clusters, Dr. and Mrs. Shapley, 119; Novæ, Miss Woods; Dr. Shapley; Mr. Joy; C. P. Olivier; Van Maanen and Sanford, 160; The Sources of Stellar Energy, Prof. Russell; Prof. Eddington, 269; The Group of Helium Stars in Orion, Dr. Bergstrand, 299; Two Stars with Large Parallaxes, Prof. F. Schlesinger, 342; Barnard's Proper-motion Star, K. Graff, 420; The Orion Nebula, Prof. W. H. Pickering, 448; Distances of the Stars of Type F, C. F. Lundahl, 479; Absolute Magnitude as a Function of Colour, F. H. Seares, 479; Spectroscopic Determination of Stellar Parallax, W. S. Adams and G. Stromberg, 511; Open Stellar Clusters, Dr. H. Shapley; Sir F. W. Dyson, and Mr. Melotte, 576; Stars of High Velocity, W. S. Adams and A. H. Joy, 612; Relative Masses of Binary Stars, G. van Biesbroeck, 643; Long-period Variables, Prof. Turner, 643; Nova in Lyra, Miss Mackie, 704

Sun:
The Sun-spot Curve, S. B. Nicholson, 160; Solar Radiation, C. G. Abbot, 160; The Great Solar Prominence of Last May, 420; The Solar Eclipse of May 29, 1919, C. R. Davidson, 544

Miscellaneous:
The Future of the Transit Circle, J. E. de Vos Van Steenwijk, 80; The Twenty-four-hour Day, 100; Hindu Spherical Astronomy, G. R. Kaye, 119; Fall of a Meteorite in America, 361; Wireless Time Signals, 380; Leeds Astronomical Society, vol. xxvi. of the Journal, 380; Discussion on Relativity, Prof. Eddington; Dr. Jeans; Sir Oliver Lodge; Dr. Silberstein; Prof. Lindemann; Dr. Jeffreys, 400; Radiation Pressure, Megh Nad Saha, 448; Centenary of the Royal Astronomical Society, Prof. A. Fowler, 674; Tides in Pipes, A. A. Michelson and H. G. Gale, 705

Astronomy: for Surveyors, The Elements of, Prof. R. W. Chapman, 499; Practical, Text-book on, Prof. G. L. Hosmer, Second edition, 3; Spectroscopic, Prof. A. Fowler, 234; The Adolfo Stahl Lectures in, delivered in San Francisco, Cal., in 1916-17 and 1917-18, under the auspices of the Astronomical Society of the Pacific, 370

Athenæum Club, Sir Daniel Hall, elected a member of the, 608

Atmosphere: Free, The Characteristics of the, W. H. Dines, 505; Internal Friction in the, D. Brant, 714; The Structure of the, when Rain is falling, Prof. V. Bjerknes, 346

Atmospheric: Air, Search for a Characteristic Equation Applicable to, Ed. Fouché, 491; and Terrestrial Radiation, W. H. Dines, 714; Refraction, The Influence of small Changes of Temperature on, Sir Arthur Schuster, 714; Observations at Gâvre by means of free Rubber Balloons, F. La Porte, 715

Atom, The Constitution of the, and the Properties of Band Spectra, Dr. H. Deslandres, 271; 347

Atomic: Disintegration and Heat Energy, Sir Oliver Lodge, 420; Energy, Sir Oliver J. Lodge, 435; Weights of the Elements, Plotting the, against their Atomic Numbers, Dr. S. Miall, 704; Weights, &c., problems of, 398

Atoms and Molecules, Prof. F. Soddy, 230

Aurora of October 1, The, Dr. C. Chree, and others, 119

Australia: Problems and Prospects, Sir C. G. Wade, 130; the Flora of, Contributions to, No. 28, A. J. Ewart and J. R. Tovey, 347; Tropical, Future of, G. Taylor, 648

Australian Army Medical Corps in Egypt, the, Lt.-Col. J. W. Barrett and Lt. P. E. Deane, 560; Educational Institutions, Bequests to, by Sir Samuel McCaughey, 127; Lepidoptera, Revision of, Part vi., Dr. A. J. Turner, 20; Lepidoptera, Part vi., Dr. A. J. Turner, 147; Opiliones, Some, H. R. Hogg, 713; Neuroptera, No. 8: Revision of the Family Ithonidæ, Dr. R. J. Tillyard, 147; Phlebotomic Diptera, new Culicidæ and Tabanidæ, and Synonymy, F. Taylor, 555; Rainfall and Wheat Yield, 606; Signposts, S. H. Ray, 643; South, Geology, 91; Stratiomyidæ (Diptera), with Description of New Species, G. F. Hill, 271

Autochrome Plates, a Simplified Method for the Development of, Lumière and Seyewetz, 137; The use of, instead of Hand-paintings for Clouds, M. de Chardonnet, 307

Automobile Engineers, Institution of, Sir Henry Fowler elected President of the, 638

Autotrophic Flagellate, The Building of an, A. H. Church, 594

Autumn Weather, the Abnormal, 417

Aviation: during the War, Progress of the Scientific Development of, L. Bairstow, 486; Pocket-book for 1919-20, The, R. B. Matthews, Seventh edition. 562; Position and Prospects of, L. Bairstow, 246; Recent Progress in, Sir Richard Glazebrook, 397

Awards for Medical Discovery, Suggested, 671

Axolotl, Metamorphosis of, caused by Thyroid-feeding, J. S. Huxley, 435

Bacterial Cell, a Single, the Isolation of, Dr. N. Mutch, 446

Bacteriology outside Medicine, Different Aspects of, Dr. A. C. Thaysen, 455

Bailleul, The Explosion at, S. Pickering, 5

Balkans, Discoveries made in the, during the War, S. Casson, 487

Bantu Languages, a Comparative Study of the Bantu and Semi-, Sir Harry H. Johnston, 129

Baphia, Afzel, A revision of the Genus, L. V. Lester-Garland, 346

Barnard College, Bequest to, by Genl. H. W. Carpentier, 167

Barnard's Proper-motion Star, K. Graff: Prof. Kustner, 420

Barometric Pressure and Underground Water-level, E. G. Bilham, 366; Variations of, and of the Specific Gravity of Air with Altitude, R. Soreau, 459

Battersea Polytechnic, courses at, 43; Dr. R. H. Pickard appointed Principal of, 325

Beats, Unpleasant, The Upper Limit of, N. Chatterjee, 708

Bedford College for Women, Decision to Extend the, 306

Bed-lice, Destruction of, by Chloropicrin, G. Bertrand, Brocq-Rousseau and Dassonville, 68

Beginning . . . . , In the, Prof. J. Ward, 325

Belfast Municipal Technical Institute, Major R. Stanley appointed Principal of the, 186

Belgian Royal Observatory, Dr. A. C. D. Crommelin, 676

Belgique, Annuaire de l'Observatoire Royal de, 1920, 158

Belgium, Gifts for Education in, 67

Benzaldoxime, Oxidation of, J. Bougault and P. Robin, 20; The Peroxide of, P. Robin, 307

Beri-beri, The Genesis of Œdema in, Lt.-Col. A. McCarrison, 345

Biological Nature-Study, A Source Book of, E. R. Downing, 465; Problems, 90; Science in Secondary Schools, Prof. S. J. Hickson, 693; Sciences, The Foundations of, Sir E. Ray Lankester, 198

Biologists, Economic, Association of, General Meeting of the, Sir David Prain elected President, 417

Biology, Fresh-water, Profs. H. B. Ward and G. C. Whipple, 498

Biometrika, Vol. xii.; Pts. iii. and iv., 579

Bird-Liming in Lower Egypt, J. L. Bonhote, 444; Migration, Dr. M. C. Grabham, 334

Birds: and the Destruction of Insect Pests, Major S. Flower, 444; Beneficial to Agriculture, F. W. Frohawk, 72; of South Uist, D. Guthrie, 136; The Migration of, over the Mediterranean Sea, C. Suffern, 418

Birkbeck College, Celebration of Founder's Day, 405; Courses at, 87

Birmingham: University, C. Grant Robertson appointed Principal of, 425; C. Grant Robertson welcomed as

Principal; J. Young appointed an Asst. Lecturer in the Department of Physics, 615; Gift to, for the Endowment of the Adrian Brown chair of Brewing; Gift to, for a Lectureship in honour of Prof. J. H. Muirhead, 648; Prof. R. H. Yapp appointed Professor of Botany, Dr. W. Cramp, Professor of Electrical Engineering in, 489
Birth-rate, The declining, The Bishop of Birmingham, and others, 157
Bistoninæ, Peculiar Sex-relationships in Inter-generic Hybrids of, Dr. J. W. H. Harrison, 574
Blade-screws, The General Theory of, G. de Bothezat, 543
Blink Microscope, The, R. T. A. Innes, 66
Blood Corpuscles, Sedimentation of, Prof. A. E. Boycott, 532
Blow-flow, The *Rôle* of Capillaries in the Regulation of the, Dr. H. H. Dale, 519
"Blue John" and other varieties of Fluorite, Cause of the Colours of, B. Blount and J. H. Sequeira, 65
Board of Agriculture and Fisheries, Reorganisation of the, and Appointments under, 319; Sir A. Griffith-Boscawen appointed Deputy Chairman, and Sir A. D. Hall Vice-Chairman of the President's Administrative Council of the, 342
Board of Trade, the appointment of Prof. S. J. Chapman as Joint Permanent Secretary of the, 135
Body-lice, History of Isolated Pairs of, and of their Offspring, Dr. E. Hindle, 456
Boiler Plants, Colliery, D. Brownlie, 120
Boronia pinnata, Smith, The Essential Oil of, and the Presence of Elemicin, H. G. Smith, 108
Borrelly's Comet, Observations of, P. Chofardet, 87; H. Vanderlinden, 326
Boston: Society of Natural History, Memoirs of the, Vol. viii., No 3, The Turtles of New England, Dr. H. L. Babcock, 23; University, Bequest to, by C. W. Lenney, 167
Botanic Gardens and Stations, British, 263
Botanical: Research, The Evolution of, Prof. J. M. Coulter, 581; Teaching, Elementary, Reconstruction of, 64
Botany at the British Association, 520
Boys' Own Book of Great Inventions, The, F. L. Darrow, 152
Bradford Technical College, Appointments at the, 345
Bread, Staleness in, The Conditions that Govern, Capt. R. Whymper, 99
Brisbane University, Bequest to, by Sir Samuel McCaughey, 108
Bristol: Museum and Art Gallery, Report of the, H. Bolton, 574; University, Appointment of Capt. J. W. McBain to the Chair of Physical Chemistry in, 167; Bequest to, by Dr. J. Wiglesworth, 126; Miss M. E. Laing appointed Research Assistant in Physical Chemistry in, 306
British: and Belgium Universities, Proposed Exchange of Teachers and Students between, 345; Antarctic (*Terra Nova*) Expedition, 1910. Cephalodiscus, Dr. W. G. Ridewood, 481; Association, The Bournemouth Meeting of the, 7; Inaugural Address of the President, the Hon. Sir Charles A. Parsons, 28; Summaries of Addresses of Presidents of Sections, 36; to be Held at Cardiff in 1920, and at Edinburgh in 1921, 52; Bournemouth, The, 51; Presidential Address to the Mathematical and Physical Science Section, Prof. A. Gray, 52; Presidential Address to the Chemistry Section, Prof. P. P. Bedson, 59; Presidential Address to the Geology Section, Dr. J. W. Evans, 102; Presidential Address to the Zoology Section, Dr. F. A. Dixey, 121; Resolutions on the Need of Grants from the Government for Research, 135; at Bournemouth, The, Presidential Address to the Geography Section, Prof. L. W. Lyde, 141; Proposed History of the, 158; Presidential Address to the Economic Science and Statistics Section, Sir Hugh Bell, 162; Presidential Address to the Engineering Section, Prof. J. E. Petavel, 181; Presidential Address to the Anthropology Section, Prof. A. Keith, 301; Presidential Address to the Physiology Section, Prof. D. Noël Paton, 312; The, and Scientific Research, 337; Presidential Address to the Botany Section, Sir Daniel Morris, 381; Presidential Address to the Educational Science Section, Sir Napier Shaw, 401; Presidential Address to the Agriculture Section, Prof. W. Somerville, 421; Physics at the, 454; Chemistry at the, 455; Zoology at the, Prof. J. H. Ashworth, 456; Geology at the, 484; Economics at the, 485; Engineering at the, 486; Anthropology at the, 487; Physiology at the, 519; Botany at the, 520; Education at the, 521; Agriculture at the, Prof. A. Lauder, 353; of Research for the Cocoa, Chocolate, Sugar, Confectionery, and Jam Trades, Formation of a, 117; Botanic Gardens and Stations, 263; Dr. W. E. Freeman; The Writer of the Article, 469; Bureau of the Office National des Universités et Ecoles Françaises, L. Poincaré at the Opening of the, 712; Cotton Industry Research Association, Prof. A. W. Crossley appointed Director of Research to the, 296; The Appointment of Prof. A. W. Crossley as Director of Research of the, 319; Chemists during the War, Services of, 8; Empire, Cotton-growing in the, Sir George Watt, 694; Enchytræid Worm, A New, Rev. H. Friend, 174; Ferns and How to Identify Them, J. H. Crabtree, 410; Fisheries Guild, Proposed Foundation of the, 638; Imperial Antarctic Expedition, A, J. L. Cope, 93; Iron Ores, Prof. H. Louis, 429; D. A. E. Evans; Prof. H. Louis, 565; Launderers' Industry, The Research Association for the, Approved, 507; Medical Association, Forthcoming Annual Meeting of the, at Cambridge, 474; Physicists, Lectures on Ten, of the Nineteenth Century, A. Macfarlane, 561; Rainfall, 1918, Dr. H. R. Mill and M. de Carle S. Salter, 411; Rubber and Tyre Manufacturers' Research Association, Establishment of the, 158; Science Exhibition, Glasgow, 343; Science Guild, Journal of the, July, 11, January, 642; Scientific Societies Founded during the Past Fifty Years, 270; Technical Optics, The Outlook of, Prof. F. Cheshire, 530; Well-worms, Rev. H. Friend, 5
Brown's Formula for Distillation, Prof. S. Young, 555
Bryophyllum calycinum, Mechanism of Regeneration in, 15
Budapest University Unable to Resume its Work through Lack of Fuel, 364
Bulla-Sydenham Area, Physiography and Geography of the, A. V. E. James, 619
Bulusan Volcano, Eruptions of the, Rev. M. S. Masò, 99
Bureau International des Poids et Mesures, Travaux et Mémoires du. Tome xvi., 12
"Burgundy Mixture," Chemistry of, R. L. Mond and C. Heberlein, 82
Bushman Engravings, Dr. L. Péringuey, 44
Butter-making: Practical. Fourth revision, C. W. Walker-Tisdale and T. R. Robinson, 528
Butyleneglycol, A Specific Reaction of 2:3-, and of Acetylmethylcarbinol, M. Lemoigne, 651

Cactaceæ, The, N. L. Britton and J. N. Rose, 41
Cairo: School of Medicine, Dr. E. Hindle Appointed Professor of Biology in the, 127; to the Cape, The Flight from, Sir H. H. Johnston, 632; Prof. J. W. Gregory, 633
Cajal formalin-silver Nitrate Impregnation Method for the Golgi Apparatus, The, H. M. Carleton, 406
Calculus; A First Course in the, Part i., Powers of X, Dr. W. P. Milne and G. J. B. Westcott, 109; Differential and Integral, Dr. H. B. Phillips, 109
Calcutta University Commission, Report of the, Sir E. Denison Ross, 537
Calendar, The Reform of the, 415
Calendrier, réforme du, Commission pour la, 415
California University; Bequest to, by General H. W. Carpentier, 167; Gift to, by E. F. Searles, 67
Californian Dialects, R. B. Dixon, and A. L. Kroeber, 541
Cambridge: Forestry Association, Archives of the, 1919, 672; Philosophical Society, Election of Officers, 267; University Press, New Catalogue of the, 639; The Universities of Oxford and, The Royal Commission on, 329; Women at, 265; University, Mr. A. J. Balfour to be Nominated as Chancellor of, 67; The Nomination of Mr. Balfour as Chancellor of, 96;

B. M. Jones Elected to the Francis Mond Professorship of Aeronautical Engineering in, 107; Resignation of the Vice-Chancellorship of, by Dr. A. E. Shipley, Election as Vice-Chancellor of Dr. P. Giles, 126; Mr. A. J. Balfour Elected Chancellor of, 146; Mr. Balfour Inaugurated Chancellor of, 266; Gift by P. A. Molteno for an Institute of Parasitology; Postponement of Special Lectures by Sir J. J. Thomson and Prof. Eddington; Recommendations of the General Board of Studies; Difficulties of Accommodation at, 305; Forthcoming Establishment of a Professorship of Physical Chemistry; Recommendation of A. Amos to the University Lectureship in Agriculture, 324; Appointment of Royal Commissioners to Consider Financial Assistance to, 325; Gift to the Institute of Parasitology, by the Executors of the late Lord Strathcona & Mount Royal; Dr. F. H. A. Marshall Appointed Reader in Agricultural Physiology; P. Lake Appointed Reader in Geography; W. B. R. King Appointed Assistant to the Professor of Geology, and C. Nicholas Appointed Demonstrator in Geology; 364; Lecture on the Theory of Relativity, Prof. Eddington; Presentation of a Portrait of Prof. H. F. Osborn; 385; K. J. J. Mackenzie Re-appointed Reader in Agriculture; W. J. Harrison Appointed University Lecturer in Mathematics, A. Wood, University Lecturer in Experimental Physics, A. G. Tansley, University Lecturer in Botany, and F. Balfour Brown, University Lecturer in Zoology, 425; A John Couch Adams Astronomership in, 615; Offer of an E. G. Fearnsides Scholarship; H. M. Fox, F. Debenham, and C. N. H. Lock Elected Fellows of Gonville & Caius College, 616
Cammellaird-Fullagar Marine Oil-Engine, The, 642
Camphor Cultivation in the West Indies, 98
Canada, the Mineral Production of, for 1918, 673
Canadian Aboriginal Canoes, F. W. Waugh, 78
Cancer Research and Vivisection, 136
Carbohydrates, The Simple, and the Glucosides, Dr. E. F. Armstrong. Third edition, 526
Carbon: Dioxide, Pure, The Separation by Solidification of, from a Gaseous Mixture, V. Cremieu and A. Lepape, 307; Monoxide in Flames of Different Gases, Production of, A. Kling and D. Florentin, 618
Carboniferous Coast Section at Malahide, The, L. B. Smyth, 427
Carnivora and the Three Classes of Food, H. Bierry, 387
Cass, Sir John, Technical Institute, E. de Barry Barnett Appointed Lecturer in Organic Chemistry, and R. H. Humphry Lecturer in Physics at the, 186
Catalysis: in Chemical Industry, Dr. H. S. Taylor, 94; in Theory and Practice, Dr. E. K. Rideal and Prof. H. S. Taylor, 463
Catalytic Actions at Solid Surfaces, Part ii., Dr. E. F. Armstrong and T. P. Hilditch, 406
Cattle: Food Calendar, Lever Bros, 119; Foods, The Classification of, J. Alan Murray, 553; the Fattening of, Application of the Food-unit Method to, Prof. J. Wilson, 682
Cawthorn Research Institute, The, Prof. T. H. Easterfield Appointed Director of; T. Rigg Appointed Agricultural Chemist at, 442
Celebes and Other Places, Dr. Th. Mortensen to Lead an Expedition to, 78
Central: America and the Antilles, The Existing Flora of, Prof. W. Trelease, 476; Canada, The Pre-Cambrian Rocks of, Dr. Miller, 485
Cephalodiscus and the Archichordates, 481
Cerebral Cortex, Sensation and the, Dr. Head, 267
Cerebro-spinal Fever, the Epidemiology, Symptoms, and Treatment of, Dr. Rolleston, 359
Cestrinus, Er. (fam. Tenebrionidæ), and Some Allied Genera, K. G. Blair, 407
Ceylon, the Problem of the Stone Ages in, E. J. Wayland, 609
Chadwick Public Lectures, Forthcoming, 712
Chætognatha in Plankton Taken off the North Coast of Java, Dr. R. van Ove, 446
Chalcostibite, a Remarkable Deposit of, in Morocco, H. Ungemach, 387
Characters in Organisms, The Existence of two Fundamentally Different Types of, Dr. R. R. Gates, 713
Charters Towers Goldfield, The, J. H. Reid, 515
Chatham School of Military Engineering, Major G. Thorp Appointed Chief Instructor in Electricity at the, 186
Cheese: and Butter-making, 528; The Book of, C. Thorn and Prof. W. W. Fisk, 528
Chemical: Dictionary, The Condensed, 622; Elements, The Discovery of, Since, 1869, Prof. H. B. Dixon and H. Stephen, 221; The Mass Spectra of the, F. W. Aston, 714; Industries, General Position of, in the Chief Countries of the World, R. P. Duchemin, 268; The Organisation of, 484; Materials, The Mechanical Handling of, G. F. Zimmer, 137; Society, changes in the Officers and Council of the, 701; Forthcoming Lectures at the, 158; The Library of the, F. W. Clifford, 298; Technology, The, 65; Warfare, The Development of, Brig.-Gen. Hartley, 455
Chemicals, The Manufacture of, by Electrolysis, A. J. Hale, 529
Chemist, the Government, Report of, 575
Chemistry: Annual Reports on the Progress of, for 1918, issued by the Chemical Society, Vol. xv., 91; Applied, in relation to University Training, Prof. G. T. Morgan, 147; at the British Association, 455; Elementary Practical, Part i., General Chemistry, Prof. F. Clowes and J. B. Coleman, Seventh edition, 688; Handbooks of, 497; Industrial, Dr. C. Ranken, 497; Industrial, 622; in the Making, Prof. H. E. Armstrong, 219; Organic, for Students of Medicine, Prof. J. Walker, Second edition, 499; Physical, Past and Present, Prof. J. C. Philip, 223; Text-book of, Prof. A. T. Lincoln, 3; Practical, Senior, H. W. Bansor, 497; Progress of, Sir Edward Thorpe, 217; The Position of, in Germany and this Country as a Result of the War, Sir William Pope, 455; The Profession of, R. B. Pilcher, 409; Theoretical, Outlines of, Dr. F. H. Getman, Second edition, 3
Chemists, the British Association of, the Second Annual Meeting of, 319
Chemists' Year Book, The, 1918-19, Edited by F. W. Atack, assisted by L. Whinyates, 2 vols., 112
Chicago University, foundation of the Edith Barnard Memorial Fellowship in, 67
China, Scientific Researches and Collections in, Proposed Swedish Grant towards, 178
Chinese Bronze, An ancient, Sir C. Hercules Read, 574
Chippawa-Queenston Hydro-electric Development Scheme, The, Dr. B. Cunningham, 483
Chlorinated Methyl Carbonates, The Properties of the, A. Kling, D. Florentin, and E. Jacob, 683
Chlorination of Methyl Formate and Methyl Chloroformate, V. Grignard, G. Rivat, and Ed. Urbain, 491
Chloromethylchloroformates, Preparation of, A. Kling, and others, 459
Chloropicrin: Comparative Action of, on the Weevil and on Tribolium, G. Bertrand, Brocq-Rousseu, and Dassonville, 619; Insecticidal Power of, Influence of Temperature and other Physical Agents on the, G. Bertrand, and others, 459; Production of a Gas in the Distillation of, J. A. Gardner and F. W. Fox, 419
Chromosome Dimensions, A further Study of, C. F. U. Meek, 426
Citizenship, Training in, Bishop Welldon, 522
Civil Engineers, Institution of, Abstracts of Papers of the, 674
Civilisation, The Origin of, with Special Reference to the Nile Valley, Prof. J. H. Breasted, 267
Classics in the Educational System of the United Kingdom, Appointment of a Committee upon, 364
Clays, Relations between Chemical Composition, Microscopic Structure, and the Ceramic Qualities of, L. Bertrand and A. Lanquine, 523
Climate, Factors Controlling, Prof. W. J. Humphreys, 610
Climates, Classification of, Proposed Alterations in the, W. Koppen, 418
Coal at Port-Gueydon, Discovery of a lens of, G. B. M. Flamand, 307
Cobalt Group, $R_2Co\ (SeO_4)_2,\ 6H_2O_1$, Crystallographic properties of the Monoclinic Double Selenates of the, Dr. A. E. H. Tutton, 447
Cocks, Alimentary Castration in, Submitted to an Exclusively Carnivorous Diet, A. Pézard, 523
Cocoa, Production and Consumption of, 10

College Studies, Prof. H. W. Stuart, 490
Colliery Boiler-plants, Performance of, D. Brownlie, 120
Colloid and Saline in Shock and Cholera, Prof. B. Moore, 131
Colloidal: Electrolytes, Soap Solutions and their Constitution, J. W. McBain and C. S. Salmon, 712; gels, Seric Toxicity and the Physical Properties of, W. Kopaczewski and Mme. Z. Gruzewska, 651
Colloids: Amphoteric, Prof. J. Loeb, 15; Recent Work on, Dr. R. S. Willows, 650
Cologne Post, The, 458
Colonial Services, Agricultural Departments in the, Appointment of a Committee to consider the, 325
Colour: and Chemical Constitution, Part ix., J. Moir, 491; Change of, in Captive Birds, Sir Herbert Maxwell, 693; in Plumage, Change of, of Captive "Sun-birds," or "Honey-suckers," H. Millar, 600; Kinematographs of the Gaumont Establishment, J. Charpentier, 387; -Matching by Natural and Artificial Light, L. C. Martin, and others, 610; Vision, A Photo-electric Theory of, Prof. J. Joly, 74; Sir Oliver Lodge, 92; Dr. H. S. Allen, 174
Columbia University, Bequest to, by Gen. H. W. Carpentier, 167
Comet: 1916*c*, Orbit of, H. Vanderlinden, 80, 119; 1919*b*, Ephemeris of, Braae and Fischer-Petersen, 138, 180; Spectrum of, Prof. Slipher, 576; 1919*g*, Dr. Halm, 612; 1920*a*, Discovery of, C. Solá, 576; Notes, 43,
Comets: Miss V. Hansen and F. Petersen; Prof. Wolf; M. Ebell, 66, 100, 269, 321, 361, 380, 448; Metcalf and Borrelly, Observations of the, L. Picart and F. Courty, 128
Common-sense Philosophy, Essays in, C. E. M. Joad, 352
Congo, Return of Dr. K. E. Laman from the, 177
Congress, Librarian of, Report of the, 43
Conquest, No. 1, 321; February, 641
Continuation Schools, Sir Robert Blair, 522
Copper: -antimony Alloys, Expansion of, P. Braesco, 651; in the Tissues of Green Plants, Distribution and Migration of, L. Maquenne and E. Demoussy, 651; -refining Industry, A new, in Great Britain, 666; the Richness in, of Cultivated Soils, L. Maquenne and E. Demoussy, 407
Coral-reefs, the "Glacial-control" Theory of the Growth of, Prof. R. A. Daly, 360

CORRESPONDENCE.

Aluminium, New Sources of, Major J. E. Bacon, 277
Atomic Energy, Sir Oliver J. Lodge, 435
Axolotl, Metamorphosis of, caused by Thyroid-feeding, J. S. Huxley, 435
Biological Science in Secondary Schools, Prof. S. J. Hickson, 693
Bird Migration, Dr. M. C. Grabham, 334
Blood Corpuscles, Sedimentation of, Prof. A. E. Boycott, 532
Blue-bottle Flies, Mortality among Snails and the Appearance of, Dr. N. Annandale, 412
British Botanic Gardens and Stations, Dr. W. E. Freeman; The Writer of the Article, 469
British Imperial Antarctic Expedition, A, J. L. Cope, 93
British Iron-Ores, D. A. E. Evans; Prof. H. Louis, 565
British Technical Optics, The Outlook of, Prof. F. Cheshire, 530
British Well-worms, Rev. H. Friend, 5
Colloid and Saline in Shock and Cholera, Prof. B. Moore, 131
Colour, Change of, in Plumage of Captive "Sun-birds" or Honey-suckers, H. Millar, 600
Colour in Captive Birds, Change of, Sir Herbert Maxwell, 693
Colour Vision, A Photo-electric Theory of, Prof. J. Joly, 74; Sir Oliver Lodge, 92; Dr. H. S. Allen, 174
Earth, The Rigidity of the, Dr. A. A. Michelson and H. G. Gale, 114
Einstein's Theory and a Map Analogue, E. Cunningham, 437
Einstein Theory, The, and Spectral Displacement, H. Fletcher Moulton, Dr. A. C. D. Crommelin, 532
Electronic Theory of Isomerism, An, W. E. Garner, 661
Elements, The Constitution of the, Dr. F. W. Aston, 393
Enchytræid Worm, A New British, Rev. H. Friend, 174
Entente Scientific Literature in Central Europe during the War, R. W. Lawson, 437; Prof. B. Brauner, 600
Euclid, Newton, and Einstein, W. G., 627
Explosion at Bailleul, The, S. Pickering, 5
Fishery Investigations and the Balance of Life, Prof. W. Garstang, 48; Prof. W. C. McIntosh, 49
"Flying Gallop," The, in Art, Dr. B. Laufer, 114
Fraunhofer Lines, The Predicted Shift of the, J. Rice, Prof. A. S. Eddington, 598
Gravitation and Light, Sir Oliver Lodge, 334, 354, 372; Sir Joseph Larmor, 412, 530
Gravitation, Radio-activity and, Sir Ernest Rutherford and Dr. A. H. Compton, 412
Gravitational Deflection of High-speed Particles, L. Page, 692
Holland and International Rivers, Dr. P. Geyl; Prof. L. W. Lyde, 333
House-fly, The Hibernation of the, Sir Herbert Maxwell, 435
International Councils, National Representation upon, Dr. Norman R. Campbell, 72
International Relations in Science, Prof. D'Arcy W. Thompson, 154; Sir E. Ray Lankester, 172
Intravenous Injections of Gum Solutions in Cholera, Sir Leonard Rogers; Prof. W. M. Bayliss, 73
Isotopes, The Separation of, Dr. A. Fleck, 565
Isotopes, The Spectra of, Dr. T. R. Merton, 93
Katmai Volcanic Gases and Encrustations, The Nature of the, J. W. Shipley, 595
King Penguin, The Breeding of the, T. H. Gillespie, 314
Light, Gravitation and, Sir Joseph Larmor, 412, 530
Light, Polarisation of, scattered by Helium Atoms, Lord Rayleigh, 412
Light Rays passing near the Sun, The Displacement of, Prof. A. Anderson, 354
Light, Scattering of, by Resonating Molecules, Lord Rayleigh, 276
Light, The Deflection of, during a Solar Eclipse, Prof. A. S. Eddington; Dr. A. C. D. Crommelin, 372; W. H. Dines; L. F. Richardson, 303; Prof. A. Anderson, 394, 436, 563; Capt. C. J. P. Cave, 413; Sir Arthur Schuster, 468
Limpet, Common, Sex-phenomena in the, Dr. J. H. Orton, 373
Lion, Fossil, Remains of a, in Ipswich, Nina F. Layard, 413
Magnetic Storm of August 11-12, 1919, The, A. Graham Bell, 74; J. Evershed, 436; Dr. C. Chree, 468
Man, The Antiquity of, J. Reid Moir; Dr. A. Smith Woodward, 335
Mirage Effects, Cicely M. Botley, 56-; S. Pickering; L. N. Norris-Rogers; H. Hillman, 630; R. Ross; A. Tarn, 662
Musical Drums with Harmonic Overtones, Prof. C. V. Raman and Sivakali Kumar, 500
National Union of Scientific Workers and Research, The, Dr. H. Jeffreys, 23
Natural History Museum, Progress of the, Dr. S. F. Harmer, 353
Neon, Dr. F. W. Aston, 334
October, 1919, Exceptional Dryness of, W. D. Christmas, 278
Optics, British Technical, The Outlook of, Prof. F. Cheshire, 530
Organisation of Scientific Work, Dr. A. B. Rendle, 691; Prof. F. Soddy, 691
Percussion Figures in Isotropic Solids, Prof. C. V. Raman, 113; J. W. French, 312; W. J. L. Abbott, 600
Pleochroic Haloes, Reversed, Prof. J. Joly and J. H. J. Poole, 92
Plumage Bill, Promotion of a, H. J. Massingham, 413; Prof. J. E. Duerden, 499; Proposals for a, L. Gardiner; W. Dewar, 564
Popular Science, Victorian, 630
Prague, A Tribute from, Prof. B. Brauner, 374
Prismatic Binocular, Use of a, for viewing near Objects, Capt. D. Wilson Barker, 532

Racehorses, The Colours of, Sir William Ridgeway, 334
Radiation Temperatures, S. Pickering, 153; Dew, S. Skinner, 277
Radio-activity and Gravitation, Sir Ernest Rutherford and Dr. A. H. Compton, 412
Radio-activity, Relativity and, Prof. J. Joly, 468
Reaction and Gravitational Field, Heat of, Prof. F. G. Donnan, 392
Refractive Index, Variations of, F. Twyman, 315
Refractive Indices, Variation of, Sir Henry A. Miers, 334
Relativity and Radio-activity, Prof. J. Joly, 468
Relativity and the Displacement of Fraunhofer Lines, Prof. W. G. Duffield, 659
Royal Meteorological Society's Phenological Returns, H. B. Adames and J. E. Clark, 437
Scientific and Industrial Research, The Control of, Dr. W. M. Travers, 597
Scientific Workers and a National Federation, Major A. G. Church, 693
Sex-phenomena in the Common Limpet, Dr. J. H. Orton, 373
Silica Glass, The Doubly Refracting Structure of, Lord Rayleigh, 153; R. W. Lawson, 335
Silkworm, Linkage in the: A Correction, Prof. W. Bateson, 315
Snails, Mortality among, and the Appearance of Blue-bottle Flies, Dr. N. Annandale, 412
Sociological Society, The, T. J. C. Fraser Davies, 662
Spectral Lines, Displacement of, R. W. Lawson, 565
Straight Path, The, Dr. A. A. Robb, 599
Strasbourg, The University of, Mathematics at, H. B. Heywood, 74
Sugar-beet Seed, Prof. T. D. A. Cockerell, 661
Sun, Power from the, A. A. Campbell Swinton, 392, 532; A. S. E. Ackermann, 500
Surface-tension, C. T. Whitmell, 278
Temperature in the Sun, A. Mallock, 113
Thermionic Valves on Aircraft, Prof. R. Whiddington, 630
Thunder, The Audibility of, Capt. C. J. P. Cave, 132; Dr. H. O. Forbes, 315
Time Relations in a Dream, J. Barcroft, 154
Ultra-violet, A Helium Series in the Extreme, Prof. T. Lyman, 314; Prof. W. M. Hicks, 393; Prof. T. Lyman, 565
Valour and Service, Statistics of, Major A. G. McKendrick, 660
Vertical-pipe Irrigation for Orchards and Market-gardens in Arid Climates, Prof. I. Giglioli, 276
Volcanic Rocks in Northern Kordofan, Sudan, W. Campbell Smith, 693
"White Water," The, Capt. A. R. Palmer; Prof. J. Stanley Gardiner, 563
Wireless Stimulation, The Response of Plants to, Sir J. C. Bose, 172
Wool, Fine, A Search for, Prof. J. C. Ewart, 153
Worms, Luminous, Rev. S. Graham Brade-Birks, 23, 93; H. E. Aldridge, 174; Rev. H. Friend, 334

Cotton: Growing in the British Empire, Sir George Watt, 694; Industry, Botanical Research Studentships in Connection with the, 186
Crabro cephalotes, Note on the Solitary Wasp, C. Warburton, 366
Craibstone Animal Nutrition Research Institute, Dr. R. H. A. Plimmer appointed Head of the Department of Bio-Chemistry of, 127
Cretaceous Plant-remains from Tennessee, &c., Dr. E. W. Berry, 542
Criminology: Dr. M. Parmelee, 687; and Nervousness, 687
Crop Plants, The Botany of, Prof. W. W. Robbins, 46
Cross-Circulation as a Physiological Method, Prof. W. M. Bayliss, 479
"Crossing-over," J. W. Gowen, 541
Crystal: A curious, from the Binnental, Dr. G. F. H. Smith, 326; -forms, New, on Pyrites, Calcite, and Epidote, L. J. Spencer, 326
Cuba, Eastern, Mammals Collected During 1917 in, Dr. H. E. Anthony, 672
Cultivated Plants, Botany of, 46
Cultural Reality, Dr. F. Znaniecki, 110
Cyanamide, The Transformation of, into Urea by the Micro-organisms of the Soil, P. Mazé, Vila, and Lemoigne, 387
Cyanogen Chloride, Ch. Mauguin and L. J. Simon, 88; Preparation of, by Held's Method, Ch. Mauguin and L. J. Simon, 44
Cycadophyta, Classification of the, Dr. G. R. Wieland, 509
Cycads, The Living, Prof. C. J. Chamberlain, 410
Cylindrical Conductors, Equal Parallel, in Electrical Problems, F. J. W. Whipple, 365
Cyprus: Excavations in, in 1913, Prof. J. L. Myres, 487; Measurements of Skulls in, L. H. D. Buxton, 487

Dabchick, The Courtship of the, J. Huxley, 359
Dairying, The Outlook in, J. Mackintosh, 554
"Daily Telegraph" Victory Atlas of the World, The. Part i., 276, 419; The Review in NATURE of the, 674
Dalhousie University, Halifax, Nova Scotia, Centenary of, 146
Dams: Studies in the Construction of, Earthern and Masonry, Prof. E. R. Matthews, 434
Danes' Dyke, T. Sheppard, 445
Dartmoor: Hydro-electric Supply Scheme, Abandonment of the, 541; Water-power and, 461
Davy-Faraday Research Laboratory, The, of the Royal Institution, 264
"Daylight," or Colour-matching Lamp, A New Form of, L. C. Martin, 358

DEATHS.

Aitken (Dr. J.), 318, 337
Barrell (Prof. J.), 444
Bissell (Dr. W. G.), 357
Chadwyck-Healey (Sir Charles), 136
Chalmers (S. D.), 318
Chapman (R. H.), 608
Cummings (B. F.), 177
Dallas (W. L.), 63
Dunlop (Sir Nathaniel), 340
Eötvös (Baron R. von), 319
Fraser (Sir Thomas R.), 474, 505
Garner (R. L.), 573
Greenwood (Dr. H. C.), 443
Groves (C. E.), 608, 637
Harcourt (Dr. A. G. Vernon), 49
Haverfield (Prof. F. J.), 117
Hazen (Dr. J. V.), 357
Headley (F. W.), 358
Hitchcock (Prof. C. H.), 358
Hopkins (Dr. G.), 442
Izat (A.), 540
Jackson (Sir John), 398
Jourdain (P. E. B.), 117
Keeling (Lt.-Col. B. F. E.), 317
King (Prof. L. W.), 27
Lyster (Dr. C. R. C.), 572
Macalister (Prof. A.), 8, 26
Macloskie (Prof. G.), 540
McKelvy (E. C.), 507
Marshall (Rev. E. S.), 377
Mercier (Dr. C. A.), 8, 50
Moreno (Dr. F. P.), 508
Nethersole (Sir Michael), 607
Osler (Sir William), 443, 472
Palmer (G. W.), 136
Pirsson (Prof. L. V.), 443
Raworth (B. A.), 135
Reynolds (Prof. J. Emerson), 701
Riccò (Prof. A.), 378
Sachs (E. O.), 63
Smith (Dr. V. A.), 671
Strassmaier (Father J. N.), 506, 540
Trail (Prof. J. W. H.), 76
Turner (H. G.), 702
Wallace (R. F.), 573
Walsingham (Lord), 376
Warre (Rev. Dr. E.), 572
Werner (Prof. A.), 376

Whitmell (C. T.), 398
Wicksteed (J. H.), 443
Wilson (Dr. J.), 539

Decimalisation of Currency, The, Allum, 579
"Dengora baiari" Initiation Ceremony, The, Lieut. E. W. P. Chinnery, 386
Diabase and Associated Rocks of the Howqua River, Victoria, E. O. Teale, 108
Dietetic Deficiency, Effect of, on Immunity to Disease, Dr. S. S. Zilva, 66
Diffraction Patterns in the Presence of Spherical Aberrations, Mrs. C. H. Griffiths, 682
Digamma and Trigamma Functions, Tables of the, E. Pairman, 341
Digitalis, Vigour of Growth, compensating Sterility, in the Hybrids of Species of, L. Blaringhem, 88
Dimethyl Sulphate, Action of Hydrates, Oxides, and Carbonates of the Alkaline Earths on, J. Guyot and L. J. Simon, 167
Dinosaurian Reptile in the Congo Region, Report of a, 396; W. D. Gray, 701
Discovery, Forthcoming Publication of a New Journal entitled, 186; No. 1, 554
Disturbance Propagated into a Medium, The Problem of Finding the Strengths of the Sources of, Sir Joseph Larmor, 419
Dolium, Antiquity of, E. A. Martin, 446
Douglas Firs, The, Prof. A. Henry and Miss M. G. Flood, 682
Dragon: The Evolution of the, Prof. G. Elliot Smith, 350; of Mythology, 350
Drainage, Sub-surface, An Interesting Form of, M. Aurousseau, 587
Dudley Technical College, Dr. J. H. Grindley appointed Principal of the, 306
Dundee: University College, Dr. J. F. Gemmill appointed Professor of Natural History at, 67; J. S. W. Boyle appointed Lecturer and Assistant in Chemistry in, 87; Capt. J. W. Low appointed Assistant in the Natural History Department of, 712
Durham University: Capt. L. L. Burchnall appointed Lecturer in Mathematics in, 385; Forthcoming Definitive Edition of the Roll of Service and Roll of Honour, 425
Dust-whirls in Sub-arid Western Australia, J. T. Jutson, 619
Dyer-va-val Initiation Ceremony, The, R. H. Matthews, 40
Dynamics. Part ii., R. C. Fawdry, 109

Earth, The Rigidity of the, Dr. A. A. Michelson and H. G. Gale, 114
Earthquake: in Mexico, A Violent, 474; Shock in the Region of Monte Amiata, near Siena, 63; Waves through the Body of the Earth, Propagation of, Prof. C. G. Knott, 477
Earthquakes, Destructive, in Mexico, 508
Earth's Interior, The Temperature of the, Prof. C. H. Lees, 713; Magnetic Field, Reducing the measurement of the Horizontal Component of the, Prof. W. Uljanin, 510
East: Africa and Uganda Natural History Society, Journal of the, 10; Indian Seas, Meteorological Conditions of the, 119
Echinus Larvæ, The Artificial Production of, with a Double Hydrocœle, Prof. E. W. MacBride, 456
Eclipses, The Cycle of, M. Auric, 459
Economic Position of the Country, The Present, A. E. Doxford, 268
Economics at the British Association, 485
Edinburgh University: Developments in, 87; Bequest to, by S. Elliott; Projected additional equipment for the Engineering Laboratory, 425; Dr. F. E. Jardine appointed Lecturer on Applied Anatomy, and Dr. D. Lees Lecturer on Venereal Diseases; Presentation of Geology volumes to the Geology Department, by Lord Lyell of Kinnordy, 425; Dr. G. M. Robertson appointed Professor of Psychiatry; Dr. J. H. Ashworth Professor of Zoology, and T. P. Laird Professor of Accounting and Business Method, 425
Educated Men, Need in the country of, for directing Business Affairs, Sir H. E. Morgan, and others, 522
Education: Adult, 452; and Life, 169; and Science, Large Gift for, J. D. Rockefeller, 457; at the British Association, 521; Board of, Appointment of a Departmental Committee of the, on the award of scholarships, and for the provision of free places in secondary schools, 186; for the Needs of Life: A Text-book in the Principles of Education, Dr. I. E. Miller, 169; Fundamental Principles in, Prof. A. N. Whitehead, 522; in British India, 101; in India, Seventh Quinquennial Review of the Progress of, H. Sharp, 156; National, Problems of, Twelve Scottish Educationists, Edited by J. Clarke, 89; Technical, Fifty Years of, J. H. Reynolds, 257
Educational: Associations, Forthcoming Conference of, 365; The Eighth Annual Conference of, 513; Conferences, 513; Grants for ex-Service Officers and Men, 68
Egypt: Irrigation in, Appointment of a Commission on, 580; Western, Desert Flora of, Capt. H. H. Thomas, 520
Eighteenth-Century Physician, An, 1
Einstein, Prof., Interview with, 541
Einstein's Theory of Gravitation, Sir Joseph Larmor, and others, 339; E. Cunningham, 354; 374; Prof. Eddington; Sir Oliver Lodge, 377; E. Cunningham, 394; Prof. A. S. Eddington, and others, 454; Dr. Crommelin, 514; C. Longo, 552; and a Map Analogue, E. Cunningham, 437; and its Observational Tests, Prof. R. A. Sampson, 458; and Spectral Displacement, H. Fletcher Moulton; Dr. A. C. D. Crommelin, 532
Electric: Amplifiers, Triode Valves as, Prof. W. H. Eccles, 501; Charge on Rain, Further Observations of the, J. A. McClelland and A. Gilmour, 682; Spark Ignition, Principles of, in Internal-combustion Engines, J. D. Morgan, 372; Waves, Diffraction of, Prof. G. N. Watson, 454
Electrical: Invention, Progress of, Prof. J. A. Fleming, 239; Properties of Gases, The Influence of Investigations on the, on our Conceptions of the Structure of Matter, Sir J. J. Thomson, 224; Resistance of the Hand, Prof. A. D. Waller, 520
Electrician, Resignation by W. R. Cooper of the Editorship; Appointment of F. H. Masters as Editor, 266
Electricity: (Supply) Bill, The, 338; Read a Second Time in the House of Lords, 376; 416
Electrification of Railways, The, R. T. Smith, 320
Electro-chemical Treatment of Seeds, A Manual of the, Dr. C. Mercier, 562
Electrode Valves, Three, Special Arrangements of. Prof. Eccles, 487
Electron: Collisions with Platinum and with Hydrogen, Effects of, F. Horton and Ann C. Davies, 618; Radium and the, Sir Ernest Rutherford, 226; Velocities for the Production of Radiation and Ionisation on Collision with Argon Atoms, Experimental Determination of the critical, F. Horton and Ann C. Davies, 406
Electrostatic: Measurements, Utility of Desiccants in, V. H. Jackson and A. T. Mukerjee, 459; Potentials, High, An Apparatus for the Production of, J. J. Dowling, 428
Electrotechnical Commission, International, Meeting of the, 177
Elementary Children, The Selection of, for Higher Forms of Education, G. F. Daniell, 513
Elements, The Constitution of the, Dr. F. W. Aston, 393
Eleotris Legendrei, The Food of, J. Legendre, 347
Embryology, Text-book of, Vol. ii., Vertebrata, with the Exception of Mammalia, Prof. J. Graham Kerr, 309
Empirical Formulas, Prof. T. R. Running, 109
Employers and Employed, The National Alliance of, Rt. Hon. F. Huth Jackson, 485
Encephalitis Lethargica, an Obscure Disease, Report of an inquiry into an, 452
Energy: Output of Dock Labourers during Heavy Work. Part i., Dr. A. D. Waller, 427; Sources of, Sir Oliver Lodge, 75
Engine Performance, Reduction of, at a Great Height, Col. Tizard, 486
Engineering: Abstracts, Separate Issue of, by the Institu-

tion of Civil Engineers, 179; at the British Association, 486; Manufacture, The Rise of, Prof. F. W. Burstall, 74; Standardisation, G. Lightfoot, 447; Workshop Practice, Modern, H. Thompson, 352
English: Rock Garden, The, A. Farrer, 2 vols., 664; The Teaching of, Sir A. Quiller-Couch, 521; in Relation to School Science, W. D. Eggar, 521
Entente Scientific Literature in Central Europe during the War, R. W. Lawson, 436; Prof. B. Brauner, 600
Entomologists at the Natural History Museum, The Pay of, 339
Equations, Solving, A Survey of the Numerical Methods of, Prof. E. T. Whittaker, 550
Essex, Pre-History in, as recorded in the Journal of the Essex Field Club, S. H. Warren, 112
Estimates, Tentative Revised, in a "Normal" Year, 177
Ethnography and Condition of South Africa before A.D. 1505, Dr. G. McCall Theal. Second Edition, 315
Etiolated Plants, Causes of the Elongation of the Stem of, H. Coupin, 683
Eton College Scientific Society, a Conversazione of the, Presentation to W. D. Eggar the retiring President; Dr. R. Whytlaw Gray elected President of the, 444
Eucalyptus: Coloration of the Young Foliage of, J. H. Maiden, 555; Oils, The Germicidal Activity of the, Part ii., Dr. R. Greig-Smith, 20; Two new Western Australian Species of, J. H. Maiden, 168; *viminalis*, Determination of the Increment of Trees by Stem Analysis, W. A. W. de Benzeville, 587
Euclid, Newton, and Einstein, W. G., 627
Eugenics: 351; and Environment, Prof. C. Lloyd Morgan, 351; Education in the Training College; Eugenics Education in the School, Dr. R. D. Laurie, 513
Europe, Boundary Delimitation in, A. R. Hinks, 445
Evolution: Facts and Factors of, 149; Heredity and, Prof. G. H. Carpenter, 81; of Ostrich Plumes, 155; Organic, The Causes and Course of, A Study in Bioenergics, Prof. J. M. Macfarlane, 149; The Factors of, Prof. L. B. Walton, 81
Exercise and Humid Heat, Effects of, upon the Pulse-rate, Blood-pressure, Body Temperature, and Blood Concentration, W. J. Young, A. Breinl, J. J. Harris, and W. A. Osborne, 345
Experimental Researches carried out in the Department of Glass Technology, University of Sheffield. Vol. i., 1917-18, 2
Exploration of the Sea, International Council for the, Vol. xxv. of the "Rapports et Procès-Verbaux" of the, 78; Forthcoming Meeting of the, 701
Explosion Motors for Rarefied Atmospheres, J. Villey, 683
Explosives: High, Manufacture of, during the War, Col. C. D. Crozier, 455; Industrial, Development of Inertness in, E. A. Mann and T. N. Kirton, 647
External and Internal Relations, Dr. G. E. Moore, 490

Familiar, The Study of the, 465
Faraday, The Work of, and the Faraday Society, Sir Robert Hadfield, 539
Farm: A Large State, A Business and Educational Undertaking, Lt.-Col. A. G. Weigall and C. Wrey, 592; Concrete, K. J. T. Ekblaw, 495
Farmer, The, and the New Day, K. L. Butterfield, 592
Farming in the New Era, Dr. E. J. Russell, 592
Fauna of the Inlé Lake, The, Dr. N. Annandale and others, 176
Fernley Observatory, Meteorological Observations made at the, in 1918, J. Baxendell, 477
Ferns: British, and How to Identify Them, J. H. Crabtree, 410; Medullated, Nature and Origin of the Pith and Inner Endodermis in, Dr. M. Thompson, 521
Fibroferrite from Cyprus, C. E. Barrs, 649
Fibula of a Newly Born Infant of the Polished Stone Period, The, and Consequences in Anatomical Philosophy, M. Baudouin, 459
Field-mouse, A New Species of, from Foula, M. A. C. Hinton, 418
Finlay Comet: Return of the, B. Baillaud, 367; Prof. Crawford and Misses Fairfield and Cummings, 380; Observations of, M. Michkóvitch, M. Giacobini, P. Chofardet, A. Schaumasse, 387; H. Godard, 459
Finnic Population, Nordic and Mongoloid Elements in the, H. Peake, 487
Fireball: A Large, 321; on December 25, 448; Large, on January 16, 544; of January 16, The, 576; Large, on February 4, 642
Fishery: Investigations, Proposed International Scheme of, 318, International Council for, Report for 1913 of the, 541; in South Africa, Report on, Prof. J. D. F. Gilchrist, 615
Fishes: Fresh-water, Distribution of, C. Tate Regan and others, 456; Larval and Post-larval, Food of, Dr. Marie Lebour, 457
Fishing, Deep-sea, The Extension of Territorial Waters in Relation to, Prof. J. Johnstone, 135; Industry, The Reconstruction of the, 133; -log of a Painter in Brittany, Golden Days from the, R. Fedden, 391
Flamsteed, John, The Bicentenary of the Death of, 417
Flashes Produced by the Fire of Artillery, M. Delpech, 187
Flax Production in Great Britain, Report on, 98
Flies, Bluebottle, Mortality among Snails and the Appearance of, Dr. N. Annandale, 412
Flint Implements from the Chalky Boulder Clay of Suffolk, J. Reid Moir, 706
Flints, Humanly fashioned, in the Middle Glacial Gravel at Ipswich, J. Reid Moir, 508
"Flora Arabica," part i., Prof. E. Blatter, 609
Flora of Macquarie Island, The Vascular, T. F. Cheeseman, 101
Flotation: A Contribution to the Study of, H. L. Sulman, 401; Principles of Ore Extraction, 401; Process, the, 673
Flow of Water through a Pipe, the Orifice as a Means of Measuring the, Davis and Jordan, 647
Flower, The, and the Bee: Plant Life and Pollination, J. H. Lovell, 132
Flowers, Cut, Longevity of, Ellinor Archer, 619
Fluorescence, Researches on, 526
"Flying Gallop," The, in Art, Dr. B. Laufer, 114
Food Production: in England, Sir T. Middleton, 553; in Scotland, J. M. Caie, 553; War-time and Post-war Problems of, Dr. E. J. Russell, 553; Substances, Accessory, Prof. W. D. Halliburton, and others, 520
Fog in London on January 31, 1918, Incidence of, C. E. P. Brooks, 675
Foraminiferæ (Cyclostègnes), The Annular, of Orbigny, H. Douvillé, 523; Hitherto unemphasised Modifications of Growth in the life-history of, E. Heron-Allen and Mr. Earland, 456
Forestry: Act, The Appointment of Commissioners under the, 318; Acts, Appointment of Commissioners under the, 295
Forthcoming Books of Science, 11, 42, 66, 80, 100, 138, 179, 298, 320, 321, 342, 360, 380, 400, 419, 447, 478, 511, 544, 576, 611
Fossils, Japanese Memoir on, 542
Fothergill, Dr. John, and his Friends: Chapters in Eighteenth-century Life, Dr. R. H. Fox, 1
Foulerton award of the Geologists' Association, T. W. Reader selected for the, 397
Fraunhofer Lines, The Predicted Shift of the, J. Rice; Prof. A. S. Eddington, 598
French Ministry of Inventions, The, 99; Republic, Welcome to London of the President of the, 295
Fresh-water Biology, Profs. H. B. Ward and G. C. Whipple, 498
Frost and the Growing Season, W. G. Reed, 95
Frosts: and Agriculture in the United States, 95; Forecasting, B. A. Keen, 450
Fruit: Culture in Malaya, J. N. Milsum, 78; -Grower, Problems of the, 558; The true species complex of, W. B. Brierley, 520
Fungi, The Species Concept among, W. B. Brierley, 708

Galton Lecture of the Eugenics Education Society, The, Prof. A. Keith, 670
Gas: Combustible, Present in the Air, Instruments for Detecting and Measuring, 65; Forthcoming Introduction

of a Bill relating to the Value and Supply of, 296; Warfare, Defensive Science in, Lt.-Col. P. S. Lelean, 646
Gases: Ignition of, by Hot Wires, Dr. Thornton, 487; Industrial, Dr. H. C. Greenwood, 622; Ionisation of, Prof. J. S. Townsend, 233; The Influence of Investigations on the Electrical Properties of, on our Conceptions of the Structure of Matter, Sir J. J. Thomson, 224; The Liquefaction of, Prof. C. H. Lees, 247; The Occlusion of, by Metals: A General Discussion held by the Faraday Society, November, 1918, 690
Gaspé Bird Sanctuaries, The, I. M. Clarke, 117
Gearksutite at Gingin, Western Australia, Dr. E. S. Simpson, 649
Gentile, Giovanni, The Philosophy of, Prof. J. A. Smith, 586
Geo-chemistry, Some Recent Problems in, Prof. Boswell, 455
Geography: Progress of, Sir John Scott Keltie 249; The Educational Aspects of, E. K. Lomas, 517; The Encouragement of, in the higher forms of Secondary Schools, T. W. F. Parkinson, 514
Geological: Society Awards, 507; Survey of Great Britain, Summary of Progress of the, 1918, 477: Work on the Western Front, W. B. R. King, 476
Geologists' Association, Some Future Work for the, G. Barrow, 510
Geology: at the British Association, 484; of India for Students, D. N. Wadia, 502; of South Australia, The. In two Divisions, W. Howchin, 91; of the country around Lichfield, 640; The Expansion of, Prof. T. G. Bonney, 203
Geometry; Analytic, Profs. M. M. Roberts and J. T. Colpitts, 390; Descriptive, H. W. Miller, Fourth Edition, 169; in Schools, Modern Teaching of, C. Godfrey, 550; Solid, including the Mensuration of Surfaces and Solids, Prof. R. S. Heath, Fourth Edition, 109
Georgia and Caucasia, Mineral Resources of, Manganese Industry of Georgia, D. Ghambashidze, 171
Geostrophic Wind, The Laws of Approach to the, F. J. W. Whipple, 458
German: Aviation Petrols, Analyses of, G. Chavanne, L. P. Clerc and L. J. Simon, 307; Prisoners of War in England, Anthropological Examination of, Prof. F. G. Parsons, 475; Technology, The Imperial League for, 65
Germany, Present position of the Chemical Industry of, E. V. Evans, Dr. G. S. Walpole, 484
Girton College, Cambridge, Gift to, 585
Glacial Retreat, Minor Periodicity in, W. B. Wright, 682
Glasgow: Technical College, Appointments at; Gifts to, 19; The British Science Exhibition, 343; University, Appointments in, 126; Installation of President Poincaré as Rector; Conferment of the Honorary Degree of LL.D. upon President Poincaré, 324; Gift to the University of Nancy; Gifts to, 325; Conferment of Honorary Degrees, 344
Glass: Experimental Researches on, 2; Research Association, The. E. Meigh, 299; R. L. Frink appointed Director of Research by the, 572; Trade, The Position of the, after the War, Dr. W. M. Travers, 455; -powder, Action of Reagents upon, P. Nicolardot, 2n
Glue, Manufacture of, in the Tropics, K. C. Srinivasan, 611
Glycerol in Fats, The Direct Replacement of, by higher Polyhydric Alcohols, Prof. A. Lapworth and L. K. Pearson, 399
Godman, the late F. Du Cane, Tribute to, Lord Walsingham, 40
Gold Coast, Discovery of Diamonds in the, A. E. Kitson 485
Gold Standard, Restoration of the, R. G. Hawtrey, 486
Gossypium in Pre-Linnæan Literature, H. J. Denham, 10
Government, the Science of, A new chapter in, B. Branford, 494
Grantia compressa, The Germ-cells and Early Development of, J. B. Gatenby, 427
Grass-land, Breaking up of, in 1918, Prof. B. Jones, 98
Gravitation and Light: Sir Oliver Lodge, 334, 354, 372; Sir Joseph Larmor, 412, 530; Einstein's Relativity, Theory of, E. Cunningham, 354, 374, 394; Radioactivity and, Sir Ernest Rutherford and Dr. A. H. Compton, 412
Gravitational Deflection of High-speed Particles, L. Page, 692
Greenland, Northern, Exploration of, 453
Grimaldi, Les Grottes de, fasc. iv., Tome i., Prof. M. Boule, 581
Guano Birds of Peru, R. E. Coker, 378
Guernsey: A Sculptured Human Figure discovered on the dolmen of Déhus, T. W. M. de Guérin, 487; The Megaliths in, Col. de Guérin, 117
Gum, Injections of, or of Plasma, after Bleeding, C. Richet, 491

Hadfields, Ltd., Essays by Apprentices of, on their Visit to London, 267
Haloes, &c., The Formation of, Capt. C. K. M. Douglas, 641
Halogen Acetic Esters, The Catalytic Reduction of the, P. Sabatier and A. Mailhe, 347
Hamburg University, Dr. F. Paneth appointed Professor of Chemistry in, 426
Handicraft, Rudiments of, W. A. S. Benson, 72
Hardening Solution for Gelatine Negatives, Ilford, Ltd., 11
Harmsworth's Universal Encyclopedia, Edited by J. A. Hammerton, No. i., 659
Harris, Sir William Snow, Work of, 417
Harvard: Observatory, The, at Mandeville, Jamaica, Prof. W. H. Pickering, 138; University, Dr. W. M. McDougall appointed Professor of Psychology in, 186
Harveian Oration, The, to be delivered by Dr. R. Crawfurd, 135
Hawaian: Bagasse, the Paper-making Qualities of, A. D. Little, 341; Island Reservation, The, A. M. Bailey, 117; Islands, &c., The Formation of the, T. G. Thrum, 508
Hazell Annual and Almanack, The New, Dr. T. A. Ingram, 562
Health, Public, The Untilled Fields of, Prof. C. E. A. Winslow, 703
Heat and Heat Engines, Examples in, T. Peel, 690; Energy, Atomic Disintegration and, Sir Oliver Lodge, 420
Helium: Series, A, in the Extreme Ultra-violet, Prof. T. Lyman, 314; Stars in Orion, The Group of, Dr. Bergstrand, 299
Hellenic Studies, the Society for the Promotion of, Retirement of G. A. Macmillan from the honorary secretaryship of, 319
Hell Gate Bridge, New York, 268
Heredity: Prof. J. Arthur Thomson, Third edition, 92; and Evolution, Prof. G. H. Carpenter, 81
Herrings, the Biometrics of the Spring-spawning, A. C. Johansen, 158
Herschel, Rev. H. Macpherson, 561
Heterochromatic Photometry, A solution of, permitting of a physical measurement of the Luminous Intensity, A. Blondel, 367
High: Pressures, Extremely, The Industrial Employment of, G. Claude, 307; Temperature, Humidity, and Wind, Effect of, on the Human Body, Lt. C. W. B. Normand, 366
Hindu: Civilisation, the Contributions of Bengal to, M. H. Shastri, 418; Spherical Astronomy, G. R. Kaye, 119
Historical Process, The, W. J. Perry, 490
History. The Outline of, being a Plain History of Life and Mankind, H. G. Wells, Part i., 371
Holland and International Rivers, Dr. P. Geyl; Prof. L. W. Lyde, 333
Holmes's Comet, Dr. Schorr, 704
Holothurioidea of the Coasts of Ireland, The, Miss Anne L. Massy, 555
Hooker, Joseph Dalton, Prof. F. O. Bower, 561
Hope: Our Legacy of, 130; The Century of, A Sketch of

Western Progress from 1815 to the Great War, F. S. Marvin, 130
Hornea Lignieri, One of the simplest Land-plants, Prof. W. H. Lang, 367
Horse: Bot-flies, Drs. S. Hadwen and A. E. Cameron, 64; Cemetery in the Nile Valley, discovery of a, Prof. G. A. Reisner, 702; -chestnuts, Experiments with, A. Gill, 575
House-fly: The Hibernation of the, Sir Herbert Maxwell, 435; in Winter, 96
Huddersfield Technical College, J. R. Taylor appointed Director of Humanistic Studies in the, 127
Hull: Municipal Museum, The Drake and Bower Geological Collections acquired by the, 9; Whaling Trade, The, T. Sheppard, 609
Human: Metabolism, 644; Personality and its survival of Bodily Death, F. W. H. Myers, Edited and Abridged by S. B. and L. H. M, 595; New Views of, Dr. Olive Wheeler 513; Vitality and Efficiency under prolonged Restricted Diet, F. G. Benedict, W. R. Miles P. Roth, and H. M. Smith, 644
Humus, The Chemical Properties of, and their Utilisation for the protection of Combatants against Asphyxiating Gases, G. du Bellay and M. Houdard, 683
Hunterian Society, Celebration of the Centenary of the, presentation of the Society's silver medal to J. Adams, 319
Huronian Iron-bearing strata of the Mesabie range in Minnesota, Structures in the, due to Algæ, F. F. Grant and T. M. Broderick, 360
Hydramides, The Oxidation of the, J. Bougault and P. Robin, 407
Hydrocyanic: Acid, Detection of, in a Case of Poisoning, L. Chelle, 367; Transformation of, into Thiocyanic Acid in the Course of Cadaveric Putrefactions, M. Chelle, 327; and Thiocyanic Acids in a Complex Medium, The Detection and Estimation of Traces of, L. Chelle, 407
Hydro-electric: Development Scheme, The Chippawa-Queenston, Dr. B. Cunningham, 483; Development Works, Dr. B. Cunningham, 161; Survey of India, The, Dr. B. Cunningham, 363
Hydrogen:-ion Concentration and Photosynthesis, J. T. Saunders, 366; The Secondary Spectrum of, T. R. Merton, 406
Hydrographic Conference, The International, 440

Immune Sera, Dr. C. F. Bolduan and J. Koopman. Fifth edition, 434
Imperial: Air Routes, Major-Gen. Sir F. H. Sykes, 634; Botanical Congress in London, The Proposed. Abandoned, 670; College of Science and Technology, Request for Power to Award Degrees, 426; Statistics, The Organisation of, G. H. Knibbs, 551
Incandescent Electric Lamps, The Luminosity of, Dr. L. Fabaro, 542
India: Cults of the Mother Goddesses in, Dr. W. Crooke, 608; Government of, Appointment by the, of a Committee on the Sugar Industry, 444; Hydro-electric Survey of, Preliminary Report on the Water-power Resources of, Compiled by J. W. Meares, 363; Review of the Mineral Production of, during 1918, 542; Sericulture in, 471; Survey of, General Report of the, for 1917-18, 509; Survey of, Maps and the Modern Development of Indian Cartography, Lt.-Col. W. M. Coldstream, 574; The Organisation of Scientific Work in, 653
Indian: *Botany, Journal of*, No. 1, 297; Geology, 502; Munitions Board, Industrial Handbook, 1919. Revised edition, 413; Museum, Calcutta, Identification of Two Statues in the, 702; Sugar-canes and Their Origin, Some, Dr. C. A. Barber, 14; Studies in, Dr. C. A. Barber, 578
Industrial: Efficiency and Fatigue, The Influence of the Six-hour Day on, Dr. H. M. Vernon, 519; Psychology, Lectures on, B. Muscio. Second edition, Revised, 687; Research, A. P. M. Fleming, 470; Associations, 551; Pamphlet on, 9; Resources of India, 413
Industrialist, A Great, 592
Industry, Elimination of Wasteful Effort in, Prof. T. H. Pear, 387
Inference, The Nature of, G. Cater, 407
Influenza: A Discussion Opened by Sir Arthur Newsholme, 275; Epidemic of 1918-19, The, 509; Epidemics, The Periodicity of, Dr. J. Brownlee, 296; Mortality Statistics in America, Prof. R. Pearl, 509; Protective Inoculation Against, in the Army, Major-Gen. Sir W. Leishman, 703; Pneumonic, The Venous Oxygen Content of the Alkaline Reserve of the Blood in, Dr. H. S. H. Wardlaw, 407; Returns, 638; Threatened Prevalence of, 573
Inks, Commercial, Use of, in Plant Histology, P. Bugnon, 459
Insect: Pests and Plant Diseases in the Vegetable and Fruit Garden, F. Martin Duncan, 467; Scales, A Periodic Structure in Many, and the Cause of Their Iridescent Colours, H. Onslow, 649
Insulating Materials, Relation between the Thermal Conductivity and the Velocity of Sound in, Prof. Thornton, 487
Intelligence, Tests of, Prof. J. Adams, 513
Interferometry, Applications of, Prof. C. Barus, 677
Internal-combustion Engines, Principles of Electric Spark Ignition in, J. D. Morgan, 372
Internal Strains Existing in a Circular Cylinder, Method of Determination of the, M. Mesnager, 618
International: Co-ordination of Scientific Effort and Action, Resolutions Respecting, 506; Hydrographic Conference, The, 440; Organisation in Science under the Peace Treaty, 506; Standardisation, 12
Inventors, Difficulties of, 543
Ionic Valve, Guide to the Study of the, Showing its Development and Application to Wireless Telegraphy and Telephony, W. D. Owen, 332
Ionisation: by Electron Collisions in Argon and Helium, Prof. Horton and Miss A. C. Davies, 454; in Solution, The Present Position of the Theory of, Dr. Senter, and others, 707
Ions: and Ionisation, 707; Effects of, on Ciliary Movement (Gills of *Mytilus edulis*), J. Gray, 366; on Spermatozoa, J. Gray, 366
Ireland: The Outpost, Prof. G. A. J. Cole, 411
Iridomermyx humilis in Madeira, Dr. M. C. Grabham, 456
Irish: Decorated and Socketed Bronze Axe, An, Sir W. Ridgeway, 445; Geographical Association, Prof. G. A. J. Cole elected President of the, 554
Irrigation in Egypt: 580; and the Sudan, Dr. B. Cunningham, 67
Iron: and Steel Institute, Dr. J. E. Stead nominated as President of the, 340; Forthcoming Annual Meeting of the, 474; Deposition, Electrolytic, An Aspect of, Lt. W. A. Macfadyen, 523; Electrolysing Solutions of, The Potential Necessary for, W. A. Noyes, jun., 407; Ores, British, Prof. H. Louis, 429; B. Smith; T. C. Cantrill, Dr. R. L. Sherlock, and H. Dewey; Prof. T. F. Sibly, 429; Solutions, Polarisation in, W. A. Noyes, jun., 683
Islands as Centres of Preservation of Human Diversities, etc., Sir C. P. Lucas, 514
Isomerism, An Electronic Theory of, W. E. Garner, 661
Isopodan Genus, A New (fam. Oniscidæ), from Lake Corangamite, Victoria, Prof. C. Chilton, 555
Isostasy: The Nature and Bearings of, and The Status of the Theory of, Prof. J. Barrell, 645
Isostatic Compensation in the Earth's Crust, 645
Isotopes: The Separation of, Dr. A. Fleck, 565; The Spectra of, Dr. T. R. Merton, 406
Italian Papers on Relativity, Dr. L. Silberstein, 552
Italy, Aeronautics in, Prof. G. H. Bryan, 656
Ithaca Agricultural Experimental Station, The, Dr. E. J. Russell, 482

Jacobi, Mary Putnam, Fellowship of the Women's Medical Association of New York, The, 616
January Weather, 638

Japan, Attempts to Discover a Forecasting Formula for, Prof. T. Okada, 509
Jasus lalandii, Some Abnormalities in the Cape Crawfish, C. v. Bonde, 148
Java, The Aphides of, P. van der Goot, 648
Jersey, Recent Excavations in, Dr. R. R. Marett, 487
Jerusalem, A Projected British School of Archæology at, Prof. J. Garstang provisionally appointed director, 398
Jurassic Chronology: I., Lias. Supplement I., West England Strata, S. S. Buckman, 586

Kalahari Lake Scheme, The, Prof. E. H. L. Schwarz, 158
Karyokynetosis, A. Paillot, 44
Kashmir and Indian Silks, 591
Katabatic Wind in the Valley of the Upper Thames of the Aerological Observatory at Benson, Oxon, Notes on Examples of, E. V. Newnham, 675
Katmai Volcanic Gases and Encrustations, The Nature of the, J. W. Shipley, 595
Ketones, Bicyclic, Some new, M. Godchot and F. Taboury, 523
"Key" Industries: A Bill to safeguard, 338; The Nurture of, 349; The Protection of our, 5
Kinema, The Educational Value of the, Sir Richard Gregory, 522
Kinematograph: in Schools, The, 580; The Ultra-rapid, H. Abraham, E. Bloch, and L. Bloch, 459
King Penguin, The Breeding of the, T. H. Gillespie, 314
King's College, London, Proposed Old Students' Association at, 712
King's Speech at the Opening of Parliament, The, 637
Kloet Volcano, Java, Eruption of the, 63
Knowledge, The Intuitive Basis of, an Epistemological Inquiry, Prof. N. O. Lossky. Translated by N. A. Duddington, 110
Korinchi Peak, Sumatra, Results of a Collecting Expedition to, 64

Laboratory: and Classroom Courses, The Divorce of, Sir Richard Gregory, 514; Management, H. Preston, 514
Labour Situation in the Country, The, Sir Robert Hadfield, 159
Lactose, The Catalytic Hydrogenation of, J. B. Senderens, 650
Lake Geneva, Theoretical Determination of the Longitudinal Seiches of, A. T. Doodson, R. M. Carey, and R. Baldwin, 714
Lambert and Photometry, A. P. Trotter, 358
Lankester, Ray, Investigators at the Marine Biological Laboratory, Plymouth, J. S. Dunkerley, and Mrs. E. W. Sexton appointed, 701
Lathe-turning Tools, Cutting power of, G. W. Burley, 478
Lava Rush in a Cave, A, 640
Laval University, Montreal, destroyed by fire, 344
L'Aviazione Aeroplani, Idrovolanti, Eliche, Dr. E. Garuffa. Seconda edizione, 656
Lecturing with the Lantern, Prof. G. A. J. Cole, 457
Ledebur Method for Oxygen in Steel, Equilibrium Conditions in the System Carbon, Iron Oxide, and Hydrogen in relation to the, 510
Leeds: Astronomical Society, Vol. XXVI. of the Journal of the, 380; University, Conferment of Honorary Degrees, 344
Leonid: Meteoric Shower, The, 342; Meteors, 299
Leopard-men in the Naga Hills, J. H. Hutton, 427
Leptospermum, Three New Species of, E. Cheel, 168
Levelling, Precise, Major E. O. Henrici, 445
Liberia, The Climate of, and its Effect on Man, E. Ross, 136
Libyan Desert, Determination of Latitude and Longitude in the, Dr. J. Ball, 574
Lice and their Relation to Disease, Prof. G. H. F. Nuttall, 456
Liddle Triennial Prize, The, of the London Hospital, 386
Life: and its Maintenance: A Symposium on Biological Problems of the Day, 90; Enjoying, and other Literary Remains of W. N. P. Barbellion (B. F. Cummings), 529
Light: Gravitation and, Sir Joseph Larmor, 412, 530; Polarisation of, scattered by Helium Atoms, Lord Rayleigh, 412; Scattering of, by Resonating Molecules, Lord Rayleigh, 276; Telephoning by, Prof. A. O. Rankine, 604; The Deflection of, during a Solar Eclipse, Prof. A. S. Eddington, Dr. A. C. D. Crommelin, 372; during a Solar Eclipse, W. H. Dines, L. F. Richardson, Prof. A. Anderson, 393; Capt. C. J. P. Cave, 413; Prof. A. Anderson, 436; Sir Arthur Schuster, 468; Prof. A. Anderson, 563; Rays passing near the Sun, The Displacement of, Prof. A. Anderson, 354
Lighthouse at the Horizon, Experimental Predetermination in the Laboratory of the Characteristic of a, J. Rey, 271
Limpet, Common (*Patella vulgata*), Sex Phenomena in the, Dr. J. H. Orton, 373
Line Spectra, A New Form for the Formulæ of, A. Lartigne, 387
Linen Industry Research Association, Establishment of the, 158
Lion, Remains of a Fossil, in Ipswich, Nina F. Layard, 413
Liquefaction of Gases, The, Prof. C. H. Lees, 247
Liquids, The Miscibility of, Prof. C. E. Fawsitt and C. H. Fischer, 555
Lister: Institute of Preventive Medicine, The, 264; Lord, Forthcoming Unveiling of Memorial Tablets to, at University College, London, 266; Unveiling of Tablets to the Memory of, at University College, 296, 312; Proposed Memorial to, in Edinburgh, 507
Liverpool: Marine Biology Committee, Annual Report of the, 677; University, Dr. J. Proudman appointed Professor of Applied Mathematics, 344; Prof. E. R. Dewsnup appointed Professor of Commerce in, 385; T. E. Peet appointed Professor of Egyptology, and Dr. J. S. Jones Professor of Veterinary Anatomy, 425; Appointment of G. E. Scholes as Professor of Engineering—Thermodynamics of Heat Engines, 648
Living off the Country, V. Stefansson, 118
Livingstone College, Annual Report of, 418
Lloyd's: Register of Shipping, Annual Report of, 320; Shipbuilding Returns, 575
Lockyer, Sir Norman, Dr. H. Deslandres, 191
Lolium, The Endophytic Fungus of, E. McLennan, 619
London: Clay, Flora of the District of the, H. W. Monckton, 520; University, Programme of University Extension Lectures, 108; Forthcoming Lectures by Sir Napier Shaw; Informal Meetings for Discussion at the Meteorological Office, Resumption of the Academic Teaching of Military Science, 127; A Bronze Medal received from the University of Paris in commemoration of the services of the universities of the Allied Nations during the war; Grants from the Drapers Company and the L.C.C.; Conferment of Doctorates, 185; Sir Cooper Perry appointed Principal Officer; Gifts to; Conferment of Degree of D.Sc. upon R. C. Rawlley; Dr. C. Bolton awarded the Charles Graham Gold Medal, 344; Dr. S. Russell Wells elected Vice-Chancellor; Sir Richard Glazebrook appointed Professor of Aviation at the Imperial College of Science and Technology; Dr. A. P. Newton appointed Professor of Imperial History at King's College; Prof. W. Bulloch appointed Professor of Bacteriology at the London Hospital Medical College, 425; Conferment of Doctorates; Dr. T. Lewis awarded the W. J. Mickle Fellowship, 426; Dr. S. Smiles appointed Daniell Professor of Chemistry at King's College; Dr. H. E. Roaf Professor of Physiology at the London Hospital Medical College; Prof. T. Swale Vincent Professor of Physiology at the Middlesex Hospital Medical School; Conferment of Doctorates on R. E. M. Wheeler and M. Tolkowsky, 616; Dr. H. L. Eason and Prof. L. N. G. Filon elected on the Senate of, 585; University College: Dr. J. G. Stewart appointed Lecturer in Engineering at, 107
Longevity, Nutrition and, 527; On, and Means for the Prolongation of Life, Sir Hermann Weber. Edited by Dr. F. Parkes Weber. Fifth edition, 527
Longitudinal Spherical Aberration, A Theory of the Second

Order, for a Symmetrical Optical System, Comdr. T. Y. Baker and Prof. L. N. G. Filon, 713
Longstreth, Edward, Medal of the Franklin Institute awarded to J. J. Skinner, 8
Loughborough Technical College, Dr. T. Stuart Appointed Lecturer in Mathematics, and G. Mavor Lecturer in Mechanical Engineering at the, 67
Low Power-factor, Effect of, from the Viewpoint of Electric Power Station Operators, E. E. Stark, 517
Lubrication and Lubricants, R. M. Deeley, and others, 451
Luminosity: in Centipedes, 705; Produced in Helium, Prof. Horton and Miss D. Bailey, 454
Luminous: Chilopoda, with Special Reference to Geophilus carpophagus, Leach, Hilda K. Brade-Birks and Rev. S. Graham Brade-Birks, 705; Radiations, Origin of, Emitted by Vapours, G. A. Hemsalech, 491; Worms, Rev. S. Graham Brade-Birks, 93; H. E. Aldridge, 174
Lunar Photography with the 100in. Reflector, F. G. Pease, 511; Studies, Prof. W. H. Pickering, 544
Lycænidæ and Hesperidæ, The Druce Collection of, at the Hill Museum, Witley, 77
Lyon, Foire de, Bulletin officiel de la, 9

Mackenzie River Basin, The, C. Camsell and W. Malcolm, 640
Macquarie Island, The Vascular Flora of, T. F. Cheeseman, 101
Magnesite Deposits, The, of Bulong, 137
Magnetic Storm of August 11-12, 1919, The, A. Graham Bell, 74; J. Evershed, 436; Dr. C. Chree, 468
Magnetite, The Atomic Space Lattice in, Prof. W. Peddie, 714
Maimed: Menders of the, The Anatomical and Physiological Principles underlying the Treatment of Injuries to Muscles, Nerves, Bones, and Joints, Prof. A. Keith, 493
Maize: the Development of, The Action of Cyanamide and Dicyanodiamide on, P. Mazé, M. Vila, and M. Lemoigne, 347; The Origin of, Y. Kuwada, 639
Malacological Society of London, Election of Officers and Council of the, 671
Malaria-like Parasite in the Blood of an Indian Buffalo, A. A. L. Sheather, 445
Mallee, Red, Water from the Roots of the, T. Steel, 20
Mallet Type of Locomotive, a Development of the, 342
Mammalian Physiology, Prof. C. S. Sherrington, 71
Man: in Britain, Pre-History of, Flint Implements from the Chalky Boulder Clay of Suffolk, J. Reid Moir, 706; The Antiquity of, Dr. A. Smith Woodward, 212; J. Reid Moir; Dr. A. Smith Woodward, 335; The Dominion of, 371
Manchester: Chemical Club Incorporated with the Manchester Literary and Philosophical Society, 178; Literary and Philosophical Society, the Future of the, Sir Henry A. Miers, 326; Sir Henry A. Miers elected President of the, 340; Municipal College of Technology, Appeal for Funds, 405; F. Watts appointed Assistant to the Director of the Department of Industrial Administration, 648; University, Appointments in, 19; An Appeal for Funds, 426; A. V. Hill appointed Professor of Physiology in, 585; F. Watts appointed Lecturer in Psychology, 616
Manganese Ores, The, of the Shimoga and Adjacent Districts, B. Jayaram, 137
Maps, Large-scale, Value of, in War, 509
Marine: Algæ, Seasonal Variation in the Chemical Composition of, L. Lapicque, 618; Animals, The Abundance of, and a Quantitative Survey of their Occurrence, Prof. W. A. Herdman, 427; Biology, Recent English, 707
Maryland: Geological Survey, Volumes of the, for 1916-18, 703; The Geography of, W. B. Clark, 703
Mathematician's Miscellany, A, 689
Mathematics: in the United States, 601; Particular and General, Dr. S. Brodetsky, 390; the Philosophy of, Lectures on, Dr. J. B. Shaw, 390
Mathematical: Analysis, Introductory, Dr. W. P. Webber and Prof. L. C. Plant, 169; Association, Forthcoming Annual Meeting of the, 386; Prof. W. P. Milne, 550; Curriculum of the Secondary Schools in the U.S., Grant for a Study of the, 19; Functions, Tables of, Dr. C. E. Adams, 517; Notes, Prof. H. F. Baker, 714; Papers for Admission into the Royal Military Academy and the Royal Military College and Papers in Elementary Engineering for Naval Cadetships for the years 1909-18, Edited by R. M. Milne, 626; Statistics, 579; Text-books, Dr. S. Brodetsky, 109, 169
Matter, the Structure of, The Influence of Investigations on the Electrical Properties of Gases on our Conceptions of, Sir J. J. Thomson, 224
Matthiola, A Graded Series of Forms in, Miss Saunders, 521
Mauritius, Royal Alfred Observatory, Reports of the, 673
Measurement of Practical Ability, Dr. P. B. Ballard, 513
Mechanical Science, Developments of, Dr. W. C. Unwin, 241
Medical: and Allied Professions, The, as a State Service, Prof. D. Fraser Harris, 508; Social War-work in Egypt, 560; Discovery, Awards for, 296; Rewards for, 488
Medical Science: Abstracts and Reviews, Vol. i., No. 5, 703
Medical: Science, X-rays in, Dr. A. C. Jordan, 237; Services of the Colonies and Dependencies, Appointment of a Committee on the, 297
Medicine: Preventive, since 1869, Dr. C. J. Martin, 210; The New Birth of, Sir T. Clifford Allbutt, 204
Mediterranean: Geography and History in the, Prof. W. M. Calder, 650; The Oceanographic Study of the, Prince of Monaco, 459
Megascolex Fletcheri, sp. nov., Structure of, Jean Shannon, 619
Melbourne Zoological Park, The Mammals in the, Dr. W. H. D. Le Souef, 297
Melinda cognata, Meig., The Larval Structure and Life-history of, Dr. D. Keilin, 399
Mendelism: Prof. R. C. Punnett, Fifth Edition, Prof. L. Doncaster, 655; The Progress of, Prof. W. Bateson, 214
Mensuration, Elementary, Constructive Plane Geometry, and Numerical Trigonometry, P. Goyen, 390
Mercury: as an Evening Star, 674; Liquid, The Thermo-electricity of, Demonstrated by means of the Galvanometer, C. Benedicks, 187
Mesa Verde National Park, Colorado, Field-work on the, Dr. J. W. Fewkes, 359
Mesopotamia, British Museum Excavations in, 341
Metabolism, Basal, in Man, A Biometric Study of, J. A. Harris and F. G. Benedict, 644
Metallic Tubes, the Fragility of, A New Method of Testing, C. Frémont, 347
Metallurgical: Position, The, in this Country and the Central Empires, Prof. Desch, 455; Specimens Presented to the Royal Microscopical Society, by Sir Robert Hadfield, Report on the, F. I. G. Rawlins, 406
Metallurgy, Modern, The Trend of, Prof. H. C. H. Carpenter 243
Metals: and Alloys, Institute of, Forthcoming Annual General Meeting of the, 671; The Journal of, Vol. Institute of, Forthcoming Annual General Meeting of xxi., Edited by G. Shaw Scott, 391; of the Rare Earths, The, Dr. J. F. Spencer, 310; The Microscopy of, 535, Sir Robert Hadfield and T. G. Elliot, 537
Metaphysical Research, 559
Metcalf's Comet, Miss V. Hansen and Mr. Fischer-Petersen; Prof. Leuschner, 12
Meteoric Shower, The December, 400
Meteorite, Fall of a, in America, 361
Meteorites, The Classification of, Dr. G. T. Prior, 649
Meteorological: Committee, International, Meeting of the, 135; Report of the, 446; Features of 1919, 475; *Magazine* (Formerly *Symons's Meteorological Magazine*), C. Salter and F. J. W. Whipple, Editors of the, 608; Observations, Monthly Record of, of Canada, Bermuda, and Newfoundland, for March, 79; Office Circulars, Nos. 37 and 38, 11; Staff, Changes in the, 135; The Position of the, 705; The Status of a, and its Relation

to the State and to the Public, Capt. C. J. P. Cave, 705
Meteorology and Aviation, Lt.-Col. E. Gold, 641; and Gunners, Dr. E. M. Wedderburn, 641; and the State, 685; in Three Dimensions, Lt.-Col. E. Gold, 505; Manual of, Part iv.; The Relation of the Wind to the Distribution of Barometric Pressure, Sir Napier Shaw, 525; On the Use of the Normal Curves of Errors in Classifying Observations in, Capt. E. H. Chapman, 675; Professional, 675; Progress of, W. H. Dines, 247
Meteors, Large 179
Methyl Alcohol, Action of Sulphuric Anhydride and of Oleum on, J. Guyot and J. J. Simon, 347
Mexico: A remarkable Picture-map from, A. C. Breton, 702; A Violent Earthquake in, 474; Strong Earthquakes in, 541; City, Stone and Terra-cotta, Remains Discovered in the Neighbourhood of, Prof. W. Niven, 9
Mica Miner's and Prospector's Guide, The, A. A. C. Dickson, 276
Michell Thrust Bearing, A, 80
Microbalance, A Cheap and Simple, Capt. J. H. Shaxby, 325
Microscope: Forthcoming Symposium and Discussion on the, 378; Symposium on the, 535, 539; Sir Robert Hadfield, Introductory Address at the, 545
Microscopes, Construction and Use of, J. E. Barnard, 546
Microscopical: Invention, The History of, Sir Robert Hadfield, 535; Optics, Prof. A. E. Conrady, 548
Military Bridges, Portable, Prof. Inglis, 486
Milk: Contamination, F. Bordas, 523; The Examination of, for Public Health Purposes, J. Race, 467
Mind and its Disorders, Dr. W. H. B. Stoddard, Third Edition, 624
Mineral: Oils, Some Laboratory Tests on, A. Philip, 298; Resources of Georgia, 171; Resources of Great Britain, Special Reports on the, Vols. viii., ix., x., 429
Mineralogical Society, Election of Officers and Council of the, 296
Mineralogy, Blowpipe Analysis, and Geometrical Crystallography, Handbook of, Prof. G. M. Butler, 434
Minerals and Ores, The Analysis of, of the Rarer Elements for Analytical Chemists, Metallurgists, and Advanced Students, Dr. W. R. Schoeller and A. R. Powell, 310
Mines: Chief Inspector of, Resignation of Sir Richard Redmayne as, 376; W. Walker appointed, 397; Stray, in the North Atlantic, Albert, Prince of Monaco, 187
Mining and Metallurgy, Institution of, Awards of the, 573; The War Memorial of the, 671
Minnesota, State Entomologist of, Seventeenth Report of the, 64
Minoan Palace at Malia, in Crete, Discovery of a, 356
Minor Planet G. M., 704
Mirage: at Ingatestone, Appearances of, G. F. Quilter, 458; Effects, Cicely M. Botley, 565; S. Pickering; L. N. Norris-Rogers; H. Hillman, 630; R. Ross; A. Tarn, 662
Modern: Briton, Racial Characters of the, Prof. F. G. Parsons, 487; Science, Aspects of, Prof. F. Soddy, 625
Molecular Weights, A New Method of Measuring, J. G. Stephens, 555
Molecules, Atoms and, Prof. F. Soddy, 230
Molluscs of the Family Turritidæ, New Species of, from the West Coast of America and Adjacent Regions, Dr. W. H. Dall, 98
Monaxonid Sponges, New Genera of, Related to the Genus Clathria, E. F. Hallmann, 555
Moon: Determination of the Position of the, by Photography, Dr. C. E. Adams, 518; The Birth of the, Prof. W. H. Pickering, 479; The Motion of the, Dr. J. K. Fotheringham, 612; The Secular Acceleration of the, Prof. E. W. Brown, 299
Morocco, Work of the French in, A. de Tarde, 298
Mosses, Herbarium of, Proposal to Purchase M. J. Cardot's, 572
Motion in Elliptic and Hyperbolic Orbits, the Theorems of Lambert and Adams on, L. V. Meadowcroft, 427
Motor Fuel, Future Supplies of, H. Moore, 554
Mural Paintings and Inscriptions at Knockmoy Abbey, H. S. Crawford, 475
Muscular Exercise, The Physiology of, Prof. F. A. Bainbridge, 590
Museums, Education, and the Board, 114
Museums, Local, and the Board of Education, E. E. Lowe, 703
Musical Drums with Harmonic Overtones, Prof. C. V. Raman and Sivakali Kumar, 500
Musk, The Trade in, A. J. Clements, 97
Mutational *v.* Recapitulatory Characters, Dr. Ruggles Gates, 521
Mutation Theory, The Present Position of the, Prof. H. de Vries, 213
Mycetozoa, The, A Short History of their Study in Britain; an Account of their Habitats Generally; and a List of Species recorded from Essex, G. Lister, 332
Mysore, Department of Mines of the State of, Report of the, for 1917-18, 641
Myxophyceæ, The, or Blue-green Algæ of Lahore, S. L. Ghose, 297

National: Academy to Sciences, Washington, Award of a Gold Medal to Prof. A. Fowler, 296; Physical Laboratory, Prof. J. E. Petavel Appointed Director of the, in Succession to Sir Richard Glazebrook, 8; Retirement of Sir Richard Glazebrook from the Directorship of, 77; The, 264; *N.P.L. Review,* Part i. of the, 400; Representation upon International Councils, Dr. Norman R. Campbell, 72; Research Council of the United States, The, 668; Scientific Organisation and Education, Prof. Ross, 578; Union of Scientific Workers and Research, The, Dr. H. Jeffreys, 23; Inauguration of a London Branch, 267; Dr. J. W. Evans Elected President of the, Address of Sir Ronald Ross to the, 297; First Annual Report of the, 340; Major A. G. Church Appointed Secretary of the, 444; Questions, Nomination of Representative Committees to deal with, 8
Nationalities, The Study of, C. E. Stromeyer, 490
Nationality and Race from an Anthropologist's Point of View, Prof. A. Keith, 476
Natural: History, Open-air, 132; Museum, Retirement of F. Jeffrey Bell from the, 157; Capt. P. R. Lowe Appointed Assistant in Charge of the Bird-room at the 340; Congress of the, Dr. S. F. Harmer, 353; The late Sir A. H. Church's Collection of Gems in the, 357; A Scientific Reunion at the, 377; Expeditions in Connection with the, 507; History of South Africa, 469; Resources, The Development of Our, and the Application of Science to Industry, Sir H. Trueman Wood, 339
Naturalist's Sketch-book, A, A. Thorburn, 432
Nature: A Great Artist of, 432; The Uniformities of, Prof. C. E. Fawsitt, 586
NATURE: The Jubilee of, Congratulatory Messages, 281; Further Official Messages, 380
Naval: Architects, The Institution of, The Cammell Laird Scholarship Awarded to H. J. R. Biles; the Parsons Scholarship to W. G. Simmonds, 186; Forthcoming Scholarship of the, 386; Forthcoming Annual Meetings of the, 573; Scholarships of the, 681; Officer, The Inheritance of the, 396; Officers: their Heredity and Development, Dr. C. B. Davenport and M. T. Scudder, 396
Navy, Hydrographer of the, Appointment of Rear-Admiral F. C. Learmouth in Succession to Rear-Admiral Sir John F. Parry, 77
Nearctic Diving Birds of the Order Pygopodes, The, A. C. Bent, 320
Neolithic Graveyard, Discovery of a Large, at Gestilren, Dr. B. Schnittger, 77
Neon, F. W. Aston, 334
Nervous Disorders: Two Points of View, 22
Nervousness, The Mastery of, Based upon Self-re-education, Dr. R. S. Carroll. Third revised edition, 687
Nettle, The Common, Formic Acid in the Stinging Hairs of, Dr. L. Dobbin, 64
Neuroterus, A Gall-fly, Nuclear Phenomena in the Oocytes of L. Hogben, 346

Newburyport, Mass., The Maritime History of, F. B. C. Bradlee, 639
New: Guinea, People of the Hilly Country of the Interior of, E. W. P. Chinnery, 488; Stonework and Goldfields in, E. W. P. Chinnery, 488; Unexplored, W. N. Beaver, 663; Jersey, The Department of Conservation and Development of, Report of, 672; South Wales, Additional Trilobites from, J. Mitchell, 587; Camden Haven District, Tabanidæ from, E. W. Ferguson and Marguerite Henry, 587; Peridineæ of, G. I. Playfair, 587; Report of the Director-General of Public Health, 1917, 475; Sequence and Correlation of the Permo-Carboniferous and Carboniferous Rocks of, Part i., C. A. Sussmilch and Prof. T. W. Edgeworth David, 587; Year Honours, The, 474
Newton's: Interpolation Formulas, D. C. Fraser, 42; Rings, An Unnoticed Point in the Theory of, J. Marshall, 714; Views on Gravitation and their Subsequent History, Prof. R. A. Sampson, 458; Zealand, A New Typographical Map of, 609; A Research Institute for, 442; Destructive Boring Crustacea in, Prof. Chilton, 78; Floral Northern Invasions of, Dr. J. C. Willis, 520; Institute, Aims and Aspirations of the, Dr. L. Cockayne, 516; National Hydro-electric Schemes for, H. Hill, 517; Plea for the Development of the Natural Resources of, Hon. G. W. Russell, 516; Science Congress, 1919, The, 516; The Economic Value of the Forests of, D. E. Hutchins, 159
Niagara Falls, The Electro-chemical Industries at the, 99
Nickel: -steel Tubes, Magnetic Strains in, Dr. C. G. Knott and Miss Dallas, 715; Chromium Steel Forgings, Andrew, Greenwood, and Green; R. H. Greaves, 480
Nigeria, Forest Administration of, Report on the, for 1918, 158
Nile Projects, The, Sir William Willcocks, 120
Nitric Oxide, Velocity of Oxidation of, E. Wourtzel, 683
Nitro-cellose, The Stress-strain Properties of, and the Law of its Optical Behaviour, Prof. E. G. Coker and K. C. Chakko, 617
Nitrogen: Problem, The, 533, 568; Products Committee, Munitions Inventions Department, Final Report, 533; Note on, Rashmat Rai, 187
Nitrous: Anhydride in the Gaseous State, Existence of, E. Wourtzel, 651; Pure, Some Properties of, and of its Solution in Nitrogen Peroxide, G. Baume and M. Robert, 407
Nobel Prizes, Award of, to Profs. M. Planck, H. Stark, and F. Haber, 318
North: Atlantic Halibut Fishery, The, P. Jespersen, 158; Atlantic Ocean, Monthly Meteorological Chart of the, 99; Central Asia, Relation of History and Ethnology, with Special Reference to, Miss M. A. Czaplicka, 487
Norway, New Sources of Aluminium in, L. Hawkes, 160
Nosema-disease in Bees, G. F. White, 41
Notched-bar Tests, Results of, Dr. W. C. Unwin, 79
Nova: Aquilæ, Observations on, Father Cortie, 454; Prof. Stroobant, 676; Discovery of a Faint, Miss Mackie, 119; Discovery of, Miss Woods, Dr. Shapley, C. P. Olivier, Van Maanent and Sanford, 160; Geminorum, Types of Spectra in, Stratton, 454; in Lyra, Miss Mackie, 704
Novaya Zemlya, Forthcoming Expedition to, led by Dr. O. Holtedahl, 357
Nullagine Formation, The, Gibb Maitland, 579
Number: Puzzles before the Log Fire, Prof. D. E. Smith, 42; Stories of Long Ago, Prof. D. E. Smith, 42
Numbers, History of the Theory of, Vol. i., Divisibility and Primality, Prof. L. E. Dickson, 4
Nutrition and Longevity, 527; The Newer Knowledge of, The Use of Food for the Preservation of Vitality and Health, Prof. E. V. McCollum, 527
Nuzhat-al-Qulūb, The Geographical Part of the, Hamd-Allāh Mustawfī of Qazwīn, Translated by G. Le Strange, 112

Oat-cross, Early and Late Ripening in an, A. St. Clair Caporn, 81
Obscure Disease, an, *Encephalitis lethargica*, 452
Occlusion of Gases by Metals: The, a General Discussion held by the Faraday Society, November, 1918, 690
Oceanography, The Birth of, Prof. D'Arcy W. Thompson, 686
October, 1919, Exceptional Dryness of, W. D. Christmas, 278
Oil-hardening Industry, The, 494
Oils: The Hydrogenation of, Catalysers and Catalysis and the Generation of Hydrogen and Oxygen, C. Ellis. Second edition, 494
Old Red Sandstone Plants showing Structure from the Rhynie Chert-bed, Aberdeenshire. Part iii., Dr. R. Kidston and Prof. W. H. Lang, 458
Olive Oil and Mannitol, The Food Value of the Synthetic Product Prepared from, Prof. Halliburton, J. C. Drummond, and R. K. Cannan, 419
Olympia Agricultural Co., Ltd., Establishment of a Research Department by the, 579
Olympia, The, to be Equipped for the Use of Oil-fuel, 379
Ophthalmology, Report of the Council of British Ophthalmologists on the Desirability of a Special Qualification in, 416
Optical: Polishing Tool, The Surface Layer of an, J. W. French, 682; Society, Election of Officers of the, 671; Systems and the Graphical Methods of Determining Images, Prof. von Rohr, 704; The Physical and, Societies', Forthcoming Annual Exhibition, 417
Optics: British Technical, The Outlook of, Prof. F. Cheshire, 530; Microscopical, Prof. A. E. Conrady, 548; Physical, Researches in, Part ii., Resonance Radiation and Resonance Spectra, Prof. R. W. Wood, 526
Orchestia tucuranna in New Zealand, Prof. C. Chilton, 41
Orchids of Hants and Dorset, Col. Godfrey, 520
Ore Extraction, Flotation Principles of, 401
Organo-metallic Derivatives of Chromium, Tungsten, and Iron, G. M. Bennett and E. E. Turner, 148
Orion Nebula, The, Prof. W. H. Pickering, 448
Orthogenetic Evolution in Pigeons, 566
Ostracod and Shell-marl, An, of Pleistocene Age from Boneo Swamp, Victoria, F. Chapman, 108
Ostrich: Phylogenetic Degeneration in the, Prof. J. E. Duerden, 609; Plumes, Evolution of, 155; Results of Crossing the Northern and Southern Forms of African, Prof. J. E. Duerden, 81
Ostriches, Breeding Experiments with, Prof. J. E. Duerden, 155
Otago University: Dr. R. J. T. Bell Appointed Professor of Pure and Applied Mathematics at, 146; Dr. D. W. Carmalt Jones Appointed Professor of Systematic Medicine in, 490
Out-of-school Training and Environment, The Need of, Sir Robert Baden-Powell, 522
Owl, The Little, a Danger to Poultry and Game, 10
Oxford: and Cambridge, The Universities of, The Royal Commission on, 329; University, Impending Retirement of Prof. S. H. Vines from the Sherardian Chair of Botany in, 167; A Record Number of Freshmen; The Resignation of Prof. Vines; R. S. Troup Elected Professor of Forestry; A Treasury Grant Received; The Question of the Admission of Women to Matriculation and Degrees, 186; Passing of the Preamble of a Statute Providing that Women may be Matriculated and Admitted to Degrees; Increase of Students in Rural Economy; A Vote to be Taken on Greek in Responsions, 681; Question of the Admission of Women; Col. T. E. Lawrence Elected to a Research Fellowship at All Souls College; The Statute Making Greek Optional in Responsions, 306; Appointment of Royal Commissioners to Consider Financial Assistance to, 325; Bequest to, by Mrs. M. L. Medley, 325; Prof. A. Keith's Boyle Lecture on Race and Nationality from an Anthropological Point of View, 344; Amendment by Prof. Gilbert Murray to the Responsions Statute Moved in Congregation and Lost, 364; G. H. Hardy Appointed Savilian Professor of Geometry in, 398; Dr. F. W. Keeble Appointed Sherardian Professor of Botany, 426; E. S. Goodrich Constituted Professor of Comparative Embryology, 616

Palæontology and the Evolution Theory, D. M. S. Watson, 485
Palestine: Some Features in the Topography and Geological History of, H. H. Thomas, 345; Upper Air over, Some Observations of the, Capt. A. J. Bamford, 366
Panama Canal, Source of Power for the Plant and Machinery of the, 400
Pan-American Union, Bulletin of the, 9
Panorpoid Complex, The, part iii.: The Wing-venation, Dr. R. J. Tillyard, 408
Paper: Micro-organisms Living in, their Resistance to the Action of Heat and of Time, V. Galippe, 347; Pulp in Australia, Manufacture of, 64
Papua, Unexplored, S. H. Ray, 663
Paravane or Otter, The, R. F. McKay, 487
Paris: Academy of Sciences, Prize Awards of the, 512; Bonaparte and Loutreuil Foundations, 550; Prizes Proposed for 1921, 577; the University of, Dr. Sebileau Appointed Professor of Laryngology in, 107; Courses of Instruction in the Faculty of Medicine of, 364; Prof. H. G. Greenish Nominated for the Honorary Doctorate Degree of, 397
Pavia University, Retirement of Prof. C. Golgi from the Chair of General Pathology and Histology in, 19
Peach-growing, H. P. Gould, 495
Pearson's Formulæ for Psychophysics, the Availability of, Prize Awarded to Dr. G. H. Thomson for a Paper on, 608
Peas, Culinary, The Genetics of "Rogues" among, Prof. W. Bateson and Caroline Pellew, 649
Peat Investigation Officer, Prof. P. Purcell Appointed, 540
Pellagra, Pathology of, Dr. H. E. Roaf, 520
Penrose's Annual, edited by W. Gamble, 690
Pensées sur la Science, la Guerre et sur des Sujets très Variés, Dr. M. Lecat, 689
Perchlorate, The Electrolytic Formation of, J. G. Williams, 523
Percussion Figures in Isotropic Solids, J. W. French, 312; W. J. Lewis Abbott, 600
Perseids, The Recent Shower of, 12
Petrified Plants from the Silicified Peat-bed in the Old Red Sandstone of Rhynie, Dr. R. Kidston and Prof. W. H. Lang, 641
Petrograd, Conditions of Scientific Men and Scientific Collections in, Dr. Tolmatcheff, 443
Petrographic Subjects, Articles on, Prof. W. Deecke, 673
Phagocytosis and Protozoa, E. S. Goodrich, 456
Pheasant and Gold Campine Fowl, The Spermatogenesis of Infertile Hybrids between, D. W. Cutler, 81
Phenakite and Scheelite at Wheal Cock, St. Just, Occurrence of, A. Russell, 326
Phenological Returns, Royal Meteorological Society's, H. B. Adames and J. E. Clark, 437
Pheretima posthuma, The Excretory System of, K. N. Babl, 359
Philippine Earthquakes in 1918, Rev. M. S. Masò, 98
Philosophical Club of the Royal Society, Annals of the, Written from its Minute Books, Prof. T. G. Bonney, 45
Phonetic Theory, Some Questions of, Chap. v., The Perception of Sound, W. Perrett, 591
Photographic: Arts and Crafts Exhibition, Forthcoming, 443; Plate, Action of a Weak Solution of a Soluble Iodide on a, S. E. Sheppard and G. Meyer, 642; Cause of the Shape of the Characteristic Curve of a, Dr. R. E. Slade and G. I. Higson, 510
Photography: of Coloured Objects, The, Sir William J. Pope, 346; Progress of, Chapman Jones, 251
Photometer, A New Form of, H. T. Harrison, 358
Photo:-electric Spectrophotometry, Experiments on, by the Null Method, K. S. Gibson, 478; synthesis and the Electronic Theory, Prof. H. H. Dixon and H. H. Poole, 682
Phyllophaga, The Natural Enemies of, J. J. Davis, 40
Physical: and Chemical Constants, an American Compendium of, Forthcoming Compilation of, 340; and Optical Societies' Annual Exhibition, The Forthcoming, 417, 514; Chemistry, Prof. W. C. McC. Lewis, 3; —Past and Present, Prof. J. C. Philip, 223; Laboratory Experiments for Engineering Students, Profs. S. Sheldon and E. Hausmann. Part i., Mechanics, Sound, Heat, and Light, 4; Properties, Measurement of, at High Temperatures, A. G. Tarrant, 523; Science, X-rays in, Prof. W. H. Bragg, 235; Society of London, Election of Officers and Council of the, 701
Physics: A Manual of, Dr. J. A. Crowther, 658; Applied, Dictionary of, Forthcoming Publication of a, 320; at the British Association, 454; Elements of, Dr. R. A. Houstoun, 658; for Medical Students, Dr. H. S. Allen, 658; in War, 2; the Commercial Applications of, Forthcoming Lectures on, C. R. Darling, 386
Physiology: and Biochemistry in Modern Medicine, Prof. J. J. R. Macleod, assisted by Dr. R. G. Pearce and others, 389; and Medicine, Prof. W. M. Bayliss, 389; at the British Association, 519; Developments of, Sir E. Sharpey Schafer, 207; *General, Journal of*, 15; General, An Introduction to, with Practical Exercises, Prof. W. M. Bayliss, 654; Mammalian, Prof. C. S. Sherrington, 71; Modern, 654; of Muscular Exercise, 590
Physique pendant la Guerre, Les Applications de la, H. Vigneron, 2
Phytopathological Society, Establishment of a Canadian Branch of the; Meeting of the; Prof. A. H. R. Buller Elected President, 541
Pigeons: Inheritance, Fertility, and the Dominance of Sex and Colour in Hybrids of Wild Species of, Prof. C. O. Whitman, edited by Dr. O. Riddle, 566; Orthogenetic Evolution in, Prof. C. O. Whitman, edited by Dr. O. Riddle, 566; The Behavior of, Prof. C. O. Whitman, edited by Prof. H. A. Carr, 566
Pines, Experimental Bacterial Tumours in, J. Dufrénoy, 168
Pistia and the Lemnaceæ, The Vegetative Morphology of, Agnes Arber, 345
Pitot Tube, An Integrating, for Measuring the Average Velocity of Variable Currents, Y. Délage, 683
Place-names, Formation of a Committee on, 97
Planets: and Comets, Aphelia of, C. D. Perrine, 343; in December, Heliocentric Grouping of, 361; Minor, 100; Dr. F. Cohn, 511; The Constitution of the Ring of, Prof. Stroobant, 676
Planetary Rotation Periods and Group Ratios, F. A. Black, 370
Plane Strain: The Direct Determination of Stress, S. D. Carothers, 617
Plankton, Contribution to the Quantitative Study of, Dr. E. J. Allen, 707
Platinum in Canada, J. J. O'Neill, 574
Plant: Life on Land, The Origin of, 624; -growth, Effect of Nitrogen-fixing Organisms and Nucleic Acid Derivatives on, W. B. Bottomley, 345; -lice in the Tropics, 648; Morphology, Applied, 578; Nutrition, Experiments on, J. S. Burd, D. R. Hoagland, 446; -sports Produced at Will, Col. H. E. Rawson, 346; the Living, Botany of, Prof. F. O. Bower, 274
Plants: The Response of, to Wireless Stimulation, Sir J. C. Bose, 172; and Ferns, A Dictionary of the, Dr. J. C. Willis. Fourth edition, 410; and Ferns, Flowering, 410
Pleistocene Deposits around Cambridge, The, Prof. J. E. Marr, 386
Pleochroic Haloes, Reversed, Prof. J. Joly and J. H. J. Poole, 92
Plumage: Bill, Promotion of a, H. J. Massingham, 413; Prof. J. E. Duerden, 499; Proposals for a, L. Gardiner, W. Dewar, 564; Relation of, to Ovarian Condition, Drs. L. J. Cole and W. A Lippincott, 81
Polarisation Electromotive Forces of Iron in Solutions of Complex Salts, N. R. Dhar and G. Urbain, 618
Political Science, Bishop J. E. C. Welldon, 494
Polypodium spinulosum, Burm. f., Identity of, Prof. E. D. Merrill, 20
Poplar, The *miellée* of the, G. Tanret, 367
Porcelain, The Porosity of, C. C. Farr, 517
Potash: Recovery at Cement Plants, 137; Salts, The Deposits of, in the Punjab Salt Range and Kohat, Dr. M. Stuart, 268
Potato-tubers, A Fungus Disease of, 341
Potentiometer, Rectangular Component Alternating-current,

A New Form of, Prof. A. E. Kennelly and E. Velander, 42
Poultry, The Secondary Sexual Characters of, Prof. T. H. Morgan, 159
Powders: Flameless, M. Delpech, 167; The Pure "B," J. Delpech, 68
Power: Circuits, The Interference of, with Telephone Circuits, E. Parry, 517; Known and Unknown, Sources of, Sir Oliver Lodge, 397
Practical Chemistry, 688
Prague, A Tribute from, Prof. B. Brauner, 374
Precious Stones, The Production of, in 1919, Dr. G. F. Kunz, 610
Precipitates, A New Method of Physico-chemical Analysis of, P. Jelibois, 523
Prehistoric Pottery in Eastern Macedonia and the Plain of Philippi, Discovery of, 178
Pre-history of Man in Britain, Flint Implements from the Chalky Boulder Clay of Suffolk, J. Reid Moir, 706
Pressure: and Temperature, The Effect of, on a Meter for Measuring the Rate of Flow of a Gas, Dr. N. W. McLachlan, 325; Distribution on the Head of a Shell Moving at High Velocities, L. Bairstow, R. H. Fowler, and D. R. Hartree, 618
Preventive Medicine since 1869, Dr. C. J. Martin, 210
Prices and Government Control, Sir Charles G. Wade, 485
Primary Current at Break, An Experimental Method of Determining the, in a Magneto, Dr. N. W. McLachlan, 366
Primates, Certain Cranial Sutures in the, Dr. R. W. Shufeldt, 44
Primeverose, Characters and Composition of, A. Goris and Ch. Vischniac, 367
Princeton and other American Universities, Bequests to, H. C. Frick, 386
Prismatic Binocular, Use of a, for Viewing Near Objects, Capt. D. Wilson Barker, 432
Probabilità, Calcolo delle, Prof. G. Castelnuovo, 464
Probabilities, The Neglected Study of, Prof. G. H. Bryan, 464
Process Year Book, The, vol. xxii. (*Penrose's Annual*), edited by W. Gamble, 690
Proctotrypid, Hyper-parasite of Aphidius (Lygocerus sp.), Preliminary Note on the Life-history of a, Miss M. D. Haviland, 366
Progress and Promise, 190
Psychical Research, Society for, Dr. W. McDougall Elected President of the, 608
Psychology, Industrial, Lectures on, B. Muscio. Second edition, revised, 687; Normal and Morbid, 624; The Modern Science of, 208
Psychoanalysis? What is, Dr. I. H. Coriat, 22
Psychonévroses de Guerre, Traitement des, G. Roussy, J. Boisseau, M. d'Œlsnitz, 22
Public Libraries, etc., Proposal for Certain Powers and Duties in Relation to, to be Transferred to the Board of Education, 522
Pultenæa, A Revision of the Genus, H. B. Williamson, 555
Pyriform Figure, the Stability of the, The Calculations of G. H. Darwin on, P. Humbert, 650
Pyrometry, Practical, The Theory, Calibration, and Use of Instruments for the Measurement of High Temperatures, E. S. Ferry, G. A. Shook, and J. R. Collins, 47
Pyrophorus Beetle, a Living, Photographs showing the Actinic Quality of the Light from, F. Martin Duncan, 345

Quadrant Electrometers, Improvements in Measurements with, Part ii., V. H. Jackson and A. T. Mukerjee, 459
Quadrilatère Complet, Premiers Eléments d'une Théorie du, A. Oppermann, 169
Qualitative Analysis, A Treatise on, Prof. F. Clowes and J. B. Coleman. Ninth edition, 688
"Quantico" Typhoon, The, Rev. J. Coronas, 79
Quarterly Journal of Microscopical Society, Jubilee of the Editorship of Sir E. Ray Lankester of the, 295
Quaternionic System, The, as the Algebra of the Relations of Physics and Relativity, Prof. W. Peddie, 715
Queensland: Lecythidaceæ, A Revised Account of the, C. T. White, 587; Mesozoic Insects of, No. 6: Blattoidea, Dr. R. J. Tillyard, 147; No. 7, Dr. R. J. Tillyard, 587
Queen's University, Kingston, Ontario, Dr. G. S. Melvin appointed Professor of Physiology in, 19

Race: and Nationality, Prof. A. Keith, 311; An Inquiry into the Origin and Growth of Patriotism, 311; Consciousness, Rev. Dr. W. Flint, 118
Racehorses, The Colours of, Sir William Ridgeway, 334
Radiation: Pressure, E. G. Barter, 188; Megh Nad Saha, 448; Temperature: Dew, S. Skinner, 277; Temperatures, S. Pickering, 153
Radiators, Improvement of the Efficiency of, in the Heating of Rooms, Prof. G. H. Bryan, 487
Radioactivité, Mesures Pratiques en Dr. W. Makower and Dr. H. Geiger. Traduit de l'Anglais by E. Philippi, 626
Radio-activity: and Gravitation, Sir Ernest Rutherford and Dr. A. H. Compton, 412; of the Water from the Large Spring at Bagnoles-de-l'Orne and its Variations, P. Loisel, 347; Relativity and, Prof. J. Joly, 468
Radio: -communication and the Thermionic Valve, 462; Principles of, 330; The Principles Underlying, 330; Direction and Position Finding, Capt. H. J. Round, 576; -finding Apparatus, The Theory and Use of, Capt. A. S. Blatterman, 137
Radiographic Prints, Exhibition of, 507
Radiology, Industrial and Medical, Dr. G. W. C. Kaye, 696
Radio: Research Board, A, Established by the Department of Scientific and Industrial Research, 638; *Review*, No. 1, 178; -Telegraphy and Telephony, The Thermionic Value and its Developments in, Prof. J. A. Fleming, 462; during the Solar Eclipse of May 29, 323; -transmission and Reception, J. H. Dellinger, 543
Radium: and the Electron, Sir Ernest Rutherford, 226; Bromide, Methods Used in France for the Production of, M. Demenitroux, 419
Rain: Electricity of, Effect Produced by the, on an Insulated Wire, A. Baldit, 387; Map of Australia for 1918, 476
Rainfall: British, 1918, Dr. H. R. Mill and M. de Carle S. Salter, 411; in England in 1919, 609; of the United States, The, 483
Ramsay: Memorial Fund, Contributions to, from Holland, 474; the late Sir William, Unveiling of a Medallion Portrait of, in the University of Glasgow, 397
"Randers Fjords Naturhistorie," 378
Rarer Elements, The, J. H. Gardiner, 310
Rat Destruction, Methods of, E. G. Boulenger, 97
Ray: Plotter, A, F. G. Smith, 682; Society, Dr. W. T. Calman Appointed Secretary of the, 158
Reaction, Heat of, and Gravitational Field, Prof. F. G. Donnan, 392
Reading, University College, Research Institute in Dairying, Appeal for Funds, 357
Reconstruction, 174
Red: Colouring Matter of Plant Galls, The, 707; "-pea Gall," The Colouring Matter of the, Dr. M. Nierenstein, 707
Rede Lecture, 1919, The, Science and War, Rt. Hon. Lord Moulton, 352
Refractive Index, Variations of, F. Twyman, 315; Indices, Variation of, Sir Henry A. Miers, 334
Refractory: Materials, Expansions of, H. J. Hodsman and Prof. Cobb, 379; Properties of Aluminous Materials, H. Le Chatelier and B. Bogitch, 128
Relatività, La Teoria di, nel suo sviluppo storico, Dr. A. Palatini, 552
Relativity: Prof. Einstein, 360; Prof. A. S. Eddington, and others, 454; An Exposition on, Sir Oliver Lodge, 339; and Radio-activity, Prof. J. Joly, 468; and the Displacement of Fraunhofer Lines, Prof. W. G. Duffield, 659; Discussion on, Prof. Eddington, and others, 400; Italian Papers on, Dr. L. Silberstein, 552; Generalised, in Connection with W. J. Johnston's Symbolic Calculus, Sir Joseph Larmor, 365; Theory, Results of the Total

Solar Eclipse of May 29, and the, Dr. A. C. D. Crommelin, 280; of Gravitation, Einstein's, E. Cunningham, 354; The Theory of, Prof. Eddington, 385; Dr. A. C. D. Crommelin, J. H. Jeans, and others, 631
Re-mapping of the World, The, 658
Reproduction of Illustrations, 1869–1919, Emery Walker, 252
Research: and its Application, Dr. W. H. Nichols, 262; Associations and Consulting Work and the Collection and Indexing of Information, Major H. J. W. Bliss, 399; Conference of, 399; Defence Society, January Report of the, 703; Laboratories, The Equipment of, Dr. W. Lawrence Balls, 399; The Organisation of, 6; The Promotion of, Sir Richard A. Gregory, 259
Resolution of a Curve into a Number of Exponential Components, J. W. T. Walsh, 325
Respiratory Exchange of Man during and after Muscular Exercise, The, J. M. H. Campbell, C. G. Douglas, and F. G. Hobson, 427
Retrospect and Prospect, Sir Archibald Geikie, 195
Reticularia lineata, Morphogenesis of, W. E. Alkins, 427

REVIEWS AND OUR BOOKSHELF.

Agriculture and Horticulture:
Bedford (Duke of), and S. Pickering, Science and Fruit-growing: Being an Account of the Results obtained at the Woburn Experimental Fruit Farm since its Foundation in 1894, 558
Butterfield (K. L.), The Farmer and the New Day, 592
Ekblaw (K. J. T.), Farm Concrete, 495
Fletcher (Prof. S. W.), Strawberry-growing, 592
Gehrs (Prof. J. H.), Productive Agriculture, 495
Gould (H. P.), Peach-growing, 495
Harris (Prof. T. S.), The Sugar-beet in America, 592
Mercier (Dr. C.), A Manual of the Electro-chemical Treatment of Seeds, 562
Thom (C.), and Prof. W. W. Fisk, The Book of Cheese, 528
Walker-Tisdale (C. W.), and T. R. Robinson, Practical Butter-making. Fourth revision, 528
Weigall (Lt.-Col. A. G.), and C. Wrey, A Large State Farm: A Business and Educational Undertaking, 592

Anthropology and Archæology:
Czaplicka (M. A.), The Turks of Central Asia in History and at the Present Day, 273
Johnston (Sir H. H.), A Comparative Study of the Bantu and Semi-Bantu Languages, 129
Oakesmith (Dr. J.), Race and Nationality: An Inquiry into the Origin and Growth of Patriotism, 311
Smith (Prof. G. Elliot), The Evolution of the Dragon, 350
Theal (Dr. G. McCall), Ethnography and Condition of South Africa before A.D. 1505. Second edition, 315
Warren (S. H.), Pre-history in Essex, as Recorded in the Journal of the Essex Field Club, 112

Biology:
Babcock (Dr. H. L.), The Turtles of New England, 23
Bower (Prof. F. O.), Botany of the Living Plant, 274
Bower (Prof. F. O.), Joseph Dalton Hooker, 561
Bower (Prof. F. O.), Prof. J. Graham Kerr, and Dr. W. E. Agar, Lectures on Sex and Heredity delivered in Glasgow, 1917-18, 351
Chamberlain (Prof. C. J.), The Living Cycads, 410
Church (A. H.), Thalassiophyta and the Subaerial Transmigration, 624
Church (A. H.), The Building of an Autotrophic Flagellate, 594
Crabtree (J. H.), British Ferns and How to Identify Them, 410
Davenport (Dr. C. B.), and M. T. Scudder, Naval Officers: Their Heredity and Development, 396
Dendy (Prof. A.), and others, Animal Life and Human Progress, 21

Root-pressure, The Phenomenon of, Prof. Priestley, 521
Rose Research Fellowship at St. Bartholomew's Hospital Medical School, Forthcoming Election to the, 319
Rothamsted: Establishment of an Entomological Laboratory at, 157; The New Laboratories at, 180
Royal: Academy of Belgium, The, and Enemy Countries, 541; Astronomical Society, Centenary of the, Prof. A. Fowler, 674; Election of Officers and Council of the, 671; Botanic Society, Suggestions of the Committee Appointed by the Board of Agriculture upon the, 116; College of Physicians, Dr. F. W. Andrewes Appointed Harveian Orator, Dr. R. C. Wall, Bradford Lecturer, and Dr. M. Flack, Milroy Lecturer; The Sharpey Prize Awarded to Prof. E. Roux, 608; College of Surgeons of England, Prof. A. Depage, Dr. P. Duval, Dr. A. Gosset, Prof. J. M. T. Finney, and Dr. C. H. Mayo Elected Honorary Fellows of the, 670; Commission on the Universities of Oxford and Cambridge, The, 329; Horticultural Society, Resignation of the Rev. W. Wilks of the Secretaryship of the; W. R. Dykes Nominated Secretary of the, 377; Institute of Public Health, Prof. M. Nicoll Appointed Harben Lecturer of the, 376; Forthcoming Congress of the, in Brussels, 377; Institution, Gifts to the, 296; Prof. W. H. Bragg to Deliver the Christmas Course of Juvenile Lectures at the, 318; Forthcoming Lectures at the, 358; Dr.

P. Sabatier, Dr. P. P. E. Roux, Dr. J. Loeb, Dr. R. A. Millikan, Dr. A. G. Webster, and Dr. W. W. Campbell Elected Honorary Members of the, 358; Meteorological Society, Election of Officers and Council of the, R. H. Hooker Elected President; The Symons Gold Medal Presented to Prof. H. H. Hildebrandsson, 573; Phenological Returns, H. B. Adames and J. E. Clark, 437; Photographic Society, Annual Exhibition of the, 157; The Scientific and Technical Group of the, 297; Society, Awards of the; Sir J. J. Thomson recommended for Re-election as President of the, 295; Anniversary Meeting of the; Resignation of R. J. Harrison of the Assistant Secretaryship; Presidential Address by Sir J. J. Thomson, 361; Medallists of the, 362; The Prince of Wales Admitted a Fellow of the, 571; Dr. E. Deller appointed Assistant Secretary to the, 572; of Edinburgh, and the Universities of Edinburgh and Glasgow, Bequests to, by Dr. J. Aitken, 376; Election of Officers and Council of the, 177
Russia, The Population of, Dr. A. Hrdlička, 341

Saccharose, The Diastatic Inversion of, H. Colin and Mlle. A. Chaudin, 367
Sahara, Discoveries in the, Col. J. Tilho, 610
Salpidæ, The, M. M. Metcalf, 40
Salt and the Salt Industry, A. F. Calvert, 497
Salters' Institute of Industrial Chemistry, Works of the, W. B. M. Bird, 398
Saltpetre, the Deposits of, near Prieska and Hay, Cape Province, Frood and Hall, 477
Sanitation Practically Applied, Dr. H. B. Wood, 311
Saphæosaurus, The Genus, G. A. Boulenger, 271
Saturn's Rings, The Albedo of, L. Bell, 138
Savilian Chairs of Geometry and Astronomy, The Foundation of the, 398
Scab in Horses, Treatment of, by the Vapours of Chloropicrin, G. Bertrand and M. Dassonville, 88
Schaumasse Comet, The Return of, G. Fayet and A. Schaumasse, 19, 347
Science: and Fruit-growing: Being an Account of the Results Obtained at the Woburn Experimental Fruit Farm since its Foundation in 1894, The Duke of Bedford and S. Pickering, 558; and Philosophy, Problems of, Aristotelian Society. Supplementary Volume ii., 559; and Sociality, Sir Archibald Geikie, 45; and the Church, the Ven. Canon J. M. Wilson, 201; and War: The Rede Lecture, 1919, Rt. Hon. Lord Moulton, 352; at Universities, Aspects of, Dr. A. Hill, 255; Books, a List of, Suitable for Use in Schools, 457; Importance of, as Part of a Liberal Education, W. W. Vaughan, 514; in Preparatory Schools, Major V. S. Bryant, 514; Masters' Association, Forthcoming Annual General Meeting of the, 306; Modern, and Materialism, H. Elliot, 625; The Realities of, J. Mills, 625; Popular, Victorian, 630; Teaching, Method and Substance of, Prof. H. E. Armstrong, and others, 521; Progress in, Sir William A. Tilden, 253
Scientific: and Industrial Research, Department of, Appreciation of the work of the, Sir Robert Hadfield, 670; Report of the Committee of the Privy Council for, for the year 1918-19, 470; The Control of, Dr. M. W. Travers, 597; and Technical Books, a Catalogue of, 66; Biography, 561; Research for Naval Requirements, 357; Need of the Encouragement of, Sir Oliver Lodge, 75; The British Association and, 337; The National Need for, A. J. Balfour, 399; Signalling and Safety at Sea, Prof. J. Joly, 41; Workers and a National Federation, Major A. G. Church, 693; Work in India, The Organisation of, 653; Organisation of, Prof. F. Soddy; Dr. A. B. Rendle, 691; Worthies, xli., Sir Norman Lockyer, Dr. H. Deslandres, 191
Sclerometer, The Magnetic, 269
Scottish: Journal of Agriculture, October, 379; Meteorological Society, Forthcoming Lectures in Connection with the; Dr. C. G. Knott elected President of the, 444; Ornithology, Report on, for 1918, Misses Rintoul and Baxter, 10
Sea-fishery Investigations and the Balance of Life, Prof. W. Garstang, 48; Prof. W. C. McIntosh, 49
Seals, Protection of, by the New Zealand Government, 475
Seashore, The, Its Inhabitants and how to know them, F. Robson, 132
Secondary: School Curriculum, The, 669; School Examination Council, Reports of the Investigators Appointed to Inquire into the Methods and Standards of Award in the Seven Approved First Examinations held in July, 1918, 669
Seedlings, Comparative Culture of, at High Altitudes and in the Plain, G. Bonnier, 523
Seed-plants, The Relation of the, to the Higher Cryptograms, Dr. Scott, 521
Seessel, Theresa, Research Fellowships, Forthcoming Award of, 457
Seistan, Aquatic Fauna of, Dr. N. Annandale, and others, 453
Sélection Humaine, La, Prof. C. Richet, 351
Selenia bilunaria, Effect of Alcohol on, Dr. J. W. H. Harrison, 609
Selenium, the Elastic Properties of, Prof. O. U. Vonwiller, 347
Sera and Vaccines, The Preparation and Conservation of, by Drying in an Absolute Vacuum, F. Bordas, 307
Sericulture in India, 471
Sewage: Effluents, The Bacterial Flora of, Purified by *boues activées*, P. Courmont and A Rochaix, 650; Waste Involved in the Discharge of, into the Sea and Rivers, Dr. V. E. Shelford, 78
Sex: and Soma, Prof. R. C. McLean, 407; and Heredity; Lectures on, Delivered in Glasgow, 1917-18, Profs. F. O. Bower, J. Graham Kerr, and Dr. W. E. Agar, 351; of Frogs Developed from Parthenogenetic Eggs, Prof. J. Loeb, 81; Phenomena in the Common Limpet (*Patella vulgata*), Dr. J. H. Orton, 373
Shackleton's Antartic Expedition of 1914-17, R. W. James, 554, 602
Shakespearean Garden, A, 441
Shan Alphabet, The Origin of the, 378
Sharply Pointed Bars, Lateral Vibrations of, The, Prof. J. W. Nicholson, 713
Sheffield: Museums and Mappin Art Gallery, Report of the, for the Past Five Years, 702; University, Gift to the Applied Science Department of, by J. D. Brunton, 67; Resignation of Prof. J. O. Arnold, 107; The Work of Prof. J. O. Arnold in, 127; Speech by D. Lloyd George at, on the Place of the University in Education, 167; A. Connell appointed Professor of Surgery in, 385; Prof. C. H. Desch appointed to the Chair of Metallurgy in, 405
Shells of the Family Doliidæ, E. W. Vredenburg, 78
Shide Seismological Observatory, Future of the, 8
Shore Processes and Shoreline Development, Prof. D. W. Johnson, 70
Shropshire: The Geography of the County, Prof. W. W. Watts, 331
Shrubs Belonging to the Genus Carissa, H. H. Haines, 159
Siberia, Forthcoming Expedition to, to be Conducted by Dr. O. Olsen, 158
Silica Glass, The Doubly Refracting Structure of, Lord Rayleigh, 153; R. W. Lawson, 335
Silk: Industry in, Report on an Inquiry into the, Prof. H. Maxwell Lefroy and E. C. Ansorge, 3 vols., 471; Industry, The, and Trade, R. C. Rawlley, 591
Silks, Kashmir and Indian, 591
Silkworm: Linkage in the, A Correction, Prof. W. Bateson, 315
Silurian Geology and Faunas of Ontario Peninsula, The, 574
Silver-leaf Disease, Symptons and Distribution of, J. Bintner, 359
Single-layer Flat Coils, The Self-inductance of, S. Butterworth, 366
Snails, Mortality among, and the Appearance of Bluebottle Flies, Dr. N. Annandale, 412
Snowfalls, Remarks on, Stapfer and Moleski, 618
Société Royale Zoologique et Malacologique de Belgique, Admission of Ten Honorary Members, 573
Sociological Society, The, T. J. C. Fraser Davies, 662

Sodium: Nitrite, Some Properties of, C. Matignon and Mlle. G. Marchal, 683; The Reversible Oxidation of, C. Matignon and E. Monnet, 683; Stearate and Sodium Oleate, The Distillation of, Pictet and Potok, 360
Soil at Night, Cooling of the, Capt. T. B. Franklin, 450, 458
Solar: Eclipse of November 22, 1919, Observation of the, I. Tarazona, 491; Eclipse of May 29, Radiotelegraphy during the, 323; Observations of the, made at Principe, Prof. A. S. Eddington, 454; The, C. R. Davidson, 544; Prominence, The Great, of last May, 420; Protuberances, 1880-1918, Heliographic Latitudes of the, A. Riccò, 187; Radiation, C. G. Abbot, 160; at the Altitude of the Mont Blanc Observatory, The Oxogenic Power of the, R. Bayeux, 407
Solution, Volume Changes in the Process of, G. J. Burrows, 147
Sound: Perception, Theories of, 591; -ranging, Prof. W. L. Bragg, 187; 278
South: The Story of Shackleton's Last Expedition, 1914-17. Sir Ernest Shackleton, 602; Africa, Fishery Investigations in, Report on, Prof. J. D. F. Gilchrist, 615; The Natural History of, Mammals, In four volumes. F. W. Fitzsimons, 469; The Pre-history of, Sir H. H. Johnston, 315; African Botanical Survey, Dr. J. B. Pole-Evans to act as Director of the, 607; Mygalomorph Spiders, J. Hewitt, 64; Termites, The Wing Venation and Respiratory System of Certain, C. Fuller, 78, 639
Southampton University College, Prof. T. Loveday appointed Principal of, 585
South-Eastern Agricultural College, Wye, Rev. S. G. Brade-Birks appointed Lecturer in Zoology at the, 167
Sparrowhawk, Nesting Habits of the, J. H. Owen, 178
Spectral Lines, Displacement of, R. W. Lawson, 565
Spectrophotometry, A New Method of, in the Visible and Ultra-violet and the Absorption of Light by Silver Bromide, R. E. Slade and F. C. Toy, 713
Spectroscopic Astronomy, Prof. A. Fowler, 234
Spermatozoa, The Relation of, to certain Electrolytes, (ii.), J. Gray, 427
Spiders, "Gynandry" among, Rev. J. E. Hull, 81
Spiral Nebulæ, The, C. L. Charlier, 68
Spitsbergen: An Account of Exploration, Hunting, the Mineral Riches and Future Potentialities of an Arctic Archipelago, Dr. R. N. Rudmose Brown, 635; The Coal Export Trade from, Dr. Rudmose Brown, 514; The Development of, 635
Squid, The, as Food, 446
St. Andrews Institute for Clinical Research, Prof. P. T. Herring, 615
Stahl, Adolfo, Lectures in Astronomy, The, 370
Standardisation, International, 12
Stannic Chloride, Action of, on Dimethyl Sulphate, Ch. Boulin and L. J. Simon, 271
Stanton Drew Stones, The, E. Sibree, 445
Stark Effect, the Electrical Resolution of the, 65
Star, Formation of a, Time and Temperature of, A. Véronnet, 367
Stars: Binary, Relative Masses of, G. van Biesbroeck, 643; Night by Night: The, Being the Journal of a Star Gazer, J. H. Elgie, 467; of High Velocity, W. S. Adams and A. H. Joy, 612; of Type F, Distances of the, C. F. Lundahl, 479; Possessing a Total Annual Proper Motion of more than 0.5″, E. Cosserat, 68; Two, with large Parallaxes, Prof. F. Schlesinger, 342
State Geological Survey, The Organisation and Functions of a, P. G. Morgan, 517
Statesman's Year-Book, The, 1919, Edited by Sir John Scott Keltie and Dr. M. Epstein, 152
Statistics: Imperial, The Organisation of, G. H. Knibbs, 551; Public, the Collection and Presentation of, a Petition Urging the Appointment of a Royal Commission or Select Committee on the Methods of, 416
Steam: -boiler Plants, the Running of, D. Brownlee, 611; Boilers and Economisers, C. E. Stromeyer, 675
Steel: A New Alloy Tool-, Prof. J. O. Arnold, 416; High-class, Reported Discovery in the Manufacture of, 702; Rails, A Cause of Rupture of, and a Means of Suppressing it, G. Charpy and J. Durand, 271; The Solution Theory of, and the Influence of Changes in Carbide Concentration on the Electrical Resistivity, Prof. E. D. Campbell, 523
Steels at High Temperatures, The Viscosity of, P. Chevenard, 326
Stellar: Clusters, Dr. and Mrs. Shapley, 119; Open, Dr. H. Shapley; Sir F. W. Dyson, and Mr. Melotte, 576; Energy, The Sources of, Prof. Russell; Prof. Eddington, 269; Parallax, Spectroscopic Determination of, W. S. Adams and G. Strömberg, 511
Stereolepis gigas, The Growth of the Young of, 703
Stomatopoda at Buitenzorg, Dr. A. L. J. Sunier, 446
Stone-axe Factory, A, at Graig-lwyd, Penmaenmawr, S. H. Warren, 346
Straight Path, The, Dr. A. A. Robb, 599
Straits Settlement Gold Medal: The, Awarded to Prof. R. T. Leiper, 540; the Award of the, to Dr. R. T. Leiper, 572
Strains, Internal Longitudinal, The Influence of various Factors on the Creation of, during the Rapid Cooling of Steel Cylinders, M. Portevin, 407
Streatfeild Memorial Lecture: The, to be Delivered by Prof. T. H. Morgan, 78; Prof. G. T. Morgan, 147
Strasbourg: The University of, Mathematics at, H. B. Heywood, 74; Inauguration of the, 345; Re-inauguration of the, 365
Stratosphere, Winds and Temperature-Gradients in the, G. M. B. Dobson, 458
Strawberry-growing, Prof. S. W. Fletcher, 592
Students, Suggested Exchange of, between Denmark and Great Britain, Dr. V. Naser, 522
Submarine Mining, Comdr. Gwynne, 487
Submarines and Sea Power, C. Domville-Fife, 433
Sucrose, A Cryoscopic Method for the Estimation of, Prof. H. H. Dixon and T. G. Mason, 554
Sudan Irrigation Works, The, Dr. B. Cunningham, 120
Suess's "Sal" and "Sima" Magmas, Dr. Holtedahl, 574
Sugar: Beet in America, The, Prof. T. S. Harris, 592; Seed, Prof. T. D. A. Cockerell, 661; Canes, some Indian, and their Origin, Dr. C. A. Barber, 14; from Formaldehyde and its Polymers, The Synthesis of, its Quantitative Relations, and its Exothermic Character, A. J. Ewart, 555; Group, Scientific Study of the, 526; Industry, Appointment by the Government of India of a Committee on the, 444; Manufacture, the Nitrogen Balance in, E. Saillard, 651
Sulphide of Silver and of Bismuth, Change in the Electrical Resistance of the, W. W. Coblentz and H. Kahler, 478
Sulphur, The Viscosity of, C. C. Farr and D. B. Macleod, 712
Sulphuric Acid, Making, by the "Grillo" Plant, R. Curtis, 341
Summer Time, 63; Impending for the Present Year, 701
Sun: Dance of the Teton Sioux, The, F. Densmore, 437; Observations of the, made at the Lyons Observatory, J. Guillaume, 491; Power from the, A. A. Campbell Swinton, 392; A. S. E. Ackermann, 500; A. A. Campbell Swinton, 532; Spot Curve, The, S. B. Nicholson, 160; Temperature in the, A. Mallock, 113
Surface-tension, C. T. Whitmell, 278
Surgery of Deformities, 493
Surgical Tradition, The, Sir John Tweedy, 418
Swanley Horticultural College, Miss F. M. G. Micklethwait appointed Principal of the, 490
Swansea University College, Dr. T. F. Sibly appointed Principal of, 616
Swiney Lectures, Forthcoming, by Dr. J. D. Falconer, 178
Sydney University: Bequest to, by Sir Samuel McCaughey, 107; Government Grant to, 616
Symons: Memorial Gold Medal of the Royal Meteorological Society, The, awarded to Prof. H. H. Hildebrandsson, 340; *Meteorological Magazine*, Sept., 99
Synapsis, Studies of a, I.; Oogenesis in the Hymenoptera, L. T. Hogben, 649; L. T. Hogben, a correction, 674
Syria, The Geographical Unity of, E. de Marbonne, 97
Syringa Vulgaris, Electrolytes in the Leaf-sap of, T. G. Mason, 427
Syringothyris Winchell, etc., F. J. North, 586

"Tactite," A New Geological Term, F. L. Hess, 574
Tanks, British, Used in the War, Sir E. H. Tennyson d'Eyncourt, 486
Taxation of Profits, The, Dr. J. C. Stamp, 486
Technical: Book Review Index of the Carnegie Library, Pittsburgh, 478; Education, Fifty Years of, J. H. Reynolds, 257; *Review,* The, 77
Teeth, Forward Protrusion of the Upper Incisor, etc., D. M. Shaw, 136
Telegony, Prof. J. Cossar Ewart, 216
Telephoning by Light, Prof. A. O. Rankine, 604
Temperatures: High, and Pressures, Researches at, Hon. Sir Charles A. Parsons, 677, 709
Tertiary Fossils: from Ooldea, F. Chapman, 619; from the Ooldea Soak, South Australia, F. Chapman, 347
Testudo Loveridgii, G. A. Boulenger, 715
Teton Sioux, The Sun Dance of the, F. Densmore, 437
Thalassiophyta and the Subaerial Transmigration, A. H. Church, 624
Theme, The Missing, 69
Thermionic: Tubes, Three-electrode, The Variations of Wave-length of the Oscillations Generated by, due to Changes in Filament Current, etc., W. H. Eccles and J. H. Vincent, 617; Valve, Radio-communication and the, 462; and its Developments in Radio-telegraphy and Telephony, Prof. J. A. Fleming, 462; Three-electrode, J. M. Miller, L. M. Hull, 510; Application of the, Prof. Fortescue, 487; Prof. Eccles, Prof. Fortescue, Dr. Whiddington, 454; on Aircraft, Prof. R. Whiddington, 630
Thompson, Elizabeth, Science Fund, The, 608
Thule Expedition to Northern Greenland, The Second, 453
Thunder, The Audibility of, Capt. C. J. P. Cave, 132; Dr. H. O. Forbes, 315
Tibesti, Volcanic Lavas of, Mineralogical and Chemical Constitution of the, A. Lacroix, 68
Tibet and Neighbouring Regions, Exploration in, Col. L. Conyngham, 570
Tidal Observations and the Prediction of Tides, The Harmonic Analysis of, Dr. C. E. Adams, 517
Tide Prediction, A Simple and Rapid Method of (including Diurnal Time and Height Inequalities), Sgt. M. E. J. Gheury, 171
Timber: Diseases in Prepared, Dr. C. J. Gahan to Assist the Science Committee of the Royal Institute of British Architects in the Matter of, 573; Mechanical Strains in, Microscopical Features of, W. Robinson, 345
Time Relations in a Dream, J. Barcroft, 154
Times: African Flight, The, Discovery of a New Volcanic Field, Prof. J. W. Gregory, 667; Survey Atlas of the World, Prepared under the Direction of Dr. J. G. Bartholomew, part i., 658
Tin-plate Manufacture, Influence of Hours of Work and of Ventilation on Output in, Dr. H. M. Vernon, 136
Toas, Description of, or Australian Aboriginal Direction Signs, the late Sir E. Stirling and E. R. Waite, 643
Tobacco Beetle, The, G. H. Runner, 301
Tool-steel, A New Alloy, Prof. J. O. Arnold, 416
Torbernite, A. F. Hallimond, 650
Toronto University, Conferment of Degree upon the Prince of Wales, 19
Torporley, Nathaniel, The Remains of, 297
Torricelli: Opere di Evangelista, Edite da Gino Loria e Giuseppe Vassura, 3 vols., 557
Total Solar Eclipse of May 29, Results of the, and the Relativity Theory, Dr. A. C. D. Crommelin, 280
Toxins and their Anti-toxins, Mutual Precipitation of, M. Nicolle, E. Debains, E. Césari, 619
Tractor: Trials, The Lincoln, 359; Work of the, on the Farm, Garrad, 98
Traiettorie dinamiche dei sistemi olonomi con tre gradi di libertà, Dr. A. Palatini, 552
Train Resistance, Experiments on, 581
Transit Circle, The Future of the, J. E. de Vos Van Steenwijk, 80
"Traube" Waves, Prof. Halliburton, 418
Tricuspidaria lanceolata, Floral Development in, Mrs. L. Porter, 346
Tri-lingual Artillery Dictionary, E. S. Hodgson. 3 vols., vol. i., English-French-Italian, 332
Trilobites, Two New, from Bowning, N.S.W., J. Mitchell, 271
Triode Valves as Electric Amplifiers, Prof. W. H. Eccles, 501
Tropical: Australia, The Future of, G. Taylor, 648; Diseases Bureau, The, 265
Tropics, Comfort and Health in the, Dr. C. Crossland, 573
Trout, The "Trypanosome" of the, Mlle. M. Gauthier, 650
Truth?, What is, Viscount Haldane, 405
Tungsten Arc ("Pointolite") Lamps, P. Freedman, 358
Turbines: Geared, for the Propulsion of Ships, R. J. Walker, 486; The Geared, supplied to the *Wrangel* and *Wachtmeister,* 160
Turkestan, Western, S. Casson, 335
Turks of Central Asia, The, Sir Henry H. Howorth, 273; in History and at the Present Day, M. A. Czaplicka, 273
Turtles of New England, The, Dr. H. L. Babcock, 23
Twenty-four-hour Day, The, 100
Tyndall Mining Research Fund Studentships, Forthcoming Award of, 457

Ultra-violet: the Extreme, A Helium Series in, Prof. W. M. Hicks, 393; Prof. T. Lyman, 565; A Spectroscopic Arrangement for the Study of, L. and E. Bloch, 683
Union of South Africa, Fifth and Sixth Reports of the Director of Veterinary Research of the, 477
United States: Cement Production in the, in 1917, 641; Concrete Shipbuilding in the, 641; General Education Board, Gift to, by J. D. Rockefeller, 158; Index of Economic Material in Documents of the States of the, The State of Pennsylvania, Adelaide R. Hasse, 704; Mathematics in the, 601; National Academy of Sciences, C. W. Beebe Awarded the Elliot Medal of the, 376; National Academy of Sciences and the National Research Council, Gift to, by the Carnegie Corporation of New York, 638; National Museum, Collection of Ecclesiastical Art in the, I. M. Casanowicz, 40; National Research Council, Work of the, 116; Rainfall of the, Some Characteristics of the, Prof. R. De C. Ward, 483; Resources and Industries of the, Prof. E. F. Fisher, 131; The National Research Council of the, 668
Universities: Science at, Aspects of, Dr. A. Hill, 255; and the Training of Teachers, F. J. R. Hendy, 681; The League of, 637
University Bureau in Connection with the Commerce Degree, Scheme for the Establishment, in London, of a, 617; College, London, Appeal on Behalf of the School of Engineering of, 586; 621; College, Southampton, Dr. A. Hill resigning the Principalship of, 306; Education, The Government and, Austen Chamberlain, 75; Women, International Federation of Forthcoming Meeting of the, 712
Upper-air Temperatures at Martlesham Heath, February, 1917, to January, 1918, Lt. W. F. Stacey, 675
Uranium, The Radio-activity of, C. Straehling, 459

Vaccine: -therapy, 466; Treatment, Practical, for the General Practitioner, Dr. R. W. Allen, 466
Vagueness and Discrimination, 110
Vagus Nerves, The Fatal Result of Section of Both, Sir E. Sharpey Schafer, 418
Valedictory Memories, Sir Norman Lockyer, 189
Valour and Service, Statistics of, Major A. G. McKendrick, 660
Vapour-pressure: Determinations, Apparatus for, R. Wright, 581; of Binary Mixtures, The, Prof. A. W. Porter, 523
Variables, Long-period, Prof. H. H. Turner, 643
Venus Cloud-covered? Is, J. Evershed, 675
Vertebrate: Embryology, 309; Remains in the Caverns of Grimaldi, 581
Vertical-pipe Irrigation for Orchards and Market-gardens in Arid Climates, Prof. I. Giglioli, 276
Veterinary: Science and Practice, 418; Staffs in the Colonies and Protectorates, Appointment of a Committee on the, 608

Vicary, The Thomas, Lecture, Sir John Tweedy, 418
Villamaninite, a New Mineral, Dr. W. R. Schoeller and A. R. Powell, 326
Vision: of the Possible: A, What the R.A.M.C. might Become: An Account of Some of the Medical Work in Egypt, together with a Constructive Criticism of the R.A.M.C., Sir J. W. Barrett, 21; The Hill of, A Forecast of the Great War and of Social Revolution with the Coming of the New Race, F. B. Bond, 690; The Theory of, Sir Oliver Lodge, 454
Visual Tests for Motor-drivers, 646
Vitalism, Prof. Dakin, 578
Volcanic Rocks in Northern Kordofan, Sudan, W. Campbell Smith, 693
Volumetric Analysis for Students of Pharmaceutical and General Chemistry, C. H. Hampshire. Second edition, 497
Voyage of a Vice-Chancellor, The, 151
Vulcanicity, Natural and Artificial, E. Belot, 575

Wales: A Primitive Type of Man in, Prof. H. J. Fleure, 487; National Museum of, Annual Report of the, 639
War Gleanings, 21
Water: in Action—Controlled and Free, Dr. B. Cunningham, 70; for Electrical Purposes, The General Principles of the Development and Storage of, J. W. Meares, 161; from the Atmosphere, Use of Trees in Extracting, P. Descombes, 491; -lily, Immersion of the Leaves of the, Causes of the, L. Daniel, 407; -power and Dartmoor, 461
Watt, James: Proposal for a Memorial to, Sir D. Brooks, 74; Centenary Celebrations in Birmingham, 63, 74; Address on, Rev. Dr. E. W. Barnes, 75; and Invention, Prof. Hele-Shaw, 75
Wave Action in Harbours, The Reduction of, Dr. Brysson Cunningham, 614
Wax Scale from New Guinea, A New Species of, W. W. Froggatt, 271

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE.

"*To the solid ground*
Of Nature trusts the mind which builds for aye."—WORDSWORTH.

THURSDAY, SEPTEMBER 4, 1919.

AN EIGHTEENTH-CENTURY PHYSICIAN.

Dr. John Fothergill and his Friends: Chapters in Eighteenth-century Life. By Dr. R. Hingston Fox. Pp. xxiv+434. (London: Macmillan and Co., Ltd., 1919.) Price 21*s.* net.

MORE than any other period, the eighteenth century is rich in memoirs and biographical history, and from these sources have been obtained most of our facts regarding the mode of life, the characters, and the mental activities of those who were representative of that age. But estimates of the lives and work of physicians have not appeared so frequently, although many medical men in the eighteenth century influenced the social life of their period profoundly enough to merit a biographical memoir.

The life of Dr. John Fothergill is a case in point, and the book under review is a valuable contribution to the biographical history of medicine. Fothergill is fully worthy of the care Dr. Fox has bestowed upon his history, for, in a sense, he was representative of his age and profession. He occupied a respectable, if not a commanding, position in medicine; he was ever ready to promote with his purse and influence the claims of science, and in an age when few paid attention to public health and education he was an energetic and enlightened reformer. Others, notably Lettsom, have essayed the portrait of Fothergill, but we do not remember any memoir in which the character of the great Quaker physician is depicted with more accuracy and skill.

The life of Fothergill may be considered from the point of view of the physician, the man of science, and the philanthropist. In all he played a considerable part, but his precise position as a physician is difficult to describe. He was, it is true, very successful in private practice, and enjoyed an unusually large share of public patronage. From accounts that have been handed down, he appears to have been a shrewd and accurate observer of the clinical phenomena of disease. But to judge from the scanty and hastily composed medical writings left by Fothergill, he does not appear to have been a sagacious scientific thinker, nor has he contributed much to the advance of medicine. He was content to cling to the traditions of the old clinician, and was uninfluenced by the advances that were being made in the study of morbid anatomy as an aid to the diagnosis and treatment of disease. As a physician he belongs to the class of which Richard Warren, Henry Revell Reynolds, and Sir Henry Halford were leaders, but he cannot be assigned a place among the great men who advanced medicine, such as Matthew Baillie, William Prout, and Richard Bright.

Fothergill's position in science was not unlike that of Sir Joseph Banks, whose influence, more than actual scientific work performed, produced a salutary effect on British science in the eighteenth century. Botany interested him keenly, and nearly all the time he could snatch from his medical commitments was devoted to the cultivation of his famous garden of thirty acres at Upton Park, where fifteen gardeners were continually employed. Fothergill's estate at Upton Park was no mere pleasure garden devised for the purpose of social entertainment, but a nursery for the rearing of shrubs and plants brought from all parts of the world by collectors in Fothergill's pay. In this way he was responsible for the introduction of many varieties which can be seen in any garden at the present day.

Besides medicine and botany, Dr. Fox gives a full account of Fothergill's work in education and politics, and his position as a leader of the Society of Friends is dealt with in a temperate and able manner. The book is trustworthy, and should commend itself to those who are interested in the intellectual progress of the eighteenth century.

PHYSICS IN WAR.

Les Applications de la Physique pendant la Guerre. By H. Vigneron. Pp. viii + 322. (Paris: Masson et Cie, 1919.) Price 7 francs net.

A BOOK with this title, appearing so soon after the termination of hostilities, could scarcely fail to excite considerable interest. The public in general and people with a scientific turn of mind in particular have been vaguely aware that, during the war, much work has been done in applying scientific principles to military purposes. In this country, as well as in Allied countries, there have been spread, in spite of the censorship, most exaggerated and distorted accounts of the practical results of these experiments. Here, then, in this book, it might have been supposed, would be afforded an opportunity of testing the truth of the rumours which have been current. To a reader in this frame of mind a perusal of the book will be somewhat disappointing. There are no great revelations, and it is a little difficult to see why the French censorship would not allow the author to publish the major portion of the contents during the war as he desired. The important subject of submarine detection and destruction, for example, is dealt with in a couple of pages. There is internal evidence that this does not arise from lack of knowledge on the part of the author, but rather from the operation of the censorship, which can have been removed in a very limited sense only. The author has, no doubt, been seriously handicapped in this way, for the French authorities appear to have been much more strict than our own.

M. Vigneron, in his preface, very properly lays stress on the important part played in the war by those men of science who, before the war, conducted speculative research without thought of the possibility of its practical application, and were forced by circumstances to join hands with the "techniciens," as he calls them. This alliance has produced far-reaching results, and there will be general agreement with the author that it should be fostered and perpetuated. The work of purely scientific workers is very liable to be lost sight of when it becomes absorbed in industry. One feels that M. Vigneron would have been able to do more justice to them had he delayed publication until it was permissible to refer more explicitly to their work. The author is evidently a believer in the practical fruits of pure science, and his advocacy of the methods of the General Electric Co. of Schenectady in this respect is sound.

The first of the seven sections of the present volume deals principally with the applications of optics for military purposes. Of particular interest are the chapters concerning rangefinders, and the many and varied uses of photography in warfare. One misses, however, any adequate reference to modern methods of signalling, such as those with infra-red and ultra-violet light, invented by Prof. R. W. Wood. Sections 2 and 3 are devoted, respectively, to the aerial and submarine aspects of war, and contain many interesting facts and diagrams. There is a long section on artillery and projectiles, containing much information, most of which was probably available before the war. The sixth section, on wireless telegraphy, is shorter than might have been expected, but gives an interesting outline of present methods, including the use of thermionic valves as oscillators and amplifiers. There is merely a mention of wireless telephony, which actually came into considerable practical use during the war. Localisation of foreign materials in the human body, mainly by means of X-rays, forms the subject of the last chapter.

The book is interesting and well written. It is illustrated with many good diagrams and photographic reproductions, which are explained clearly in the text. What is lacking with regard to "secret" developments the author will, we hope, take up in a subsequent volume.

EXPERIMENTAL RESEARCHES ON GLASS.

Experimental Researches Carried Out in the Department of Glass Technology, University of Sheffield. Vol. i., 1917–18. (Reprinted from the Journal of the Society of Glass Technology.) Pp. iii + 178. (Sheffield: The University, n.d.)

DR. W. E. S. TURNER is to be congratulated upon the success which has attended the formation of the Department of Glass Technology, Sheffield University, of which he is the head, and of the Society of Glass Technology, of which he is secretary, and in the foundation of which he played a leading part. The results of the experimental researches carried out in the department are now reprinted from the journal of the society, together with certain reports to the council of the university.

Glass is a peculiarly elusive subject for scientific investigation, but neither man of science, technologist, nor practical worker will deny that it is a fascinating one. We know practically nothing about the nature of glass, and in this respect we are much in the position of the metallurgists prior to the introduction of thermal and micrographic methods of investigation. We have as yet no key to the constitution of glass, and this must be sought in the purely scientific study of simple mixtures rather than in the investigation of complex glasses, which experience has proved to be practically useful.

At the beginning of the war very little information was available with regard even to the essential facts relating to scientific glassware, miners' lamps, and electric bulbs, which our glass manufacturers were called upon to supply with the least possible delay. Which was the best of the various brands of beakers and flasks at the moment in everyday use in chemical laboratories? was a question to which only the vaguest answer could be given. As to how these glasses should anneal so as to withstand the strain of laboratory use nothing was known at all.

The researches which are now republished relate mainly to the practical class of problems. The seven papers on the testing of laboratory glassware contain information which has been of the greatest value to glass manufacturers. They should also be very carefully studied by everyone engaged in analytical work. The attention of chemists and physicists is also directed to some interesting papers relating to the calibration of volumetric apparatus and to blowpipe work.

Experimental work in connection with refractory materials, furnace problems, etc., is also being undertaken, but only preliminary notes on the results are as yet available.

The publication contains an account of the educational activities of the department, which includes a school of instruction in blowpipe work.

M. W. T.

PHYSICAL CHEMISTRY.

(1) *Text-book of Physical Chemistry*. By Prof. A. T. Lincoln. Pp. viii + 547. (London: G. G. Harrap and Co., Ltd., 1918.) Price 12*s*. 6*d*. net.

(2) *Outlines of Theoretical Chemistry*. By Dr. F. H. Getman. Second edition, thoroughly revised and enlarged. Pp. xvi + 539. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1918.) Price 16*s*. 6*d*. net.

IN the matter of text-books, physical chemistry seems to be coming into its own. It is a healthy sign. Not, indeed, that mere numbers of text-books are any trustworthy measure of the growth and vigour of a science, nor is the unrestricted compilation of them to be encouraged, but physical chemistry is a relatively youthful science, and there is still ample room for individual exposition of the subject.

We have before us two general text-books of physical chemistry of moderate size and scope, and it may be said at once that both can be recommended to students who are commencing the subject. In books of this kind the great difficulty for the writer is to know what to exclude, for, of course, much has to be excluded, and no very detailed discussion of any problem is possible. The two books, although of much the same "standard," naturally exhibit their individuality in this respect. There is one point which should not be overlooked: both books are by American authors. It is evident that physical chemistry is taken much more seriously in America than it is in our own country. The fact is that the Americans, like the Germans before them, have realised the fundamental importance of physico-chemical thinking, not only for advance on the theoretical side, but equally so for technical and industrial progress.

(1) Prof. Lincoln's book is well written, and the fundamental principles are clearly developed and explained. Considerable attention is paid to the laboratory side of the subject. There are a few historical references, which give added interest to the text. Without going into detail, it may be said that optical properties are particularly well treated, as is also the general problem of heterogeneous equilibrium—*e.g.* the phase rule and its manifold applications, the principles of fractional distillation, and the solubility relations of three components. (In the last connection a particularly good account is given of the use of the triangular diagram.) There is likewise a fairly comprehensive discussion of colloids, of non-aqueous solutions, and of the ionising power of a solvent. Except in a few sections, only the most elementary mathematics is employed. This makes the book very suitable for those beginning the subject, but, of course, limits its scope. There are a few misprints—*e.g.* Frick for Fick on p. 434—and a rather remarkable statement on p. 378 in connection with hydration, which is not quite what the author intends. The absence of a name index is perhaps a drawback, and the use of the term *heat-tone* as a translation of *Wärmetönung* is to be deprecated.

(2) Dr. Getman's book, which now reaches its second edition, is an excellent exposition of physical chemistry for those commencing the subject. Again only elementary mathematics is used, and, although numerous thermodynamical results are quoted and applied, the author has not attempted any systematic treatment of the principles of thermodynamics which would have taken him beyond the general aim and scope of the book. It may be mentioned that the subject of conduction of electricity through gases is given much more prominence than is usual in a book of this kind. The same thing is true of the subjects radio-activity, atomic structure, polarisation, and photochemistry. The results of modern research have been incorporated in a skilful manner, and the student is frequently referred to original sources for further information. The presentation of the whole subject is consequently very much up to date. Each chapter is furnished with a set of problems which will be of good service in enabling the student to grasp thoroughly the meaning of what he reads.

W. C. McC. LEWIS.

OUR BOOKSHELF.

Text-book on Practical Astronomy. By Prof. George L. Hosmer. Second edition, revised. Pp. ix + 205. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1917.) Price 9*s*. 6*d*. net.

THE professed object of the author was to satisfy the requirements of civil engineering students, who are unlikely to take up a more advanced study of astronomy, and to produce a text-book intermediate between those formally devoted to astronomy and geodesy, and the short chapter on astronomy generally to be met with in works on surveying. By the lucidity of the explanations and the simplicity of the general treatment of the subject, the book seems well adapted to the needs of such students, and suggests comparison with the work on astronomy by the late Hugh Godfray, which has held the field in our universities for so many years. A good deal of space is wisely devoted to the chapter on time, for the experience of teachers generally will confirm the remark made in the preface that "this subject seems to cause the student more difficulty than any other branch of practical astronomy."

The young student of spherical trigonometry, entering upon the practical solution of triangles, is sometimes a little bewildered by the number and variety of the formulæ put before him for the determination of an angle from three given sides, by means of the halved sine, cosine, tangent, etc. A somewhat novel feature of Prof. Hosmer's work is a short discussion of the conditions under which one of these is to be preferred to the others.

To each chapter is appended a small collection of examples, some numerical, some calculated to test the grasp obtained upon the subject-matter of the chapter. These should be of great assistance to the student. H. B. G.

History of the Theory of Numbers. Vol. i. *Divisibility and Primality.* Publication No. 256. By Prof. L. E. Dickson. Pp. xii+486. (Washington: Carnegie Institution of Washington, 1919.)

THIS work appears to be a chronological encyclopædia rather than a history as that word is usually understood. Prof. Dickson has aimed at giving references to all papers bearing on the subject, and in most cases he has given a summary of the contents.

These papers are so numerous that the need for brevity has forced the author into a style which is often abrupt and occasionally irritating, but the subject-matter will be found invaluable by all who aim at original work in the theory of numbers.

The volume begins with an account of the theory of perfect numbers[1]; these are now of historical interest only, but the quest for all perfect numbers has proved one of the greatest driving forces in the general theory of numbers.

The next topic includes the theorems of Fermat and of Wilson; it is remarkable that the first proof known of the one and the first enunciation of the other are both due to Leibniz.

The section on indices, binomial congruences, and circulating decimals includes a large number of writings of an unusually miscellaneous character, and the reader will find that this source contains much information which has not been easily accessible hitherto.

The most elaborate chapter bears the title "Sum and Number of Divisors"; and this chapter contains many references to the analytical theory of numbers, which has grown so rapidly of late years. On the other hand, recent work on prime number theory is but lightly sketched, and rightly so, inasmuch as the treatise by Landau and subsequent reports have provided all the necessary material.

[1] The Greeks called a number *perfect* if the number happens to be equal to the sum of its divisors. For example, we have

$$6=1+2+3.$$
$$28=1+2+4+7+14.$$

Physical Laboratory Experiments for Engineering Students. By Prof. Samuel Sheldon and Prof. Erich Hausmann. Part i. *Mechanics, Sound, Heat, and Light.* Pp. v+134. (London: Constable and Co., Ltd., 1919.) Price 6*s.* net.

THIS book, prepared for use in the Polytechnic Institute of Brooklyn, is suitable for candidates for engineering degrees who have already pursued laboratory courses in physics. "Each experiment has been chosen because of its close connection with engineering work, and in many cases the theoretical result may be calculated from the constants of the apparatus with which that result obtained by experiment may readily be compared. As these two results approach to an equality the student gains confidence in the apparatus, confidence in the theory, and confidence in himself." This is well said. There can be no doubt that many students lose not only confidence but also interest in physics when they find that owing to inefficient apparatus results of reasonable accuracy cannot be obtained. The experiments here described are well selected, and as apparatus of engineering design has been chosen, the equipment with ordinary care in use should continue to give sufficient accuracy. Special mention may be made of the apparatus for the study of the harmonic motion of a rotating system, which appears to be unknown to British instrument makers. The book is printed on good paper, and is well illustrated.

H. S. A.

The North Riding of Yorkshire. By Capt. W. J. Weston. Pp. viii+161. (Cambridge: At the University Press, 1919.) Price 2*s.* 6*d.* net.

IN view of the time which has elapsed since the greater proportion of these well-known county geographies were issued, one had almost feared that the greatest county had been overlooked. It is now apparent that three volumes will be issued for Yorkshire, one for each Riding, and the first of these, dealing with the North Riding, has just appeared. As we are fairly familiar with all that have previously been published, it is a pleasure to be able to state that this is one of the best; the author seems to have had a better grasp of the object of the work he has had in hand, resulting in a volume which is much more a geography than a guide-book. The illustrations are numerous and well chosen; misprints, as usual, are few—which makes that in the word "Montreal" on p. 58 all the more glaring. The only statement we cannot agree with is in reference to the "raised beach" at Saltburn, which is now known to be a "kitchen midden." The colouring of the geological map at the end, for which the author is not responsible, does not seem quite so successful as with the maps in the earlier volumes.

T. S.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can be undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Explosion at Bailleul.

THE reports referred to in NATURE of August 28 (p. 511) of the effects observed at Denmark Hill, Norwich, and elsewhere by the explosion of a munition dump at Bailleul at 1.10 p.m. G.M.T. on August 8 suggest that these effects were due mainly to earth tremors caused by the explosion, since the rattling of windows, extending in one case throughout two and a half minutes, is alone mentioned. Here, however, at Harpenden, and also at Luton and Stevenage, an actual sound of a very marked character was heard. The first impression produced in my own case was that a ceiling or heavy picture had fallen in one of the upper rooms, and I at once went round the house to ascertain if that was the case. Everyone in the immediate neighbourhood seems to have heard the noise equally clearly, and it was very generally attributed at first to an explosion of a factory or munition dump four to six miles distant. The noise, which may have lasted two seconds, was preceded by a lesser sound, or perhaps only a tremor, which made one anticipate that something was coming. This, of course, is usual in the case of explosions. SPENCER PICKERING.

Harpenden, Herts.

British Well-worms.

FROM facts which have recently come to light, I am led to believe that there is a good deal yet to be learned about the Oligochæts which occur in our wells and water-supplies. It is now many years since I directed attention to the occurrence of *Pachydrilus* (*Lumbricillus*) *subterraneus*, Vejd., in tap-water and elsewhere. The first well-worm to be discovered in the country was named by me *Diachaeta curvisetosa*. It was afterwards discovered that it belonged to the Haplotaxidæ, and is now known as *Haplotaxis curvisetosa*, Friend. In spite of Michaelsen's conclusion to the contrary, this is quite a distinct worm from *Haplotaxis gordioides*, which I have found in this country. Another well-worm, the description of which may be expected to appear shortly in the Quarterly Journal of the Microscopical Society, is *Anagaster fontinalis*, Friend, which has been found in East Anglia. I have notes of other species of worms found in water, including Rhynchelmis, taken in Hampshire, and some which have not been named for want of perfect material. As I am now engaged on the preparation of a monograph of British Oligochæts, it seems very desirable that our knowledge of this branch of the subject should be perfected, and it would be esteemed a great favour if persons who find worms in their wells, pumps, taps, and water-supply would send me the same for identification and record. HILDERIC FRIEND.

"Cathay," Solihull, August 29.

THE PROTECTION OF OUR "KEY" INDUSTRIES.

IT has long been foreseen that one of the immediate consequences of peace would be to subject this country to a flood of manufactured articles from Germany. It has been known for some time past that German manufacturers were preparing, by every means in their power, to recover and retain their former hold on our home markets. They were steadily accumulating stocks to be "dumped" in Great Britain on the first possible opportunity. It was a policy of despair, but it was the only policy open to them. The salvation of certain of their industries depended on their being able to thwart, by fair means or foul, the expansion of such of these industries as the exigencies of war had called into existence in this country. Our national welfare, indeed, was bound up in these industries. The country was quick to recognise their importance, and the Government responded to public pressure by the steps it took to foster their initiation and development. Some of these steps were of paramount necessity as war measures, but they had a still wider significance. With the outbreak of war the Empire realised, as never before, that it had in large measure failed to perceive the full importance of the bearing of science upon industry. Owing to a variety of causes on which it is no longer necessary to dwell, we had allowed our chief enemy to take over and gradually to obtain almost exclusive possession of certain "key" industries depending upon the applications of physical science, such as the manufacture of synthetic dyestuffs and drugs, analytical reagents and other chemical products, optical glass and instruments, electrical apparatus and magnetos, etc. We had become wholly dependent upon Germany for a large number of articles comprised under these categories which are absolutely essential to the prosecution of war under modern conditions. It speaks volumes for the innate genius of our race that our men of science and our manufacturers, when thus confronted with a national emergency, should have responded as they did to the country's call. We have not only triumphed over difficulties which at one time seemed well-nigh insuperable, but, as is well known, we have also in many cases bettered the example of our enemies, and certain of our manufactured articles have reached a pitch of excellence which Germany never attained.

This pre-eminence—the fruit of so much anxiety and toil—ought surely to remain with us. Our legislators would be false to their trust if they allowed political expediency and party faction to rob the country of the position it has now gained through the circumstances and fortune of a war which was thrust upon it. The common sense of the nation demands that those industries which we have been compelled by the necessities of this war to establish by a great expenditure of effort and capital, and which are everywhere recognised as no less important in times of peace, should be preserved and fostered. "Never again" has become a watchword. But, even apart from any question of security, the country would be blind to its opportunity if it allowed these "key" industries to fall back into their pre-war condition. The few years of their existence are, however, too short to have brought them into a position of stability. There is an enormous amount of leeway to make up. One cannot expect in four years to reach the position which it has taken forty years of organisation, skill, and enterprise on the part of Germany to secure.

The country, therefore, will welcome the steps which the Board of Trade has taken, in conformity with the Prime Minister's recent statement in Parliament, to protect goods manufactured in Great Britain and Ireland against "dumping," and to check any flood of imports (for instance, from Germany) that might arise from a collapse of exchange so disproportionate to costs of production in the country of origin as to enable sales to take place in this country at prices altogether below costs of production here. It is, of course, too much to expect that this action will pass unchallenged. There is a school of politicians in this country who, like the Bourbons, learn nothing and forget nothing. They are a decreasing faction, it is true, and recent events have tended to submerge the survivors. In a few years they will be as extinct as the dodo. It is a significant fact that the fiscal tenets of the Manchester School are never cherished by a real democracy.

Pending the legislation which is to be introduced into Parliament when it reassembles in the autumn, the Board of Trade under the powers conferred upon it will, as from September 1, 1919, prohibit the importation into the United Kingdom of synthetic dyestuffs, drugs, and "intermediates" needed in their manufacture; also synthetic flavourings and perfumes, synthetic photographic chemicals, and a considerable number of inorganic products and medicaments of which the manufacture had to be started in this country in consequence of the war, and which German manufacturers had intended to "dump" into this country as soon as trade relations were re-established.

In addition to the chemical products enumerated in the schedule of the proclamation, the Board of Trade is taking steps to protect the new industries dealing with optical glass, scientific glassware, laboratory porcelain, and a number of products of which the Germans by various means, some of them of a very dubious character, had secured a monopoly. This action will, no doubt, occasion great perturbation in the Teutonic mind. It may even amount to dismay. The enemy had probably calculated, and as usual miscalculated, on prejudices which occasionally seem to obscure the recognition of our true interests as a trading community. "'Tis sport to have the engineer hoist with his own petar."

THE ORGANISATION OF RESEARCH.

PART of the scheme devised by the Department of Scientific and Industrial Research for the administration of the funds placed at its disposal by Parliament was the formation of associations among groups of manufacturers, and a conference was held on July 29 of representatives of the associations already formed for the purpose of discussing some of the many problems which have presented themselves in connection with their work.

In the absence of Mr. H. A. L. Fisher, President of the Board of Education, the chair was taken by Sir William McCormick, chairman of the Advisory Council. Sir Frank Heath, secretary of the Department of Scientific and Industrial Research, was also present, besides some sixty to seventy representatives. A great diversity of subjects was thus represented, though some, especially the great chemical industries, were conspicuously unrepresented.

The meeting was informed that nine research associations were in operation, eight more have been approved and are only waiting the licence of the Board of Trade, while twelve others are under discussion. So much having been accomplished in the three years which have elapsed since the idea originated, it may be assumed that a general approval has been given to the scheme by the industrial world, but the initial difficulties are far from being overcome as yet.

Among the subjects discussed at the conference the first was the formation of a records bureau, and the second the difficult and important one of the conditions of employment of research workers engaged by the associations. Other questions related to co-operation among the associations, and the amount and method of assessment of the subscriptions to be paid by the associated firms in addition to the subsidy from departmental funds.

The formation of a bureau of information and for the recording of results secured by research is a matter of the utmost importance. In the first place it is proposed that its task should consist in storing up the results of work done by the associations, but even this will be found very expensive and not free from difficulties, owing to the views prevalent in some quarters as to secrecy. The associations require access to information of every kind, and apparently the representatives assembled have something to learn with regard to the existing sources of much of the information they require, for throughout the discussion no reference was made to the magnificent journals, containing both original papers and abstracts, issued by some of the British and American engineering and chemical societies. It seems to be recognised that a large number of reference libraries will have to be established, especially in the neighbourhood of great centres of industry; but it ought also to be understood that every association will require a library stored with works of reference, and especially journals cognisant of the subjects it represents; indeed, every works which has a laboratory for research must be similarly provided. All this represents a large outlay of money, the amount of which can scarcely be calculated as yet.

The other serious point under discussion concerned the interests of the separate associations, and perhaps more particularly those of the individual research workers. And here it would be well to consider the difference between discovery and invention. The former is usually the result of protracted inquiry by highly skilled and highly educated workers, while invention may, and does often, result from the recognition of a need or opportunity for improvement in a machine or process by a mere workman, ignorant of science in a general sense, but whom long experience in some one industry has led to realise the technical difficulties peculiar to the work in which he has been engaged. The question before the conference was how to estimate the value of the services rendered by a successful employee and the right way to reward them. This is a very difficult problem. Any system of bonuses would be for various reasons undesirable and perhaps unfair. There was agreement that the scale of remuneration must be liberal, in order, for one thing, that the man so employed may be free from anxieties as to his own future. But it is becoming clear to everyone that if industry is to enjoy the advantage of engaging the best brains of the nation this kind of calling must be made attractive to the rising young men and women. At present, as pointed out by the chairman, the new research associations are finding that there are not sufficient scientific workers to go round.

THE BOURNEMOUTH MEETING OF THE BRITISH ASSOCIATION.

The success of the meeting of the British Association, which opens in Bournemouth on September 9, should be a foregone conclusion if one may judge by its appeal to the imagination. It may be said that a scientific history of the war will be presented. Commencing with the inaugural address of the president (the Hon. Sir Charles A. Parsons, K.C.B.), which will deal with "Engineering and the War," throughout the week the invaluable war-work of men of science, which played so magnificent a part in our victory, will be the subject of a great variety of lectures and debates. Secrets which have hitherto been jealously preserved will be made public, and it should be possible after the meeting to estimate as never before the enormous importance of science in modern military operations.

Apart from questions of war, a large proportion of the papers and discussions will be closely in touch with the problems and activities of the Empire to-day. Education, citizenship, and economic and industrial difficulties will all be prominent features of the programme.

There is every reason, therefore, to believe that the meeting will be of unique interest and importance. Whether it will be an equal success in point of numbers in attendance is less certain. The amount of interest shown locally in the proceedings cannot at the time of writing be said to have come up to expectations. This comparative lack of enthusiasm is not, however, surprising in a town of so many and diverse distractions. The number of applications for associateship and membership is at present much smaller than anticipated, but in the opinion of those competent to judge the eleventh hour will bring a marked improvement in this direction.

One of the greatest problems which the local executive committee has had to face has been that of finding accommodation for visitors. A popular seaside resort in September inevitably presents extraordinary difficulties in this respect. Great efforts have been made to deal with the situation, and considerable public spirit has been displayed by hotel-keepers and others in helping the committee in its task.

The local preparations for the meeting are well in hand. The work of adapting the Municipal College to the needs of the Association is practically complete, and better accommodation has probably never been provided.

THE PROTECTION OF WILD BIRDS.

The Report of the Departmental Committee on the Protection of Wild Birds, which has just been issued, after a considerable delay due to war conditions, marks an important step towards the proper and efficient control of British bird-life, which has been subject to the varying and complicated regulations of a long series of legislative enactments. The report foreshadows unified and simplified lines of regulation which, if adopted in law, ought to make the protection of wild birds not only more practicable, but also more effective. Of the fresh suggestions made by the expert Departmental Committee, to which the thanks of all naturalists are due, the most far-reaching is that regarding the formation of a permanent Ornithological Advisory Committee, which would sit in London and not only advise the Central Authority on all ornithological questions, but also collect information and control investigations bearing upon the activities and status of wild birds. It is astounding to learn, though it is undoubtedly on a par with the official attitude towards science, that the Wild Birds Protection Acts have been administered without any expert ornithological assistance, except in the case of Scotland. Even there the matter of advice seems to have been, so to speak, behind the scenes, for there is no evidence of public acknowledgment of this highly technical information and advice.

Of many suggested improvements upon the old laws, mention can only be made of a few. All birds are recommended for protection during the breeding season, from May 1 to September 1, subject to the right of the owner or occupier, but even this exception is abolished in the case of scheduled birds, which, in Schedule A, including more than fifty species, are absolutely protected during the breeding season, and in Schedule B, including about twenty-seven species, are absolutely protected throughout the year. The unifying of the schedules for the protection of both birds and eggs is a vast improvement upon the present independence of the two groups, which has led only to confusion; while the protection of all birds and eggs on Sundays and the licensing of bird-catchers and bird-dealers are new and valuable suggestions. It must be the hope of the British naturalist that as soon as possible these recommendations will be adopted and become the law of the land.

NOTES.

WE are informed that the council of the Royal Society has nominated representative committees to deal with national questions connected with the international unions which it is intended to form under the International Research Council. The committee for astronomy will consist of the Astronomers Royal for England, Scotland, and Ireland, the Superintendent of the Nautical Almanac, six members nominated by the Royal Society, six members nominated by the Royal Astronomical Society, two members nominated by the Royal Society of Edinburgh, two members appointed by the Royal Irish Academy, and two members appointed by the British Astronomical Association. The committee for geodesy and geophysics will consist of the Astronomers Royal, the Director of the Meteorological Office, the Director-General of the Ordnance Survey, the Hydrographer of the Navy, two representatives of the Royal Society of Edinburgh, two representatives of the Royal Irish Academy, two members nominated by the British Association, and two members nominated by the Royal Society. Since their formation these committees have advised the council of the Royal Society on the formation of the international unions in their respective subjects, and nominated the delegates to the recent meeting at Brussels. The Federated Council for Pure and Applied Chemistry was also recognised as the national committee on that subject. As regards other subjects, similar committees will no doubt be established, but, no definite proposals having been submitted by any country, no action has hitherto been taken, and the powers of the delegates attending the meeting at the invitation of the council of the Royal Society were limited to the obtaining of information with regard to the views of other countries concerning the establishment of international unions. The recommendations made only express the personal views of delegates attending the conference, and will, no doubt, be submitted to the proper authorities before any action is taken.

AT the death of Prof. Milne in 1913 the British Association Seismological Committee decided to maintain the work at Shide, both the actual observations with seismographs and the collation of results from the Milne stations scattered over the globe. The seismographs were mounted in a disused stable; the clerical and computational work was carried on in an annexe built to the dwelling-house by the liberality of the late Mr. M. H. Gray. Mr. J. H. Burgess and Mr. S. W. Pring, two residents in the neighbourhood who had worked with Prof. Milne, were able to devote part of their time to the work under the general superintendence of the committee. The war steadily rendered this arrangement more and more difficult; Mr Burgess and Mr. Pring both ultimately left Shide, and early in the present year Mrs. Milne, from whom the observatory had been rented by the committee, announced her desire to sell the house, including the observatory, and to return to her home in Japan. In anticipation of the difficulties becoming acute, preparations had been made for transferring the work to Oxford. A seismograph was mounted last October in the basement of the Clarendon Laboratory, where Prof. C. V. Boys made his well-known gravity determination. Permission to make trial of this site was kindly granted by Mr. James Walker, then in charge, and has since been confirmed by Prof. F. A. Lindemann. The results have been eminently satisfactory, and there is ample room for the other component. The arrangements for housing the Milne seismological library (definitely left in his will to the British Association Committee) and the computational work are not yet finally settled, but no serious difficulty is anticipated in finding a solution. The arrangements are necessarily of a provisional type at this moment, and liable to be modified by future events, such as the possible establishment of a geophysical institute at Cambridge, and the action ultimately taken by the Seismological Section of the International Union of Geodesy and Geophysics recently established at Brussels. The Union itself was fully constituted, but the Seismological Section was suspended until some legal formalities connected with the extinction of the former International Seismological Association have been completed.

WE regret to announce the death on September 2, at seventy-five years of age, of Prof. Alexander Macalister, F.R.S., professor of anatomy in the University of Cambridge.

DR. C. A. MERCIER, physician for mental diseases to Charing Cross Hospital, and a distinguished authority upon mental diseases and related subjects, died on September 2 at sixty-seven years of age.

THE Lord President of the Council has appointed Prof. J. E. Petavel, F.R.S., to be director of the National Physical Laboratory in succession to Sir Richard Glazebrook, C.B., F.R.S., who retires on reaching the age-limit on September 18 next. Prof. Petavel is professor of engineering and director of the Whitworth Laboratory in the University of Manchester. He is a member of the Advisory Committee for Aeronautics of the Air Ministry.

THE committee of the Wireless Society of London met on July 24, under the presidency of Mr. Alan A. Campbell-Swinton, with a view to an early resumption of activities. The hon. secretary, Mr. R. H. Klein, having resigned, and been elected an acting vice-president, Mr. Leslie McMichael, of 30 West End Lane, West Hampstead, N.W.6, has been elected hon. secretary, and to him all communications should be addressed. The society is open to all those interested in the study and furtherance of wireless telegraphy, amateur or professional.

THE Edward Longstreth medal of the Franklin Institute, Philadelphia, has been awarded to Mr. J. J. Skinner, of the Bureau of Plant Industry of the U.S. Department of Agriculture, for his papers on "Soil Aldehydes," concerning which the committee reported: "These papers present the results of scientific study of a new class of deleterious soil constituents, clearly described and effectively illustrated, the whole forming a valuable contribution to the science of agricultural chemistry, and one of marked practical importance."

FROM the Proceedings of the Institute of Chemistry we note that the preparation of an account of the services of British chemists during the war is under consideration. A synopsis of the possible contents of a book on the subject has been drawn up, and preliminary arrangements have been entered into with publishers. Such a work may be made both interesting and valuable, and it is to be hoped that the project will be worthily carried out. All chemists who are in a position to assist in the matter are invited to communicate with the registrar of the institute.

Two important geological collections of more than local interest have recently been acquired by the Hull Municipal Museum, viz. the Drake and Bower collections. The first was formed by the late H. C. Drake, F.G.S., who spent many years in the Scarborough district, and also collected largely among the saurian and other vertebrate remains of the Oxford Clay in the Peterborough area. The other collection was formed by the Rev. C. R. Bower. Many of the specimens are described and some figured in his paper on "The Zones of the Lower Chalk of Lincolnshire" in the Proceedings of the Geological Association for 1918. This collection consists of more than a thousand excellently cleaned Chalk fossils, carefully labelled and localised, including many of those which have been figured in his paper, as well as one of the two known examples of *Actinocamax boweri*, the other specimen being in the British Museum. The collections are largely from the Lower Chalk of Lincolnshire and the Chalk of Yorkshire, and there is an interesting series from the Upper Cretaceous of Dover, Folkestone, Kent, and Norfolk.

THERE is no denying the value of intelligent propaganda for increasing business and cultural relations between various nations. As an example of the right kind of propaganda we would mention the Bulletin of the Pan-American Union, published in English, Spanish, Portuguese, and French. This magazine contains authoritative articles on North and South American activities, most of them being splendidly illustrated.

THE *Bulletin officiel de la Foire de Lyon*, of which two recent issues are to hand, is the outcome of the first Lyons Fair, and its object is to keep manufacturers and others in touch with the development of these fairs in France and other countries. In this connection it is interesting to note that the next Lyons Fair will be held on October 1–15 next. The previous fair was a great success, but it is hoped that British manufacturers will be more adequately represented at the forthcoming fair. American competition in France, especially in matters engineering, is very keen, and it is up to British enterprise to see that no trouble is spared in order that French traders, engineers, consumers of scientific products, etc., may know exactly what Britain is able to offer them.

IN the current issue of the *Quarterly Review* Sir Lynden Macassey discusses very ably "The Economic Future of Women in Industry." The author is specially well qualified for his task, as he was a member of the War Cabinet Committee which made extensive inquiries into the subject, and during the war he acted as arbitrator in innumerable labour disputes. He rightly states that the public in general but little appreciates the enormous latent and unutilised capacities for production possessed by the women of the nation. He points out that between 1914 and 1918 more than 700,000 women directly replaced men in industry, and did work customarily done by men. On repetition work, which was such a pronounced feature of war-time employment, women often proved superior to men, as they do not suffer from the monotony to which men are so susceptible. On the other hand, they are not man's equal in skilled work, and because of their greatly inferior physical strength they cannot replace him in the heavier types of industry. As regards the future, there ought to be no trade union rules which debar women from any employment which is commensurate with their industrial qualifications, but women must not be allowed to undercut and displace men. They must come in as additional workers to accelerate the increased productivity which is such a crying need of the present day. Sir Lynden Macassey approves the conclusion of the Committee that women on piece-rates must, as compared with men, receive "equal pay for equal work," but both he and they have missed the fallacy involved in such a contention. If the average woman has as large an output as the average man she is entitled to equal pay, but not otherwise. In most industries the cost of establishment and machinery is far higher than the cost of wages, and if, for instance, the woman produces only four-fifths as much as the man, it would not be reasonable for her employer to pay her four-fifths his wages. Probably he could not afford to give her even three-fifths as much.

AMONG the pamphlets on reconstruction problems recently published by H.M. Stationery Office is one relating to Industrial Research (No. 36, price 2*d*.), which ought to be read by the public, whether directly concerned with industry or not. It contains in fewer than thirty pages a very instructive sketch of the position in the past, and of what has already been accomplished in the way of instituting and organising new fields of research and indicating what may be hoped for in the future. At the present time there can be few people who are not convinced of the necessity for research in its relation to industry, but it was not always so. Looking back only forty years or thereabouts, it may be asserted that at that time practically no provision was made by manufacturers for improvements in their several industries. Among the earliest of the manufacturers of iron and steel to carry on research were Sir Isaac Lowthian Bell and Sir Bernard Samuelson, but in other directions there was practically nothing to be seen in the way of research except—to their credit be it said—among the great brewers, who set a fine example to the rest of the world in the way they proceeded to apply the results of Pasteur's discoveries. In connection with agriculture the work of Sir John Lawes at Rothamsted, aided through many years by Sir Henry Gilbert, represented an advance of incalculable importance. Besides showing what can be done, their work seems to illustrate the fact that research, and hence discovery, have in the past depended chiefly on the enthusiasm of the individual man of science. It remains to be seen how far this will continue to be the case. This certainly seems probable in connection with pure science, but we have yet to learn the extent to which organisation will facilitate the discovery of new facts and principles, though there can be no doubt as to the more abundant results which must accrue from the application of such facts and principles to practical purposes. It is now clear that as there must be more scientific work done, there must be a larger number of properly trained scientific workers; and one of the first duties of the State will be to see that the universities and places of higher instruction are provided with the means of giving the instruction needed, and that conditions are so improved as to give the encouragement wanted to induce the most capable among the rising generation to pursue science as a career. It is rightly pointed out in the pamphlet that working-class opinion especially should be made aware of the vital importance of research.

THE *Mexican Review* of July describes, with photographs, a remarkable series of stone and terracotta remains discovered in the neighbourhood of the city of Mexico by Prof. W. Niven. The writer supposes that these remains, rude in design and workmanship in comparison with those from the upper strata, represent Chinese, Egyptian, and negro faces, buried under deposits of lava from volcanoes in prehistoric times. Besides these were found beads of jade, "presumably from China," and seals, "in imitation, or perhaps precedence, of like objects found in the Babylonian and other ruins of the Far East." It is to be hoped that these articles will soon be examined by experts. If these statements can be verified, they will furnish valuable evidence in support of the conclusions of Prof. Elliot Smith and other advocates of the theory of culture transmission.

We have received No. 14 of the Journal of the East Africa and Uganda Natural History Society, written by residents in the African tropics, but printed in this country and published by Messrs. Longmans and Co. The issue contains descriptive articles on such subjects as the transmission of human and animal diseases by blood-sucking insects, and a number of short original notes on the habits of various African animals, such as baboons, crocodiles, and the aardvark.

The report on Scottish ornithology for 1918 by the Misses Rintoul and Baxter, which appears in the July–August issue of the *Scottish Naturalist*, is an excellent and comprehensive compilation, and affords much information on a variety of subjects associated with bird-life. Though the necessary field-work during the year was carried out under greater disadvantages than ever before, yet the contributions of the numerous recorders relate to observations on no fewer than 184 species. No new birds were added to the avifauna, and the list of uncommon alien visitors is a short one, but a number of species are mentioned as appearing in counties in which they were previously unknown. The influence of weather on bird-life during the year, the results of "ringing," and notes on plumage, food, habits, etc., are also given. The final section of the report deals with the migratory movements of both native species and birds of passage. The observations, which are concisely treated, have been made throughout the mainland and at coastal and insular stations from the Muckle Flugga—the northernmost outpost of the British Isles—to the Tweed and the Solway. The data relate to the comings and goings of no fewer than 160 species.

The *Times* of August 18 contained an interesting article on the little owl as a danger to poultry and game. This bird was not originally a native of the British Isles, but was introduced into several parts of England in some numbers about a quarter of a century ago by several well-known ornithologists, who cannot have been aware of its harmful proclivities. Apart, however, from its vices, it is an attractive little bird. Since its introduction it has increased very rapidly, and is now widely distributed over England, and some have found their way into Wales, Scotland, and Ireland. Wherever it has established itself it has become a pest to poultry-keepers and game-preservers owing to the havoc it makes among the chicks. It also destroys great numbers of small birds up to the size of a blackbird. Although the little owl's record is, in the main, a black one, and far outweighs anything that can be placed to its credit, yet it must be admitted that it destroys large numbers of small rodents, such as field-voles, as well as beetles and other insects, and thus renders some service to the agriculturist. The article is evidently based upon a wide knowledge of the bird, and affords much information on other aspects of its life-history.

In the Bulletin of the Imperial Institute (vol. xvii., 1919, pp. 40–95) there is an excellent detailed account of the production and consumption of cocoa, chiefly in the different countries of the Empire, and showing very clearly the disparities between them in various parts of the world. The United States, using 66,500 tons in 1913, is the greatest consumer, whilst its production is negligible. The United Kingdom in 1913 consumed about 28,000 tons, a great deal of which was imported from foreign countries, while the Empire produced about 88,000 tons, the bulk of which had to go abroad for consumption. In 1917, owing chiefly to the enormous increase of cultivation on the Gold Coast and elsewhere in West Africa, the production increased to 142,800 tons. No attempt is made to describe the methods of preparation in use in the different Colonies, and one is left to infer, when noting the comparative values of cocoa given in various places, that in general they leave a good deal to be desired. The cocoa situation at present evidently turns upon the crop of West Africa, and if that country continues to turn out such enormous quantities of an inferior article, trouble is certain to ensue. The great desideratum at the moment is to increase the consumption of this most valuable food and palatable drink, and it is difficult to do so if the quality be but poor. Cocoa, it is well known, can be produced with less trouble than many other tropical crops, especially if some of the poorer Forastero varieties be employed, but to prepare it of really good quality—as, for instance, it is prepared by the English planters of Ceylon—involves much trouble and the use of better varieties. Nothing less than this, however, will save the market from being glutted with inferior brands of cocoa.

Under the title "Gossypium in Pre-Linnæan Literature" (Botanical Memoirs No. 2, Oxford University Press), H. J. Denham traces the literature of cotton-yielding plants from the earliest writers to the time of Linnæus. The earliest reference to the use of cotton for textiles is by Herodotus, who mentions trees in India "the fruit whereof is a wool" of which the natives make clothes. The first reference in botanical literature is by Theophrastus (370–285 B.C.), who speaks of a wool-bearing tree on the Island of Tylos (in the Persian Gulf). Pliny (A.D. 23–79) repeats the information, but quotes the name "Gossypinum" for the trees. Between the classical writers and the herbalists who followed the Renaissance no botanical mention of cotton occurs. By this time the plant was well known around the Mediterranean. The first figure of Gossypium in European literature would seem to be in the "Herbal" of Dorstenius (1540) under the name of Bombax—apparently a conventional drawing of the Asiatic species, *Gossypium herbaceum*. A better figure of this plant was given by Fuchs ("Historia Stirpium," 1542), with a detailed account; but that of Matthioli ("Kreutterbuch," 1563) is more satisfactory. Cæsalpino (1583) was the first botanist to indicate the relationship of the plant to the mallows. In 1592 Prosper Alpinus, in his account of the flora of Egypt, describes and figures another species, *G. arboreum*, a small perennial shrub, a native of northern Africa. Columbus and the early explorers had found cotton in cultivation in the New World, and in 1651 Hernandez figured a Mexican species, *G. mexicanum*, the possible parent of the upland cottons. The botanical history of cotton in the later pre-Linnæan writers is mainly a record of the attempt to simplify the confusion created by the description of different species under the same headings, as, for instance, by Plukenet ("Phytographia," 1691), though fortunately in this case the specimens from which the plates were drawn are preserved in the Sloane Herbarium in the British Museum. Linnæus (1753) defined four species, the two Old World forms and two American, one of the latter being *G. barbadense*, presumably the parent of the "Sea Island" cotton.

METEOROLOGICAL Office Circulars Nos. 37 and 38, issued July 1 and August 1 respectively, deal with current official notices. Reference is made in the July circular to Professional Notes No. 7—"The Climate of North-West Russia," which was prepared for the use of the British forces acting on the Murman coast. The general climate is discussed for the district extending from the Arctic Ocean on the north to Petrograd and the Gulf of Finland on the south, and from the Swedish frontier on the west to 45° east on the east. It deals with the dates of the thawing and freezing of the rivers. The temperature of the upper air is discussed, and other meteorological information is given. Upper-air temperatures in the north-east of France are given for the end ot April last as being of interest in connection with the heavy snowfall over England on April 27. The upper air was abnormally cold. The August circular has an obituary notice of Lord Rayleigh.

THE very effective hardening solution for gelatine negatives that Messrs. Ilford, Ltd., recently introduced is applied as a preliminary bath, before development, and enables development, etc., to be carried on at as high a temperature as 110° F. without any cooling being necessary. In the specification of the patent granted to Messrs. Agnew and Renwick, both of Messrs. Ilford, Ltd. (see *British Journal of Photography*, August 8), it is stated that the formaldehyde, which is the real hardening agent, is mixed with a salt of the class which tends to restrict the swelling of dry gelatine in water and raise its melting-point, so that even though the bath may be at as high a temperature as 110° F., the gelatine has no opportunity of melting before it is hardened by the formaline. This class of salts includes acetates, tartrates, citrates, oxalates, sulphates, phosphates, chromates, bicarbonates, and horates. Example formulæ are given, using sodium sulphate and ordinary sodium phosphate.

A PAMPHLET issued by the Optical Pyrometer Syndicate, of Audrey House, Ely Place, E.C.1, contains some notes on optical pyrometers in general, and a special account of the "wedge" pyrometer and its uses. The early form of this instrument was described in NATURE for July 22, 1915, the principle relied upon being the complete extinction of the source of light by means of a wedge of dark glass interposed between the eye and the source, the temperature being deduced from the thickness of dark glass needed to secure extinction. It is claimed that not only can concordant results be obtained by a single observer trained to the use of the instrument, but also that separate observers may obtain readings agreeing to within 20° C. at 1500° C. One of the disadvantages of all optical pyrometers is that the personal judgment of the operator must be relied upon, either in matching tints or in producing total extinction, and for these purposes all eyes are not equally sensitive. In view of the great increase in the use of optical pyrometers, an impartial investigation of the various types from this point of view would be an advantage, due regard being paid to the type of observer employed in workshops. If the agreement in readings claimed for the "wedge" pyrometer should prove to be general for all types of observer, this instrument ought to be very useful, and its simple construction a recommendation for industrial purposes.

ACCORDING to an editorial note in the *Scientific American* for July 19, the romance of invention is to be illustrated in a series of articles on Americans who have produced inventions of the first rank which have proved financially successful. The whole record shows that the ability to invent and the ability to make a commercial success of an invention are seldom combined in one man, and the editor almost regards them as mutually exclusive. The first article of the series deals with the telephone. Dr. Graham Bell, who is now seventy-two, invented the telephone in 1876. He himself says he is not a business man and that his interest in the commercial side of an invention is small. He was, however, in the early days of the telephone so fortunate as to be associated with able business men who not only made it a commercial success, but also safeguarded the inventor's interests in such a way that its success was of benefit to him. It is not desirable that so large a proportion of those who invent or discover something of the greatest value to humanity should see the reward pass to others while they themselves get little or no recognition from their country or the world at large.

THE Journal of the British Science Guild for July contains a summary of the proceedings of various committees, including those dealing with education and with the metric system, and an account of the thirteenth annual meeting held on June 17. The education committee emphasises the unfavourable position of this country, as regards both the financial position of institutions for higher education and the number of students of university grade, in comparison with other countries. A detailed report on "Industrial Research and the Supply of Trained Scientific Workers" has been sent to the Prime Minister, to the President of the Board of Education, and to universities and similar educational bodies. Special attention has also been devoted by the guild to the organisation of research in relation to fisheries, and importance is attached to the establishment of an institute and museum of oceanography, similar to those in existence in Berlin and in contemplation in Denmark. The attention of the Government has also been directed to the importance of establishing a strong optical industry in this country. A measure recommended is the introduction of certificates of origin of optical goods as a safeguard against fraudulent competition. The report of the thirteenth annual meeting includes the addresses delivered on that occasion by Major-Gen. Seely, Lord Sydenham, and Sir J. J. Thomson. The journal also contains an appreciation of the late Sir Boverton Redwood by Prof. F. Clowes.

Mr. Edward Arnold announces a new series entitled The Modern Educator's Library. The general editor is Prof. A. A. Cock, and the aim is to present the considered views of teachers of wide experience and ability upon the changes in method involved in the development in educational theory and practice, and upon the problems as yet unsolved. The first volume of the series (by Prof. T. Percy Nunn) will form an introduction to it, and will deal with the fundamental questions which lie at the root of educational inquiry. It will be entitled "Education: Its Data and First Principles." Succeeding volumes will be "Moral and Religious Education," Dr. Sophie Bryant; "The Teaching of Modern Foreign Languages in School and University," Prof. H. G. Atkins and H. L. Hutton; and "The Child under Eight," E. R. Murray and H. Brown Smith. Other books announced by the same publisher are:—"A Physician in France," Sir Wilmot Herringham; "The Struggle in the Air, 1914–18," Major C. C. Turner; "Memories of the Months," Sir Herbert Maxwell, Bart., sixth series; "Gardens: Their Form and Design," Viscountess Wolseley; and "Modern Roads," H. P. Boulnois. *Messrs. Thomas Murby and Co.* announce:—"An Introduction to Palæontology," Dr. A. Morley Davies; "Petrographic Methods and Calculations," Dr. A. Holmes; and "A Nomenclature of Petrology," Dr. A. Holmes. *Messrs. Scott, Greenwood, and Son* have ready for publication the second English edition of "Chemical Reagents: Their Uses, Methods of Testing for Purity, and Commercial Varieties," Dr. C. Krauch; a new edition, by A. B. Searle, of the translation of E. Bourry's "A Treatise on Ceramic Industries"; and a new edition of "Modern Brickmaking," A. B. Searle.

ALL communications for the Imperial Mineral Resources Bureau should in future be sent to 2 Queen Anne's Gate Buildings, Westminster, S.W.1, to which address the Bureau has recently removed.

OUR ASTRONOMICAL COLUMN.

METCALF'S COMET.—The following orbit of the comet discovered by Mr. Metcalf on August 21 is by Miss Vinter Hansen and Mr. Fischer-Petersen from observations on August 21, 22, 25:—

$$T = 1919 \text{ Oct. } 16{\cdot}1984 \text{ G.M.T.}$$

$$\left.\begin{array}{l}\omega = 128^\circ\ 33{\cdot}32' \\ \Omega = 311^\circ\ 22{\cdot}93' \\ i = 19^\circ\ 58{\cdot}03'\end{array}\right\} 1919{\cdot}0$$

$$\log q = 9{\cdot}68280$$

Error of middle place (observed *minus* computed), $+0{\cdot}39' + 0{\cdot}09'$.

Ephemeris for Greenwich Midnight.

13 ...	12 47 47	58 37·0	9·9515	9·4016

The magnitude remains nearly constant at 6½, so that it is on the verge of naked-eye visibility.

Prof. Leuschner telegraphs that he identifies the comet with comet 1847 V (Brorsen), which was expected about this time. If this is confirmed, it will be the fourth member of the Neptune group to be observed at a second return, the others being Olbers's, Pons-Brooks's, and Westphal's. Halley's comet is not reckoned.

THE RECENT SHOWER OF PERSEIDS.—The return of these meteors was fairly well observed this year, though the full moon occurring on August 11 greatly moderated the visible aspect of the display. The weather was very favourable, and a considerable number of meteors were recorded by Mrs. F. Wilson at Totteridge, Mr. S. B. Maltey at Ilfracombe, Mr. A. King at Scunthorpe, in Lincolnshire, and Mr. Denning at Bristol. The radiant point appeared rather more diffuse or scattered than usual, but it exhibited the usual E.N.E. movement amongst the stars when observed on successive nights. A companion shower between α and β Persei was strikingly evident this year, and it furnished some fine meteors radiating from the point $48^\circ+44^\circ$. Other contemporary showers were remarked from $336^\circ-10^\circ$, $310^\circ+80^\circ$, $313^\circ+48^\circ$, $303^\circ-9^\circ$, and $303^\circ+24^\circ$; and between August 22–29 many small, slowish meteors were traced from positions at $332^\circ+57^\circ$ and $348^\circ+61^\circ$. The most brilliant Perseid seen flashed out on August 12 at 10h. 32m. G.M.T., and it was recorded at Totteridge, Bristol, and several other places. Its height was from 76 to 51 miles, and it passed from a point above 10 miles W.N.W. from Worcester to 10 miles E. of Tredegar in South Wales.

INTERNATIONAL STANDARDISATION.[1]

M. GUILLAUME, the distinguished director of the Bureau International, is to be congratulated on the issue of this important volume.

And yet it is a sad record; the greater part is occupied with the *procès-verbaux* of the fifth International Conference of Weights and Measures held at Paris in 1913, and attended by representatives of all the principal countries of the world, many of whom will never meet again. Much of the rest is the last work of Pierre Chappuis, whose death is recorded in a note to one of the papers by M. Guillaume, and to whose labours are due the determinations of so many important constants.

The *procès-verbaux* of the conference demand our first attention, for the meeting was, in many respects, important, and new ground was broken in various directions. The decisions reached by the delegates remain unfulfilled, and it will no doubt be the business of the sixth conference—which it is generally understood is to meet shortly—to consider the steps that should now be taken to give effect to them or to modify them as may seem best; for on some of the matters discussed considerable difference of opinion may well arise.

The fundamental business of the conference concerns weights and measures, the determination of standards of mass and length, the kilogram and the metre. The accurate calibration of these at once involves the measurement of temperature, and accordingly much of the work of the Bureau has dealt with scales of temperature; the scale of the constant-volume hydrogen thermometer was chosen as standard, and all temperatures referred to it. For the range 0° to 100°, or, indeed, for one rather outside these limits, this sufficed, but accurate determinations of temperature are now required down to the temperature of liquid air and up to perhaps 2500° C. The hydrogen thermometer is useless for such a range, and some steps were necessary to secure international agreement throughout the scale. There was no doubt that the absolute thermodynamic scale was the standard to aim at; on the other hand, there was no certainty as to the methods to be taken to realise that scale over the greater portion of the range. And so the conference, after emphasising the importance of researches which had for their object the perfecting of our knowledge of thermometric scales, expressed itself as (1) ready to substitute for the international service of weights and measures the Absolute scale in place of the "normal"—*i.e.* hydrogen—scale so soon as the relationship between these scales had, thanks to the researches contemplated, been determined with sufficient certainty, and (2) approving the determination of a certain number of standard temperatures as fixed points of the scale, to be suitably chosen and agreed upon as soon as possible.

With the view of giving effect to this last resolution, the conference invited the International Committee on Weights and Measures to arrange with the directors of the national laboratories which had been dealing with the measurement of temperature to meet at the Bureau to select the standard temperatures and to take steps to secure their general adoption. In

1 "Travaux et Mémoires du Bureau International des Poids et Mesures." Tome xvi. (Paris: Gauthier-Villars et Cie, 1917.)

view of this invitation there was to have been a preliminary meeting of the directors of some of the laboratories concerned in Berlin in September, 1914; much correspondence had passed and all arrangements were complete. Representatives of the Reichsanstalt visited the National Physical Laboratory in June, 1914, to compare standards. *Sed dis aliter visum.* So far as England and America are concerned, uniformity has been secured over the range from −182° C. to about 1100° C. by agreement between the directors of the Bureau of Standards and the National Physical Laboratory, and a common scale is in use at those institutions.

Another important question dealt with by the conference related to the standardisation of end measures of length. M. Pérard presented an interesting report on the results of his investigation as to the methods of comparing end measures and line measures, and particularly as to the accuracy with which a length gauge built up of a number of Johannsen slips, the use of which has become so familiar during the war, represented the sum of the lengths of the individual gauges. He states as the result of his measurements that it is necessary to add an amount of about eight-hundredths of a micron for each contact in the complex gauge, a quantity which is negligible for all practical purposes when using the standards. But the report led to an interesting discussion on another point. The metre is standard at 0° C.; end gauges are used chiefly in engineering work, and the temperature in engineering shops is probably between 15° C. and 20° C. If, then, a gauge is standard at zero, it is necessary when using it at 20° to know its temperature coefficient with some accuracy; two gauges, one of steel, the other of gun-metal (say), both correct at the standard temperature, differ appreciably at the temperature of use. Accordingly it has been proposed to standardise gauges for industrial purposes at a temperature more nearly that of an average shop; the correction which would then be required would in most cases be so small as to be negligible. English practice, of course, secures this; our measures are standard at 62° F. ($16^2/_3$° C.). In America a temperature of 20° C. has been suggested.

The International Committee of Weights and Measures had in 1909 preferred to accept 0° C. as the standard temperature, and the French Technical Section of Artillery had adopted that in the standards employed by it. After discussion the matter was referred to a special committee consisting of Dr. Foerster and MM. Blumbach,[2] Egoroff, Guillaume, and Pérard, and on their recommendation the conference decided to invite the International Committee to pursue its investigations with the view of reaching as complete knowledge as possible of the metrological properties of steels, as well as of the construction, standardisation, and method of use of end standards of length. Sir David Gill pointed out that, while recognising that the adoption of 0° C. as the standard temperature was theoretically desirable, he accepted the resolution as one which reserved a final decision on the question until the completion of the experiments. The question is a vital one if international standardisation is to become a reality. Its importance was illustrated during the war. A number of screw gauges about 2 in. in diameter were ordered on the Continent; the first batch received failed to pass inspection. They had been made correct at the freezing-point, and the expansion between that temperature and the English standard, 62° F., brought them outside the limits for acceptance. A visit to the Continental works was necessary to explain the point and put matters straight, causing delay and loss when time was of great importance.

A third decision of the conference is of special interest to meteorological circles. In correcting a barometer to a standard, sea-level at latitude 45° has been accepted, and a formula due to Clairaut, but modified by Broch, based on the accepted value of g in latitude 45° and its variations with latitude, has been employed. The accepted value for g at sea-level at latitude 45° has been 980·665 cm./sec.^{2}; recent observations, however, lead to 980·615 cm./sec.^{2} as the more correct value,[3] and it became a question whether to modify the normal standard or not. The conference decided against any modification in view of the fact that the figure 980·665 cm./sec.^{2} had received legislative sanction in many countries. They agreed, however, that observations into which the local value of g entered should be reduced, not by the usual formula, but by means of a numerical factor "determined, if possible, directly for the locality in question."

Now the unit of barometric pressure is the millibar —a pressure of 1000 dynes per sq. cm.—and the length of the column of mercury the weight of which gives rise to a pressure of one millibar is known as a baromil. A barometer the scale of which is graduated in baromils reads pressure in millibars. The length of the baromil is dependent on the value of g, and so varies with the locality, but it has been agreed by the International Conference of Meteorologists to take as standard the value of g at sea-level in latitude 45°, and the relation of the baromil to the mm. or the inch has been evaluated on the hypothesis that the standard value of g is 980·617 cm./sec.^{2}, the value assigned to it by Helmert. The decision, then, of the International Conference of Weights and Measures to retain as the standard value of g the old figure 980·665 involves, if it be used, a reduction of about 5 parts in 100,000 in the height of the column of mercury producing under standard conditions a pressure of one millibar. The certificates usually issued with barometers state the temperature at which the scales read pressure in millibars under standard conditions. If reduction is to be made to a nominal standard of gravity of 980·665 cm., these temperatures will all need to be reduced correspondingly. The difficulty, of course, is avoided if we take the true value of g at latitude 45° instead of the standard value as the figure to be used in calculating the length of the baromil, *i.e.* if we assume that this is one of the cases in which a numerical factor directly determined is to be employed, and some such course as this no doubt will be adopted.

A fourth matter of some interest which was discussed was the proposal to adopt in future legislation for metric countries the M.K.S. system of units, in which the unit of length is the metre, that of mass the kilogram, and of time the second. On this system the unit of force is the "Newton," the force required to produce per second in a mass of 1 kilogram a velocity of 1 metre per second. Thus,

$$1 \text{ Newton} = 1000 \times 100 \text{ C.G.S. units} = 10^5 \text{ dynes.}$$

The unit of work will be the work done by a Newton in moving its point of application 1 metre or $10^5 \times 10^2$ ergs, and this is the joule of the C.G.S. system. Accordingly, the unit of power is the watt.

As a result of the discussion the International Committee was invited to continue the study of all questions connected with legislation based on metrical units.

At the last session of the conference M. Battistella, the Italian delegate, raised a far-reaching question. The work of the conference and of the committee

[2] M. Blumbach's many friends will be glad to know that he is well: a message has been received from him asking for help to reconstitute the Weights and Measures Department in Russia.

[3] The value given by Helmert is 980·617 cm./sec.^{2}.

had hitherto, he pointed out, been limited to the fundamental standards of mass and length and questions intimately connected with these. M. Battistella urged that this was insufficient to secure uniformity in all the details of importance to international science. In the name of his Government he directed attention to (1) the necessity for a legal definition, not only of the fundamental units of mass and length, but also of a whole series of connected units—units dealt with in the study of light, heat, engineering, and electrical problems, and others, as well as for the specification of the instruments best suited for the measurement of these quantities; and (2) the importance of the standardisation of the types of instruments to be employed so as to secure uniformity among countries using the metric system. As a result the International Committee was entrusted with the mandate of examining the proposal of the Italian delegate with the view of securing agreement on the questions raised.

Enough has, perhaps, been written to show that the matters under discussion were of no small importance. None of them were settled; it remains for a future conference to examine them afresh and to decide each in the manner which promises best to be of service to the world and to turn to advantage the lessons of the past five years of trial.

And now there is no space to describe the other half of the volume: M. Pérard's elaborate note on the reduction of certain classes of observation or M. Chappuis's two papers on the determination of the boiling-point of sulphur and the coefficient of dilatation of mercury. It must suffice to mention the results. For the boiling-point of sulphur on the thermodynamic scale under normal pressure he finds the value, 444·60°. Holborn and Henning give 444·51°, and Day and Sosman 444·55°. The value at present in use at the National Physical Laboratory is 444·5°.

For the coefficient of dilatation of mercury his value is $0{\cdot}18162884 \times 10^{-3} + 8{\cdot}5962282 \times 10^{-9}\,T$. This value does not differ greatly from that deduced from his own earlier experiments of 1890; the differences between these results and those of Callendar and Moss (Phil. Trans., 1911) are considerably greater. For the range from 60° to 100°, where Chappuis's two results agree very closely, the difference between them and the figures of Callendar and Moss would correspond with a temperature error of 0·25°, an error ten times greater than that which M. Chappuis considers possible.

M. Chappuis died as the proofs of his paper were passing through the press. Those who know his work will wish to join in M. Guillaume's tribute to his memory. He writes:—"These two determinations of the coefficient of dilatation of mercury, separated by a quarter of a century, carried out by methods entirely different and with instruments which had no part in common, and yet in close agreement, will remain for metrologists of the future among the finest examples of the work of an experimenter gifted with consummate skill, with a devotion to his task which stood every test and with an intense desire to reach the truth." R. T. G.

SOME INDIAN SUGAR-CANES AND THEIR ORIGIN.

DR. C. A. BARBER, Government Sugar-Cane Expert, Madras, continuing his studies on Indian sugar-canes, has given an account of the classification of two new groups which he describes as Saretha and Sunnabile (Memoirs of the Department of Agriculture in India, Botanical Series ix., No. 4). In the course of study of the Indian canes a sharp distinction was observed between two classes. There was, on one hand, a large series of thick, juicy canes commonly grown on a crop-scale in the more tropical parts, or in the northern parts usually in small plots under high cultivation near large towns, in which they were used for eating as fruit. A second series of thin, hardy canes, grown under field conditions all over India, especially in the north, were unfitted for chewing, but were crushed and made into "jaggery" or "gur." It is this second series which includes the subject of the memoir. In contrast with the first series these thin canes are considered to be indigenous to India, and were found to include several well-defined classes. A number of apparently isolated forms from all parts of the country were at first difficult of arrangement, but were afterwards found to fall into two groups, characterised by bending or erect leaf-tips and presence or absence of circlets of hairs at the nodes; the canes known as Saretha and Sunnabile have been selected to give names to the new groups. In classifying varieties under these two groups the characters usually employed in systematic work, such as differences in the floral organs and size of organs and plants, have not been found helpful, but dependence has been placed on a series of minute local differences. Thus in all the Saretha group there is a minute incrustation on the rind, as if it had been attacked by a small mite, whereas this is absent in the Sunnabile group. The density of bloom is greater in the Saretha group, but the blackening of this bloom by fungus is sharper and more circumscribed in the Sunnabile group. Thickness of stem and size and vigour of plant seem to be of no value; and the existence of insignificant characters in canes differing considerably in external appearance, and extending through wide stretches of country under varying climatic and cultural conditions, adds to their importance. Some sixty to seventy such characters are dealt with in detail.

Dr. Barber further points out that his classification is not merely an empirical statement of unconnected differences, a sort of analytical key for the separation of varieties, but also presents data for a statement on the lines of evolution among a section of cultivated canes. He claims to have advanced towards solving the origin of cultivated canes from their wild ancestor, and to have established a series of connecting links between cultivated canes and the wild species of Saccharum now growing in India. A wide collection of specimens shows that there are some very distinct varieties of *Saccharum spontaneum* more or less confined to definite geographical regions. A development in the size of the vegetative organs is observed in passing from the dry to the humid tracts in India similar to that met with in the Saretha and Sunnabile series of sugar-canes, and in the detailed list of characters showing differences between the two groups we find a number mentioned in which the Saretha group approaches *S. spontaneum*. Such are the black incrustation on the stem, the circlet of hairs on the nodes, and certain leaf-characters, and these resemblances suggest that the Saretha group is the more primitive. But as a study of the seedlings of *S. spontaneum* raised at Coimbatore shows differences among themselves similar to those obtaining between the two groups, it is considered that the Sunnabile varieties are also traceable to the same wild species.

Dr. Barber describes a method for building up an ideal cane for each variety and group. The results have been reduced to curves, which show the differences sufficiently well, but involve considerable labour, as in some cases they are based on as many as

10,000 individual measurements. He has recently dissected some fifty stools, representing twenty-four varieties, and finds overwhelming evidence that the late canes are the thickest, thus reversing earlier conclusions drawn from the behaviour of the Punjab canes late in the season.

GENERAL PHYSIOLOGY.

INCREASED specialisation brings with it further subdivision of the sciences, and most of the new journals which are founded are restricted to narrower fields than those of existing publications. Now and then, however, an attempt is made to counteract the evils of specialisation by insistence on broad principles and by the provision of a meeting-place for workers in various branches of the same or of kindred subjects. Some such considerations must have led to the recent foundation of the *Journal of General Physiology*, which is edited by Prof. Jacques Loeb, a physiologist, and Prof. W. J. V. Osterhout, a botanist, and published by the Rockefeller Institute of Medical Research. This journal, which was referred to in our issue of October 31 last, is "devoted to the explanation of life-phenomena on the basis of the physical and chemical constitution of living matter," and first appeared in September last. Its scope may, to some extent, be illustrated by a number of reprints which we have received; they are of papers by Prof. Loeb, some physico-chemical, some botanical in nature.

In three papers on amphoteric colloids, which have appeared in the first three numbers of the new journal, Prof. Loeb has continued work previously published by him in the *Journal of Biological Chemistry*. Contrary to what is generally stated in the literature of colloid chemistry, he concludes that the physical properties of gelatin near the point of neutrality are affected only by the cations of a neutral salt, and not by its anions. "The error into which the colloid chemists have fallen is due to the fact that they always investigated the effect of a neutral salt on a protein in the presence of the salt, while the writer took the precaution to wash the excess of salt away after it had time to act on the gelatin." Accordingly, a quantity of finely powdered gelatin is left for one hour in contact with a neutral salt solution of known concentration. The powder is then filtered off, and the excess of salt removed by repeated washing with water. The gelatin is liquefied by heating to 50° C., and diluted with water to make a 1 per cent. solution. Then, for instance, the osmotic pressure of the solution is determined in a collodion bag. Treatment with salts of a bivalent metal ($MgCl_2$, $CaCl_2$) does not lead to an increase of osmotic pressure, but treatment with sufficiently concentrated solutions of salts of monovalent metals (NaCl, NaCNS, $LiNO_3$, Na_2SO_4) results in an increased osmotic pressure. When the powdered gelatin is similarly treated with hydrochloric acid of varying concentrations, it is found that about N/256 HCl (which brings the gelatin to its isoelectric point, $p_H = 4{\cdot}7$) makes the total swelling, the osmotic pressure, the conductivity, and the "alcohol number" minima. On the less acid side gelatin is regarded as existing as a negative ion (*e.g.* $\overset{-}{\text{gelatin}}\text{-}\overset{+}{\text{H}}$ or $\overset{-}{\text{gelatin}}\text{-}\overset{+}{\text{Na}}$); on the more acid side as a cation ($\overset{+}{\text{gelatin}}\text{-}\overset{-}{\text{Cl}}$ or $\overset{+}{\text{gelatin}}\text{-}\overset{-}{\text{OH}}$).

In a later paper the author has determined the amount of bromine in combination with gelatin after treatment with hydrobromic acid of varying concentrations. He regards the curves of osmotic pressure as an "unequivocal function" of the number of gelatin bromide molecules formed. Prof. Loeb has evidently not seen the recent very careful and elaborate investigation, by Sörensen and his collaborators, of egg-albumin; in the *Comptes rendus* of the Carlsberg laboratory. A considerable section of this monograph deals theoretically and practically with the osmotic pressure of an amphoteric colloid of great purity in the presence of electrolytes, and takes into account factors which are not dealt with by Prof. Loeb's simple procedure. It will be interesting to see whether, after a perusal of Sörensen's monograph, Prof. Loeb still maintains his somewhat sweeping criticism of colloid chemists.

The botanical reprints are concerned with the mechanism of regeneration in *Bryophyllum calycinum*. The leaves of this plant possess peculiar dormant buds in each of the notches, which buds may give rise to roots and shoots so soon as the leaf is separated from the plant. The chemical mechanism of the process is dealt with in a paper in the *Annales de l'Institut Pasteur*, and is a rare example of work published in English in a French journal. In other papers in the new journal the influence of the mass of a leaf on the quantity of shoots regenerated in an isolated piece of stem is measured, and the physiological basis of polarity is discussed. It is suggested that an inhibitory influence of the leaf upon shoot-formation (as compared with root-formation) is due to inhibitory substances secreted in the leaf, and carried by the sap from the leaf towards the base of the stem.

ÆTHER AND MATTER: BEING REMARKS ON INERTIA, AND ON RADIATION, AND ON THE POSSIBLE STRUCTURE OF ATOMS.[1]

PART I.—INERTIA.

WE are each of us flying through space at nineteen miles a second, probably much more. Nothing is propelling us; we continue to move by our own inertia, simply because there is nothing to stop us. Motion is a fundamental property of matter. No piece of matter is at rest in the æther, the chances are infinite against any piece having the particular velocity zero; every bit is moving steadily at some given speed, unless acted on by unbalanced force. Then it is accelerated—changed either in speed or direction, or both.

As a matter of fact, we, like other bodies on the earth, are acted on by two slight, unbalanced forces—one which makes us revolve round the earth once a day, like a satellite; the other which makes us revolve round the sun once a year, like a planet or asteroid. Our annual revolution is not because we are attached to the earth; we are not attached, but revolve as independent bodies, and would revolve in just the same time and way if the earth were suddenly obliterated; only then we should find the diurnal revolution transmuted into a twenty-four-hour rotation round our own centres of gravity, and the eccentricity of our annual orbit very slightly changed. In any case, there is no propelling force, only a residual radial force producing curvature of path.

A railway train, or a ship moving steadily, is likewise subject to no resultant force. Propulsion and resistance balance. The whole power of an engine, after the start, is spent in overcoming friction. The motion continues solely by inertia. Any steadily moving body is an example of the first law of motion. You need not try to think of a body under no force

[1] Amplified from a discourse delivered at the Royal Institution on Friday, February 28, 1919, by Sir Oliver J. Lodge, F.R.S.

at all; you cannot think of such a body on the earth, but you can think of one under no resultant force, *i.e.* under balanced forces. Such a body moves by reason of its inertia alone. It is in equilibrium; it is not at rest.

But we have no sense of straightforward locomotion, and not the slightest clue to either the magnitude or direction of our motion through space. We can ascertain approximately how the sun is moving with reference to our system or cosmos of stars, but we do not know at what rate that system is itself moving. For all we know, it may be moving very fast, hundreds of miles per second.

We have a sense of acceleration, however; we experience it in a lift as it begins to descend; and if the sensation is repeated often enough, as on a rough sea, the result is unpleasant. We have also a sense of rotation; we can tell when our vehicle—say a Tube train—turns a corner in the dark. Most animals appear to have a sense of rotation, apparently located in the ear. But we have no sense of direct translation; and we have so far failed to devise any instrumental means for detecting our motion through the æther of space.

The failure is not for lack of trying. Many experiments have been tried, but there is always some compensating effect; so we get no answer to the question: At what rate and in what direction are we moving? The best known experiment is that of Michelson and Morley, the result of which seems to assert that the æther clings to the earth, or that the earth is not moving through any kind of substance. But Fizeau's classical experiment showed that a transparent body carried with it none of the internal æther of space; and experiments made by myself[2] at Liverpool in the nineties of last century showed that a rapidly moving opaque body carries no external æther with it, that there is no perceptible viscous drag or cling between matter and æther, and accordingly demonstrates that stagnation or absence of relative æther drift past the earth is not a reasonable explanation of Michelson's negative result.

The two experiments together, in fact, ought to be taken as establishing the reality of the most interesting of all the compensating effects yet discovered, viz. the FitzGerald-Lorentz contraction of all matter in motion, which the electrical theory of cohesion renders so extremely probable. It only amounts to a 3-in. shrinkage in the whole diameter of the earth in the direction of motion; but it is enough. This slight contraction or change of shape in moving bodies I regard as the definite and interesting compensating effect in this case. Incidentally, moreover, it establishes the electrical, *i.e.* the chemical, nature of cohesion. For, given that cohesion is a residual chemical affinity—due to the outstanding attraction of molecules composed of neutral groups of equal and opposite electric charges, brought so near together that the attraction between molecules is no longer averaged to zero[3]—then, on orthodox Maxwellian electric theory, a diminution of this force due to lateral motion is inevitable. And the resulting lateral expansion or longitudinal contraction, or both, is of the right order of magnitude. So this acts as a previously quite unsuspected compensating effect, which exactly neutralises the drift effect otherwise to be anticipated. Thus, by superposition of two positive consequences of drift, the Michelson experiment, like every other yet made, declines to indicate that there is any drift at all.

Hence, after many such negative results, it seems to become hopeless to inquire experimentally as to our motion through æther, unless, indeed, gravitation were exempt from the otherwise universal compensation. In that case the electrical theory of matter applied to the motion of planets might yield a residual result. But my recent inquiry into this problem has suggested that gravitation, too, is in the conspiracy,[4] and in that case there is some ground for the contention of the extreme Relativists, not only that we do not know our motion—with which everyone agrees—but also that we never shall know it; and, in fact, that motion of matter through æther is a phrase without meaning.

I hope we shall not too readily shut the door on further attempts in this direction; and as a conservative physicist I may be allowed to lament the extraordinary complexity introduced into physics and into natural philosophy by the principle of relativity, as so remarkably and powerfully developed by the mathematical genius of Einstein, with complication even of our fundamental ideas of space and time. The complications do not commend themselves to all of us, and I for one should be glad to return to the pristine simplicity of Newtonian dynamics, modified, of course, by the electrical theory of matter; admitting the FitzGerald-Lorentz contraction, and admitting also the variation of effective inertia with speed. These things do not destroy, but supplement, Newtonian dynamics. They generalise it in a legitimate and intelligible manner. Such complications as these are clearly in accordance with truth, and are to be welcomed; but the complicated theory of gravitation created this century by Einstein, and developed by his successors, and the consequent overhauling of space and time relations, do not at present commend themselves to me, or, I think, to others of what I suppose must be called the older school.

Meanwhile, the full-blown theory has the courage of its conviction and has predicted a definite result, viz. the deflection of a ray of light by the sun's limb, equal to 1·75 seconds of arc. The prediction is going to be tested during the solar eclipse of May 29 this year, between Brazil and the Gulf of Guinea. Let the issue be clearly understood. If a star-ray grazing the sun is deflected ¾ second it will mean only that light has weight, that the wave-front not only simulates the properties of matter by carrying momentum—as we know it does from the investigations of Nichols and Hull, Poynting and Barlow, and others—but that it is even subject to gravity. For this would be the angle between the asymptotes of a cometary orbit when the comet is moving with the speed of light and passing close to the sun.[5] But the principle of relativity—through the refractive or converging influence of a strong divergent gravitational field—demands a greater deflection than this, more than twice as great. So there are three alternate deflections before us, to be settled by observation:—1·75 sec.; 0·75 sec.; and zero. Let us hope that the result of this or of some other eclipse-opportunity may be definite enough to discriminate clearly and quantitatively between these three alternative values, any one of which should be equally welcome to any lover of truth.

If the first answer is given decisively, it will be a conspicuous triumph for the theory of relativity, and will for a time be hailed as a death-blow to the æther. I claim beforehand that such a contention is illegitimate, that the reality of the æther of space depends on other things, and that the establishment of the principle of relativity leaves it as real as before; though truly it becomes even less accessible, less

amenable to experiment, than we might have hoped. Nevertheless, the æther is needed for any clear conception of potential energy, for any explanation of elasticity, for any physical idea of the forces which unite and hold together the discrete particles of matter whether by gravitation or cohesion or electric or magnetic attraction, as well as for any reasonable understanding of what is meant by the velocity of light. Let us try to realise the position beforehand; for we shall be handicapped in the progress of our knowledge of the relation between matter and æther until these fundamental things are settled, and until everyone agrees that the æther has a real existence. I want people generally to admit that the æther is itself stationary as regards locomotion, and that it is the seat of all potential energy; and further, at least as a surmise, that it is the medium out of which matter is probably made, and in which matter is perpetually moving by reason of its fundamental property called inertia—a property the full explanation of which must, I expect, ultimately be relegated to and considered as a property derived from the æther itself.

I call this lecture "Æther and Matter," but I might equally well have called it "Inertia," for that is the main theme with which I have to deal—at least, in this first part.

Is there anything else besides matter which possesses or seems to possess inertia? Faraday discovered that an electric current had a property which bore some analogy to inertia, a property clearly depending on its magnetic field. Every current, even a convection current, is necessarily surrounded by lines of magnetic force, and when the magnetic field is intense the current behaves as if it had considerable inertia. Faraday at first called the effect "the extra current." Maxwell called it "self-induction." The latter is the better name.

To show it, I start a current in a circuit containing a stout ring of laterally subdivided iron round which the current-conveying wire is wound, and I put in circuit an instrument which only responds when the current has risen to nearly its full strength. A current usually rises what is called instantaneously, but here there is a very noticeable delay between pressing down the key and the response of the instrument. The lag shown is only a second or two, but with care I can adjust it until it is a quarter of a minute. Such delay or lag in establishing a current would be fatal to electric telegraphy. In practice the delay is reduced to a minimum by using its early values, and the actual response is exceedingly quick. Still, the law of rise of current is quite definite; there is no exception, it is only a question of degree; and the law is the same as that appropriate to the pulling of a barge on a canal. A barge gets up speed slowly, at a rate depending on its mass or inertia, and it ultimately attains a steady speed when the resistance balances the pull.

That is exactly the case of a steady current obeying Ohm's law; the E.M.F. is balanced by the resistance, the propelling force is zero, and the current flows by what we may call its own inertia—its own momentum.

To stop the current you must either increase the resistance or suspend the propelling force. If you interpose an obstacle suddenly, the motion stops with violence—a collision in the case of a train or barge, a flash in the case of electric current. This is what Faraday called "the extra current at break"; and if you are holding the wires in your hand when a current is suddenly broken in a circuit of large self-induction, you may get a nasty shock.

If you could abolish electric resistance, a current would go on for ever without propelling force.

An amazing experiment has been made by Kamerlingh Onnes at Leyden, who first cooled a metal ring down to within 4° of Absolute zero by means of liquid helium, and then started a current through it by a momentary magnetic impulse. Instead of stopping in a minute fraction of a second, as usual, the current went on and on, not for seconds, but for days. In four days it had fallen to half-strength, and there were traces of it a week later. A most suggestive experiment as to the nature of metallic conduction, as well as a demonstration of the fly-wheel-like momentum of an electric current!

This electromagnetic analogue to mechanical momentum or inertia is explicable (or supposed to be explicable) in terms of the magnetic field surrounding the current, *i.e.* really (as I think) in terms of a property of the æther of space. It exactly simulates inertia; but is it an imitation or is it the same thing? Can it be said that an electric charge possesses inertia in its own right, and retains it always, as matter does, whether it be moving or whether it be stationary?

The question was brilliantly answered by your professor of natural philosophy, Sir J. J. Thomson, so long ago as 1881. He calculated the inertia or quasi "mass" of an electric charge e on a sphere of radius a, and showed that it was $m=\frac{2\mu e^2}{3a}$.

The μ need not be attended to now, though it is really the most important of all—being a great æthereal constant of utterly unknown value [6]—but for our present purpose the μ merely signifies that the e must be measured in electromagnetic, not electrostatic, measure when the formula is interpreted numerically with $\mu=1$.

At the date 1881 this expression for true electric inertia, though an interesting result, seemed too absurdly small to have any practical significance. Take a sphere like a football, 20 cm. or 8 in. in diameter; charge it until it is ready to give more than an inch spark, say up to 60,000 volts; then calculate the inertia or equivalent mass corresponding with the charge. If I have done the arithmetic right, it comes out one-third of a millionth of a millionth of a milligram (3×10^{-16}). Absurdly small! Yes, but not zero. And whenever a quantity is not nothing, there is no telling what importance may not have to be attached to it sooner or later. Nothing real can be so small as to be really negligible in the long run as knowledge progresses. Something at present unforeseen may bring it into prominence. So it has turned out in this case. The infinitesimal result of nearly forty years ago to-day dominates the horizon. It was in some sort the dawn of a new era in physics.

Consider it further. Clearly the inertia depends not on the charge only, but on its concentration. The radius of the sphere occurs in the denominator of the expression. The same charge on a sphere 2 cm. in diameter would have ten times the inertia; on a sphere as small as an atom the inertia would be a hundred million times bigger still. But then even that is small; moreover, an atom could scarcely be expected to hold such a charge. Nevertheless, allowing only a reasonable potential, it might seem that atomic inertia could be sensibly increased by an electric charge. But, no; even on a sphere as small as an atom the concentration turns out insufficient; the effect is still excessively minute. Yet as electric inertia at given potential depends on linear dimen-

[6] I have guessed that it is a density of 10^{12} grams per c.c.$\div4\pi$. See "The Æther of Space," Appendix 2; also the *Phil. Mag.* for April, 1907.

sions, while material inertia depends on those dimensions cubed, there must be a size when the two are equal, *i.e.* when one might account for the other.

Write the charge in terms of electrostatic potential V,

$$e = KaV$$

then
$$m = \frac{2KaV^2}{3c^2}$$

where c is $1/\sqrt{(\mu K)}$, the velocity of light.

Put this expression for m equal to $\pi a^3 \rho$, the ordinary mass.

Then the potential at which the two will be equal is

$$V_1 = ac\sqrt{\left(\frac{2\pi\rho}{K}\right)}$$

which, for density of water and for a sphere 10^{-13} cm. radius, is two volts—quite a reasonable electrolytic value, such as is to be expected among atoms.[7]

The moral of this elementary, but not very satisfactory, argument is that not for bodies of atomic size, but for something 100,000 times smaller in linear dimensions, is it possible to explain inertia electromagnetically. But forty, or even twenty, years ago one would have said: There are no bodies of this size; nothing can be smaller than an atom! The strange thing is that, as nearly everyone knows now, bodies of this size have been discovered. They were isolated by Sir J. J. Thomson in 1899, having been gradually led up to by Crookes's and many other experiments on cathode rays; and they are shown to be an apparently invisible unit or atom of electricity the inertia of which is wholly electric.

The proof of this last statement I can only briefly indicate. It is established by the effect of speed on electric inertia. If an electric charge is moving with something approaching the velocity of light, its inertia increases without limit; and the formula given about 1889 by Heaviside, Thomson, and others for electric inertia as a function of speed is, in its very simplest form,

$$m = \frac{2\mu e^2}{3a}\left(1 + \frac{v^2}{2c^2} + \text{higher powers}\right).$$

The velocity of light squared occurs in the denominator, so, before we can observe the increase, enormous speeds are necessary. A cannon-ball, or even the earth in its orbit, is hopelessly slow; and we know no artificial means of getting up such a speed as this last, viz. about nineteen miles a second. But, fortunately, radium does spontaneously what we cannot do; it expels electrons with something less, but not very much less, than the speed of light; and Kauffmann's measure of the mass of these projectiles, thus flying at prodigious velocities, confirms the theory, and removes any doubt as to the reality of purely and wholly electric inertia for electrons.

Furthermore, it was found that the very same electrons can be split off or detached from any or every kind of atom, that there is only one kind of negative electron; and though at first there appeared to be many kinds of positively charged particles, the evidence is tending to the discovery of a single kind of positive electron likewise; so it is natural to suppose that electrons are an essential ingredient in matter. And since they possess inertia, even those which are clearly disembodied electric charges, it becomes possible to surmise that in some sense, or in a certain grouping, they constitute the atom; that they confer upon it the inertia with which we are familiar; and that, in fact, electric inertia is the only inertia that exists.

Electric inertia began as the simulacrum of material inertia; it has shown itself the very same thing, and it seems likely to end by displacing every other kind of inertia altogether.

This is the electrical theory of matter.

Assuming this theory for the present as a working hypothesis, we may say that material inertia is explained electromagnetically, *i.e.* is explained in terms of the magnetic field which necessarily surrounds and accompanies every charge in motion, since a charge in motion constitutes a current. For on this view a material body is but an aggregate of such charges grouped according to some definite pattern, positive and negative charges interlaced or somehow intertwined, and so far apart in proportion to their size that they do not interfere with each other or cancel each other, nor apparently overlap or encroach on each other's field, to any measurable extent. Is this possible? It is. For, comparing the size of an electron with the size of an atom, we perceive that they are relatively of the same order as the size of a planet and the size of a solar system. So it becomes possible to think of an atom as a sort of solar system, with a positive nucleus or sun surrounded by negative electrons revolving in regular orbits round it.

On this view, or, indeed, in any form of the electrical theory of matter, the atom of matter consists mainly of empty space; in other words, it is excessively porous, just as the solar system is mainly empty space, and may be spoken of as excessively porous, the actual material lumps being almost infinitesimal in proportion to the total bulk. A rapid projectile or a ray of light passing through the solar system would be unlikely to hit anything; the chances would be strongly against a collision. So also, if a point be thrown through an atom, the chance of its hitting anything is about 1 in 10,000. It might pass through 10,000 atoms before striking. This experiment has been tried by C. T. R. Wilson and others, and that is, roughly speaking, the result. Sooner or later a radium projectile meets with an obstacle and is stopped, but it traverses a good number of atoms on the average; it traverses quite a perceptible distance even in a dense solid before it strikes a nucleus.

Matter accordingly seems to me—to us, I may say, for in this most physicists are, I think, agreed—a gossamer or milky-way structure, an impalpable acci-

[7] The argument is plausible, and, taken as an illustration on ordinary lines, will serve; but considered seriously it may be quite fallacious, although the main consequences which in the text are going to be drawn are correct. Few things are more surprising than the extraordinarily large charge held by or constituting an electron in proportion to its size. The charge is so large that ordinary arguments about electricity as it exists on material spheres cannot be expected to apply. If they did, or in so far as they do, the potential of an electron would not be two volts, but well over a million volts; and the density of the æthereal substance of which it is presumably composed (if its electric inertia is to be derived in any simple, ordinary way from its bulk) would have to be nothing like that of water, but of the order 10^{12}, or a billion times the density of water. A thousand tons, in fact, to the cubic millimetre.

We are here out of our depth among quantities on which a great deal of work has to be done to reduce them to order. Yet it must not be supposed that these figures are nonsensical. They require serious consideration; and that is all that can be said for them. I do not think there is any sense in talking about the potential of an indivisible unit of charge, but we can talk about the potential existing at the confines of an atom; and that is a reasonable magnitude, about 14 volts in the case of hydrogen, and not very different for other elements.

But on the other side of the subject everything points to the density of æther being exceedingly high, though perhaps not so high as the above estimate. It must at least be greatly denser than platinum or lead, and probably immensely denser.

A difficulty is often felt as to how ordinary matter like a planet can move through such a medium without friction. Density, however, does not involve viscosity; the two are disconnected; and resistance to motion would be caused only by viscosity, of which the æther appears to have none. There are many ways, more or less satisfactory, of picturing the perfectly free motion of matter through an exceedingly substantial æther of space; there would be innumerable difficulties in supposing friction and consequent generation of heat. It is quite certain that whatever the æther does it does not dissipate energy. That imperfection belongs to the province of molecularly constituted matter.

dent in the substantial æther. Here a speck and there a speck, but, for the great bulk of it, empty space!

"Impalpable" is not the right word, for matter is essentially palpable. It is because it appeals so directly to our senses that we attend to it so vividly. It forces itself on our attention, while the æther eludes us. And why? Clearly because our bodies are composed—our sense organs are composed—of this very matter. On the material side we are part of, and thoroughly at home in, the material universe. Whereas the æther is elusive—we know nothing of it directly—and though our eyes are instruments for receiving æthereal tremors excited by agitated electrons, we only know that fact, or half know it, by rather recondite inference. Light really tells us nothing about its own nature, but only about the superficial aspect of that gross and palpable matter which has interfered with and scattered it before it enters our eye.

Nevertheless, the atoms of this solid-seeming flesh and matter as we know it, when analysed into constituents, are turning out to be composed each of a definite grouping of ultra-minute particles, the positive and negative electrons, which themselves scarcely occupy any space (save as soldiers occupy a country), and which appear to be of two kinds only: the ultimate indivisible units of positive and negative electricity.

(*To be continued.*)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

MANCHESTER.—The following appointments are announced:—Mr. A. G. Ogilvie, reader in geography; Mr. J. Macmurray, lecturer in philosophy; Messrs. A. Gardner and R. L. Newell, demonstrators in anatomy. Mr. E. N. Ramsbottom has been elected to a research fellowship in public health.

DR. J. GRAHAM has been appointed professor of anatomy in the Anderson College of Medicine, Glasgow, in succession to the late Dr. A. M. Buchanan.

THE sum of 700,000*l.* has been given by Mr. G. Eastman, head of the Eastman Kodak Co., for the establishment of a school of music in connection with the University of Rochester, New York.

DR. G. SPENCER MELVIN, lecturer on experimental physiology in the University of Aberdeen, has been appointed professor of physiology in Queen's University, Kingston, Ontario.

THE PRINCE OF WALES, in acknowledging the degree of LL.D. conferred upon him on August 26 by the University of Toronto, said that the anti-toxin establishment with which the University is equipped had rendered invaluable service during the war for the forces of the British Empire and the Allies.

PROF. C. GOLGI has retired from the chair of general pathology and histology in the University of Pavia, but he remains in charge of the institute connected with it. A gold medal and souvenir album were recently presented to him, and a scholarship founded in his honour is to be given to the orphan of some physician killed during the late war.

DR. F. J. WILSON has been appointed professor of inorganic and analytical chemistry, and Dr. I. M. Heilbron professor of organic chemistry, at the Glasgow Technical College. Mr. W. Kerr has been appointed research assistant in the department of mechanical engineering at the same institution. The new development fund of the college has now reached the total of 35,000*l.*, the following donations having recently been received:—From Mr. W. J. Chrystal, 1000*l.*; Mr. and Mrs. George Morton, 500*l.*; Messrs. W. Teacher and Sons, 500*l.*; Messrs. Alexander Stephen and Sons, Ltd., 500*l.*; the Anchor Line (Henderson Bros.), Ltd., 250*l.*; Messrs. Macfarlane, Lang, and Co., Ltd., 250*l.*; and Mr. James Reid, 250*l.*

THE Civil Service Commissioners announce that an examination will begin on October 28 for the purpose of filling vacancies as assistant examiners in the Patent Office. The examination will be confined in the main to candidates who have served in his Majesty's Forces, and will consist of a qualifying examination followed by interview by a selection board. The subjects of the qualifying examination are English composition, *précis*-writing, general knowledge, and *one* of the following:—General chemistry, electricity and magnetism, or mechanics and mechanism. The limits of age are 20–30. Initial salary 150*l.* a year, together with a war bonus. Copies of the regulations and forms of application may be obtained from the Secretary, Civil Service Commission, Burlington Gardens, London, W.1. The last day for making application is September 18.

THE United States General Education Board has granted 16,000 dollars to the National Committee on Mathematical Requirements, appointed by the National Mathematical Association of America, for the purpose of undertaking a study looking to improvements in the mathematical curriculum of the secondary schools of the country. Mathematicians, as well as educators in general, have in recent years criticised the prevailing high-school work in mathematics on the ground that much of the material is of little practical value, and on the further ground that the high-school curriculum in mathematics takes too little account of modern developments in this science. The American Mathematical Association is made up of the leading professors and teachers of mathematics in American colleges and universities. It has appointed to conduct the inquiry a committee composed of four university professors of mathematics and four secondary-school teachers of mathematics. Having no funds, this body applied to the General Education Board for assistance. The board itself will not take any part in the study or make recommendations. Prof. Young, of Dartmouth College, and Prof. Fobert, Technical High School, Chicago, will devote their entire time to the work for a year or more.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 18.—M. Léon Guignard in the chair.—G. **Humbert**: The particular representations of an integer by positive forms of Hermite in an imaginary quadratic body.—H. **Andoyer**: The development of a general function of the radius vector of the eccentric anomaly in elliptic movement.—E. L. **Bouvier** and d'E. **de Charmoy**: Mutation of a Caridina into an Ortmannia, and general observations on the evolutive mutations of fresh-water shrimps of the family of the Atyidæ.—E. **Kogbetliantz**: Ultraspherical series.—R. **Garnier**: Vectorial fields with indeterminate asymptotic directions.—E. **Jouguet**: A problem of generalised hydraulics. Flow of a burning gaseous mixture.—A. **Véronnet**: Ellipsoidal figures of equilibrium of a liquid in rotation; variation of the major axis.—G. **Fayet** and A. **Schaumasse**: The next return of the periodic comet 1911 VII. (Schaumasse). Taking into account the perturbations in the orbit caused by the proximity of the comet to Jupiter in 1913, new elements have been worked out. It should be sought for in the beginning of September.—R. **Baillaud**: An impersonal photographic astrolabe.—P. **Nicolardot**: The action of reagents upon glass-powder. Eight kinds of glass were studied, and the amounts dissolved by pure water and decinormal hydrochloric acid determined for three grades of powder, fine, medium, and coarse.—S. **Posternak**: The saturated sodium salt of inosite hexaphosphate. A correction of data given in an earlier paper.—Ch. **Boulin** and L. J. **Simon**: The evolution of a mixture of methyl sulphate and chlorosulphonic acid.—J. **Bougault** and P. **Robin**: The oxidation of benzaldoxime. This oxime, on treatment with iodine and sodium carbonate, gives benzoic acid, benzaldoxime peroxide, benzoyl-benzaldoxime, and dibenzenyl-oxoazo-oxime.

SYDNEY.

Linnean Society of New South Wales, June 25.—Mr. J. J. Fletcher, president, in the chair.—Dr. A. J. **Turner**: Revision of Australian Lepidoptera. Part vi. (continued). Thirty-two genera and ninety-five species of the subfamily Boarmianæ are recorded or described, five genera and forty species being described as new.—Dr. R. **Greig-Smith**: The germicidal activity of the eucalyptus oils. Part ii. Eucalyptus oils are irregular in their action upon *B. coli communis*, and duplicate experiments may show a considerable amount of variation. Cineol begins to act in about a minute and a half; phenol acts instantly. The curves of cineol and phenol cross in 5 minutes with a dilution of 1 : 75 at 20°. The phenol coefficient of cineol in 15 minutes at 20° is 3·1; it rises to 3·4 in 30 minutes, and then slowly declines to 2·8 in 4 hours. Aromadendral is the most active of the constituents of the oils. The phenol coefficient is 21·1 in 30 minutes. The next most active is piperitone (4·1), and possibly phellandrene. Pinene and sesquiterpene are low (0·8 to 0·5). The rectified oils of *E. cinerea* and *E. Smithii* are more efficient than the crude oils. In the case of the oil of *E. cinerea*, this appears to be due to the hydrolysis of the esters and the subsequent oxidation of the alcohols to aldehydes. Treatment with alkali did not reduce the efficiency of the acid-rectified oil. The addition of acetic acid to the crude oil doubled the germicidal power in the course of 3½ months. The germicidal activity of the rectified and crude oils of *E. cinerea* is proportional to the starch-iodide reaction, and not to the acidity, but this does not hold for the oils as a class. The rectified oil of *E. polybractea* is less efficient than the crude oil. This may be due to the elimination of aromadendral during rectification. The oil of the Braidwood variety of *E. australiana* is the best and cheapest disinfecting oil (phenol coefficient=5·8 in 30 minutes). The oil of *E. cinerifolia* was the second best crude oil tested (phenol coefficient=4·8 in 30 minutes); its activity is probably due to its aromadendral content. As in the case of phenol, the addition of acid to the water used in emulsifying the oils greatly increases the germicidal activity.—T. **Steel**: Water from the roots of the red mallee. A chemical investigation of water from the roots of this plant from Fowler's Bay, South Australia.—Prof. E. D. **Merrill**: The identity of *Polypodium spinulosum*, Burm. f. The author, by comparing Burman's figure with Australian material, concludes that the plant described as *P. spinulosum* from Java represents the W. Australian plant, *Synaphea polymorpha*, R. Br., and that the locality record is an error.

ZOOLOGY AND HUMAN WELFARE.

Animal Life and Human Progress. Edited by Prof. Arthur Dendy. Pp. ix+227. (London: Constable and Co., Ltd., 1919.) Price 10*s.* 6*d.* net.

THIS volume is the outcome of a series of public lectures organised by Prof. Dendy at King's College, London, in 1917-18 under the auspices of the Imperial Studies Committee of the University of London. The object of the course was to inform the public regarding zoological results already applied in furtherance of human progress, and to emphasise the claims of zoological science to recognition on terms of equality with other departments of learning. The college and the editor are to be congratulated, not only on their courage and public spirit in having, during the dark days of the war, arranged a course which makes so much for enlightenment and for reconstruction, but also on having made the subject-matter accessible to all through the medium of this volume. The lectures are most informing, and if we express regret at the absence of consistently full citation of the authors quoted, this is done in tribute to their permanent value.

Prof. Dendy contributes the preface and an opening lecture on "Man's Account with the Lower Animals." To the weighty material items in that account he adds the pregnant idea that much of our æsthetic sense is founded on insect æsthesis, since the marvellous forms, colours, and fragrances of flowers arose "in the course of evolution in response to what we may fairly call the tastes of insects long before man appeared on the scene." Prof. Bourne adds a thoughtful essay on "Some Educational and Moral Aspects of Zoology." Prof. J. A. Thomson writes with his usual vivid grace and wealth of illustration on "Man and the Web of Life." Mr. Tate Regan discusses "Museums and Research," incidentally putting in a strong plea for the view that evolution has been mainly adaptive, and that a change of structure has followed, not preceded, a change of habits.

"The Origin of Man" is dealt with by Prof. Wood Jones, who concentrates on primitive anatomical features exhibited by man, differences between man and other Primates, certain striking resemblances to Tarsius, and the probable remoteness of origin of the human stock. With perhaps a little special pleading one could use a good many of his data in a thesis having for its subject "Non-Arboreal Man." "Some Inhabitants of Man and their Migrations" is the subject of Dr. Leiper's lecture, which will be read with all the more interest in view of his own recent researches on Bilharzia. In "Our Food from the Sea" Prof. Herdman emphasises the vital importance of sea fisheries, while "Tsetse-Flies and Colonisation" receives exposition from Prof. Newstead.

"I saw before me a great place where men and women were making and imparting knowledge." Thus begins Prof. Punnett's "dream" at the end of his most readable lecture on "The Future of the Science of Breeding." May the dream come true for every branch of zoological science. Meantime we find emphasised, over and over again, in the work before us a sad disproportion between the public support given to the study of animal life and the splendid results this study has achieved and can yet achieve for the furtherance of human progress.

J. F. GEMMILL.

WAR GLEANINGS.

A Vision of the Possible: What the R.A.M.C. Might Become: An Account of some of the Medical Work in Egypt; together with a Constructive Criticism of the R.A.M.C. By Sir James W. Barrett. Pp. xx+182. (London: H. K. Lewis and Co., Ltd., 1919.) Price 9*s.* net.

SIR JAMES BARRETT has added another vigorous and stimulating book to those he has already published dealing with military medical matters in the past war. The book treats mainly of questions which came under his notice whilst serving in Egypt, where he held posts which enabled him to gain a broad outlook, as they gave him an insight into the workings of the military medical organisation, not only at its local centre, but also in many of its peripheral sections. His dicta have therefore the refreshing qualities of first-hand observations in many fields with which he was familiar. It must be added that they are not less dogmatic when relating to spheres with which he was less well acquainted; but there is always a note of sincerity and conviction which compels attention.

The first section gives a general account of the author's activities as an aural specialist, and describes, by means of actual instructions issued, the improvements in the treatment of ear diseases and in the disposal of the men suffering from them which were effected. In this connection stress is rightly laid on the advantages gained by "the educational means adopted. The whole service was taken into confidence, the problem was explained, and the help of the medical officers was invited."

It may be asked why so much education in the treatment of ailments common in the civil population was required by medical men taken for the most part straight from civil practice. This the author explains in a later section of the book, where he says: "The training of the average medical man is intense and narrow; all his energies are concentrated on one problem, doing the best for the sick man professionally. He consequently speculates on remote risks. . . .

 C

With obligation to the State he is not concerned. In the Army, on the other hand, everything must be done for the good of the Service." In other words, a man engaged in a desperate enterprise, such as war, may be allowed in the common interest to take risks, often small, which his medical attendant would not sanction at ordinary times, and some education is required to alter the civil point of view.

With the writer's advocacy of professional conferences and instruction there can be nothing but sympathy; he does not appear to be aware of the developments on these lines, which were so great a feature in other theatres of war, and have assuredly come to stay.

Some 100 pages are taken up in considering the question of boards and the physical classification of recruits and soldiers. They form interesting and instructive reading. The author states: "In general, about one-third of the B class *personnel* who arrived in Egypt were immediately placed in the A category." They were sent to the front and made good. He roundly accuses the boards at home of classifying men too low and of depleting the reserves by an undue number of rejections. It is interesting to recall that a Parliamentary Committee sat to investigate the widespread allegations in this country that home boards had classified the men too high.

But it is in the concluding part of the book, dealing with the organisation of the military medical service and the modifications suggested, that the main interest lies. There is common agreement as to several of the desiderata mentioned. Some are on their way to attainment, whilst others have already been attained.

Allowing for a certain amount of special pleading, the book raises many points of cardinal interest, lucidly, if forcibly, expressed, and there are not many connected with the medical services, either as clinicians or administrators, who will not glean some profit from a perusal of its pages, whilst the general reader will not find it too technical for his enjoyment.

NERVOUS DISORDERS; TWO POINTS OF VIEW.

(1) *What is Psychoanalysis?* By Dr. I. H. Coriat. Pp. 124. (London: Kegan Paul, Trench, Trübner, and Co., Ltd., 1919.) Price 3*s*. 6*d*. net.

(2) *Traitement des Psychonévroses de Guerre.* Par G. Roussy, J. Boisseau, M. d'Œlsnitz. (Collection Horizon.) Pp. 191. (Paris: Masson et Cie, 1918.) Price 4 francs.

(1) DR. CORIAT'S attempt to collect into one small volume the chief articles of the psychoanalytic faith, and, moreover, to lay them out along the rigid scaffolding of a shorter catechism, is certainly an act of bravery or temerity. The reader is asked to defer his decision between these two descriptions until he has finished this very interesting and challenging small book. For the concreteness—one had almost written the ferro-concreteness—of this exposition cannot fail to delight, at one stroke, the erudite student of Freud, who has long been yearning for some psychoanalytic Baedeker to indicate with a judicious distribution of asterisks the really important halting-places on this perilous journey; the implacable enemy of the new movement, who will surely regard the pages of this book as a conveniently bound packet of targets; and the teacher of psychology, who can now prepare three full lectures on what someone has assured him Freud really means.

Most people must have felt that such a book ought to appear some day, though, perhaps, not everyone would have regarded the present time as suitable. But Dr. Coriat might immediately point out, and with justice, that the procrastinator is a person upon whose mentality more light has been thrown from Vienna than from any other quarter in recent years, and certainly there is little that can be called undecided in the way the present book is written.

The answer to the question "What is Psychoanalysis?" occupies 118 pages, at which stage Dr. Coriat ends, and, one presumes, Dr. Adler and Dr. Jung would desire to begin. For it seems clear that the present answer is the answer of Freud alone. And this is, we think, a pleasing feature, if one could ensure that the book did not fall into the eager hands of the entirely uninitiated. The book is, so to speak, a diagram of Freud's teaching. When we can place by it similar diagrams of Adler's and Jung's theories (drawn very strictly to scale, with the congruent portions clearly indicated) and get them well into our heads, discussions on psychoanalysis may gain in clarity what they will assuredly lose in heat.

But, like many diagrams, the present one often seems to err on the side of too great simplicity, and it is too heavily outlined. The book reads, in fact, far too glibly. It seems scarcely fair to Freud to write without further explanation of the "way that a normal individual conveniently '*forgets*' the unpleasant experiences of his life" (p. 14), and to say dogmatically: "If the nervous symptoms grow worse during the course of the analysis, this must be interpreted as due either to the resistances or to the course of the disease, and not to the treatment" (p. 70); or to ask the question of questions "Can psychoanalysis be harmful?" and to "answer" it by merely remarking that "wild" psychoanalysis can, and that the analyst may fall into errors. What the average man presumably wants to know is whether, in any circumstances, orthodox, thorough-going, complete psychoanalysis can be harmful, and, if so, why? Especially, perhaps, does the average English reader, who has seen the course of the thread linking the writings of McDougall, Shand, and Trotter on one hand with those of Freud and Jung on the other, ask this question. And, so far, it has not been answered.

(2) A conception of quite a different nature is presented in the book by Dr. Roussy and his colleagues on the treatment of the psychoneuroses of war. Their work deals chiefly with those "accidents d'ordre hystérique" which they describe as the most important of the psychoneuroses observed during this war. A comparison of their book with such a treatment as Dr. MacCurdy's in "War Neuroses" (recently reviewed in these columns) provokes the reflection that a wider conception of the war psychoneuroses than that held by these French authors seems to be necessary if medical science is to learn all it can from the experiences of war psychotherapy. The book deals with the causation, treatment, and prophylaxis of these hysterical disorders, and discusses the recent "reflex," "dynamogenic," and "dyskinetic" theories of their nature. It is clearly written and excellently illustrated.

OUR BOOKSHELF.

Memoirs of the Boston Society of Natural History. Vol. viii. No. 3. *Monographs on the Natural History of New England. The Turtles of New England.* By Dr. Harold L. Babcock. Pp. 327–431 + 16 pls. (Boston, Mass.: 1919.)

This is a very interesting and excellently produced monograph dealing with seventeen species out of sixty-one now recognised by American authors. Considering that New England includes the northern limit of distribution of the Chelonians of eastern North America, this is a good number. The author has collected most of the observations published on the life-histories of these species, and such a compilation is a valuable addition to the descriptive and iconographic part of the work.

Objection may be taken to the title of the monograph, as the term "turtle" is usually taken to apply to thoroughly aquatic Chelonians only. As the author tells us, it has been suggested that (1) all Chelonians of the land only should be called tortoises; (2) all Chelonians of fresh water should be termed terrapins; and (3) all Chelonians of the sea should be called turtles. It is somewhat difficult to draw a limit between the two first categories, and one does not quite like the name "terrapin" to be bestowed on the soft-shelled or river Chelonians, the Trionychidæ. Perhaps these might be termed river-turtles in opposition to sea-turtles.

The descriptive part is preceded by an introduction, in which the author deals with Chelonians generally. Three statements call for criticism. (1) The skull is stated to be more solid and compact than in other reptilian orders; but what about crocodiles? (2) Some marine turtles are said to be strictly herbivorous (p. 330); this can only be meant to apply to the green turtle (*Chelone mydas*), which is chiefly, but not exclusively, so; and further on (p. 340) we are told of a specimen in captivity greedily taking large pieces of raw fish. Among the terrapins, *Batagur* and *Dermatemys* are also chiefly herbivorous. (3) Speaking of the longevity of land tortoises, instances of existence for much more than a century might have been given; and to the statement that Gilbert White's famous tortoise (*Testudo ibera*) lived nearly sixty years, "in capitivity" should have been added. A still better record for the same species is furnished by an individual, on which the writer of this notice has reported, that has been kept in Cornwall for ninety-six years.

G. A. B.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can be undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.]*

Luminous Worms.

The Rev. Hilderic Friend in his letter to Nature of August 7 (p. 446) asks: "Is it possible that light can influence Annelids in some way, and so facilitate sexual processes?" He cites the affirmation of Flaugergues made in 1771 that luminosity disappears in certain cases after copulation.

There is the other way of approaching the subject. We know that the luminous earthworms, with which Dr. Gilchrist has dealt in his recent paper, can be stimulated to luminesce; so may we not ask: Is it possible that sexual processes may facilitate the excretion of the substance or substances to which luminosity is due?

We are acquainted with the fact that in other invertebrate groups muscular contraction, due to a stimulus to the nervous system, will expel the contents of glands secreting the substances essential for the production of light. For example, we know that sometimes excitement due to the attack of enemies will cause phosphorescence in centipedes (Thomas, cited by Dahlgren, Journal of the Franklin Institute, January, 1917, p. 85 of reprint). In a forthcoming paper Dr. Brade-Birks and I shall indicate several other ways in which the same result can be brought about among the Chilopoda.

A careful reading between the lines may show that fear, shock, *and sexual processes* each provide the stimulus to the nervous system which results in the expulsion of the essentials of luminosity by a contraction of the muscles in the case cited by Mr. Friend, and that if that stimulus were sufficient to exhaust the store of secretion the animal mentioned by Flaugergues would, of course, fail to exhibit luminosity again until the secretion had had time to re-accumulate.

S. Graham Brade-Birks.

16 Bank Street, Darwen, Lancashire.

The National Union of Scientific Workers and Research.

One of the chief aims of the National Union of Scientific Workers is "to secure adequate endowment for research and to advise as to the administration of such endowment." A committee of active workers in all the principal subjects has been appointed to consider methods of carrying out this object. While the committee is agreed upon the general aim of making it possible for the scientific worker to make research his profession (subject, of course, to efficiency), concrete suggestions regarding methods of achieving this are essential; and as the committee is a comparatively small body it cannot expect to be acquainted with all the relevant facts concerning the conditions under which research is conducted at present. To overcome this difficulty it is proposed to associate with the committee a number of advisory panels consisting of persons in the principal research centres in the British Isles. Will those workers (whether already members of the Union or not) who would be willing to supply the information required, or to make definite suggestions concerning possible methods of improving these conditions, please communicate with the undersigned or some other member of the committee?

The present committee consists of the following:—Dr. O. L. Brady (Chemistry, Imperial College), Dr. J. W. Evans, F.R.S. (Geology, Imperial College), Mr. W. F. Higgins (Experimental Physics, National Physical Laboratory), Dr. A. Holmes (Geology, Imperial College), Dr. H. Jeffreys (Mathematical Physics, Cambridge), Dr. F. Kidd (Plant Physiology, Cambridge), Dr. M. C. Rayner (Botany, General Branch), Dr. C. Shearer, F.R.S. (Zoology, Cambridge), Mr. E. Sinkinson (Chemistry, Imperial College), Dr. C. West (Plant Physiology, Imperial College), Miss D. M. Winch (Pure Mathematics, Cambridge).

HAROLD JEFFREYS.

St. John's College, Cambridge.

WIRELESS NAVIGATION FOR AIRCRAFT.

THE determination of the position of ships at sea involves dead reckoning and the use of sights on terrestrial or celestial bodies. Dead reckoning methods often give fairly accurate results, even when no sights can be taken. With aircraft, however, drift plays so large a part that dead reckoning methods are not sufficiently trustworthy. Hence the necessity for other methods for determining position.

Directional wireless gives a means of finding one's position under almost any conditions, and thus enables navigation to proceed in cases where it would otherwise be dangerous, such as in fog. It uses chiefly the well-known property of loops, that if the plane of a loop makes an angle θ with the direction of propagation of the waves, the E.M.F. produced in the loop is $E_0 \cos \theta$. The rate of variation of this with θ is greatest when $\theta = 90°$, *i.e.* when the signal strength is a minimum, and bearings have hitherto been obtained by turning the loop until the minimum is obtained.

There are two distinct ways in which this navigation might be effected:—

(1) The aircraft should emit ordinary wireless signals and directional stations on the ground determine various directions of the aircraft, the central ground station working out the position of the aircraft and re-transmitting it to the aircraft. This method has been used considerably by the Germans.

(2) There should be ordinary transmitting stations on the ground which should transmit ordinary wireless signals, and the aircraft should determine bearings of each of these known ground stations, the navigator working out his position from these bearings. This method has very many obvious advantages over the first method, such as the fact that an unlimited number of aircraft can work out their own positions at the same time, and also the fact that in case of warfare the position of the aircraft need not be disclosed to the enemy. This second method was adopted in the R.A.F. to a great extent.

In attempting to place directional gear on aircraft there were considerable difficulties:—(1) There is much extraneous noise on aircraft; (2) the space available on aircraft is not abundant, and in any case it is not easy to get large loops; (3) the possibility that the waves would be deviated in the neighbourhood of the aircraft, thus producing errors which would have to be determined.

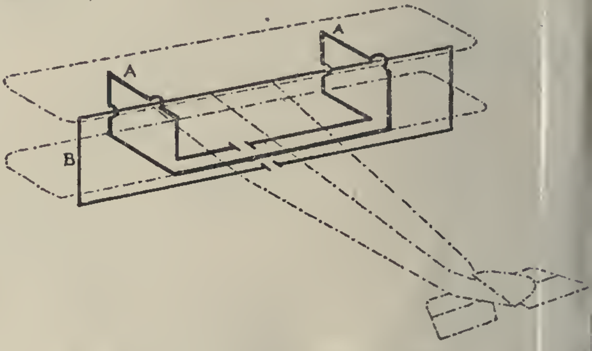

FIG. 1.—A, main aerial; B, auxiliary aerial.

It was obvious that the best amplification of signals that could be obtained would have to be used. Even with the best amplification known, it was found that the extraneous noise was so considerable that the ordinary minimum method of using a loop aerial to find direction was of very little use. Because of the extraneous noise the minimum was considerably widened, and even with powerful signals there might be a region as large as 40° to 60° where no signals at all were obtained. It was hence necessary to devise some method by which signals could be heard whilst the bearing was taken. For this purpose the following method was devised:—

Two loops at right angles are used. These loops are rigidly fixed together and rotate round the same vertical axis. When one of these loops is on its maximum the other will be on the minimum. When the maximum or main coil is used alone, the maximum of the signals is first roughly obtained, and then the second or auxiliary coil is introduced, the connections of this second coil being reversed from time to time. If the main coil is on its maximum the reversal of the auxiliary coil will not alter the strength of the signals, but if the main coil is not correctly on the maximum the reversal of the auxiliary coil will give signals of different intensity; hence the method to employ is to rotate the coils, using the main coil alone until somewhere near the maximum, and then to introduce the auxiliary coil, making the final adjustment so that on reversing the auxiliary coil there is no change in the intensity of the signals. The sensitiveness that can be obtained by this method is under control and depends on the ratio of the area turns of the auxiliary and the main coils. By "area turns" is meant the summation of the areas of the various turns of a loop. If this ratio is of the order of 3 to 1, a bearing can be determined quite easily to within 1°. If this ratio is 10 to 1, the coils are accurate to less than $\frac{1}{4}$°. It is quite simple to show the reason for this theoretically. There are two distinct methods of applying this method to aeroplanes:—

(1) The coils are rigidly attached to the aeroplane and the aeroplane rotated until the correct bearing is obtained. This is called the wing coil system. The main coil is fixed in the fore-and-aft direction on the struts and the wings. The auxiliary coil is athwart-ships on the struts and the wings. Fig. 1 shows diagrammatically how this is done.

(2) The coils are placed in the fuselage of the machine and are rotated independently of the machine. Method (1) has the advantage that stronger signals are obtained and can hence be used for long distances, such as for the cross-Atlantic flight. This method has the disadvantage that it is necessary to deviate the machine from its course to determine any bearing. It has also the advantage that there are no errors due to the deviation of waves.

Method (2) has the advantage that the machine can carry on on a steady course whilst bearings are being taken. It has, however, disadvantages that signals are much weaker and that errors are introduced in the bearings. Such errors are quadrantal in nature and can be determined by swinging the machine and taking bearings on the same station for different directions of the head of the machine.

On aeroplanes the extraneous noise can be divided into two distinct classes: (1) The noise of the engine and the rushing of the wind; (2) the disturbance produced by the magneto.

The noise of the engines can be minimised by increasing the amplification of signals, but magneto noise cannot be eliminated in such a way because, as the amplification is increased, the effect of the magneto disturbance also increases. It was absolutely necessary to determine methods to cut out this magneto disturbance. It was found that the magneto disturbance was principally due to the emission of very short waves of the order of 5 to 30 metres. The most effective method for cutting out these disturbances was completely to shield the magneto system. The magneto leads were made of braided wire, the braiding being earthed every 18 or 24 in. It was also necessary in cases where the engine is not completely cowled to enclose the magnetos and their distributors in metal shields.

A large number of results of determinations of position by wireless bearings have been obtained. The beacon stations used were principally long-wave spark stations (wave-lengths of 2000 metres and upwards), the distances of the beacons being from 10 to 500 miles, and occasionally more distant. Some of the stations used were Poldhu, Paris, and Nauen.

On the ground, when two or more of these beacons were used, the mean error in the determination of position was two miles. In aeroplanes the accuracy was not so good owing to the compass errors, due to the swinging of the compass. The mean error in bearing in the air was $1\frac{3}{4}$°, and the mean error in position when two or more beacons were used was seven miles.

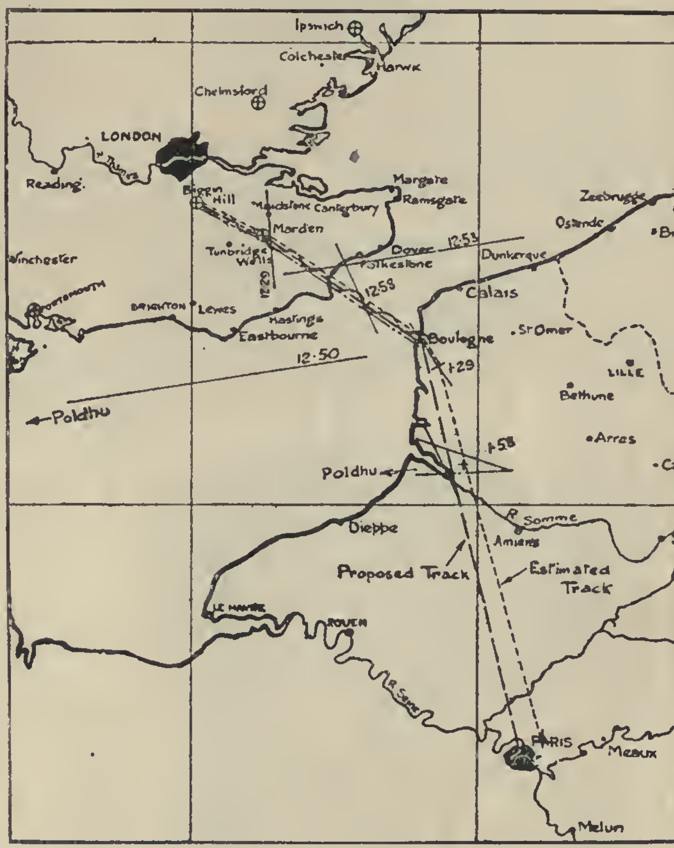

FIG. 2.—Outward journey. Dotted line, thus — ·· — ·· — indicates actual track of machine as followed by map reader.

Long-distance flights have been made in which, under adverse weather conditions and without reference to the ground, by the sole use of directional wireless the machine was navigated with extraordinary accuracy. The details of a flight from Biggin Hill to Paris and back to Brighton are shown in Figs. 2 and 3. The aeroplane was above the clouds half the time, and the navigator was in a position which precluded any possibility of seeing out of the machine. He was, nevertheless, able to direct the course of the machine, forecast the time of arrival half an hour in advance with an error of less than two minutes, and find the force and direction of the wind deflecting the machine from her course from time to time, such predictions being found to be accurate when compared with the meteorological report later in the day.

In certain circumstances excellent results can be obtained when only one beacon station is available. This is especially useful when the beacon is at one's destination, when head bearings alone are used. J. ROBINSON.

PROF. ALEXANDER MACALISTER, F.R.S.

IN the death of Prof. Macalister, at the age of seventy-five, British anatomy loses a singularly gentle and kindly master, who, in a quiet and unobtrusive way, exerted a great influence upon the teaching of his subject during the last fifty-nine years—for he had qualified to practise medicine, and had become a demonstrator of anatomy in the Royal College of Surgeons in Dublin before he was seventeen years of age!—and upon the development of the medical school in Cambridge, where he was professor of anatomy for thirty-six years. While acting as demonstrator in anatomy at the Royal College of Surgeons he was a student at Trinity College; at the age of twenty-five he became professor of zoology there, and eight years later succeeded to the chair of anatomy and chirurgery. At Trinity College he developed that craving for encyclopædic knowledge which throughout his life he was continually striving to satisfy. He was especially devoted to the study of Celtic archæology and ancient Egyptian literature, and in his own subject his wonderful powers of memory and his persistent accumulation of facts by personal observation gave him a knowledge of the details of anatomy and the literature relating to it which was almost uncanny and at times disconcerting to those who sought his advice. For, without intending to discourage youthful adventurers in anatomical research, the formidable record of what had already been accomplished, which he was able to give quite impromptu to one who was contemplating some original investigation, was responsible for bringing to nought not a few budding aspirations. Prof. Macalister never seemed to realise the crushing effects of his vast erudition. In the latter years of his life he often discussed with the writer the efforts he had made to encourage men to do research, and his difficulty in understanding why so little came of it.

When he succeeded to the chair of anatomy in Dublin he took Sir George Humphry, of Cambridge, as his guide and master, and began a series of detailed investigations in comparative anatomy and especially myology; but when he became Humphry's successor he devoted himself more and more to osteology, and to the end of his life he continued to collect data and fill note-book after note-book with the records of his observations and admirable pencil drawings. Unfortunately, only a relatively small proportion of these results have been published. When, from time to time, his friends pressed him to make his work available for other anatomists, he would modestly disclaim that any journal would find space for the contents of his voluminous note-books, or urge that they were always available for anyone to use; and, in fact, he was ever generously ready to give the results of his work to anyone who asked for them. Prof. Macalister spent his life in amassing facts, and avoided generalisation and the formulation of explanations or theories. This thirst for facts and lack of interest in their interpretation is nowhere more clearly displayed than in his choice of subjects for investigation. Perhaps the most striking instance of this is his monograph on the lachrymal bone. In spite of this curious trait, Prof. Macalister was mainly responsible in this country for maintaining an interest in morphology at a time when anatomy was threatened with the fate of being reduced to the mere mechanical craft of the dissecting-room. His text-book on anatomy was the instrument by means of which his influence was extended far and wide, especially among teachers of the subject. The great anthropological collection which he made in Cambridge will always remain as a memorial of his zeal and energy. But to those who have been closely associated with Prof. Macalister either as students or colleagues the recollection that has been imprinted most deeply in their memories is that of a generous and kindly soul who throughout the whole of his long career as a teacher of anatomy continued to perform the duties of a junior demonstrator gently "helping lame dogs over stiles" in the dissecting room.

PROF. L. W. KING.

THE death of Prof. Leonard W. King on August 20 is a serious blow to archæology and to the British Museum. Prof. King had made himself one of the foremost Assyriologists of the day, and his comparatively recent appointment to the chair of Assyriology in the University of London was a recognition of his work that was much appreciated by him, and commended itself wholly to all students of the subject. From the time when, a few years after his appointment to the British Museum in 1893, Mr. King published his first studies in Assyriology, his work has been known by its clarity, sanity, and critical acumen. "Prove all things; hold fast that which is good," may be said to have been his guiding principle in his work. All scientific work was to be criticised fearlessly, and what seemed to his clearly distinguishing mind the true solution of a problem was to be upheld without hesitation. All he sought was the truth, as it seemed probable to him. And no other consideration moved him. He was a fine type of the modern scientific worker in the field of archæology, and the loss to science of such a man in the flower of his age and activity can scarcely be estimated.

Prof. King was born in the year 1869. He was therefore only forty-nine years of age when premature death overtook him, largely as the result of heavy double labour during the war as an official attached to the Intelligence Department of the Admiralty and as student of Assyriology, which adversely affected a system already, as we can see now, severely tried by illness contracted in the course of his excavations for the British Museum at Kuyunjik (Nineveh) several years ago. To outward seeming Prof. King was a man of robust health and physique, but in reality the rigours of archæological work in Assyria under the conditions of fifteen years since had undermined his constitution, and when, in the present year, the results of severe war labour coincided with a recrudescence of old illness, he fell.

Prof. King was a Rugbeian and a King's man. The book in which he first made his mark was "The Life and Letters of Hammurabi," the great law-giver-king of Babylon. His works on the Assyrian language are well known, and as a proficient Semitic scholar his pronouncements on this subject were always worthy of great respect. His real interest, however, lay rather in the elucidation of ancient history by means of the cuneiform inscriptions than in the ancient languages themselves, and a notable contribution to this end is his edition of the Inscriptions of Darius on the Rock of Bisitun (Behistun), which he re-copied and edited, in conjunction with Mr. R. Campbell Thompson, after their joint expedition to the spot on behalf of the British Museum, which was carried out in circumstances of considerable difficulty and hardship. His two more recent works, "The History of Sumer and Akkad" and "The History of Babylon," are the standard histories of those lands in English. It is ever to be regretted that he was not able to bring out the third work of the trilogy he had planned, "The History of Assyria," but the war compelled him to put it by for the time, and then illness stopped all further work. It is to be hoped, however, that he will be found to have left his manuscript sufficiently complete for his publishers to produce the result of his labours.

In his historical books the same clean-cut critical faculty is shown as in his other work. This criticism was welcomed by his friends and fellow-workers in the same and kindred fields, for King's interests were by no means confined to the Land of the Two Rivers. He was keenly interested in Egyptian archæology, but for the study of the hieroglyphs or of Coptic he had no time; the demands of cuneiform were enough for him, for he did all things thoroughly, and never dabbled. In a minor degree the work of his colleagues in the museum on Mycenæan archæology also interested him. His Cambridge training made him somewhat suspicious of the so-called "all-round man"; but he had an interest in all branches of archæology, and read everything that others had written on their several subjects, and his remarks on their work were always of value, and inspired by sound common sense; his comments were always conspicuous for balance and sense of proportion. To other workers in his own field he was always scrupulously courteous and anxious to give credit where it was due; his juniors were always sure to receive their due meed of appreciation and in addition energetic support. He will leave among them a name of happy and grateful memory, while his personal friends feel a very deep and grievous loss. It is always to be regretted that he did not survive to receive the honour of admission to the British Academy, to mark his signal services to his science in this country.

Rugby, King's College, Cambridge, and the British Museum, not to speak of the University of London, have lost in him one of their most distinguished members. H. R. HALL.

THE BOURNEMOUTH MEETING OF THE BRITISH ASSOCIATION.

WRITING on the day before the opening of the meeting at Bournemouth, it is not possible to give exact figures of the number of members and associates enrolled. The number is approximately one thousand, and steadily increasing. All day the Municipal College has been the scene of great activity, and the officials have had hard work to cope with the rush of applications and inquiries. The figures compare very favourably with those of previous years, and, while no new records are likely to be established, it is believed that the attendance will be in excess of that at any meeting held during the war.

Local enthusiasm has been late in manifesting itself, but has now reached a high pitch. The town's privilege in being the scene of so important and in many respects unique a meeting is at last fully appreciated. The greatest interest is being shown in the proceedings of the Association, and a most cordial welcome extended to the distinguished men of science visiting the town. The citizens' lectures arranged in co-operation with the Workers' Educational Association are also likely to be exceptionally well attended.

The great difficulties of securing accommodation have been successfully met, and the many visitors find the arrangements in every way excellent. The careful organisation of the local executive committee in other directions is in evidence on all sides, and its results meet with the keen appreciation of members and associates.

The weather is fine and warm, a fortunate circumstance in view of the numerous sectional excursions to points of interest in the neighbourhood taking place during the week.

Even at this early hour it is possible to pronounce the Bournemouth meeting a decided success.

(*Tuesday evening.*)

The weather to-day has been brilliantly fine, and with Bournemouth looking its best the meeting has opened under the happiest conditions.

More than 1200 tickets have been issued, and many fresh applications are still being received. The section lectures and discussions and the excursions to-day were exceedingly well attended. This evening the Winter Gardens Pavilion was crowded by a keenly appreciative audience on the occasion of the president's inaugural address. The attendances are not so large as at certain meetings held before the war, but they are regarded here as most gratifying and quite equal to expectations.

The interest displayed in the citizens' lectures exceeds all anticipation, and the accommodation provided, based on the experience of previous years, has proved quite inadequate. All the tickets have been disposed of, and large numbers of intending auditors have been disappointed. This points to a useful development of the work of the Association in the future.

All the conditions are exceptionally favourable, and the "Peace" meeting is proving eminently successful in every way.

Prof. W. A. Herdman, who has been general secretary of the Association since 1903, has been elected to fill the office of president for the year 1920–21, beginning with the Cardiff meeting.

INAUGURAL ADDRESS BY THE HON. SIR CHARLES A. PARSONS, K.C.B., M.A., LL.D., D.Sc., F.R.S., PRESIDENT.

THREE years of anxiety and stress have passed since the last meeting of the British Association. The weight of the struggle which pressed heavily upon us at the time of the Newcastle meeting in 1916 had increased so much in intensity by the spring of 1917 that the council, after consultation with the local committee at Bournemouth, finally decided to cancel the summer meeting of that year. This was the first time in the history of the association that an annual meeting was not held.

We all rejoice to feel that the terrible ordeal through which the whole Empire has been passing has now reached its final phases, and that during the period of reorganisation, social and industrial, it is possible to resume the annual meetings of the association under happier conditions. We have gladly and with much appreciation accepted the renewed invitation of our friends and colleagues at Bournemouth.

We are gathered together at a time when, after a great upheaval, the elemental conditions of organisation of the world are still in flux, and we have to consider how to influence and mould the recrystallisation of these elements into the best forms and most economic rearrangements for the benefit of civilisation. That the British Association is capable of exerting a great influence in guiding the nation towards advancement in the sciences and arts in the most general sense there can be no question, and of this we may be assured by a study of its proceedings in conjunction with the history of contemporary progress. Although the British Association cannot claim any paramount prerogative in this good work, yet it can certainly claim to provide a free arena for discussion where in the past new theories in science, new propositions for beneficial change, new suggestions for casting aside fetters to the advancement in science, art, and economics have first seen the light of publication and discussion.

For more than half a century it has pleaded strongly for the advancement of science and its application to the arts. In the yearly volume for 1855 will be found a report in which it is stated that:—"The objects for which the association was established have been carried out in three ways: First, by requisitioning and printing reports on the present state of different branches of science; secondly, by granting sums of money to small committees or individuals, to enable them to carry on new researches; and thirdly, by recommending the Government to undertake expeditions of discovery, or to make grants of money for certain and national purposes, which were beyond the means of the association." As a matter of fact it has, since its commencement, paid out of its own funds upwards of 80,000*l*. in grants of this kind.

Developments Prior to the War.

It is twenty-nine years since an engineer, Sir Frederick Bramwell, occupied this chair and discoursed so charmingly on the great importance of the next-to-nothing, the importance of looking after little things which, in engineering, as in other walks of life, are often too lightly considered.

The advances in engineering during the last twenty years are too many and complex to allow of their description, however short, being included in one address, and, following the example of some of my predecessors in this chair, I shall refer only to some of the most important features of this wide subject. I feel that I cannot do better than begin by quoting from a speech made recently by Lord Inchcape, when speaking on the question of the nationalisation of coal:—"It is no exaggeration to say that coal has been the maker of modern Britain, and that those who discovered and developed the methods of working it have done more to determine the bent of British activities and the form of British society than all the Parliaments of the past hundred and twenty years."

James Watt.—No excuse is necessary for entering upon this theme, because this year marks the hundredth anniversary of the death of James Watt, and in reviewing the past it appears that England has gained her present proud position by her early enterprise and by the success of the Watt steam-engine, which enabled her to become the first country to develop her resources in coal, and led to the establishment of her great manufactures and her immense mercantile marine.

The laws of steam which James Watt discovered are simply these:—That the latent heat is nearly constant for different pressures within the ranges used in steam-engines, and that, consequently, the greater the steam pressure and the greater the range of expansion, the greater will be the work obtained from a given amount of steam. Secondly, as may now seem to us obvious, that steam from its expansive force will rush into a vacuum. Having regard to the state of knowledge at the time, his conclusions appear to have been the result of close and patient reasoning by a mind endowed with extraordinary powers of insight into physical questions, and with the faculty of drawing sound practical conclusions from numerous experiments devised to throw light on the subject under investigation. His resource, courage, and devotion were extraordinary.

In commencing his investigations on the steam-engine he soon discovered that there was a tremendous loss in the Newcomen engine, which he thought might be remedied. This was the loss caused by condensation of the steam on the cold metal walls of the cylinder. He first commenced by lining the walls with wood, a material of low thermal conductivity. Though this improved matters, he was not satisfied; his intuition probably told him that there should be some better solution of the problem, and doubtless he made many experiments before he realised that the true solution lay in a condenser separate from the cylinder of the engine. It is easy after discovery to say, "How obvious and how simple," but many of us here know how difficult is any step of advance when shrouded by unknown surroundings, and we can well appreciate the courage and the amount of investigation necessary before James Watt thought himself justified in trying the separate condenser. But to us now, and to the youngest student who knows the laws of steam as formulated by Carnot, Joule, and Kelvin, the separate condenser is the obvious means of constructing an economical condensing engine.

Watt's experiments led him to a clear view of the great importance of securing as much expansion as possible in his engines. The materials and appliances for boiler and machine construction were at that time so undeveloped that steam pressures were practically limited to a few pounds above atmospheric pressure. The cylinders and pistons of his engines were not constructed with the facility and accuracy to which we are now accustomed, and chiefly for these reasons expansion ratios of from twofold to threefold were the usual practice. Watt had given to the world an engine which consumed from five to seven pounds of coal per horse-power hour, or one-quarter of the fuel previously used by any engine. With this consumption of fuel its field under the conditions prevailing at the time was practically unlimited. What need was there, therefore, for commercial reasons, to endeavour still further to improve the engine at the risk of encountering fresh difficulties and greater commercial embarrassments? The course was rather for him and his partners to devote all their energy to extend the adoption of the engine as it stood, and this they did, and to the Watt engine, consuming from five to seven pounds of coal per horse-power, mankind owes the greatest permanent advances in material welfare recorded in history.

With secondary modifications, it was the prime mover in most general use for eighty years, *i.e.* until the middle of last century. It remained for others to carry the expansion of steam still further in the compound, triple, and, lastly, in the quadruple expansion engine, which is the most economical reciprocating engine of to-day.

Watt had considered the practicability of the turbine. He writes to his partner, Boulton, in 1784:—"The whole success of the machine depends on the possibility of prodigious velocities. In short, without God makes it possible for things to move them one thousand feet per second, it cannot do us much harm." The advance in tools of precision, and a clearer knowledge of the dynamics of rotating bodies, have now made the speeds mentioned by Watt feasible, and, indeed, common, everyday practice.

Turbines.—The turbine of to-day carries the expansion of steam much further than has been found possible in any reciprocating engine, and owing to this property it has surpassed it in the economy of coal, and it realises to the fullest extent Watt's ideal of the expansion of steam from the boiler to the lowest vapour pressure obtainable in the condenser.

Among the minor improvements which in recent years have conduced to a higher efficiency in turbines are the more accurate curvature of the blades to avoid eddy losses in the steam, the raising of the peripheral velocities of the blades to nearly the velocity of the steam impinging upon them, and details of construction to reduce leakages to a minimum. In turbines of 20,000–30,000 h.p., 82 per cent. of the available energy in the steam is now obtainable as brake-horse-power; and with a boiler efficiency of 85 per cent. the thermodynamic efficiency from the fuel to the electrical output of the alternator has reached 23 per cent., and shortly may reach 28 per cent., a result rivalling the efficiency of internal-combustion engines worked by producer-gas.

During the twenty years immediately preceding the war turbo-generators had increased in size from

500 kilowatts to 25,000 kilowatts, and the consumption of steam had fallen from 17 lb. per kw.-hour to 10·3 lb. per kw.-hour. Turbines have become the recognised means of generating electricity from steam on a large scale, although they have not superseded the Watt engine for pumping mines or the drawing of coal, except in so far as it is a means for generating electricity for these purposes. In the same period the engine-power in the mercantile marine had risen from 3900 of the *King Edward* to 75,000 of the *Mauretania*.

As regards the Royal Navy, the engine-power of battleships prior to the war had increased from 12,000 i.h.p. to 30,000 s.h.p., while the speed advanced from 17 knots to 23 knots, and during the war, in ships of the *Queen Elizabeth* class, the power amounted to 75,000 s.h.p., with a speed of 25 knots. In cruisers similar advances were made The i.h.p. of the *Powerful* was 25,000, while the s.h.p. of the *Queen Mary* was 78,000, with a speed of 28 knots. During the war the power obtained with geared turbines in the *Courageous* class was 100,000 s.h.p., with a speed of 32 knots, the maximum power transmitted through one gear-wheel being 25,000 h.p., and through one pinion 15,500 h.p.; while in destroyers speeds up to 39 knots have been obtained. The aggregate horse-power of war and mercantile turbined vessels throughout the world is now about 35,000,000.

These advances in power and speed have been made possible mainly by the successive increase in economy and diminution of weight derived from the replacement of reciprocating engines by turbines direct-coupled to the propellers, and later by the introduction of reduction gearing between the turbines and the propellers; also by the adoption of water-tube boilers and of oil-fuel. With these advances the names of Lord Fisher, Sir William White, and Sir Henry Oram will always be associated.

The Work of Sir William White.—With the great work of the Royal Navy fresh in our minds, we cannot but recall the prominent part taken by the late Sir William White in its construction. His sudden death, when president-elect for 1913, lost to the nation and to the association the services of a great naval architect who possessed remarkable powers of prevision and dialectic. He was Chief Constructor to the Admiralty from 1885 to 1901, and largely to him was due the efficiency of our vessels in the great war.

White often referred to the work of Brunel as the designer of the *Great Eastern*, and spoke of him as the originator of the cellular construction of the bottoms of ships, since universally adopted, as a means of strengthening the hull and for obtaining additional safety in case of damage. Scott Russell was the builder of this great pioneer vessel, the forerunner of the Atlantic liners, and the British Association may rightly feel satisfaction in having aided him when a young man by pecuniary grants to develop his researches into the design and construction of ships and the wave-line form of hull which he originated, a form of special importance in paddle-wheel vessels.

So much discussion has taken place in the last four years as to the best construction of ship to resist torpedo attacks that it is interesting to recall briefly at the present time what was said by White in his Cantor lectures to the Royal Society of Arts in 1906:—"Great attention has been bestowed upon means of defence against underwater torpedo attacks. From the first introduction of torpedoes it was recognised that extreme watertight subdivision in the interior of warships would be the most important means of defence. Experiments have been made with triple watertight skins forming double cellular sides, the compartments nearest the outer bottom being filled, in some cases, with water, coal, cellulose, or other materials. Armour-plating has been used both on the outer bottom and on inner skins." He also alludes to several Russian ships which were torpedoed by the Japanese, and he concludes by saying:—"Up to date the balance of opinion has favoured minute watertight subdivisions and comparatively thin watertight compartments, rather than the use of internal armour, the use of which, of course, involves large expenditure of weight and cost."

The present war has most amply confirmed his views and conclusions, then so lucidly and concisely expressed.

While on the subject of steamships, it may perhaps be opportune to say one word as to their further development. The size of ships had been steadily increasing up to the time of the war, resulting in a reduction of power required to propel them per ton of displacement. On the other hand, thanks to their greater size and more economical machinery, speeds have been increased when the traffic has justified the greater cost. The limiting factor to further increase in size is the depth of water in the harbours. With this restriction removed there is no obstacle to building ships up to 1000 ft. in length or more, provided the volume and character of the traffic are such as to justify the capital outlay.

Tungsten Steel.—Among other important pre-war developments that have had a direct bearing upon the war, mention should be made of the discovery and extensive use of alloys of steel. The wonderful properties conferred upon steel by the addition of tungsten were discovered by Muschet in 1868, who has not been sufficiently credited with his share in making the Bessemer process a practical success, and later this alloy was investigated and improved by Maunsel White and Taylor, of Philadelphia. The latter showed that the addition of tungsten to steel has the following effect:—That after the steel has been quenched at a very high temperature near its melting point, it can be raised to a much higher temperature than is possible with ordinary carbon tool-steel without losing its hardness and power of cutting metal. In other words, it holds the carbon more tenaciously in the hardened state, and hence tungsten-steel tools, even when red-hot, can cut ordinary mild steel. It has revolutionised the design of machine tools, and has increased the output on heavy munition work by 100 per cent., and in ordinary engineering by 50 per cent.

The alloys of steel and manganese with which Sir Robert Hadfield's name is associated have proved of utility in immensely increasing the durability of railway and tramway points and crossings, and for the hard teeth of machinery for the crushing of stone and other materials, and, in fact, for any purposes where great hardness and strength are essential.

Investigation of Gaseous Explosions.—Brief reference must also be made—and it will be gratifying to do so—to the important work of one of the committees of the British Association appointed in 1908, under the chairmanship of the late Sir William Preece, for the investigation of gaseous explosions, with special reference to temperature. The investigations of the committee are contained in seven yearly reports up to 1914. Of the very important work of the committee I wish to refer to one investigation in particular, which has proved to be a guiding star to the designers and manufacturers of internal-combustion engines in this country. The members of the committee more directly associated with this particular investigation were Sir Dugald Clerk, Prof. Callendar, and the late Prof. Bertram Hopkinson.

The investigation showed that the intensity of the heat radiated by the incandescent gases to the walls of the cylinder of a gas-engine increases with the size of the cylinder, the actual rate of this increase being approximately proportional to the square root of the depth of the radiating incandescent gas; the intensity was also shown to increase rapidly with the richness of the gas. It suffices now to say that the heat in a large cylinder with a rich explosive mixture is so intense that the metal eventually cracks. The investigation shows why this occurs, and by doing so has saved enormous sums to the makers of gas- and oil-engines in this country, and has led them to avoid the large cylinder, so common in Germany before the war, in favour of a multiplicity of smaller cylinders.

Science and the War.

In coming to this section of my address I am reminded that in the course of his presidential address to Section G, in 1858, Lord Rosse said:—"Another object of the Mechanical Section of the association has been effected—the importance of engineering science in the service of the State has been brought more prominently forward. There seems, however, something still wanting. Science may yet do more for the Navy and Army if more called upon."

Comparatively recently, too, Lord French remarked: "We have failed during the past to read accurately the lessons as regards the fighting of the future which modern science and invention should have taught us."

In view of the eminent services which men of science have rendered during the war, I think that we may be justified in regarding the requirement stated by Lord Rosse as having at last been satisfied, and also in believing that such a criticism as Lord French rightly uttered will not be levelled against the country in the future.

Though British men of science had not formerly been adequately recognised in relation to war and the safety of their country, yet at the call of the sailors and the soldiers they whole-heartedly, and with intense zeal, devoted themselves to repair the negligence of the past, and to apply their unrivalled powers and skill to encounter and overcome the long-standing machinations of the enemy. They worked in close collaboration with the men of science of the Allied nations, and eventually produced better war material, chemicals, and apparatus of all kinds for vanquishing the enemy and the saving of our own men than had been devised by the enemy during many years of preparation planned on the basis of a total disregard of treaties and the conventions of war.

Four years is too short a time for much scientific invention to blossom to useful maturity, even under the forced exigencies of war and Government control. It must be remembered that in the past the great majority of new discoveries and inventions of merit have taken many years—sometimes generations—to bring them into general use. It must also be mentioned that in some instances discoveries and inventions are attributable to the general advance in science and the arts which has brought within the region of practical politics an attack on some particular problem. So the work of the men of science during the war has perforce been directed more to the application of known principles, trade knowledge, and properties of matter to the waging of war than to the making of new and laborious discoveries; though, in effecting such applications, inventions of a high order have been achieved some of which promise to be of great usefulness in time of peace.

The advance of science and the arts in the last century had, however, wrought a great change in the implements of war. The steam-engine, the internal-combustion engine, electricity, and the advances in metallurgy and chemistry had led to the building up of immense industries which, when diverted from their normal uses, have produced unprecedented quantities of war material for the purposes of the enormous armies, and also for the greatest Navy which the world has ever seen.

The destructive energy in the field and afloat has multiplied many hundredfold since the time of the Napoleonic wars; both before and during the war the size of guns and the efficiency of explosives and shell increased immensely, and many new implements of destruction were added. Modern science and engineering enabled armies unprecedented in size, efficiency, and equipment to be drawn from all parts of the world and to be concentrated rapidly in the fighting line.

To build up the stupendous fighting organisation, ships have been taken from their normal trade routes, locomotives and material from the home railways, the normal manufactures of the country have been largely diverted to munitions of war; the home railways, tramways, roads, buildings and constructions, and material of all kinds have been allowed to depreciate. The amount of depreciation in roads and railways alone has been estimated at 400,000,000*l.* per annum at present prices. Upon the community at home a very great and abnormal strain has been thrown, notwithstanding the increased output per head of the workers derived from modern methods and improved machinery. In short, we have seen for the first time in history nearly the whole populations of the principal contending nations enlisted in intense personal and collective effort in the contest, resulting in unprecedented loss of life and destruction of capital.

A few figures will assist us to realise the great difference between this war and all preceding wars. At Waterloo, in 1815, 9044 artillery rounds were fired, having a total weight of 37·3 tons, while on one day during the last offensive in France, on the British front alone, 943,837 artillery rounds were fired, weighing 18,080 tons—more than 100 times the number of rounds, and nearly 540 times the weight of projectiles. Again, in the whole of the South African War 273,000 artillery rounds were fired, weighing approximately 2800 tons; while during the whole war in France, on the British front alone, more than 170,000,000 artillery rounds were fired, weighing nearly 3,500,000 tons—622 times the number of rounds, and about 1250 times the weight of projectiles.

However great these figures in connection with modern land artillery may be, they become almost insignificant when compared with those in respect of a modern naval battle squadron. The *Queen Elizabeth* when firing all her guns discharges 18 tons of metal and develops 1,870,000 foot-tons of energy. She is capable of repeating this discharge once every minute, and when doing so develops by her guns an average of 127,000 effective h.p., or more than one-and-a-half times the power of her propelling machinery; and this energy is five times greater than the maximum average energy developed on the Western Front by British guns. Furthermore, if all her guns were fired simultaneously, they would for the instant be developing energy at the rate of 13,132,000 h.p. From these figures we can form some conception of the vast destructive energy developed in a modern naval battle.

Engineering and the War.

With regard to the many important engineering developments made during the war, several papers by authorities are announced in the syllabus of papers constituting the sectional proceedings of this year's meeting. Among them are "Tanks," by Sir Eustace d'Eyncourt; "Scientific Progress of Aviation during the War," by L. Bairstow; "Airships," by Lt.-Col. Cave-Brown-Cave; "Directional Wireless, with Special Reference to Aircraft," by Capt. Robinson; "Wireless in Aircraft," by Major Erskine Murray; "Wireless Telegraphy during the First Three Years of the War," by Major Vincent Smith; "Submarine Mining," by Comdr. Gwynne; "Emergency Bridge Construction," by Prof. Ingles; and "The Paravane," by Comdr. Burney. Accordingly, it is quite unnecessary here to particularise further except in the few following instances:—

Sound-ranging and Listening Devices.—Probably the most interesting development during the war has been the extensive application of sound-listening devices for detecting and localising the enemy. The Indian hunter puts his ear to the ground to listen for the sound of the footsteps of his enemy. So in modern warfare science has placed in the hands of the sailor and soldier elaborate instruments to aid the ear in the detection of noises transmitted through earth, water, air, or æther, and also in some cases to record these sounds graphically or photographically, so that their character and the time of their occurrence may be tabulated.

The sound-ranging apparatus developed by Prof. Bragg and his son, by which the position of an enemy gun can be determined from electrically recorded times at which the sound-wave from the gun passes over a number of receiving stations, has enabled our artillery to concentrate their fire on the enemy's guns, and often to destroy them.

The French began experimenting in September, 1914, with methods of locating enemy guns by sound. The English section began work in October, 1915, adopting the French methods in the first instance. By the end of 1916 the whole front was covered, and sound-ranging began to play an important part in the location of enemy batteries. During 1917 locations by sound-ranging reached about 30,000 for the whole Army, this number being greater than that given by any other means of location. A single good set of observations could be relied upon to give the position of an enemy gun to about 50 yards at 7000 yards' range. It could also be carried on during considerable artillery activity.

The apparatus for localising noises transmitted through the ground has been much used for the detection of enemy mining and counter-mining operations. Acoustic tubes, microphones, and amplifying valves have been employed to increase the volume of very faint noises.

For many years before the war the Bell Submarine Signalling Co., of which Sir William White was one of the early directors, used submerged microphones for detecting sound transmitted through the water, and a submerged bell for sending signals to distances up to one mile. With this apparatus passing ships could be heard at a distance of nearly a mile when the sea was calm and the listening vessel stationary.

Of all the physical disturbances emitted or produced by a moving submarine, those most easily detected, and at the greatest distance, are the pressure-waves set up in the water by vibrations produced by the vessel and her machinery. A great variety of instruments have been devised during the war for detecting these noises, depending on microphones and magnetophones of exceedingly high sensitivity. Among them may be particularly mentioned the hydrophones devised by Capt. Ryan and Prof. Bragg, being adaptations of the telephone transmitter to work in water instead of air. These instruments, when mounted so as to rotate, are directional, being insensitive to sound-waves the front of which is perpendicular to the plane of the diaphragm, and giving the loudest sound when the diaphragm is parallel to the wave-front.

Another preferable method for determining direction is to use two hydrophones coupled to two receivers, one held to each ear. This is called the biaural method, and enables the listener to recognise the direction from which the sound emanates.

When the vessel is in motion or the sea is rough, the water noises from the dragging of the instrument through the water and from the waves striking the ship drown the noises from the enemy vessel, and under such conditions the instruments are useless. The assistance of eminent biologists was of invaluable help at this juncture. Experiments were made with sea-lions by Sir Richard Paget, who found that they have directional hearing under water up to speeds of six knots. Also Prof. Keith explained the construction of the hearing organs of the whale, the ear proper being a capillary tube, too small to be capable of performing any useful function in transmitting sound to the relatively large aural organs, which are deep set in the head. The whale therefore hears by means of the sound-waves transmitted through the substance of the head. It was further seen that the organs of hearing of the whale to some degree resembled the hydrophone.

The course now became clear. Hollow towing bodies in the form of fish or porpoises were made of celluloid, varnished canvas, or very thin metal, and the hydrophone suitably fixed in the centre of the head. The body is filled with water, and the cable towing the fish contains the insulated leads to the observer on board the vessel. When towed at some distance behind the chasing ship disturbing noises are small, and enemy noises can be heard up to speeds of fourteen knots, and at considerable distances. Thermionic amplifying valves have been extensively used, and have added much to the sensitiveness of the hydrophone in its many forms.

After the loss of the *Titanic* by collision with an iceberg, Lewis Richardson was granted two patents in 1912 for the detection of above-water objects by their echo in the air, and under-water objects by the echo transmitted through the water. The principles governing the production and the concentration of beams of sound are described in the specification, and he recommends frequencies ranging from 4786 to 100,000 complete vibrations per second, and also suggests that the rate of approach or recession from the object may be determined from the difference in the pitch of the echo from the pitch of the blast sent out. Sir Hiram Maxim also suggested similar apparatus a little later.

The echo method of detection was not, however, practically developed until French and English men of science, with whom was associated Prof. Langevin, of the Collége de France, realising its importance for submarine detection, brought the apparatus to a high degree of perfection and utility shortly before the armistice. Now with beams of high-frequency sound-waves it is possible to sweep the seas for the detection of any submerged object, such as icebergs, submarines, surface vessels, and rocks; they may also be used to make soundings. It enables a chasing ship to pick up and close in on a submarine situated more than a mile away.

The successful development of sound-ranging apparatus on land led to the suggestion by Prof. Bragg that a modified form could be used to locate under-water explosions. It has been found that the shock of an explosion can be detected hundreds of miles from its source by means of a submerged hydrophone, and that the time of the arrival of the sound-wave can be recorded with great precision. At the end of the war the sound-ranging stations were being used for the detection of positions at sea required for strategical purposes. The same stations are now being used extensively for the determination of such positions at sea as light-vessels, buoys which indicate channels, and obstructions such as sunken ships. By this means ships steaming in fog can be given their positions with accuracy for ranges up to 500 miles.

Among the many other important technical systems and devices brought out during the war which will find useful application under peace conditions as aids to navigation I may mention directional wireless, by which ships and aircraft can be given their positions and directed, and on this subject we are to have a paper in Section G.

Leader-gear, first used by the Germans to direct their ships through their minefields, and afterwards used by the Allies, consists of an insulated cable laid on the bottom of the sea, earthed at the further end, through which an alternating current is passed. By means of delicate devices installed on a ship, she is able to follow the cable at any speed with as much precision as a railless electric 'bus can follow its trolley-wire. Cables up to fifty miles long have been used, and this device promises to be invaluable to ships navigating narrow and tortuous channels and entering or leaving harbours in a fog.

Aircraft.—It may be justly said that the development in aircraft design and manufacture is one of the astonishing engineering feats of the war. In August, 1914, the British Air Services possessed a total of 272 machines, whereas in October, 1918, just prior to the armistice, the Royal Air Force possessed more than 22,000 effective machines. During the first twelve months of the war the average monthly delivery of aeroplanes to our Flying Service was 50, while during the last twelve months of the war the average deliveries were 2700 per month. So far as aero-engines are concerned, our position in 1914 was by no means satisfactory. We depended for a large proportion of our supplies on other countries. In the Aerial Derby of 1913, of the eleven machines that started, not one had a British engine. By the end of the war, however, British aero-engines had gained the foremost place in design and manufacture, and were well up to requirements as regards supply. The total horse-power produced in the last twelve months of the war approximated to eight millions of brake-horse-power, a figure quite comparable with the total horse-power of the marine-engine output of the country.[1]

Much might be written on the progress in aircraft, but the subject will be treated at length in the sectional papers. In view of the recent trans-Atlantic flight, however, I feel that it may be opportune to make the following observations on the comparative utility of aeroplanes and airships for commercial purposes. In the case of the aeroplane, the weight per horse-power increases with the size, other things being equal. This increase, however, is met to some extent by a multiplicity of engines, though in the fuselage the increase remains.

On the other hand, with the airship the advantage increases with the size, as in all ships. The tractive effort per ton of displacement diminishes in inverse proportion to the dimensions, other things, including the speed, being the same. Thus an airship of 750 ft. length and 60 tons displacement may require a tractive force of 5 per cent., or 3 tons, at 60 miles per hour; and one of 1500 ft. in length and $8\times60=480$ tons displacement would require only $2\frac{1}{2}$ per cent. $\times$ $480=12$ tons at the same speed, and would carry fuel for double the distance.

With the same proportion of weight of hull to displacement, the larger airship would stand double the wind-pressure, and would weather storms of greater violence and hailstones of greater size. It would be more durable, the proportional upkeep would be less, and the proportional loss of gas considerably less. In other words, it would lose a less proportion of its buoyancy per day. It is a development in which success depends upon the project being well thought out and the job being thoroughly well done. The equipment of the airsheds with numerous electric haulage winches, and all other appliances to make egress and ingress to the sheds safe from danger and accident, must be ample and efficient.

The airship appears to have a great future for special commerce where time is a dominant factor and the demand is sufficient to justify a large airship. It has also a great field in the opening up of new countries where other means of communication are difficult. The only limitation to size will be the cost of the airship and its sheds, just as in steam-vessels it is the cost of the vessels and the cost of deepening the harbours that limit the size of Atlantic liners.

Such developments generally take place slowly, otherwise failures occur—as in the case of the *Great Eastern*—and it may be many years before the airship is increased from the present maximum of 750 ft. to 1500 ft. with success, but it will assuredly come. If, however, the development is subsidised or assisted by the Government, incidental failures may be faced with equanimity and very rapid development accomplished.[2] In peace-time the seaplane, aeroplane, and airship will most certainly have their uses. But, except for special services of high utility, it is questionable whether they will play more than a minor part as compared with the steamship, railway, and motor transport.

Electricity.—The supply and use of electricity has developed rapidly in recent years. For lighting it is the rival of gas, though each has its advantages. As a means of transmitting power over long distances it has no rival, and its efficiency is so high that, when generated on a large scale and distributed over large areas, it is a cheap and trustworthy source of power for working factories, tramways, suburban railways, and innumerable other purposes, including metallurgical and chemical processes. It is rapidly superseding locally generated steam-power, and is a rival to the small- and moderate-sized gas and oil engines. It has made practicable the use of water-power through the generation of electricity in bulk at the natural falls, from which the power is transmitted to the consumers, sometimes at great distances.

Fifteen years ago electricity was generated chiefly by large reciprocating steam-engines, direct-coupled to dynamos or alternators, but of late years steam turbines have in most instances replaced them, and are now exclusively used in large generating stations because of their smaller cost and greater economy in fuel. The size of the turbines may vary from a few thousand horse-power up to about 50,000 h.p. At the end of last year the central electric stations in the United Kingdom contained plant aggregating 2,750,000 kilowatts, 79 per cent. of which was driven by steam turbines.

Much discussion has taken place as to the most economical size of generating stations, their number,

[1] See Lord Weir's Paper read at the Victory Meeting of the North-East Coast Institution of Engineers and Shipbuilders, July, 1919.

[2] The literature on this subject includes an article which appeared in *Engineering* on January 3, 1919.

the size of the generating units, and the size of the area to be supplied. On one hand, a comparatively small number of very large or super-stations, instead of a large number of moderate-sized stations dotted over the area, results in a small decrease in the cost of production of the electricity, because in the super-stations larger and slightly more economical engines are employed, while the larger stations permit of higher organisation and more elaborate labour-saving appliances. Further, if in the future the recovery of the by-products of coal should become a practical realisation as part of the process in the manufacture of the electric current, the larger super-stations present greater facilities than the smaller stations. On the other, super-stations involve the transmission of the electricity over greater distances, and consequently greater capital expenditure and cost of maintenance of mains and transmission apparatus, and greater electrical transmission losses, while the larger generating unit takes longer to overhaul or repair, and consequently a larger percentage of spare plant is necessary.

The greatest element in reducing the cost of electricity is the provision of a good load factor; in other words, the utilisation of the generating plant and mains to the greatest extent during the twenty-four hours of each day throughout the year. This is a far more important consideration than the size of the station, and it is secured to the best advantage in most cases by a widespread network of mains, supplying a diversity of consumers and users, each requiring current at different times of the day. The total load of each station being thus an average of the individual loads of a number of consumers is, in general, far less fluctuating than in the case of small generating and distributing systems, which supply principally one class of consumer—a state of affairs that exists in London, for instance, at the present time. It is true that there may be exceptional cases, such as at Kilmarnock, where a good load factor may be found in a small area, but in this case the consumers are chiefly mills, which require current for many hours daily.

There is no golden rule to secure cheap electricity. The most favourable size, locality, and number of generating stations in each area can only be arrived at by a close study of the local conditions, but there is no doubt that, generally speaking, to secure cheap electricity a widespread network of mains is in most cases a very important, if not an essential, factor.

The electrification of tramways and suburban railways has been an undoubted success where the volume of traffic has justified a frequent service, and it has been remarkable that where suburban lines have been worked by frequent and fast electrical trains there has resulted a great growth of passenger traffic. The electrification of main-line railways would no doubt result in a saving of coal; at the same time, the economical success would largely depend on the broader question as to whether the volume of the traffic would suffice to pay the working expenses and provide a satisfactory return on the capital.

Municipal and company generating stations have been nearly doubled in capacity during the war to meet the demand from munition works, steel works, chemical works, and for many other purposes. The provision of this increased supply was an enormous help in the production of adequate munitions. At the commencement of the war there were few steel electric furnaces in the country; at the end of last year 117 were at work, producing 20,000 tons of steel per month, consisting chiefly of high-grade ferro alloys used in munitions.

The Future.

The nations which have exerted the most influence in the war have been those which have developed to the greatest extent their resources, their manufactures, and their commerce. As in the war, so in the civilisation of mankind. But, viewing the present trend of developments in harnessing water-power and using up the fuel resources of the world for the use and convenience of man, one cannot but realise that, failing new and unexpected discoveries in science, such as the harnessing of the latent molecular and atomic energy in matter, as foreshadowed by Clerk Maxwell, Kelvin, Rutherford, and others, the great position of England cannot be maintained for an indefinite period. At some time more or less remote—long before the exhaustion of our coal—the population will gradually migrate to those countries where the natural sources of energy are the most abundant.

Water-power and Coal.—The amount of available water-power in the British Isles is very small as compared with the total in other countries. According to the latest estimates, the total in the British Isles is less than 1,500,000 h.p., whereas Canada alone possesses more than 20,000,000 h.p., of which more than 2,000,000 h.p. have already been harnessed. In the rest of the British Empire there are upwards of 30,000,000 h.p., and in the remainder of the world at least 150,000,000 h.p., so that England herself possesses less than 1 per cent. of the water-power of the world. Further, it has been estimated that she only possesses 2½ per cent. of the whole coal of the world. To this question I would wish to direct our attention for a few minutes.

I have said that England owes her modern greatness to the early development of her coal. Upon it she must continue to depend almost exclusively for her heat and source of power, including that required for propelling her vast mercantile marine. Nevertheless, she is using up her resources in coal much more rapidly than most other countries are consuming theirs, and long before any near approach to exhaustion is reached her richer seams will have become impoverished, and the cost of mining so much increased that, given cheap transport, it might pay her better to import coal from richer fields of almost limitless extent belonging to foreign countries, and workable at a much lower cost than her own.

Let us endeavour to arrive at some approximate estimate of the economic value of the principal sources of power. The present average value of the royalties on coal in England is about 6*d.* per ton, but to this must be added the profit derived from mining operations after paying royalties and providing for interest on the capital expended and for its redemption as wasting capital. After consultation with several leading experts in these matters, I have come to the conclusion that about 1*s.* per ton represents the pre-war market value of coal in the seams in England.

It must, however, be remembered that, in addition, coal has a considerable value as a national asset, for on it depends the prosperity of the great industrial interests of the country, which contribute a large portion of the wealth and revenue. From this point of view the present value of unmined coal seems not to have been sufficiently appreciated in the past, and that in the future it should be better appraised at its true value to the nation.

This question may be viewed from another aspect by making a comparison of the cost of producing a given amount of electrical power from coal and from water-power. Assuming that 1 h.p. of electrical energy maintained for one year had a pre-war value of 5*l.*, and that it requires about eight tons of average coal to produce it, we arrive at the price of 6s. 3d. per ton, *i.e.* crediting the coal with half the cost. The capital required to mine eight tons of coal a year in England is difficult to estimate, but it may be taken approximately to be 5l., and the capital for plant and machinery to convert it into electricity at 10l., making a total of 15l. In the case of water-power the average capital cost on the above basis is 40l., including water rights (though in exceptionally favoured districts much lower costs are recorded).

From these figures it appears that the average capital required to produce electrical power from coal is less than half the amount that is required in the case of water-power. The running costs, however, in connection with water-power are much less than those in respect of coal. Another interesting consideration is that the cost of harnessing all the water-power of the world would be about 8,000,000,000l., or equal to the cost of the war to England.

Dowling has estimated the total coal of the world as more than seven million million tons, and whether we appraise it at 1s. or more per ton its present and prospective value is prodigious. For instance, at 6s. 3d. per ton it amounts to nearly one hundred times the cost of the war to all the belligerents.

In some foreign countries the capital costs of mining are far below the figures I have taken, and, as coal is transportable long distances and, generally speaking, electricity is not so at present, therefore it seems probable that capital will in the immediate future flow in increasing quantity to mining operations in foreign countries rather than to the development of, at any rate the more difficult and costly, water-power schemes. When, however, capital becomes more plentiful the lower running costs of water-power will prevail, with the result that water-power will then be rapidly developed.

As to the possible new sources of power, I have already mentioned molecular energy, but there is another alternative which appears to merit attention.

Bore Hole.—In my address to Section B in 1904 I discussed the question of sinking a shaft to a depth of twelve miles, which is about ten times the depth of any shaft in existence. The estimated cost was 5,000,000l., and the time required about eighty-five years.

The method of cooling the air-locks to limit the barometric pressure on the miners and other precautions were described, and the project appeared feasible. One essential factor has, however, been queried by some persons: Would the rock at the great depth crush in and destroy the shaft? Subsequent to my address I wrote a letter to NATURE, suggesting that the question might be tested experimentally. Prof. Frank D. Adams, of McGill University, Montreal, acting on the suggestion, has since carried out exhaustive experiments, published in the *Journal of Geology* for February, 1912, showing that in limestone a depth of fifteen miles is probably practicable, and that in granite a depth of thirty miles might be reached.

Little is at present known of the earth's interior, except by inference from a study of its surface, upturned strata, shallow shafts, the velocity of transmission of seismic disturbances, its rigidity and specific gravity, and it seems reasonable to suggest that some attempt should be made to sink a shaft as deep as may be found practicable and at some locality selected by geologists as the most likely to afford useful information.

When we consider that the estimated cost of sinking a shaft to a depth of twelve miles, at present-day prices, is not much more than the cost of one day of the war to Great Britain alone, the expense seems trivial as compared with the possible knowledge that might be gained by an investigation into this unexplored region of the earth. It might, indeed, prove of inestimable value to science, and also throw additional light on the internal constitution of the earth in relation to minerals of high specific gravity.

In Italy, at Lardarello, bore-holes have been sunk which discharge large volumes of high-pressure steam, which is being utilised to generate about 10,000 h.p. by turbines. At Solfatara, near Naples, a similar project is on foot to supply power to the great works in the district. It seems, indeed, probable that in volcanic regions a very large amount of power may be, in the future, obtained directly or indirectly by boring into the earth, and that the whole subject merits the most careful consideration.

While on the subject of obtaining power, may I digress for a few moments and describe an interesting phenomenon of a somewhat converse nature, *i.e.* that of intense pressure produced by moderate forces closing up cavities in water?

A Committee was appointed by the Admiralty in 1916 to investigate the cause of the rapid erosion of the propellers of some of the ships doing arduous duties. This was the first time that the problem had been systematically considered. The Committee found that the erosion was due to the intense blows struck upon the blades of the propellers by the nuclei of vacuous cavities closing up against them. Though the pressure bringing the water together was only that of the atmosphere, yet it was proved that at the nucleus 20,000 atmospheres might be produced.

The phenomenon may be described as being analogous to the well-known fact that nearly all the energy of the arm that swings it is concentrated in the tag of a whip. It was shown that when water flowed into a conical tube which had been evacuated a pressure of more than 140 tons per square inch was recorded at the apex, which was capable of eroding brass, steel, and, in time, even the hardest steel. The phenomenon may occur under some conditions in rivers and waterfalls where the velocity exceeds 50 ft. per second, and it is probably as great a source of erosion as by the washing down of boulders and pebbles Then again, when waves beat on a rocky shore, under some conditions, intense hydraulic pressures will occur, quite sufficient of themselves to crush the rock and to open out narrow fissures into caves.

Research.—The whole question of the future resources of the Empire is, I venture to think, one which demands the serious attention of all men of science. It should be attacked in a comprehensive manner, and with that insistence which has been so notable in connection with the efforts of British investigators in the past. In such a task some people might suggest we need encouragement and assistance from the Government of the country. Surely we have it. As many here know, a great experimental step towards the practical realisation of Solomon's House as prefigured by Francis Bacon in the *New Atlantis* is being made by the Government at the present time. The inception, constitution, and methods of procedure of the Department, which was constituted in 1915, were fully described by Sir Frank Heath in his paper to the Royal Society of Arts last February, and it was there stated by Lord Crewe that, so far as he knew, this was the only country in which a Government Department of Research existed.[3]

It is obvious that the work of a Department of this kind must be one of gradual development with small beginnings in order that it may be sound and

[3] The Italian Government are now establishing a National Council for Research, and a Bill is before the French Chamber for the establishment of a National Office of Scientific, Industrial, and Agricultural Research and Inventions.

lasting. The work commenced by assisting a number of researches conducted by scientific and professional societies which were languishing as a result of the war, and grants were also made to the National Physical Laboratory and to the Central School of Pottery at Stoke-on-Trent. The grants for investigation and research for the year 1916–17 totalled 11,055*l*., and for the present year are anticipated to be 93,570*l*. The total income of the National Physical Laboratory in 1913–14 was 43,713*l*., and, owing to the great enlargement of the laboratory, the total estimate of the Research Department for this service during the current year is 154,650*l*.

Another important part of the work of the Department has been to foster and to aid financially associations of the trades for the purpose of research. Nine of these associations are already at work; eight more are approved, and will probably be at work within the next two months; and another twelve are in the earlier stage of formation. There are also signs of great increase of research by individual factories. Whether this is due to the indirect influence of the Research Department or to a change in public opinion and a more general recognition of the importance of scientific industrial research it is difficult to say.

The possibility of the uncontrolled use on the part of a nation of the power which science has placed within its reach is so great a menace to civilisation[4] that the ardent wish of all reasonable people is to possess some radical means of prevention through the establishment of some form of wide and powerful control. Has not science forged the remedy by making the world a smaller arena for the activities of civilisation, by reducing distance in terms of time? Alliances and unions, which have successfully controlled and stimulated republics of heterogeneous races during the last century, will therefore have become possible on a wider and grander scale, thus uniting all civilised nations in a great league to maintain order, security, and freedom for every individual and for every State and nation liberty to devote their energies to the controlling of the great forces of Nature for the use and convenience of man, instead of applying them to the killing of each other.

Many of us remember the president's banner at the Manchester meeting in 1915, where Science is allegorically represented by a sorrowful figure covering her eyes from the sight of the guns in the foreground. This year Science is represented in her more joyful mien, encouraging the arts and industries. It is to be sincerely hoped that the future will justify our present optimism.

SUMMARIES OF ADDRESSES OF PRESIDENTS OF SECTIONS.

Agriculture.

IN his address to Section M, Prof. Somerville pointed out that during the war the area of land in the United Kingdom under grass was reduced by more than three million acres, with a corresponding increase of the area under tillage crops. Even were this increase of cultivated land maintained there would still remain more than 30 million acres under permanent and temporary grass, exclusive of about 16 million acres of mountain land used for grazing. Several attempts have been made to discover a relationship between the botanical composition and the feeding properties of permanent pastures, but the results have been largely negative; neither has it been possible by chemical analysis to differentiate between grass of poor and of high quality. The only trustworthy test of quality that can be applied would appear to be through the agency of animals consuming the produce of the meadows or pasturing the fields. This work was initiated at Cockle Park in Northumberland in 1897, and has been extended to some twenty other experimental stations in various parts of the United Kingdom and in New Zealand. It has been conclusively proved that poor grass land is susceptible of rapid and profitable improvement, especially through the agency of phosphates. In many cases the stock-carrying capacity of land has been more than doubled, while the progress of the individual animals has also been largely increased, so that the output of meat or milk from land suitably manured has often been trebled or quadrupled with advantage to the nation and substantial profit to the farmer. One conspicuous result of experiments on manuring-for-meat has been the long-continued action of dressings of phosphate, 200 lb. per acre of phosphoric acid in the form of basic slag still producing very marked effects at the end of nine years. Nitrogen, potash, and lime as an addition to phosphates have been tried at several stations, but in most cases with comparatively little effect. Indirect manuring through feeding stock with cake has also given unsatisfactory results.

Research during recent years has been directed towards discovering how the marked improvement secured by an initial dressing of phosphate can be maintained, and it has been found that in no way can the maintenance of fertility of pasture be better secured than by means of supplementary dressings of phosphate.

Anthropology

Prof. Arthur Keith, as president of Section H, devoted his address to "The Differentiation of Mankind into Racial Types." It was maintained that an overwhelming majority of anthropologists were convinced that all varieties of living human races were descendants of a common ancestral stock, and that some varieties had departed less from the original pattern than others. There was no agreement, however, as to how the differentiation had come about. Natural and sexual selection were certainly parts of the evolutionary machinery which had given the Negro, the Chinaman, and the European their distinctive features of face, skull, and body, and also certain characteristics of mind, but it was clear that they did not constitute the whole of the machinery. Nothing was more desired by anthropologists at the present time than a rational explanation of how mankind has come by its racial characteristics.

There were many indications that the key to such problems was to be obtained by a close study of the disturbances or disorders which occasionally affect the development and growth of the human body. The disorders of growth are of many kinds; some are definitely proved to result from a functional derangement of one or more of the glands of internal secretion—the pituitary, thyroid, pineal, adrenal, and genital glands. In a manner which we are only beginning to perceive, the functions carried on in these glands regulate, not only the dimensions of the body, but also the shape and size of each individual part.

The machinery of race differentiation is resident in the growth-controlling glands of the body. The mistake is sometimes made of regarding each gland as carrying on a simple function, whereas each carried on a multitude of functions. Substances contained in the secretion of the pituitary gland not only could affect the size and proportion of the body, but also might pick out and emphasise the growth of one or

[4] For instance, it might some day be discovered how to liberate instantaneously the energy in radium, and radium contains 2,500,000 times the energy of the same weight of T.N.T.

more physiological systems. The same was true of the thyroid. The racial features of the Mongolian type were simulated by growing Europeans who were affected by deficiency disorders of the thyroid gland. The features of the Negro could best be accounted for by the nature of the growth-regulating mechanism centred in the thyroid and suprarenal glands. European features were connected with a dominance in the functions of the pituitary. As we came to understand the machinery of growth, matters which now puzzle us about the differentiation of varieties and species of mankind would disappear.

Botany.

Sir Daniel Morris began his address to Section K by remarking that since the Association met at Newcastle in 1916 there has been decided progress in every branch of science, and also a fuller recognition of the value of science and education as means whereby the material interests of the world may be enlarged. A new branch of botany has lately come into prominence as one of the results of the devotion to nature study and the contemplation of the characteristic features of vegetation as we find it distributed over the world's surface. Ecology is capable of enormously extending the outlook of botany, and it has so largely added to the interest of field work that we may wonder that the phenomenon of vegetation so long displayed before our eyes had not suggested its sociological aspects long ago. It is hoped ecology will mitigate some of the admitted drawbacks of purely laboratory work and revive the old natural history spirit of former days.

Travelling somewhat outside the scope of previous addresses, an attempt was made to summarise the results of the many efforts to promote not only the interests of the homeland, but of the Empire as a whole. The establishment of an Imperial Department of Agriculture in the West Indies, followed by similar highly equipped departments in India and in such tropical colonies as Ceylon, Mauritius, Federated Malay States, Fiji, and in East and West Africa, has greatly advanced scientific research on the applied side in connection with sugar, cotton, indigo, rice, india-rubber, and other important industries. The admirable work done by Biffen at Cambridge and the Howards in India in raising new and improved varieties of wheats clearly demonstrates the value of thorough acquaintance with pure botany as a qualification for grappling with questions of economic importance.

As the result of Biffen's plant-breeding work at Cambridge, new wheats have been produced and grown over extensive areas in the eastern counties that have yielded crops at the rate of 50 to 60 bushels per acre. In one instance an area of a little over twenty-seven acres has yielded 2072 bushels, or an average of 77 bushels per acre. This is to be compared with the average yield of wheat in this country at about 32 bushels per acre. The new wheats are not only more productive, but are less liable to disease, and the quality of the flour is superior to that of ordinary English wheats. In regard to India it is estimated that the Pusa wheats raised by the Howards will shortly be established over five million acres, and it is anticipated that they will bring in an increase in the value of the agricultural produce of India, in one crop only, of 75 lakhs of rupees or five millions sterling.

Henry's researches in regard to hybrid trees and his elaborate investigation into the history of the London plane were generally regarded as valuable contributions to science. It was claimed in the case of many trees that it is possible to produce much greater bulk of timber in a given time; while, according to Dawson, the common belief that quickly grown timbers are of an inferior quality is said not to hold good in respect of any quality in ash, oak, and walnut.

It is widely felt that the most pressing of all investigations at the present time is the study of plant diseases. The recently established Institute for Plant Pathology at Rothamsted may be the means of introducing entirely new methods in mycological investigations.

It was further suggested that all research work should be organised on the broadest possible lines and combine the biological services of the whole Empire. We have a first step in this direction in the Imperial Bureau of Entomology with its headquarters at the British Museum. Those acquainted with the efficient work done by this bureau, and the valuable publications issued by it, will heartily welcome the establishment of the proposed Imperial Bureau of Mycology, at Kew, to carry on work on similar lines.

Chemistry.

The periodic law, of which this year may be regarded as the jubilee of its announcement by Mendeléeff, formed the chief subject of the address in Section B by Prof. P. P. Bedson. After dealing with the inception of this law, its utility as a means of classifying the elements, and the revision of the atomic weights demanded by it, the influence of the discovery of argon, helium, and the allied elements was reviewed, as also the important part that the knowledge of the properties of helium has played in the elucidation of the remarkable properties of radium and other radio-active elements. Some of the speculations as to the composite nature of the elements were described, and allusion was made to the confirmation of such conceptions provided by the investigations of Sir J. J. Thomson on the discharge of electricity through gases. Amongst other matters relating to the elements dealt with in the address are the deductions drawn by the late Lieut. Moseley from the examination of the X-ray spectra of the elements, which make it possible to assign a number to an element, the atomic number, which corresponds with its position in the table of the elements based upon their arrangement in the order of the atomic weights. Further, attention was directed to the remarkable facts brought to light by the investigations in radio-activity, especially the existence of elements which are indistinguishable by chemical properties, yet possess slightly different atomic weights. The concluding section of the address was concerned with some points arising from the work of chemists during the war and the awakening of the public and the Government to the importance of the chemical industries.

Economic Science and Statistics.

In the presidential address to Section F, Sir Hugh Bell reviewed the economic situation brought about by the war. Attention was directed to the extent and nature of the devastation the war has produced and the extinction of vast quantities of the wealth accumulated in the past. He commented upon the light-hearted way in which, not only during the war, but also before its outbreak, the national expenditure had been increased. A distinction was drawn between pre-war expenditure for useful purposes and the absolute waste of the greater part of the war expenditure. The address dealt with the various suggestions which have been made to cope with the situation. It was urged that none of these provides a real remedy which will assist in slowly re-accumulating the wealth which has been destroyed. This, it was contended, is the essential problem of the moment.

Sir Hugh Bell discussed questions of taxation, and distinguished between imposts of a confiscatory character, which are suggested in some quarters, and those which do not fall into this class. He pointed out the difficulties of graduation, though he accepted taxation of this character. He proceeded briefly to sketch the progress of the National Debt for the past hundred years, and to examine the change which has taken place in the foreign investments of the country since the outbreak of war. Claims on the national purse were discussed. The case of housing was dealt with, and also that of the railways. It was urged that both these must be treated from the economic viewpoint, and specially that the railways cannot be allowed to become a charge on the State.

The way in which human activities are applied to production was stated, and an endeavour made to distinguish among these. It was pointed out that the only way in which the desires of various classes can be gratified is by their having something to offer in exchange for these additional gratifications, and the necessity for greater output was insisted upon. Reference was made to the figures disclosed by the Census of Production and the examination of these by Prof. Bowley and Mr. H. G. Williams.

The difficulty of drawing a line between capital and labour was pointed out and the dependence of all classes on capital was stated. Reference was made to the proposals for nationalisation, and the difficulties of any such solution were mentioned. A distinction was drawn between the political freedom acquired within the last hundred years with comparative ease and the economic freedom now sought, which it is maintained will be much less easy to accomplish.

None of the remedies proposed touches the difficulty. We must obtain a larger product if we are to have more to divide. None of the short cuts now proposed will lead us to our goal. Can we convince those most deeply interested of the truth of this? The task is not an easy one, for promises without end are made to accomplish what is desired without pursuing the patient and laborious course which alone can lead to a happy solution.

None of these things can be accomplished by Acts of Parliament. Statutory prices and statutory hours offer no solution—rather increase the evil than lessen it. There is no royal road by which we can travel to a solution. We must by patience and mutual forbearance seek to alter the present hostile attitude.

EDUCATIONAL SCIENCE.

Sir Napier Shaw's address to Section L had for its subject "Educational Ideals and the Ancient Universities." It started from the principle that the character of the education of the country depends upon the ideals which are displayed by the universities, particularly by the ancient Universities of Oxford and Cambridge. It showed that those ideals are confused and indistinct on account of the traditional system of government of the universities and colleges under which the university has no voice in the selection of the students who are to enjoy the privileges of membership. Students are presented to the university by the colleges which hold entrance examinations of their own, or even make use of university examinations for the purpose, while the university itself has no examination for entrance. The control of the university by the colleges impresses the competitive ideal upon the whole system. The position of the university was regarded as being as hard as that of Portia in the lottery of the caskets imposed as a condition by her father's will. The ideals of the universities were reviewed, and found to be splendid so far as the ethical side is concerned, because that depends upon success in fair competition between students and between colleges; but, so far as the intellectual side is concerned, the ideals were found to be vague and unsatisfactory because of the competition between the colleges which is so successful on the social or ethical side. Sir Napier Shaw reached the conclusion that the educational system cannot become ideal until the traditional government is modified in such a way as to give the university, as distinguished from the colleges, more control over its own destiny.

ENGINEERING.

The address of Prof. Petavel to Section G included a brief outline of the part played by engineering during the war and some discussion of the problems involved in industrial and economic reconstruction. The feature of the day is an insistent craving for better and easier conditions of life, and this aim can be attained by increased production. The industrial development obtained during the war by standardisation and systematic organisation, the rapid progress which resulted from the stimulus to research and invention, and the immediate application of the results, indicate the path to be followed. Complete success, however, requires the willing co-operation of all classes of the population, and this can be achieved only if each individual knows that his reward will depend on, and be commensurate with, his efforts.

GEOGRAPHY.

Prof. L. W. Lyde's address to Section E was on "International Rivers," mainly from the political and historical points of view, nearly all international problems to-day being explicitly or implicity dependent on access to the ocean. The word "river" by itself suggests a physical unit, on which a political unit may be appropriate; but the qualifying word "international" suggests regional relations, not local unity. In the United States and Australia it has been found necessary for the Commonwealth to have supreme power over the regulation of the rivers (for irrigation), and no individual State has any local standing or riparian claim against the Commonwealth.

The same principle should hold in Europe for navigation, at least on all important rivers. Freedom of navigation is really dependent on the administration, as has been proved on the Danube between different nations, and on the Rhine between different parts of the same nation, Prussia having persistently hampered the development of other German States. As international rivers are *world*-features, their world-relation is the first consideration, and it demands world-control, *i.e.* control by a body consisting of non-riparian as well as riparian Powers. This is really in the interest also of the *weaker* riparian States, as proved on the Danube.

France has a very honourable record, and Holland a very tarnished one, in relation to the problem. Once on the Rhine, France declared and worked for real freedom of the river—in 1792 and following years; and it was only while France was submerged after 1815 that the good work was undone. Holland was able, meanwhile, to neutralise all the advantages granted by France. By legal quibbles and "voluntary negligence" she has completely crippled Belgian use of the Maas, the Terneuzen Canal, and the Scheldt—showing a pardonable human selfishness, but an unpardonable blindness to her own ultimate advantage.

GEOLOGY.

Dr. J. W. Evans in his address to Section C considered, in the first place, the methods by which the progress of geological research could be promoted most effectively. He emphasised the need for a large and widely distributed body of workers to carry on geological research, and discussed the means by which a wider interest in geology might be stimulated. Dr. Evans thought that much might be done to popularise the work of the Geological Survey. He advocated the issue of cheap colour-printed editions of the 6-in. maps of agricultural as well as of mining areas, with sections on the same scale, which would be more easily understood than maps and sections on smaller scales. A simple explanatory pamphlet should be published for each map, describing briefly and in popular language the meaning of the geological colouring and symbols employed, the nature of the rocks and their relation to agriculture, water-supply, and other economic questions. If these and other measures suggested involved some extra expense, it would be well worth while if it enabled the fullest advantage to be taken of the expenditure incurred in any event by the Survey. Dr. Evans contended that those engaged in genuine geological research should be assisted by concessions in the matter of railway fares. He advocated a systematic underground survey by means of deep borings, and the investigation of the geological configuration of the sea-bottom. The address then discussed in some detail the application of experimental methods to the determination of the conditions under which igneous and metamorphic rocks have been formed. The possibility was also suggested of obtaining further information as to the structure of the earth's crust by means of observations of vibrations originated by artificial explosions, and reflected from subterranean surfaces of discontinuity.

Mathematical and Physical Science.

In his presidential address to Section A, Prof. A. Gray dealt in the main with the utilisation of scientific knowledge and the employment of scientific men in the conduct of the war. He directed attention to the fact that the organisers of the details of our share of the defence against the German attack were without scientific knowledge, and therefore unfitted to counter the assaults of a war machine perfected by decades of hard work in a country where every available agency had been carefully organised to ensure success and victory. Our military chiefs—the War Office Staff and the rest—seemed to have no idea except the naïve and simple one of destroying Germans by rifles, machine-guns, etc., which in point of fact were, to a great extent, non-existent.

Prof. Gray proceeded to describe a scheme of organisation and registration of scientific workers which he believes might have been adopted early in the progress of the war, and still advocates for future eventualities. He then dealt with the entire ignorance of science, apparently even contempt for science, which characterises the statesmen of this country. This he attributes in great measure to our present fashionable but archaic system of education, which takes no account of entirely new provinces of knowledge, and leaves the members of the well-to-do and upper classes quite untrained as regards one side of their minds, and therefore destitute of scientific imagination. Glaring examples of this deliberate neglect of science were cited. The remedy proposed is a radical improvement of our educational system, which ought to be helped and stimulated more by the concerted action of scientific men themselves.

The methods of encouraging and testing inventions during the war were criticised, and a better system was advocated. A strong plea was advanced for an organisation of scientific workers to secure for themselves proper recognition and proper reward for their labour. If care is not taken, a new era of exploitation of the men with ideas will begin, and will be worse than the former one.

The organisation of research was also shortly discussed, and the distinction between industrial and purely scientific research emphasised. The importance of leaving the latter perfectly untrammelled by bureaucratic control was insisted upon

The remainder of the address was devoted to some details of methods of dynamical teaching and with some recent results of physical research.

Physiology.

The president of Section I, Prof. D. Noël Paton, considered the possibility that the guanidin part of the protein molecule exercises a physiological action, just as the amino-acids manifest a physiological action in stimulating the metabolism and increasing the production of heat.

The probable liberation of guanidin from protein and its formation from substances in the egg were considered. The existence of free guanidin or methyl-guanidin in muscle and its physiological action in stimulating the outgoing neurons of the spinal cord and the neuro-myal junctions were dealt with. Its increase in tetania parathyreopriva and in idiopathic tetany with the production of their characteristic symptoms was described.

The fate of the free guanidin or methyl-guanidin was discussed, and the probability of its being detoxicated by synthesis into creatin was supported by the experimental investigations carried out along with Wishart, which showed that the creatin of muscle is increased after intravenous injection of guanidin sulphate. The significance of urinary creatin was then considered in the light of these conclusions. The advantages of studying this on such animals as birds where creatin alone is present were pointed out, and in the light of Prof. Paton's previous work the conclusion was arrived at that, in fasting, the creatin excreted is an index of the breakdown of muscle, and that by considering the creatin excretion along with the excretion of total nitrogen an estimate may be formed of the relative extent to which muscle and other tissues are being disintegrated. The evidence as to the fate of creatin in the normal animal on an adequate supply of carbohydrates seemed to indicate that creatin may again be built into the substance of muscle, that it may act as an anabolite.

Zoology.

The presidential address by Dr. Dixey in Section D began with a brief reference to the effect of the war upon scientific research and upon the estimation in which scientific subjects are held by the general public. It was urged that while the general attention is more easily attracted by the achievements of applied science, the claims of science for its own sake should not be overlooked. A more assured place for scientific subjects in a general education was advocated, and it was suggested that much time might be gained by an improvement in the present methods of instruction; particularly in the teaching of classics.

The main part of the address was devoted to a discussion of certain features of insect mimicry, with especial reference to certain groups of butterflies inhabiting New Guinea and some of the Malayan Islands. The verification of a prediction made fifty years ago by Alfred Russel Wallace was noted, and attention was directed to the geographical element in the phenomena that have to be explained. The parallelism between the respective species of two distinct genera was illustrated and discussed, and instances were adduced of a mimetic form uniting in its own aspect the warning colours, or "aposemes," of two distinct models. Various objections to the theories of Bates and Müller were noticed, and it was contended that the facts at present known are more favourable to an explanation based on the principle of natural selection than to any other as yet offered. It was admitted that this involves the recognition of adaptation as influencing the development of the colour patterns in question, and it was allowed that the pursuit of the "new teleology" may, like other biological speculations, have been here and there carried too far.

The address ended by emphasising the value of scientifically managed collections of insects in their bearing upon biological problems.

NOTES.

WE are informed that the office of Scientific Attaché at the American Embassy is being closed; the question of the closing being permanent or not is, however, under discussion, and it is possible that the office may re-open in the course of a few months. The Scientific Attaché in London has been the representative of the Research Information Service of the U.S. National Research Council, and the Service will in future be glad to receive communications addressed c/o the National Research Council, 1023 Sixteenth Street, Washington, D.C., U.S.A.

WE learn from *Science* that an American Meteorological Society is in course of formation, and that it will be definitely organised at the meeting of the American Association at St. Louis in December next. The purpose of the society is to fill the need for an easy interchange of ideas among those interested in atmospheric phenomena and their effects on man, and thereby to promote instruction and research in these subjects. It is pointed out that these objects may be brought about by general meetings with the American Association and local meetings at other times; by the use of the *Monthly Weather Review* as a medium for the publication of meteorological and climatological articles; and by the issue of a monthly leaflet containing news, announcements, notes, and queries.

No one is better qualified than Lord Walsingham to express the high estimation in which the late Frederick Du Cane Godman was held by all who knew him, whether in his scientific or in his private capacity. The appreciation of his lamented friend, which has been reprinted by Lord Walsingham from the Proceedings of the Entomological Society of London, speaks in fitting terms of the immense service rendered to the systematic study of natural history by the zeal and generosity of Godman. The sixty-three volumes of the "Biologia Centrali-Americana," the whole expense of which was borne by him, is a splendid monument to the labours of this great naturalist and of his friend and associate, Osbert Salvin. All those who were ever in his company will agree with Lord Walsingham that "there was a peculiar charm of personality which pervaded his whole nature; a generous sympathy with all those whose tastes, pursuits, or studies were kindred to his own; a genuine desire to help, encourage, and enlighten their efforts, and to contribute to the objects for which they were striving." It is intended to establish a memorial to Godman in connection with the British Museum, of which he was an active and efficient trustee.

PRIOR to the war the Wireless Society of London appointed an advisory committee to assist the officials of the Post Office in sifting their numerous applications for licences and recommending those which should be accepted. We now learn from the hon. secretary of the society that the offer of the services of the committee has again been accepted in the same capacity. Several questions in connection with the proposed new licences have still to be decided, particularly with respect to transmitting, but we gather that the genuine experimenter and the amateur who is prepared to conform to reasonable regulations may depend upon the society doing all that can be done at the moment to further their interests.

IN the *Queensland Geographical Journal*, issued in a single number for the years 1916–18, Mr. R. H. Mathews describes the ceremony of initiation, known as Dyer-va-val, amongst the Birdhawal Tribe, whose hunting grounds were situated in the north-east corner of the State of Victoria. There are interesting points of resemblance to the similar rite practised by the aborigines of some northern rivers of New South Wales. During the long course of instruction, which began when the novices were separated from their mothers until they were finally recognised as men, they were taught which foods were lawful and which were taboo. On certain occasions they were taken to the place where the women were assembled, when their mothers and other female relatives gave them vegetable food, and authorised them to eat a particular vegetable from that time onward. On another day, the boys were brought up, and the women gave them water in a native vessel, after which they could drink from any stream in the tribal territory.

THE United States National Museum possesses a considerable collection of examples of ecclesiastical art, a catalogue of which has been prepared by the assistant curator, Mr. I. M. Casanowicz, and issued as No. 2287 in vol. lv., Proceedings of the Museum. The pamphlet is something more than a catalogue, as the compiler has collected a considerable amount of information on the subject. He divides the catalogue into: (1) Ecclesiastical Art of the Roman Catholic Church; (2) of the Eastern Church; (3) of the Armenian Church. With this is given a collection of illustrations of the more important exhibits. Much further material, we are told, remains in storage owing to lack of space.

AN exceptionally interesting bionomic study of a group of insects is found in Mr. John J. Davis's "Contributions to a Knowledge of the Natural Enemies of Phyllophaga" (Bull. Illinois Nat. Hist. Survey, vol. xiii, art. 5). This is a genus of chafers which in North America have much the same economic importance as the cockchafers and their allies have in Europe, the adult beetles eating leaves and the larvæ devouring roots. Black digger-wasps (Tiphia) "are without doubt the most efficient and abundant of the many parasites known to attack Phyllophaga," but the Tiphiæ are themselves parasitised by larvæ of bombylid flies. In his elucidation of such life-relations the author gives much information on the structure and habits of parasitic and predaceous insects of various orders. The importance of birds and mammals (including the domestic pig and the notorious skunk) as devourers of the "white grubs" is also illustrated.

THOSE fascinating tunicates, the Salpidæ, form the subject of an important recent memoir by Maynard M. Metcalf (Bull. 100, U.S. Nat. Mus., vol. ii, part 2), who gives anatomical details of the nervous system and musculature in many species, a "taxonomic study" of the whole family, and an interesting discussion on their distribution. He believes that "while the comparative anatomy of the adult tunicata tells us little of the origin of the Doliolidæ and Salpidæ, the comparative study of the manner of budding gives us reason for believing that Doliolum arose from Pyrosoma-like ancestors . . . and that from Doliolum-like ancestors arose the Salpidæ."

A BRIEF systematic paper of exceptional distributional interest has lately been published by Prof. C. Chilton in the *Ann. Mag. Nat. Hist.* (9), vol. iii., pp. 376–386. He identifies specimens of a sandhopper collected at Picton, New Zealand, with Fritz Müller's *Orchestia tucuranna* from South Brazil—a species known to some naturalists not specialists in the Amphipoda through references in Müller's "Facts and Arguments for Darwin," published in 1869. Another South American Orchestia, *O. chiliensis,* had previously been recognised by Prof. Chilton on the New Zealand coasts.

THE U.S. Department of Agriculture has published (Bull. 780) a pamphlet on Nosema-disease in bees by G. F. White, who gives interesting facts as to the resistance of Nosema spores to heat, drying, and other adverse conditions. His observations as to the occurrence of Nosema in North America and its effect on bees that harbour it will be valuable for comparison by workers in these countries, though he believes that "it is not possible to state whether the Isle of Wight disease and Nosema disease [as present in America] are one and the same disorder." He strangely neglects the work of Fantham and Porter on the subject, barely referring to their papers of 1911 (*Proc. Zool. Soc. Lond.*) and 1912 (*Suppl. Journ. Board Agric.*), and ignoring their subsequent publications.

THE Carnegie Institution of Washington has recently published the first volume of a memoir entitled "The Cactaceæ: Descriptions and Illustrations of Plants of the Cactus Family," by N. L. Britton and J. N. Rose. The systematic study of succulent plants, such as the Cactaceæ, is beset by many formidable difficulties. As a consequence, such study is far from general. Fortunately these difficulties have always proved attractive to a select band of workers gifted with that infinite capacity for taking pains which the peculiar exigencies of the case demand. Among early authors who have earned renown in this exacting field we may recall the names of A. P. De Candolle with his artist colleague P. J. Redoute, of Adrian Henry Haworth, and of Prince Salm-Reifferschied-Dyck. The fit, if few, who labour in this particular field to-day include no one whose name is more honoured than that of the veteran Mr. N. E. Brown. The volume now issued as Publication No. 248 of the Carnegie Institution shows that this chosen band of workers has been augmented by the addition of two worthy recruits. Their handsome and craftsmanlike treatise, which deals with the tribes Pereskieæ and Opuntieæ, is illustrated by thirty-six plates, of which twenty-eight are coloured, and by 302 text-figures, many of them reproduced from photographs. The thorough manner in which the attendant difficulties have been overcome by the careful study of type-specimens and original descriptions, by the extensive collection of living and of herbarium material, and by prolonged field-observation, deserves the highest commendation. The excellence of the illustrations and the lucidity of the descriptions render the work one of the most important contributions yet made to the taxonomy and natural history of a family of succulent plants. It should make relatively simple what has hitherto been an exceedingly difficult task to the botanist and to the cultivator. Both should now be able to identify with some confidence many of the cactaceous plants grown in European plant-collections, and to discard from their lists a host of superfluous names which have long encumbered our catalogues. Grower and systematist alike will look forward with keen expectation, and, indeed, with something like impatience, to the appearance of the further volume in which our authors are to deal with the Cereæ, the last of the three tribes that compose the Cactaceæ.

THE Tyndall lectures delivered by Prof. John Joly before the Royal Institution in April, 1918, have now been published in pamphlet form with the title "Scientific Signalling and Safety at Sea." The lectures were devoted to two of the most urgent problems which confront a sailor, viz. the determination of his position upon near approach to the coast, and the means of avoiding collision at sea, when owing to thick weather, fog, or snow visibility is very low. Until recent years the only aids the sailor had were untrustworthy fog-signals, the use of the lead, and the use of his steam-whistle. Sound is conveyed in a very capricious way through the atmosphere. Apart from the effects of wind, which causes sound to carry badly or to be inaudible owing to the noise and uproar around a ship, large areas of silence are often found in different directions and at different distances from a fog-signal station in calm weather. In spite of these circumstances, these time-honoured methods have been of inestimable value. Prof. Joly suggests that the time has now come when the resources of science should be invoked to supplement the older methods. He advocates the use of "synchronous signalling"—this is, the use of signals propagated in different media, but timed so as to start at the same instant. The particular system recommended is the combination of wireless signals with under-water sound signals. Both methods of signalling are practically independent of atmospheric conditions, and have a much greater range than air-borne signals. The difference between their speeds of propagation suffices to determine the *distance* of the source and the use of either a radio-goniometer or a directional hydrophone enables the *direction* of the source to be ascertained. It is pointed out that the necessary wireless apparatus is now available, and, thanks to the efforts of the Submarine Signal Co., efficient under-water signalling apparatus, such as the submarine bell, Fessenden oscillator, hydrophones, etc., are also obtainable commercially. Several interesting applications of the synchronous signalling method are given, and the pamphlet is to be commended to all who have an interest in those who go down to the sea in ships.

SUMMER weather has this year at times proved very disappointing, although August, which is the general holiday month, was for the most part particularly fine. August was the warmest summer month; the mean temperature at Greenwich was 64·9°, which was 6° warmer than July and 4·5° warmer than June. The mean maximum temperature in August was 75·6°, and there were eleven days with the highest day temperature above 80°, whilst in July the thermometer failed to touch 80°, and in June that reading was only attained on four days. The mean temperature at Greenwich for the whole summer was 61·4°, which is 1° warmer than the summer last year and nearly 3° warmer than in 1916. It is 3·4° cooler than the memorable summer of 1911, which was more abnormal than any summer of recent years; when in both July and August the mean maximum or day temperature was 81°. The weekly weather reports published by the Meteorological Office show that the warmest summer weather occurred during the week ending August 16, when the mean temperature was 3° to 5° F. above the normal, and the maximum day readings exceeded 80° over the whole of England. The total rainfall for the three summer months at Greenwich was 6·03 in., which is 0·6 in. less than the normal for sixty years. The wettest month was July with 2·26 in., and in August the fall was 2·20 in. The summer rainfall was 3 in. less than in 1918, and 4·7 in. less than in 1917; it was more than in 1911, 1913, and 1914. In 1903 the summer rainfall amounted to 16·17 in. Rain fell in all on thirty-four days, and of these July had fifteen wet days. The duration of bright sunshine at Greenwich for the three months was 591 hours. July was the least sunny with 119 hours, which is less than one-half of the sunshine in June and very little more than one-half of that in August.

"NEWTON'S Interpolation Formulas," by Mr. Duncan C. Fraser, originally published in the Journal of the Institute of Actuaries, has been issued as a separate pamphlet. It brings together the whole of Newton's work on interpolation by means of formulæ of finite differences. The three main sources are Newton's short treatise, "Methodus Differentialis," a letter written in 1875 to J. Smith, and Lemma No. 5 in Book iii. of the "Principia." These are supplemented by a letter from Leibnitz to Oldenburg (1672–3) and two letters from Newton to Oldenburg to be communicated to Leibnitz (1676). These letters show that Newton was in possession of the methods of calculation many years before 1711, when the "Methodus Differentialis" was first published. Mr. Fraser gives an English translation of the treatise, correcting some errors and adding useful comments. The pamphlet should be in the hands of all interested in the theory of series and in their use for calculation. It demonstrates that Newton at the age of twenty-three had worked out for himself all the methods of computation now in use, with the exception of calculating machines; and the idea of these, we are reminded, originated with Newton's contemporary, Pascal.

PROF. D. E. SMITH has successfully "filled a gap" by writing a booklet on the early history of numbers that will be the delight of the young, and will prove a "mine of interesting information" to many of their elders. Even as a mere "reader" his charmingly written and beautifully illustrated "Number Stories of Long Ago" (Messrs. Ginn and Co., 48 cents) is well calculated to sow the good seed. Where it falls on fruitful soil the results may not indeed be immediately manifest, but may ultimately astonish that large section of the community who hold that all that deals with number is inherently unattractive, or even repulsive, to mortals. The text also contains problems and tricks designed to amuse and instruct. To these a key, "Number Puzzles before the Log Fire," has been issued by the publishers, price 6*d*. Here we find in disguise many friends, both old and new—echoes from Diophantus, Achilles, and the "turtle," down to products of our modern civilisation, such as :—"A man with $1 wanted $1.25. He pawned the $1 for 75 cents, and then sold the pawnticket for 50 cents. Who lost?" Or again :—"In a certain town 3 per cent. of the inhabitants are one-legged, and half of the others go barefoot. How many shoes are necessary?" It is no doubt well for the civilisation of the future that the answer is "As many shoes as there are people in the town."

IN the Journal of the Franklin Institute for July Prof. A. E. Kennelly and Mr. E. Velander describe a new form of rectangular component alternating-current potentiometer which consumes little power and avoids the use of electromagnetic phase-shifting devices. It is constructed on the principle introduced by Larsen in 1910—that is, it measures the alternating potential required by balancing it against the fall of potential down a non-inductive resistance through which an auxiliary alternating current is passing, and a mutual inductance the primary of which is in series with the resistance. The balance is obtained by means of a vibration galvanometer. The mutual inductance consists of forty-one double coils arranged to form a toroid with a wooden core. The resistance is wound so as to be free from inductance and capacitance. The instrument may be used up to a frequency of 2000. During its use by the inventors the importance of reducing the mutual capacitance between the two windings of the inductance coil has been emphasised.

ALTHOUGH the greatest care is used in the selection of wood for the spars of aeroplane wings, it is not always possible to detect the presence of a "pocket" of resin in the place of sound wood-fibre in some important part of a spar. On this account the United States Forest Service has instituted at its laboratory at Madison a series of tests of the effects of such "pockets" on the strength of spars, and the results of the work already done are summarised in an article by Mr. J. R. Watkins in the August issue of the Journal of the Franklin Institute. Spars 6 ft. long of spruce and Douglas fir of I section, with "pockets" of known size in flanges or web, were tested under load against sound spars. A "pocket" 5–6 in. long, ⅛ in. wide, and 1 in. deep in the compression flange diminishes the strength considerably. "Pockets" up to 4 in. long in the tension flange have little effect on the strength, but in the web produce a serious decrease of the strength of the spar in horizontal shear. On the whole, the author concludes that small "pockets" produce effects less than has been supposed.

AMONG the forthcoming science books in the new announcement list of *Messrs. Longmans and Co.* are :—"The Feeding of Nations: A Study in Applied Physiology," Prof. E. H. Starling; "Modern Science and Materialism," H. Elliot; "The Elements of Physics," R. A. Houstoun; "Life in Early Britain: A Survey of the Social and Economic Development of the People of England from Earliest Times to the Norman Conquest," N. Ault, and a new impression of "The Profitable Culture of Vegetables, for Market Gardeners, Small Holders, and Others," T. Smith.

Messrs. Macmillan and Co.'s autumn list of announcements which has just been issued contains many books of scientific interest, *e.g.* "Catalysis in Theory and Practice," E. K. Rideal and Dr. H. S. Taylor; "Alcohol: Its Production, Properties, Chemistry, and Industrial Applications; with chapters on Methyl Alcohol, Fusel Oil, and Spiritous Beverages," C. Simmonds; "Science and Fruit Growing. Being an account of the results obtained at the Woburn Experimental Fruit Farm since its foundation in 1894," the Duke of Bedford and S. Pickering; a new edition—the fourth—of "Mendelism," Prof. R. C. Punnett; "Essays on the Surgery of the Temporal Bone," Sir Charles A. Ballance, with the assistance of Dr. C. D. Green, 2 vols.; "An Introduction to Anthropology: A General Survey of the Early History of the Human Race," Rev. E. O. James; "The Ila-speaking Peoples of Northern Rhodesia," Rev. E. W. Smith; "Among the Natives of the Loyalty Group," Mrs. E. Hadfield; "Through Deserts and Oases of Central Asia," Miss E. Sykes and Sir Percy Sykes; "Implication and Linear Inference," Dr. B. Bosanquet; "The Idea of Progress: An Inquiry into its Origin and Growth," Prof. J. B. Bury; "Mind Energy," Prof. H. Bergson, translated, in collaboration with the author, by Prof. H. Wildon Carr; "Geology of India for Students," D. N. Wadia; "Aircraft in Peace," Dr. J. M. Spaight; "England," edited by F. Muirhead (The Blue Guides); "Highways and Byways in Northumbria," P. A. Graham, illustrated by Hugh Thomson, and a new edition of "The Handbook to Cyprus," H. C. Luke and D. J. Jardine.

MR. F. EDWARDS, 83 High Street, Marylebone, W.1, has just issued an interesting list (No. 393) of some four hundred books, engravings, and original drawings relating to India. While not mainly devoted to science, it contains particulars of many scientific publications, and is worth perusal. We notice that Mr. Edwards has for sale the Sanskrit library of Prof. J. Ebbeling, consisting of about five hundred volumes.

ERRATUM.—On p. 18 of NATURE of September 4, col. 1, line 9, for "m equal to $\pi a^3\rho$" read "m equal to $\frac{4}{3}\pi a^3\rho$."

OUR ASTRONOMICAL COLUMN.

COMET NOTES.—There does not seem to be any reasonable doubt of the identity of Metcalf's comet (1919 *b*) with that of Brorsen. The following were the elements deduced for Brorsen's comet after the former apparition:—

$$T = 1847 \text{ Sept. } 9{\cdot}5427$$
$$\left.\begin{aligned}\omega &= 129^\circ\ 23'\ 17''\\ \Omega &= 309^\circ\ 48'\ 49''\\ i &= 19^\circ\ 8'\ 25''\end{aligned}\right\} 1847{\cdot}0$$
$$e = 0{\cdot}97256$$
$$a = 17{\cdot}7795$$
$$\text{Period} = 74{\cdot}97 \text{ years}$$
$$\log q = 9{\cdot}6883$$

The actual period is 72y. 37d., nearly three years shorter than that formerly taken as the most probable. e and a will need modification in consequence, but $\log q$ will not be much affected.

As new elliptical elements are not yet to hand, the ephemeris has been continued from the parabolic elements given last week.

Ephemeris for Greenwich Midnight.

	R.A. h. m. s.	N. Decl. ° ′	Log r	Log Δ
Sept. 15 ...	12 29 21	52 42	9·9341	9·4396
17 ...	12 17 17	47 36	9·9163	9·4789
19 ...	12 8 36	43 11	9·8979	9·5179
21 ..	12 2 8	39 18	9·8788	9·5560
23 ...	11 57 11	35 52	9·8590	9·5937

The comet will probably be some 24′ south of these positions.

Another comet (1919*c*) was announced in Europe as having been discovered by M. Borelly on August 23. It subsequently appeared that Mr. Metcalf found it a day earlier. Possibly it will be known by their joint names.

Miss Vinter-Hansen and Mr. Fischer-Petersen have deduced the following orbit from observations on August 24, 25, and 26:—

$$T = 1919 \text{ Dec. } 19{\cdot}125 \text{ G.M.T.}$$
$$\left.\begin{aligned}\omega &= 176^\circ\ 15{\cdot}61'\\ \Omega &= 110^\circ\ 35{\cdot}08'\\ i &= 47^\circ\ 21{\cdot}24'\end{aligned}\right\} 1919{\cdot}0$$
$$\log q = 0{\cdot}17608$$

Error of middle place (observed *minus* computed) +0·02′, 0·00′.

Ephemeris for Greenwich Midnight.

	R.A. h. m. s.	N. Decl. ° ′	Log r	Log Δ
Sept. 10 ...	14 34 23	19 26		
14 ...	14 41 37	17 44	0·2987	0·3957
18 ...	14 49 5	16 0		
22 ...	14 56 46	14 16	0·2838	0·3918

The magnitude on September 22 is given as 8·7m. It is slowly brightening.

Mr. Burnet desires to point out that in the occultation of a faint star by Jupiter for which his prediction was lately given in this column, the date should read September 14d. 15h., not 15d. 15h. That is, in civil reckoning it is at 3 a.m. on September 15.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

A LIMITED number of grants-in-aid to persons employed in chemical works in or near London desirous of extending their knowledge of chemistry will shortly be made by the Salters' Institute of Industrial Chemistry. Applications must be made before September 20 to the Director of the institute, Salters' Hall, St. Swithin's Lane, E.C.4.

THE University of Queensland is seeking for a lecturer of geology to act under the direction of the professor of geology and mineralogy. The appointment is for five years, and the commencing salary will be at the rate of 400*l.* per annum. Applications must be forwarded to reach the Registrar of the University of Queensland, Brisbane, not later than November 15 next. Each applicant must state his age, supply full particulars as to his teaching experience and general qualifications, and furnish certified copies of his certificates and testimonials. A recent photograph should also be forwarded. If not resident in Australia, 50*l.* travelling expenses will be granted to the successful applicant.

THE new session of Battersea Polytechnic opens on Tuesday, September 23, and particulars of all the courses are given in the Calendar of the Polytechnic, obtainable on application to the Secretary, Battersea Polytechnic, London, S.W.11. The courses include the following:—Full day and evening courses in preparation for the University of London Intermediate and Final Degree Examinations (internal and external) in science, engineering, and music; day courses in mechanical, civil, electrical, and motor engineering; architecture and building; chemistry; gas engineering and manufacture; paper-making and wholesale stationery work; mathematics; physics; teachers' courses in domestic science; courses for sanitary inspectors and health visitors, and in art and crafts. Evening courses in mechanical and electrical engineering, mathematics, physics, chemistry, hygiene and physiology, photography, art and crafts, languages, domestic science, music, physical training, and general subjects.

THE report of the Librarian of Congress (U.S.A.), now before us, deals with the fiscal year ending June 30, 1918. The influence of the war on the library at Washington reproduces fairly closely the experience of the libraries in this country. There has been some falling off in accessions due to the closing of the book markets of the world, and also a change in the character of the library work. Workers new to their task have invaded the reference department with inquiries of a novel character which have thrown a great strain upon the energies of a depleted staff, some cases apparently revealing the deficiencies of the library. That again is an experience common to us all. But "the apex of our curve of stress," says the report, "has also shifted from morning to evening and from week-days to Sundays through the presence here of thousands of new Government employees, who can come to us only after their office-hours are over," the average of Sunday readers per hour being three times greater than the week-day average. Thus there is no "early closing" movement in the United States as the result of war conditions. The Oriental division reports that in consequence of the break-up of the European centres of Jewish learning and the increased immigration of Jewish settlers in the United States, Hebrew literature is reviving, and a great strain has been thrown upon the services of the Oriental department by its new *clientèle*. The report is well indexed. When will our Departments take the hint and supply proper indexes to the reports issued under their authority?

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 25.—M. Léon Guignard in the chair.—A. **Lacroix**: Report on the creation of an international council of scientific research by the Conference of the Allied and Associated Academies held at Brussels, July 18–28 last.—G. **Humbert**: The representations of an integer by positive forms of Hermite in an imaginary quadratic body.—G. **Bigourdan**: The work of La Caille, particularly at the observatory of the Mazarin College.—N. E. **Nörlund**: An equation of finite differences.—P. **Lévy**: The notion of the mean in the functional domain.—Ch. **Platrier**: Interior forces in an isotropic homogeneous body in elastic equilibrium.—B. **Baillaud** (telegrams): Two discoveries of comets, one by Metcalf at Harvard Observatory, the other by Borrelly at Marseilles.—M. **Giacobini**: Observations of the Metcalf and Kopff comets made at the Paris Observatory with the east tower equatorial of 40 cm. aperture.—P. **Chofardet**: Observations of the Kopff periodic comet and the Metcalf comet (1919*b*) made with the bent equatorial at the Besançon Observatory.—Ch. **Mangin** and L. J. **Simon**: The preparation of cyanogen chloride by Held's method. Cyanogen chloride can be prepared by the action of chlorine upon the double cyanide of sodium and zinc in nearly quantitative yield.—Ch. **Pussenot**: Remarks on a recent submersion of the coasts of Morbihan.—A. **Guébhard**: The prism formation of basalt.—P. **Parmentier**: Irrigation in Syria and Palestine. A new method of applying water directly to the roots is suggested in the place of the usual methods of irrigation or surface watering. Great economy in water (85 per cent.) is claimed for the method.—Em. **De Wildeman**: *Macaranga soccifera*. A discussion of the relation of this plant with ants.—A. **Paillot**: Karyokynetosis: a new reaction of natural immunity observed in the caterpillars of the Macrolepidoptera.

CAPE TOWN.

Royal Society of South Africa, July 16.—Dr. L. Péringuey in the chair.—Dr. L. **Péringuey**: Bushman engravings. A preliminary account of the author's investigations of various Bushman engravings, and consideration of the theories which may be advanced as to their significance.—Dr. R. W. **Shufeldt**: Comparative study of certain cranial sutures in the primates. The paper is based upon the examination and comparison of several thousand human skulls in the collections of the department of physical anthropology of the United States Natural History Museum and the entire collection of skulls of primates in the divisions of mamals of the same institution.

SCIENCE AND SOCIALITY.

Annals of the Philosophical Club of the Royal Society, written from its Minute Books. By Prof. T. G. Bonney. Pp. x+286. (London: Macmillan and Co., Ltd., 1919.) Price 15s. net.

THE Royal Society is not only our most eminent body of men of science, but also one of the oldest and perhaps the most illustrious of all the learned academies of the world. To be elected into the number of its Fellows has always been regarded by the cultivators of science in this country as one of the highest distinctions to which they can aspire. To "shine in the dignity of F.R.S." was a coveted honour in the days of the "Dunciad," and is in even higher repute to-day. The recent publication of two volumes, however, shows that this "dignity" has from the first been combined with the saving grace of strong social and convivial instincts. The first of these volumes, "Annals of the Royal Society Club" (reviewed in NATURE of August 30, 1917), showed that the philosophers, while they doubtless conducted their scientific investigations and discussions with all the zeal and solemnity credited to them, were at the same time fond of the free, personal intercourse of the dinner-table. In true English fashion, they met in some tavern, and after two or three hours of pleasant talk, adjourned to the meeting of the society; or, if that meeting took place earlier in the day, they dined together after the scientific discussions were over. There is, indeed, some reason to believe that the Royal Society itself may have been actually born in a coffee-house. We know how much Samuel Pepys enjoyed these prandial meetings. It was not, however, until after his time that the choicer spirits formed themselves into a dining fraternity, with formal rules and a limited membership, the president of the society being chairman. They sat down weekly before a portentous bill of fare and with the spirit of true deipnosophists,

> Tried all *hors-d'œuvres,* all liqueurs defined,
> Judicious drank, and greatly daring dined.

Thus arose the "Royal Society Club" in the early part of the eighteenth century. Since then, while one generation has followed another, and Presidents and Fellows in long succession have come and gone, the Club still flourishes more vigorously than ever. It has migrated from tavern to tavern, from the City westwards to the precincts of Burlington House, and has learnt to dine from a less ample and miscellaneous cuisine, now still further retrenched by the war and the high cost of food. Yet it still maintains the hospitality which has always been one of its prominent features.

After the Royal Society Club had lived for rather more than a century, a number of the younger and more actively scientific Fellows of the Society began to be increasingly dissatisfied with the way in which the elections into the membership were conducted, and they put such pressure on the council as eventually to lead to a complete and salutary reform of that and other grievances. These ardent innovators, having purged the Society in 1847, may have thought of directing the tide of purgation into the Club. Any serious change in that social institution, however, even if considered desirable, would not have been easy of accomplishment. The triumphant reformers included in their number some nine members of the Club, but years would obviously have to pass before the rest of the active brigade could obtain admission. Besides, the atmosphere of the Club may have been too close and conservative for the comfort of the innovators, who would not be likely to find there much sympathy with their iconoclastic determination to keep a vigilant eye upon the doings of the council. They accordingly resolved to found a new dining confraternity, which was ultimately named the Philosophical Club, the history of which has now been compiled by Prof. Bonney in the second of the two volumes above referred to.

The aims for which this fresh organisation was created were more ambitious than those of its forerunner, and went much beyond social intercourse among members. In the language of its founders it was meant "to promote as much as possible the scientific objects of the Royal Society; to facilitate intercourse between those Fellows who are actively engaged in cultivating the various branches of natural science and who have contributed to its progress; to increase the attendance at the evening meetings [of the Society]; and to encourage the contribution and discussion of papers." Its numbers were limited to forty-seven, all of whom must be Fellows of the Royal Society and likewise authors of a paper published in the Transactions of one of the Chartered Societies, or of some work of original research in natural science. It was further provided that at least thirty-five of them must be resident within ten miles of the London General Post Office. They dined once a month at half-past five o'clock, and adjourned at a quarter past eight, when they were each expected to attend the meeting of the Society, unless unavoidably prevented. Perhaps the rule which most strongly marked them off from the older club was that which formally excluded all strangers from their meetings, with the exception of scientific foreigners temporarily visiting this country. Thus from the genial hospitality which had always distinguished the Royal Society Club and had been so useful in bringing men of letters, of art, of politics, of the Navy and Army, of public life, and of commerce and industry into contact with the men of science, the Philosophical Club, in its zeal for the prosecution of science, deliberately separated itself. Possibly to make amends for this abnegation of variety from the outside, it was customary for the chairman to invite the members present to make communications to the meeting on any subject of special

D

scientific interest, and the treasurer was instructed to record such communications in the minutes.

The two clubs continued for fifty-four years to live apart and in amity. But the fervid reforming zeal of the younger fraternity, having gained its first object, and having no obvious cause for further activity, gradually slackened. Many Fellows of the Society were members of both clubs, and it slowly dawned upon even the most conservative intellects that the co-existence of two dining clubs in connection with the same society was inconvenient and unnecessary. At last, in the summer of 1901, the Philosophical was formally incorporated with the Royal Society Club.

The "Annals" of the older corporation having been published in the summer of 1917, it was unanimously decided that the history of the younger fraternity should also be put into the more durable form of print, and that the task of compiling the narrative should be entrusted to Prof. Bonney, who happened to be the oldest surviving member of the dissolved club. It required no little courage to undertake this labour, and the veteran professor deserves the best thanks of the united Club and of the public for having accomplished it. His volume of "Annals of the Philosophical Club" is divided by him into two sections. The first of these, dealing with the business done at the meetings, in chronological order from the beginning to the close, shows from year to year the organisation and work of the club, the gradual disappearance of the old members and the advent of their successors. To the minutes that record these particulars the editor has added a short but adequate biographical notice of each of the new members.

The second and more interesting and important section contains the reports of the verbal "communications" made at the meetings, in chronological order, from May 6, 1847, when the institution was fairly started on its career, down to the time of the amalgamation of the two clubs. It was these communications which gave its distinctive character to the Philosophical Club, and it was well that this feature of its existence should be faithfully recorded. Prof. Bonney must have had difficulty in choosing how best to deal with them. He finally decided to place them all together by themselves in his second section, keeping them in chronological order under the dates of the successive meetings at which they were made. He has given us the whole available material, and has evidently treated it with the most patient care, taking infinite pains to verify and illustrate the text. Nevertheless, as a matter of convenient and effective arrangement we venture to think that it would have made the book more attractive had the two sections been fused into one continuous narrative—in other words, had the "communications," instead of being divorced from the account of the business meetings, been inserted, where they were actually made, after the business. At many meetings there was no business, and no mention of these meetings was required in section i. of the volume, but on turning to section ii. we may find for the same year a succession of meetings recorded, at which various communications were made. Thus the whole doings of the club in the year 1867 are comprised in eight lines in the first section, while in the second section reference is made to seven meetings in that year, each marked by communications which occupy in all four pages of the volume. Again, the business transacted in 1869 is summed up in two short lines, while in the second section the communications made at no fewer than eight meetings in that year cover three pages. We feel that the intercalation of these statements and discussions in the account of the more formal business would have gone far to relieve the narrative of the history of the club in section i., which, save for the editor's luminous little biographies, is confessedly of only limited interest.

Section ii. forms a truly remarkable record of the after-dinner talk of a body of the foremost men of science of our time. The topics mentioned or discussed range over the whole realm of Nature, from the centre of the earth to the furthest nebula. We are let, as it were, into the private study or the laboratory of the scientific worker; we are permitted to hear the earliest outlines of a discovery from the lips of the man who made it; we seem to be in the highest or inner council of science, listening to the words of its most trusted leaders. The entries are sometimes provokingly brief, yet so interesting that had one been there the temptation would have been great to ask the speaker to go on, or to request the treasurer to report the communication in full. The whole collection of communications is an amazing *olla podrida*, to be read only in little snatches at a time, and bearing somewhat the same relation to the speakers and their audience that the crushed and faded flowers of a herbarium do to their beauty as they lived. The perusal of it, however, cannot but impress on the reader a profound respect for the Philosophical Club and a conviction that this club must have been an institution of great scientific driving power and that when it was amalgamated with the Royal Society Club it introduced fresh healthy blood into the older corporation. Its "Annals," therefore, well deserved to be compiled, and the volume in which Prof. Bonney has told the story will take its place among the permanent records of the progress of science in the nineteenth century.

ARCH. GEIKIE.

BOTANY OF CULTIVATED PLANTS.

The Botany of Crop Plants. A Text and Reference Book. By Prof. W. W. Robbins. Pp. xx+681. (Philadelphia: P. Blakiston's Son and Co., 1917.) Price 2 dollars net.

IN the prefatory words of the author, "the issuance of this book has been stimulated in part by the expressed need . . . for a text or reference book which will give the student a knowledge of the botany of common orchard, garden, and field crops. . . ." A text-book which achieved this object would be indeed a boon, for, with the exception of Percival's "Agricultural Botany," we know of no book which treats of economic plants in such a way as to expound the principles of botanical science and to provide knowledge directly useful to the person interested in the cultivation of food crops.

The method adopted by the author is to give a rapid exposition of botanical principles—histological, physiological, genetical, and morphological—in the course of sixty-seven pages, and then to treat in some detail the series of crop plants of field, garden, and orchard.

This method is open to the fatal objection that it evades the first duty of the teacher, which is so to select and present common facts that the essential generalisations, which cohere them into a scientific system, either suggest themselves to the student's mind, or, at all events, appear natural and convincing when the teacher, as is often the case, is compelled by the defectiveness of his method, or the indifference of his students, to expound them.

Instead of attempting this the author is content to hand out the usual stock of botanical facts. He begins by talking about undifferentiated plants and a thallus (p. 1), tells the student in p. 2 that the tendril of a pea is morphologically a leaf, and a potato tuber a modified stem, when, of course, the duty of the teacher is to promote the discovery by the student of these facts, and thereby to stimulate interest, illustrate morphological principles, and train the eye and mind to see essential things.

Histology is dealt with in chap. ii. in six pages, and the student is told sundry facts—that leucoplasts and chloroplasts exist, that protoplasm is a "proteid" and that it feels slimy, that the cell-wall may contain lignin, suberin, cutin, and pectin. Even in the general introduction it is evident that the mind of the writer is set on the "practical" economic part which is to come later. Thus (p. 25) he asserts as a general truth that many new varieties of fruit are bud varieties, that a certain branch on a tree is seen to possess peculiarities, and that it is taken off and propagated as a new variety. A more misleading statement, if intended to be of general application, it would be hard indeed to make. It would be interesting to know what variety of apple, pear, plum, currant, raspberry, or gooseberry is known to have arisen by bud variation!

Part ii., which consists of nearly 600 pages, contains much useful information with respect to the botany of cultivated plants. Members of the Gramineæ—cereal and other—are treated of at length and well, though from the teacher's point of view the work is too full for a text-book, and not full enough for a work of reference—for example, Mendelism is dealt with in half a page (p. 421), and, needless to say, the few words devoted to this all-important subject are not adequate to impress the student with the value of this method of genetical research.

The book contains much miscellaneous information which may perhaps interest the American student—that 44 million pounds of dried apples were produced in the United States in 1909, and that in 1915 more than 230 million bushels of apples were produced in that country; but, so far as may be discovered, nothing is said on the fascinating subject of pruning, which might, if scientifically treated, be the means of illustrating many important principles of physiology. Excellent as is much of the matter which it contains, this volume does not, in our opinion, give agricultural and horticultural teachers or students what they want—a new presentation of botanical principles based on the study of those plants among which they have to work. F. K.

OUR BOOKSHELF.

Practical Pyrometry: The Theory, Calibration, and Use of Instruments for the Measurement of High Temperatures. By E. S. Ferry, G. A. Shook, and J. R. Collins. Pp. vii + 147. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1917.) Price 7s. net.

The subject of pyrometry, so important nowadays in many industrial processes, is not as yet overburdened with literature of the text-book description. The present volume contains in a small compass most of the information required for an intelligent understanding of the principles and instructions as to the correct methods of manipulation of pyrometers, including the mathematical theory. Descriptions of historical interest only, with which such books are often burdened, are omitted, and the subject-matter is well chosen to give helpful instruction.

A separate chapter is devoted to each of the four principal types of pyrometer—namely, the resistance, thermo-electric, radiation, and optical pyrometers—with a preliminary chapter on the standard temperature scales. The best chapter in the book is that on optical pyrometry; the principles and construction of the various varieties are very clearly described and in a more thorough manner than is usual in text-books.

Exception might be taken to the omission of some of the simpler forms of pyrometer, such as the water pyrometer and the mercurial expansion and sentinel types. These appeal to many manufacturers, especially where great accuracy is not required, and guidance as to their use would therefore be acceptable.

The book is written for three classes of readers—college students, technically trained men who deal with processes requiring high-temperature measurements, and less trained observers who may make the measurements. To this end the more mathematical portions, such as Foote's mathematical investigation of cold junction error, and the more mathematical treatment of optical pyrometers, might with advantage have formed separate appendices for particular study, rendering the text clearer for the less technical reader.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can be undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Sea-fishery Investigations and the Balance of Life.

The impression that Prof. McIntosh's address, published in Nature of July 3 and 10, must leave upon the minds of readers unfamiliar with the history and progress of sea-fishery research must be that there has been a great deal of misdirected energy during the past fifteen or twenty years in the attempt to gain control of the output of the sea by the application of science to sea-fishery problems. If, as Prof. McIntosh still maintains, the prodigality and bounty of Nature mock all human efforts to modify the natural course of events in the sea for good or ill, it becomes surely a national duty to oppose all further applications for national expenditure upon sea-fishery investigations. As this, judging from his concluding paragraph, is not the aim which Prof. McIntosh has in view, it seems desirable to inquire a little more closely into the basis for his views, and to give at least the broad outlines of the superstructure of knowledge which has been reared above the basis of that fundamental work of his own, which has been a source of legitimate pride to himself as of appreciation by his successors and colleagues.

I think it will be conceded that the leading features of Prof. McIntosh's expressed views are, broadly speaking, as follows:—(1) The fecundity of sea-fishes is so great, and the ultimate food-supply for the fishes themselves is so completely independent of human influence that the idea of exterminating any species of food-fish—or even of seriously diminishing its total numbers—by intensive fishing is chimerical; (2) so long as man fails to make any serious impression upon the multitudes of young fishes, there is no need for anxiety; (3) no serious inroad upon the numbers of young fishes has hitherto been made; (4) therefore all is well, the fears of the pessimists are pointless, the claims of the optimists are established.

As Prof. McIntosh and "J. J." have been good enough to assign me the *rôle* of arch-pessimist, I may as well clear the ground by the remark that, when I approached the study of sea-fishery problems twenty years ago, the dominating question was: Is the practice of sea-fishing affecting the yield of the fishing grounds, or is it not? It was a case of *absolute stability* versus *depletion or impoverishment.* When, therefore, I find a tendency to re-define the question as being one of *slight deterioration* versus *extinction,* I demur. If I am to be dubbed a pessimist, that word must be understood to mean a person who, twenty years ago, urged that the "bottom fisheries" were not in a stable condition, not "holding their own," but showing clear signs of progressive impoverishment; and this was explained as meaning that "the rate at which sea (food) fishes multiply and grow, even in favourable seasons, is exceeded by the rate of capture" ("Impoverishment of the Sea," p. 8).

Passing on to points (2), (3) and (4), and restricting myself to plaice, as a test-case, the following quotations from Prof. McIntosh's recent articles are relevant:—"Plaice have been taken from the North Sea from time immemorial, and yet are *distributed* to-day over its entire area, while their tiny young swarm on every suitable sandy or muddy beach" (i., p. 356); "the removal of the larger fishes by intensive fishing is the rule, but the gaps thus made *are filled later* by the swarms of the smaller" (p. 357); "The idea that the North Sea can be fished out is chimerical, for even if all were gone over thrice or more frequently a year, such *could not produce depletion or exhaustion* of its fisheries—plaice included" (ii., p. 377); and, *à propos* of the International Council's findings with regard to the plaice question: "In other words, all that can be said is that the plaice are not less numerous, but . . . they are smaller—*a finding which leaves the plaice* in safety" (*l.c.*).

Putting these ideas together, it is plain that Prof. McIntosh regards the progressive diminution in the available numbers of the larger fish as negligible, and the continuous lowering of the average size as of no significance, so long as there are plenty of little fishes on the beaches. He ignores the evidence that the rate of growth of these little fishes and their rate of emigration to the offshore grounds no longer keep pace with the rate of capture. He treats the over-fishing problem as one of reproduction and numbers to the exclusion of rate of capture, rate of growth, and actual size attainable.

Apply this principle to agriculture, and consider what our meat-supply would be if the farmers killed all their cattle as calves except the minimum breeding stock necessary to keep up the number of—calves; or if, when thinning their turnips, they had regard, not to the production of the greatest possible weight, but merely to the production of that minimum number of mature plants which should give them seed sufficient for the next sowing!

Prof. McIntosh asks: "Where have the melancholy anticipations of the pessimists been demonstrated; where has the serious diminution of any food-fish occurred; where have the principles enunciated in 'The Resources of the Sea' been traversed by the International Fisheries Council?" (i., p. 355). The answer to the open mind is "on every page."

And what are the practical conclusions of "vigorous optimism"? "Let the authorities and the public place implicit confidence in the resources of the ocean and the ways of Nature therein" (ii., p. 378); "Be vigilant in guarding the national trust!" (*l.c.*). One may well ask of what comfort is the "marvellous plenitude and endurance of the sea-fishes" if they become measurably smaller year by year, or the "prodigality of Nature in their vast abundance and variety" if codlings are to represent cod, and plaice and lemon soles be replaced by dabs and long-roughs. And does "vigilance" consist in ignoring the plainest evidence accumulated by other people, while we sing hymns of praise to Pan or Poseidon? Let us turn now to the superstructure.

The qualitative basis of sea-fishery science, to which no one contributed more effectively than the veteran professor at St. Andrews, already shows the outlines of a quantitative structure upon it. Some of these outlines are still mere scaffolding, but the broad features of the building are discernible.

The idea of boundless prodigality, with its "chains of life" from diatoms to fishes, is not the end but the beginning. It is being steadily replaced by the conception of a balance or equilibrium of life, the two sides of which are the world of plant-life and small invertebrates on the one hand, and the world of fish-life on the other. The former has hitherto been beyond the influence of man, though subject to fluctuations in its total quantity in consequence of annual fluctuations of temperature, sunshine, and similar factors known to influence plant production, and, indirectly, the invertebrate and small vertebrate forms immediately dependent for subsistence upon the former. The fish-world, on the other hand, while undergoing annual and cyclical fluctuations in quantity depending on those of the plant side, is also subject to the influence of man's fishing operations. These do not necessarily diminish the total yield of fish: on the contrary, they are probably powerless to affect the general balance, so far as total productivity is concerned. But the elimination of the larger fishes favours the survival of increasing numbers of the small, since the stock of food remains practically unchanged, while the enemies and competitors of the small are progressively reduced. It follows that the total *numbers* of the young of a given species may be appreciably *increased* as a result of fishing operations, through the progressive diminution of their infantile mortality.

Thus while the total quantity (weight) of the fish-side of the balance of life probably remains constant, its character may deteriorate sensibly. This deterioration is manifested not merely in the substitution of large numbers of small fish for smaller numbers of large fish of the same species, but also in the increasing survival of relatively small and worthless species which partly fill the gaps made by the progressive elimination of their larger competitors, *e.g.* dabs and long-rough dabs in lieu of plaice and lemon soles. Signs of this aspect of deterioration have been noticed in many areas, *e.g.* the Scottish bays, the Devon bays, Dogger Bank, etc.

In the case of plaice, the young of which are restricted to the coastal margins, while the adults range freely within 30 fathoms or so, the general tendency of intensive fishing is (*a*) to deplete the total density of plaice on the offshore grounds, and (*b*) to increase the number of small plaice along the shores. Thus large areas offshore have been opened up for the multiplication and growth of relatively worthless dabs, while the increasing accumulations of the young inshore have set up conditions of over-crowding, impoverished growth, and delayed emigration to the offshore waters.

The growth of a quantitative science of fish-life is thus tending to the production of a co-ordinated body of knowledge capable of deductive application to special practical and administrative problems. The continued growth of this knowledge is of the first importance for the development of the sea-fisheries. Without it administrators are at the mercy of every passing cry and excited agitation; with it, they will be enabled not merely to estimate more accurately the value of particular suggestions, but themselves to inaugurate a new era in the rational exploitation of the hitherto untamed forces of the sea. It should be needless to add that the value of particular investigations will have to be judged in future, not from the point of view of the mere resourcefulness of the sea, but from consideration of the extent to which they furnish means for intelligently controlling it. Walter Garstang.

August 27.

"Impoverishment" dies hard, and there is much glamour around it. My able friend, Prof. Garstang, commenced his campaign by showing that the great increase in the number of boats was accompanied by a diminished catch in each, and that, therefore, there were fewer fishes to catch than formerly, a view which did not survive publication. His modified "Balance of Life" will not rescue the Council from its responsibility on the question of "impoverishment."

The idea of gaining control of the "output" of the sea, as in a mine or quarry, is a novel way of dealing with the ponderous remit from the Government.

Prof. Garstang, like the Council, stakes his position on the plaice, an old tale, and one which is not proven. Large plaice do not frequent, as a rule, the areas of the smaller, and therefore the size is often a question of locality. For generations the same North Sea bay, as, for instance, St. Andrews, will produce the same sizes of plaice. Besides, adult plaice are not caught napping when they see a trawl coming: hence the well-known increase of the catch at night.

The "measurably smaller fishes year by year" probably refers to the boxes at Grimsby and other ports, an uncertain basis for generalisations. Again, are the herrings, gadoids, gurnards, mackerel, breams, wolf-fishes, and frog-fishes, the turbot, soles, and dabs, getting smaller year by year? It is a mistake to aver that dabs and long-rough dabs have anywhere usurped the areas of the "vanished" plaice.

No possible comparison can be made between human agencies in the hands of the farmer (*in re* cattle and turnips) and the ways of Nature in the sea. Such would not even fit the seals and the whales. The native farm-weeds, such as "quicken" and "knot-grass," are sufficient to illustrate Nature's powers.

The facts given in the "Resources of the Sea" (a second edition of which is ready for the press), stand in little need of a "superstructure or co-ordinated body of knowledge capable of deductive application to special administrative problems."

Truly, every encouragement is needed for scientific fisheries researches in marine laboratories and elsewhere. W. C. McIntosh.

DR. A. G. VERNON HARCOURT, F.R.S.

By the death of A. G. Vernon Harcourt, on August 23, in his eighty-fifth year, there has passed away a chemical teacher endeared to many generations of Oxford students, a singularly skilful experimenter, and a pioneer in the new domain of physical chemistry. He was one of the first who planned experiments to enable him to follow the course of a chemical change, to measure the velocity of a reaction, and to study the conditions that determine it; he rebelled against the idea that chemists had to concern themselves only with the preparation of new substances and the elucidation of their properties—for him the interesting thing was *how* the change happened, not what was the result.

Starting with Brodie, first as his pupil and then as his assistant, Harcourt began his researches with the exact determination of the oxygen absorbed by the metals potassium and sodium—allowing air to enter slowly into a flask containing the pure liquid metal heated in an atmosphere of nitrogen. In this first paper one can see that it is the initiation and progress of the oxidation that interest him. "Soon after the dry air has begun to mix with the nitrogen, the grey film which covers the molten metal changes to a deep blue; the surface gradually becomes roughened by little wrinkles and projections, and a moment arrives when a single spluttering spark appears at one point and a dust of white oxide rises. . . . At the point where the spark appears the blue crust becomes white, and this change passes in a moment over its whole extent."

In 1859 Harcourt was elected Lee's reader in chemistry and a senior student of Christ Church, but it was not until some years after his appointment that he began his work in the Lee's laboratory. Meanwhile he had started those researches on the rate of chemical change which—in conjunction with those of Berthelot in France and those of Guldberg in Norway—were to establish on a quantitative basis Berthollet's law of mass action. In the interpretation of his results Harcourt was associated with William Esson, whose special mission in Oxford seemed to be—as the writer knew him—to illuminate mathematically the obscure records of chemical velocities. Harcourt and Esson first studied the reaction between oxalic acid and potassium permanganate in acid solution. They found that the rate of change varied with the amount of manganous sulphate formed, and that the reaction was probably *nil* in the complete absence of manganous salt; but, once started, the velocity would increase to a maximum and then slack off—the curve representing the course of the change having a point of contrary flexure. They liken their curves to those obtained by Bunsen and Roscoe in the course of photochemical induction—thus suggesting that the "inductive period" in the union of hydrogen and chlorine was due to the action of another substance, a suggestion which finally was proved to be correct. Seeking for a less complicated reaction, Harcourt found that in dilute solutions hydrogen peroxide decomposed hydrogen iodide with velocities that could be easily followed, and the amount of change could be accurately ascertained. The method of carrying out the experiment in a stream of carbon dioxide, and the device by which the iodine liberated was reconverted into iodide by the successive additions of exactly equal drops of concentrated thiosulphate, show Harcourt at his best as an experimenter. The time-intervals between the successive appearances of the iodine proved that the velocity of the change varied directly with the quantities of each of the reacting substances—when the other conditions were kept constant. The rates found, however, do not prove that the change is necessarily a trimolecular one as Harcourt supposed:—

$$H_2O_2 + 2HI = 2H_2O + I_2.$$

The change most probably takes place in two stages, each of which is di-molecular; but, one stage being much faster than the other, the observed rates follow the simple law.

In studying the effect of temperature on the rate of this reaction Harcourt and Esson arrived at a zero of chemical action in wonderful agreement with the absolute zero calculated from physical data.

Harcourt was so strongly convinced that chemical change followed mechanical laws that his laboratory became a centre where the experiments of Bunsen and his school on "chemical induction" and "sprungweise" explosions were repeated and criticised.

Harcourt's work as one of the metropolitan gas referees led him to take up the investigation of sulphur impurities in coal gas and to design a new standard of light—the Pentane standard. His method of converting carbon disulphide into the easily removed hydrogen sulphide has only recently been adopted on a large scale in the South Metropolitan Gas Works through the energy and skill of Dr. Carpenter, but its success seems assured. The 10-candle Pentane lamp is not only the official British standard, but also as a practical unit is not approached by the German amyl acetate lamp.

Few men have been so completely happy in their work, or lived so much in the lives of their students. The writer, whose good fortune it was to fall under his influence at Oxford, has to acknowledge that he owes his career to Harcourt's affectionate interest and to his example.

H. B. D.

DR. CHARLES A. MERCIER.

It is not possible to give, in a few words, more than a mere indication of the value of the late Dr. Mercier's scientific work. With a rare, natural capacity for clear thinking, as well as for acquiring and retaining knowledge, he was a master of luminous and logical expression in speech and writing. These qualities inform all his many and various works, whether of purely scientific or mainly literary nature. Some of his books deal with the practical aspects of his professional speciality—insanity—such as the management of asylums, instructions to nurses, etc.; and others, like his essays on "Temperaments," treat of psychology and conduct for the general reader, as well as for the expert. But the main works, on which his reputation will rest, are scientific studies of the nervous system in health and disease, and include specially the whole subject of the causes, conditions, and expressions of mental action, normal and morbid. He was, as a student, much influenced by the writings of Herbert Spencer, and by the personal teaching of Dr. Hughlings Jackson, and their influence is seen in many of his works; but no less evident is his originality of thought, as especially seen in some of his more recent publications, which indicate strongly a marked change of attitude towards the so-called "Lamarckian" doctrine of biological evolution to which at first he strongly adhered. Like his two chief teachers, he made much use of the deductive step in reasoning, but he did not often fail to verify his conclusions by further evidence before adopting them. Judged from the scientific viewpoint, some of his most important works—*e.g.* on the "Nervous System and the Mind," on "Psychology, Normal and Morbid," and those dealing with insanity, may be considered as holding the highest rank among books of this kind, and as at least equal in value (though greatly differing in certain respects) to the now classical works of the late Dr Henry Maudsley, his illustrious senior and contemporary, on the "Physiology and Pathology of Mind," "From Organic to Human," "Body and Mind," etc.

Dr. Mercier's work, "The New Logic," has not pleased some professorial logicians, but, as a handbook of logical reasoning for scientific students, it is of great value. Nor does it appear that his criticisms of the prevalent logic of the schools have been materially shaken, or that his acute comments on Mill's "Canons of Induction" have ever been refuted. His two important books on "Criminal Responsibility" and "Crime and Criminals" are written with much knowledge and careful thought, and form together one of the most notable contributions in the English language to the psychology of criminals and to the nearly allied subject of criminal jurisprudence.

THE BRITISH ASSOCIATION AT BOURNEMOUTH.

BEFORE the delivery of Sir Charles Parson's presidential address to the British Association last week, Sir Arthur Evans, the retiring president, announced that it was proposed to present an address to the King. The announcement was received with much satisfaction, and the address, which is as follows, was enthusiastically approved :—

Your Majesty,—On the occasion of the outbreak of the great war we, the members of the British Association for the Advancement of Science, at that time assembled in our eighty-fifth congress, gave an unanimous expression to our devoted loyalty to your Majesty's person, which your Majesty was graciously pleased to acknowledge.

To-day, once more assembled in our eighty-seventh congress, it is our heartfelt desire, on the victorious conclusion of the war and the formal proclamation of peace, to renew those assurances, and to express in more than a formal manner our high sense of the example of self-sacrificing devotion to the service of the country that has been so simply offered by your Majesty throughout this long and arduous struggle.

We are painfully aware, indeed, that, in spite of the decision in the field, the period of stress is by no means over. We cannot, from our special point of view, be blind to the extent to which the bitter emergencies of war-time have been prejudicial to those ideas and methods which it is our mission to promote. But in the not less arduous struggle that lies before us to regain the stable paths of peace we are heartened by the knowledge that the same wise and conciliating influence and high example that was of such sovran help to the British people in war-time will still be with them.

In vacating the presidential chair Sir Arthur Evans referred to the unprecedented period of three years during which he had occupied it, and he added :—

Let it at once be said that, though the public meetings of the association have been suspended, its organisation was constantly directed, at times in conjunction with other bodies like the Royal Society, towards rendering active assistance to the Government of our country in its hour of need. This has been the case, not only in fields of activity such as chemistry and engineering or the conservation of fuel and other economic objects—in matters, that is, that had a more direct bearing on the emergencies of the struggle—but I think I may say, to a greater or less degree, in every section of our body.

That expert assistance, as we know, has not always been welcomed by the powers-that-be. The dire necessities of war-time have led to rough-and-ready expedients altogether foreign to scientific method, and often conflicting with the most elementary knowledge. On every hand we see improvised controls as unscientific as they are arbitrary. We witness the constant overriding of expert experience by a new-fangled bureaucracy. At every turn we are met with a mischievous interference with natural laws and the perpetuation of uneconomic devices under conditions that no longer even palliate them. Though formal peace has been proclaimed, we are confronted by an evil heritage of war, and at no time has the British Association had more urgent occasion to inculcate those scientific methods and ideas by which alone the country can hope to regain its equilibrium.

The attendance at the meeting numbered nearly 1500, which is about the same as that at Manchester in 1915, and must be regarded as very satisfactory after so long an interval since the last assembly at Newcastle, where the attendance was only 826. A noteworthy point of the Bournemouth meeting was the large attendances in all the sections, several of which were uncomfortably filled on more than one occasion. This is a sign both of activity and interest, and it suggests that most of those who attended the meeting this year are concerned directly or indirectly with the advancement of science. In this, as in other respects, the meeting differed somewhat from those of former years, and marked a promising beginning of a new era.

A Committee appointed by the Council reported upon various matters relating to the working of the Association, and the report was adopted with slight changes by the General Committee. The fee for new life members is to be 15*l.* instead of 10*l.*, and for annual membership 1*l.* 10*s.* instead of 1*l.*, the right to receive the annual volume being included in both cases. The class of associateship has been abolished. The General Committee decided that after the Cardiff meeting next year, which will be held from a Tuesday to the following Saturday, the old plan of meeting from Wednesday to Wednesday shall be followed. When the Association was founded the meetings began on Wednesdays because the old stage coaches took about a couple of days to bring members to them from other towns, but though this condition no longer holds good there was a general feeling that the week-end break which a Wednesday to Wednesday meeting gives has advantages from the point of view of social intercourse, and that the Association could profitably revert to it. A preferable plan would be to consult the Local Committee as to which of the two periods—Tuesday to Saturday or Wednesday to Wednesday—would best suit the town and district in which a meeting was being arranged instead of laying down a hard-and-fast rule for all meetings.

The question of the position of the Association as regards grants for scientific research was raised in the report of the special Committee referred to, and was discussed at a meeting of the General Committee. During its existence the Association has voted from its funds more than 80,000*l.* to its research committees, and it is scarcely too much to say that every pound of this large sum has been well expended. The grants are allocated each year by the Committee of Recommendations, which usually consists of the presidents and recorders of the various sections, together with the general officers. Every research committee has thus to present its case for support to an expert body of adjudicators which frequently devotes several hours to dividing up the 1000*l.* or so available at the end of each meeting into grants of 5*l.* and upwards for research committees put forward by the sectional committees. It has been suggested that in view of other claims upon the revenue of the Association the funds devoted to purposes connected with research should be more closely limited to incidental expenses inasmuch as other funds are now available to assist research itself. However this may be, the principle by which men of science themselves allocate grants in aid of research, as they do at a British Association meeting, is generally accepted to be the best, whether the funds are their own contributions or are entrusted to them for research purposes. The Association is, therefore, to continue the present system by which grants are allocated by the Committee of Recommendations, but the list of grants so made is afterwards to be submitted to the Department of Scientific and Industrial Research, which will select subjects it can support, and will relieve the Association of the financial obligations relating to such subjects.

It remains to be seen whether this method will provide the most effective link between the Department and the Association. A joint Committee, consisting of four members appointed by the General Committee, and four by the Council, is to inquire into the whole matter of the existing provision of grants in aid of scientific research and the organisation of research. No change in the Association's method is contemplated, but there is a feeling that a useful purpose would be served by a survey of what is now being done to promote research through grants in aid by various societies and other bodies, the methods by which such grants are allocated, and the conditions to be fulfilled by the recipients.

Next year's meeting is to be held at Cardiff under the presidency of Prof. W. A. Herdman, who has been succeeded as general secretary by Prof. J. L. Myres. An invitation to meet in Edinburgh in 1921 was unanimously accepted by the General Committee. The new members of the Council of the Association are: Prof. A. Fowler, Dr. E. H. Griffiths, Prof. A. W. Kirkaldy, and Dr. W. H. R. Rivers.

SECTION A.

MATHEMATICAL AND PHYSICAL SCIENCE.

OPENING ADDRESS BY PROF. A. GRAY, M.A., LL.D., F.R.S., PRESIDENT OF THE SECTION.

I HAVE devoted some little time to the perusal of the addresses of my predecessors in this chair. These have a wide range. They include valuable philosophical discussions of the nature of scientific knowledge and expositions of scientific method, as well as highly instructive *résumés* and appreciations of the progress of mathematics and physics. But as this is the first meeting of the British Association since the conclusion of peace, I have decided to disregard in the main these precedents, and to endeavour to point out, in the first place, some of the lessons which the war has, or ought to have, taught our country and those who direct its policy, and in particular ourselves, whose vocation it is to cultivate and to teach mathematical and physical science.

Before proceeding with this task I must refer to the loss which physical science and the British Association have suffered this year through the deaths of Prof. Carey Foster and Lord Rayleigh. Both these great physicists were regular in attendance at the meetings of the association, and they will be greatly missed.

What Carey Foster was as a man of science, as a teacher, and as a friend of all students of physics has been worthily set forth in the columns of NATURE with all the knowledge and affectionate reverence of one who was at once his pupil and his fellow-worker at University College. To that eloquent tribute I will not, though I knew Carey Foster well, venture to add a word.

It is not for me to appraise here the work of Lord Rayleigh. But I may say that for something like half a century his name has stood, not only for things that are great in physical discovery, but for sanity of judgment and clarity, elegance, and soundness of treatment of outstanding and difficult problems of mathematical physics. His researches, too, in experimental science have been fruitful in results of the utmost importance in chemistry as well as in physics. With him there was no shirking of the toil of monotonous and systematic observation from day to day in the pursuit of the greatest attainable accuracy; take, for example, his work on electrical units. But his influence on applied mathematics has also been enormous, and places him for all time in the foremost rank of the great physical mathematicians, at the head of which stands Isaac Newton. One has only to read his treatise on "The Theory of Sound" and his papers on optics and wave theory to find some of the most striking examples in all scientific literature of the working of a mind, not only of the first order of originality, but imbued with a feeling for symmetry of form and clearness of exposition.

Lord Rayleigh's genius was, it seems to me, essentially intuitive and practical. Though he was not given to any striving after the utmost rigidity of formal proof—which, as he himself remarked, might not be more but less demonstrative to the physicist than physical reasons—no man made fewer mistakes. He is gone, but he has left an inspiring example to his order and to his countrymen of a long life consecrated to the object for which the Royal Society, of which he had been the honoured president, was founded: the furtherance of natural knowledge.

The part which physical science has played in the conduct of the war on our side has been an important one, but it has by no means been so decisive as it might and ought to have been. And here lie the lessons which I think we can draw from the terrible events which have taken place. Some few people, mostly hostile to or jealous of science, whose vision of facts and tendencies seems to me to be hopelessly obscured by prejudice, would try to impose on the advance of natural knowledge and the supposed increased influence of scientific ideas on the minds of men, or, perhaps more precisely, on the diminution of the study of the so-called humanities, the sole or the main responsibility for the outbreak of war.

It seems to me that a good many people allow themselves to be misled by a name. The name "humanity" is given in the Scottish universities to the department of the Latin language and literature, and in a wider usage the study of Latin and Greek is referred to as that of *litterae humaniores*. But I am not aware that there is any more humanity, in the common acceptance of the term, about these studies than there is in many others. And experience has shown that the assertion that these studies have a special refining influence, while the pursuit of science has a brutalising tendency, is based on ignorance and partiality. The truth is that the man who knows nothing of science, and he who has neglected the study of letters, are both imperfectly educated.

Well, the accusation I refer to may be dismissed without argument. This is certainly not the time or the place for a discussion of the causes of the war, or of the ethics of the extraordinary methods introduced into warfare by our enemies. But one thing I will say in this connection. Even poison gas is innocent in itself, and it occurs as a product in perfectly indispensable and eminently useful chemical processes. The extraordinary potency of scientific knowledge for the good of civilised mankind is frequently conjoined with a potency for evil; but the responsibility for an inhuman use of it does not lie with the scientific investigator. The guilt lies at the door of the High Command, of the high and mighty persons, themselves in feeling and temper utterly unscientific, who approved and directed the employment of methods of attack which destroyed the wounded and helpless, and wrecked for ever the health of many of those who emerged alive from the inferno.

As regards the help which British science was able to render in the defence against the German attack and the operations which followed when the fortune of war changed so dramatically, and the enemy was driven back towards the chain of fastnesses from behind which he originally emerged, one or two obvious reflections must have occurred to everyone. In one form or another these have been referred to by various writers, but I may recall one or two of them; for as a people we are incorrigibly forgetful, and appear to be almost incapable of profiting from experience, which, according to the Latin proverb, teaches even fools.

Nearly twenty years ago the urgent necessity for the reorganisation of our military machinery had been, in the view of civilians at least, who had to bear the cost of the war in South Africa, demonstrated *ad nauseam*, but nothing of real importance in the way of reforming the War Office seems to have been done. The shocks we had received were forgotten, and soon the nation returned to its insular complacency, the old party cries resounded in the market-place, the hacks of party politics again resumed their occupation of camouflage and hoodwinking, and the country drifted on towards its fate.

All this time an enormously powerful war machine was being built up on the Continent, and its different parts tested so far as that could be done without actual warfare. The real object of these preparations was carefully veiled by an appearance of frankness and professions of goodwill, though it was revealed every now and then by the indiscretions of the German military caste. To these indications and to others the country, ostrich-like, closed its eyes.

Now it is often alleged that men engrossed in the pursuit of science are unbusinesslike, but I think that if there had been any truly scientific element in the *personnel* of the Government (there never is by any chance), attention would have been directed at a much earlier period to our hopeless state of unpreparedness for the storm which was gradually gathering against us on the other side of the German Ocean. In discussions of our unpreparedness the emphasis has been placed on our lack of arms and munitions. But important as these are, the entire absence of a scientific organisation to guide us in the exigencies of a defensive war with the most scientific and most military nation of Europe was even more serious.

It is this deficiency in our organisation—a deficiency the avoidance of which would have had no provocative effect whatever—which concerns us here very specially. It is, moreover, a deficiency which, in spite of the lessons they have received, has, I fear, not yet been brought home to our military chiefs. When war broke out nothing had been done to ensure the utilisation for special service, in the multitude of scientific operations which war as carried on by the German armies involved, of the great number of well-trained young scientific men available in the country. The one single idea of our mobilisers was to send men to the trenches to kill Germans, and for this simple duty all except certain munition workers and men in the public services were summoned to the Army. Some modifications were made afterwards, but I am speaking of the failure of prevision at the outset. The need of men for special service, the inevitable expansion of the Navy for patrol and other purposes and the like, were, if they were thought of at all, put aside, without regard to the difficulties which would inevitably arise if these matters were delayed. Even how the new soldiers were to be trained, almost without rifles or machine-guns, to meet the Germans in the field nobody knew. And I for one believe that but for the vigour and energy of Lord Kitchener, and the almost too late expression of conviction of our danger, and consequent action, by one outstanding politician, all would have been lost. We worried through, but at a loss of life and treasure from which it will take us long to recover, and which I could wish seemed to weigh more heavily on the minds and consciences of politicians.

The Germans, I believe, had a complete record, not only of all their men fitted only for the rank-and-file, but also of all who had been trained to observe and measure. For the use of even the very simplest apparatus of observation a certain expertness in reading graduated scales, and generally a certain amount of trained intelligence, is required. For this the laboratories of Germany amply provided, and the provision had its place in the enemy's mobilisation. Our people apparently did not even know that such a need existed or might arise.

In a letter which I sent to the council of the Royal Society at the end of 1915 I ventured to propose that the Royal Society might set on foot an organisation of some such character as the following:—First, a central committee should be established, in some degree representative of the different centres of scientific teaching and work in pure and applied science. Then this committee should nominate representatives at each centre, at least one at each university or college, and one at the headquarters of each local society, such, for example, as the Institution of Engineers and Shipbuilders of Scotland and the similar society which represents the North-East of England and has its offices at Newcastle-upon-Tyne. This arrangement, it was hoped, would enable the central committee to obtain readily information as to what men were available, and would therefore do something to bring the schools of science, and all the great workshops and laboratories of applied science, into co-operation. Thus could be formed at once a list of men available for particular posts, for the task of solving the problems that were certain to arise from day to day, and for the special corps which it was soon, if dimly, perceived were a necessity. Some such linking-up of London with the provinces is really indispensable. The districts of, for example, the Tyne and the Clyde are too much ignored in almost all Government action of a general kind.

My letter was printed and sent out to some prominent men, by whom its proposals were highly approved. A conference on its subject was held in London, and two special committees were appointed. I was a member of one of these, the principal duty of which was to provide scientific men for special service. It included representatives of the various great departments actively engaged in the conduct of the war. For some reason or other, which I never learned, the committee after a week or two ceased to be called, and I believe that little was done in comparison with what might have been accomplished. It was certainly not because such a committee would not work. Everybody was most willing, with proper notice, to attend such meetings as were involved, and to take any amount of personal trouble; moreover, the scheme was such as to provide that there should always be a nucleus of members in London to consult and act in any emergency.

I may briefly refer to one or two examples of the chaos which prevailed and the attempts that were made to cope with it. Very soon after the formation of the first Kitchener Army the organisation of the different corps apparently became a source of anxiety to the War Office. It began to be seen that officers in sufficient numbers could not possibly be obtained by the usual channels, so the expedient (a poor one by itself) was hit upon of placing the nominations to commissions in one at least of the two great scientific corps of the Army—the Royal Engineers—in the hands of the presidents of certain technical institutions which have their headquarters in London. These gentlemen, with the help of the official secretaries, no doubt did the best they could, but a very regrettable, though perfectly natural, amount of strong feeling was evoked among the young scientifically educated men in the provinces, who were keenly anxious to join this corps. The Engineers, I may scarcely say, is no refuge for men who are in the least concerned about their personal safety, for the percentage of casualties among engineers on active service was notably higher than in the regiments of the line. Over and over again young engineers came to me and complained that under the arrangements made they had no chance of obtaining commissions or of qualifying as cadets, and begged me to write to the authorities. Of course, young graduate engineers do not, as a rule, join societies such as the Institutions of Civil, Mechanical, or Electrical Engineers until they have made their way to some little extent and begun to earn a little money.

The procedure I have indicated had in time to be relaxed, but such a central committee as I suggested, with antennæ stretching out to the educational and technical centres of the country, would, I am sure, have recruited the Engineers quickly with the best possible material for officers to be found in the country, to the satisfaction of all concerned. It may be said that full information regarding every man in the country was in the hands of the authorities. In a sense, this was true; the information existed in millions of returns and thousands of pigeon-holes, but no attempt was made, or could be made, by office staffs in London, enormous as these quickly became, to digest and utilise it.

A large number of engineers and physicists and many others of mechanical skill and aptitudes found congenial occupation in the Royal Naval Air Service and the Royal Flying Corps; but even there, where things could be better done, since a new force had to be brought into existence, arrangements were to a considerable extent haphazard and ill thought out. Excellent self-sacrificing service was rendered by many who risked and gave their lives, and of what was done we may well be proud. But from a scientific point of view there is room for great improvement. The hasty and ill-considered —as I think—amalgamation of these two branches of the Air Service, in which naval traditions were sacrificed to those of the War Office, which deserved no such deference, will certainly have to be undone in the near future or very greatly transformed. To anyone who considers the possibilities and probabilities of warfare in the future, it appears clear that this country will have to depend more and more upon its Navy, and that an Air Service Corps will be the companion of every division of our Fleet, with landings on the warships. Thus a new and highly scientific Service, which will have to be to a great extent naval, will be brought into existence.

Well, then, to return for a moment to my proposal to the Royal Society, why should the organisation which I suggested in 1915 not be established now? I wish all success to the League of Nations, but we shall prove ourselves even greater fools than we have been in the past if we do not use all possible means to prepare ourselves against eventualities. One attempt by our enemies outside our own borders to hold us to ransom has failed. Can we be so sure that no other attempt will ever be made, or that no *casus belli* between ourselves and another great nation will ever arise? This, I notice, is beginning to be assumed even in the midst of the welter of confusion and unrest that exists, and, among others, by just the very people who used to teach that the possibility of war was a great illusion.

The formation of a record of scientific graduates for special service ought not to be difficult. The material already in great measure exists. Each university and college has its roll of graduates or diploma-holders; and with slightly more detailed entries these rolls would give the record. Each graduate of a university is kept track of through the necessity for keeping the electoral roll up-to-date, and it ought to be possible to devise a means of maintaining touch with the diploma-holder. If each university or college were a local centre of the central committee, the making of the roll of graduates would be achieved at the different local headquarters, and would be a valuable supplement to the O.T.C. work now undertaken so willingly and done so well. The Government machinery which manages the O.T.C. movement might control the keeping of the register which I have suggested.

I turn now to another side of scientific work during the war. It was my lot to serve for nearly three years on the Inventions Panel of the Ministry of Munitions, and as the result of that experience I venture to make some observations on the utilisation of scientific knowledge and genius in the production of inventions useful for the public service. We had an enormous multitude of inventions to consider, and the Panel was divided into Committees for this purpose. For each invention or proposal a file or *dossier* was prepared and most carefully kept. There were also present at the meetings of the Panel very efficient officers representing different branches of the Service. Everything received careful attention, and for the ability and fairness with which the initial examination was made by the corps of examiners, and the *précis* of the invention presented, I have great admiration. Much has been said about the inefficiency and the mistakes of various Government Departments during the war. The Ministry of Munitions Inventions Department was, so far as I could see, eminently well managed.

Many of the so-called inventions were not inventions at all. Some were not at all new; in other cases an idea only was mooted. Could so-and-so not be done? and so on, and the Department was supposed to be grateful for the idea, and to do the rest, besides rewarding the proposer. A favourite notion, which illustrates the diffusion of scientific knowledge among different classes of people, was that of taking a magnet—any magnet—up on an aeroplane, and using it to attract Zeppelins and other aircraft. Others suggested electromagnets fed by machines which would have involved carrying into the air on an aeroplane a fully equipped power-house! Another favourite notion, inspired, no doubt, by a certain sensational type of article in the fiction magazines, was that of rays charged in some way with electricity, or some other mysterious agency, and therefore intensely destructive.

But there was a residuum of valuable inventions which fully justified the existence of the Department. These were recommended for further consideration by the various departments of the Services or by General Headquarters. It by no means followed that all that came to this stage received careful further consideration. Everybody was very hard worked, and many were overdriven. And it was by no means certain that when important approved appliances were sent to G.H.Q. a thoroughly well-informed and capable officer would in all cases have the duty of explaining and showing their action. The absence of such an officer, I am sure, often resulted in delay and serious error, and, I fear, also in the rejection of what was in itself exceedingly good, but was not understood. People who knew nothing about the matter took charge, and ordered things to be done which brought disaster to the apparatus. I know of one very important machine which was ruined, with much resulting delay. A brigadier or major-general with a confidence born of blank ignorance ordered a motor-generator to be put on town electric mains, and, of course, burnt it out.

Then, again, we were told that G.H.Q. did not want this or that, and here, as in all human affairs, mental inertia certainly played a considerable part. The willingness, however, of some Departments to adopt at once a device captured from the enemy was pathetic. Often quite clumsy and relatively inferior contrivances were adopted in the midst of hesitation about our own. Anything German of this sort some people assumed must be good—a foolish idea, the result of want of confidence, often well founded, I am afraid, in their own judgment. It is legitimate to copy from the enemy, and in several important things we have not been slow to do so.

The delays that occurred were to some of us at home, who were anxiously dealing with all kinds of contrivances, exceedingly exasperating. Some were undoubtedly unavoidable, but others were, as I have indicated, far otherwise. Deficiency in scientific education was the cause. It is to enforce the need for such education that I refer to such matters at all. The "playing fields of Eton" are all very well. I for one do not scoff at what the old saying stands for, but scientific laboratories and good intelligent work in them are indispensable. A man who directs in whole or in part a great machine must know something of its structure and capabilities.

I feel bound to allude to another aspect of the inventions business which, to my mind, was very serious. In doing so, however, I wish it to be clearly understood that I am criticising a system, and in no way here referring to particular individuals concerned in its administration. Various inventions which had passed satisfactorily the first examinations by responsible judges were submitted to technical departments at home to be subjected to practical tests. These inventions were frequently proposed solutions of problems on which technical officers, of the departments required to conduct the tests, had long been engaged. It was natural, indeed inevitable, that some of these officers should have come to regard the solving of these problems as their own special job, and so did not much welcome the coming of the outside inventor. Then, no doubt, they often felt that they were just on the point of arriving at a solution—a feeling that certainly could not facilitate the avoidance of delay. It was manifestly most unfair to ask them to judge the work of the outside inventor, or to place in their hands details of his proposals, for exactly the same reason which in civil life restrains a man from acting as a juror in a case in which he is personally interested. Nobody of good sense feels offended when attention is directed to such a rule in practice.

Thus I have no hesitation in expressing the opinion that a testing board of practical, well-qualified physicists and other experts, with a properly qualified staff, should be formed for the purpose of carrying out all tests of inventions. No insuperable difficulty would, I believe, be experienced in forming such a board. It should be formed carefully, not by more or less casual nomination of one another by a few persons. Expert knowledge of a subject should be a necessary qualification; the so-called "open mind" of the much-lauded but untrained practical man is not worth having. But on that board neither inside nor outside inventors of the same kind of appliances should have any place, though, of course, consultation with the author of an invention under test would be absolutely necessary. Also those actually carrying out the tests and those collating the results should not be men in any way in the employment of, or under the supervision of, inventors, whether "outside" or "inside." It is imperative in the interests of the country that delay in such matters should be avoided, and that all such work should be done without fear or favour.

The value of university and college men trained in science has been thoroughly proved in the Artillery, the Engineers, and in their offshoots, the Special Sound-ranging and Survey Corps, though its recognition by the authorities of Whitehall has been scanty and grudging. Some of the old-fashioned generals and staff officers could not be got to see the use of men who had not been trained to field exercises by a long course of drill. What is the good of officers, they said, who are not skilled leaders of men? This is the old crude idea again of destroying Germans with rifles, bayonets, and hand-grenades. The falsity of these antiquated notions has now, I believe, been amply demonstrated.

The objection to these men, however, lies a good deal deeper. Even those scientifically educated officers who came into the new armies when they were formed, and were trained by the service of years of warfare superadded to the initial course of drill, have been demobilised in a nearly wholesale manner, without the least regard to even very exceptional qualifications. Many of these were, it seems to me, the very men who ought, above all, to have been retained in the Service. Now (though, as I write, improved regulations are being issued) they are to a great extent to be replaced by the public school-*cum*-Sandhurst young gentlemen, who, it appears, are the "pukka" officers *par excellence*.

The old system of the rule of politician chiefs whose only or main function is to sign the edicts of heads of departments seems to have returned in full force, and the coming of the cleansing Hercules that many people desire for the War Office does not seem to be within the bounds of possibility.

The real cause of the prevailing neglect of science, with all its pernicious results, is that almost all our political leaders have received the most favoured and fashionable form of public school education, and are without any scientific education. An education in classics and dialectics, the education of a lawyer, may be a good thing—for lawyers; though even that is doubtful. For the training of men who are to govern a State the very existence of which depends on applications of science, and on the proper utilisation of available stores of energy, it is ludicrously unsuitable. We hear of the judicial frame of mind which lawyers bring to the discussion of matters of high policy, but in the majority of scientific cases it is the open mind of crass ignorance. The result is lamentable; I myself heard a very eminent counsel declare in a case of some importance, involving practical applications of science, that one of Newton's laws of motion was that "friction is the cause of oscillations"! And the helplessness of some eminent counsel and judges in patent cases is a byword.

As things are, eminence in science is no qualification; it would even seem to be a positive disqualification for any share in the conduct of the affairs of this great industrial country. The scientific sides of public questions are ignored—nay, in many cases our rulers are unconscious of their existence. Recently in a discussion on the Forestry Bill in the House of Lords a member of that illustrious body made the foolish assertion that forestry had nothing to do with science; all that was needed was to dig holes and stick young trees into them. Could fatuity go further? This hereditary legislator who, as things are, has it in his power to manage, or mismanage, the conversion into available energy of the radiation beneficently showered on a certain area (his area) of this country of ours does not seem to be aware that the growing of trees is a highly scientific industry; that there are habits and diseases of trees which have been profoundly studied; that, in short, the whole subject of sylviculture bristles with scientific problems, the solutions of which have by patient labour been to a considerable extent obtained.

Take also the case of the dyes industries. The publicists and the good business men—the supermen of the present age—who wish to control and foster an industry which owes its very existence to an English chemist, refuse to have on the committee which is to manage this important affair any man of scientific eminence, and no remonstrance has any effect. These great business men are, as a rule, not scientific at all. They are all very well for finance; in other respects their businesses are run by their works-managers, and, in general, they are not remarkable for paying handsomely their scientific assistants.

I myself once heard it suggested by an eminent statesman that an electrical efficiency of 98 per cent. might by the progress of electrical science be increased fourfold. This, I am afraid, is more or less typical of the highly educated classical man's appreciation of the law of conservation of energy; and he is—save the mark!—to be our Minister or Proconsul and the conservator of our national resources. It is not surprising, therefore, that in connection with a subject which for several weeks occupied a great space in the newspapers, and is now agitating a large section of the community, the nationalisation of our coal-mines, there was not a single word, except perhaps a casual vague reference in the report of the chairman, to the question which is intimately bound up with any solution of the problem which statesmen may adopt—I mean the question of the economic utilisation, in the interests of the country at large, of this great inheritance which Nature has bestowed upon us. In short, are Tom, Dick, and Harry, if we may so refer to noble and other coalowners, and to our masters the miners, to remain free to waste or to conserve at their own sweet will, or to exploit as they please, this necessity of the country's existence?

The fact is that until scientific education has gone forward far beyond the point it has yet reached, until it has become a living force in the world of politics and statesmanship, we shall scarcely escape the ruin of our country. The business men will not save us; as has been said with much truth, the products of modern business methods are, to a great extent, slums and millionaires. It lies to a great extent with scientific men themselves to see that reform is forthcoming; and more power to the British Science Guild and to any other agency which can help to bring about this much-needed result.

While scientifically educated men, whether doing special work or acting as officers, have been held of far slighter account in the Services than they ought to have been, for physicists as such there has been little or no recognition, except, I believe, when they happened to be ranked as research chemists! How did this happen? Why, the various trades asserted themselves, and the result was a sufficiently long list of "reserved occupations"—a list remarkable both for its inclusions and for its exclusions. There was, for example, a class of "opticians," many of whom have no knowledge of optics worth mentioning. They are merely traders. One of these, for example, the proprietor of a business, made a plaintive appeal to myself as to how he could determine the magnifying powers of certain field-glasses which he wished the Ministry of Munitions to purchase. But for a young scientific man, even if he were an eminent authority on theoretical and practical optics, but who was not in the trade, there was no place.

Research chemists received their recognition in consequence of the existence of the Institute of Chemistry. I am extremely glad to find that something is now being done to found an Institute of Physics. I hope this movement will be successful, and that it will be thoroughly practical and efficient. I hope its president and council, its members and its associates, will be jealous for science, and especially for physics. It ought to be a thoroughly hard-working body, without any frills, destitute of work value. They have an example in the General Medical Council, which has so effectively cared for the interests of the medical profession.

I am glad that something is being done at last for the organisation of scientific research. This movement has started well in several, if not in all, respects, and I wish it all success. There are, however, one or two dangers to be avoided, and I am not sure—I may be much too timid and suspicious—that they are fully recognised, and that the result will not be too much of a bureaucracy. Somehow or other I am reminded by the papers I have seen of the remark of a poor man who, asking charity of someone in Glasgow, was referred to the Charity Organisation Society of that city. "No, thank you," he said; "there is a good deal more organisation than charity about that institution." So I hope that in the movement on foot the organisation will not be more prominent than the science, and the organisers than the scientific workers.

There is, to my mind, too much centralisation aimed at. Everything is to be done from London;

a body sitting there is to decide the subjects of research and to allocate the grants. There may be a good deal to be said for that in the case of funds obtained in London. But apparently already existing local incentives to research work are to be transferred to London. The Carnegie Trust for the Universities of Scotland, soon after its work began, inaugurated a scheme for research work in connection with these universities. The beneficiaries of the Trust, it is well known, must be students of Scottish nationality. The action of the Trust has been most excellent, and much good work has been done. Now, so far as chemistry and physics are concerned, it has been proposed, if not decided, to hand over to the organisation in London the making of the awards, a process of centralisation that will probably not end with these subjects. I venture to protest against any such proceeding. The more incentives and endowments of research that exist and are administered in the provinces the better. Moreover, this is a benefaction to Scottish students which ought not to be withdrawn and merged in any provision made for the whole country, and administered in London by a bureau which may know little of the Scottish universities or of Scottish students. The bureau might, with equal justice or injustice, be given command of the special research scholarships of all the universities both in England and Scotland, and administer them in the name of the fetish of unification of effort. I do not know, but can imagine, what Oxford and Cambridge and Manchester and Liverpool would say to that. But even Scotland, where of course we know little or nothing about education of any kind, may also have something to say before this ultra-centralisation becomes an accomplished fact.

There is, it seems to me, another danger to be avoided besides that of undue centralisation in London. In most of the statements I have seen regarding the promotion of research work, the emphasis seems to be on industrial research—that is, in applied science. This kind of research includes the investigation of physical and chemical products of various kinds which may be used in arts and manufactures, and its deliberate organised promotion ought to be a commercial affair. I observed, by the way, with some amusement, that according to the proposals of one committee for applied science, which is prepared to give grants and premiums for researches and results, the professor or head of a department, from whom will generally come what are most important, the ideas, is to have no payment. He is supposed to be so well paid by the institution he belongs to as to require no remuneration for his supervision of the committee's researches. And the results are to be the sole property of the committee!

There is in this delightfully calm proposal at least a suggestion of compulsion and of interference with institutions and their staffs which ought to be well examined. Also some light is thrown on the ideas of such people as managing directors of limited liability companies, who are members of such a committee, as to what might reasonably be expected of men of high attainments and skill whose emoluments taken all round are, on the whole, miserably insufficient.

I think that it is in danger of being forgotten that, after all, pure science is by far the most important thing. Most of the great applications of science have been the products of discoveries which were made without any notion of such an outcome. Witness the tremendous series of results in electricity of which the beginning was Faraday's and Henry's researches on induction of currents, and the conclusion was the work of Hertz on electric waves. From the first came the production and transmission of power by electricity; from the last the world has received the gift of wireless telegraphy. I am not at all sure whether the great men who worked in the sixty or seventy years which I have indicated would have always received grants for proposed researches, which to many of the good business directors and other supermen serving on a great bureau of investigation, had such then existed, would have appeared fantastic and visionary. In research, in pure science at least, control will inevitably defeat itself. The scientific discoverer scarcely knows whither he is being led; by a path he knows not he comes to his own. He should be free as the wind. But I must not be misunderstood. Most certainly it is right to encourage research in applied science by all available and legitimate means. But beware of attempting to control or "capture" the laboratories of pure science in the universities and colleges of the country. Let there be also ample provision for the pursuit of science for its own sake; the return will, in the future as in the past, surpass all expectation.

I had intended to say something about scientific education as exemplified by the teaching of physics. I have left myself little time or space for this. I cannot quite pass the matter over, but I shall compress my remarks. In the first place, I regard dynamics, especially rotational dynamics, as the foundation of all physics, and it is axiomatic that the foundation of a great structure should be soundly and solidly laid. The implications of dynamics are at present undergoing a very strict and searching examination, and now we may say that a step in advance has been taken from the Newtonian point of view, and that a new and important development of dynamics has come into being. I refer, of course, to the new theories of relativity which are now attracting so much attention. I hope to learn from the discussions, which we may possibly have, something of the latest ideas on this very fundamental subject of research. It is a matter for congratulation that so many excellent accounts of relativity are now available in English. Some earlier discussions are so very general in their mathematical treatment and notation as to be exceedingly difficult to master completely. I have attacked Minkowski's paper more than once, but have felt repelled, not by the difficulties of his analysis, but by that of marshalling and keeping track of all his results. Einstein's papers I have not yet been able to obtain. Hence it is a source of gratification to have Prof. Eddington's interesting report to the Physical Society and the other excellent treatises which we have in English. But continual thought and envisaging of the subject is still required to give anything approaching to instinctive appreciation such as we have in ordinary Newtonian dynamics. I venture to say that the subject is pre-eminently one for physicists and physical mathematicians. In some ways the new ideas bring us back to Newton's point of view as regards so-called absolute rotation—a subject on which I have never thought that discussions of the foundations of dynamics had said absolutely the last word. I, for one, still cling to the æther, and am strongly of opinion that the whole subject of æther and matter and electrons require much more complete physical treatment than it has yet received from relativists.

The better the student of physics is grounded in the older dynamics, and especially in the dynamics of rotation, the sooner will he be able to place himself at the new point of view, and the sooner will his way of looking at things begin to become instructive.

With regard to the study of physics in our universities and colleges, I had written a good deal. I have put that aside for the present, and will content myself with only a few general observations. First, then, it would, I think, be conducive to progress if it were more generally recognised that dynamics is a physical subject, and only secondarily a mathematical one. Its study should be carried on in the departments of physics, not in those of mathematics or in separate departments of applied mathematics. It is, or ought to be, essentially a subject of the physical lecture-room and the physical laboratory. The student should be able to handle rotating bodies, to observe and test the laws of precession and nutation—to work himself, in a word, into an instinctive appreciation of at least the simpler results of rotational theory. He should learn to think in vectors, without necessarily referring either to Hamilton or to Grassmann. Some people appear to censure the use of vector ideas without the introduction at the same time of some form of vector notation. I do not feel drawn to any system of vectors in particular—all have their good points, and in some ways for three-dimensional work the quaternion analysis is very attractive—but vector *ideas* are of the very utmost importance.

Hence I deprecate the teaching, however elementary, which as a beginning contents itself with rectilineal motion. The true meaning of rate of change of a directed quantity, even of velocity and acceleration, is missed, and instead of having laid a foundation for further progress the teacher, when he desires to go beyond the mere elements, has practically to relay his foundations; has, in fact, to extract imperfect ideas from his pupils' minds and substitute new ones, with the result that a great deal of avoidable perplexity and vexation is produced. The consideration of the manner of growth of vectors—the resultant vector or it may be component vectors, according to convenience—is the whole affair. As an illustration of what I mean, take this:—A vector quantity has a certain direction, and also a magnitude L. It is turning in a certain plane with angular speed ω. This turning causes a rate of production of the vector quantity about a line in that plane and perpendicular to the former, and towards which the former is turning, of amount $L\omega$. Thus a particle moving in a curve with speed v has momentum mv forwards along the tangent at the position of the particle. The vector is turning towards the principal radius (length R) of curvature at the point at rate v/R. Hence towards the centre of curvature momentum is growing up at time-rate mv^2/R.

Dealt with in this way, with angular momentum instead of simple momentum, the motions of the principal axes of a rigid body give the equations of Euler instantly and intuitively, and all the mind-stupefying notions of centrifugal couples and the like are swept away.

With regard to mathematics, the more the physicist knows the better, and he should continually add to his store by making each physical subject he takes up a starting-point for further acquisition. Some very philistine notions as to mathematics prevail, and are very mischievous. For example, I once heard an eminent practical engineer declare that all the calculus an engineering student requires could be learned in an hour or two. This is simply not true, nor is it true, as some exponents of ultra-simplicity seem to suggest, that the professional mathematical teacher wilfully makes his subject difficult in order to preserve its esoteric character. Like the engineer or physicist himself, he is not always so simple as he might be; but the plain truth is that no good, progressive mathematical study can be carried out without hard and continued application of the mind of the student to the subject. And why should he depend on the mathematical reader? Let him be his own teacher! There are plenty of excellent books. If he has a determination to help himself he will, if he makes a practice of reserving difficulties and returning to them, find them vanish from his path.

As I have said, I am specially interested in rotational dynamics. In the course of the war I have been appalled by the want of appreciation of the principles of this subject which, in spite of considerable acquaintance with the formal theory, seemed to prevail in some quarters. I do not refer to mistakes made by competent people—it is human to err—but to the want of appreciation of the true physical meaning of the results expressed by equations. A gyrostat, as ordinarily considered, is a closed system, and its dynamical theory is of a certain kind. But do away with the closedness, and the dynamical theory is quite a different affair. Take, as an example, the case of two interlinked systems which are separately unstable. This compound system can be made stable even in the presence of dissipative forces. A certain product of terms must be positive, so that the roots of a certain determinantal equation of the fourth degree may all be positive. The result shows that there must be angular acceleration, not retardation, of the gyrostat frame. This acceleration is a means of supplying energy from without to the system, the energy necessary to preserve in operation the functions of the system.

I have ventured to think this stabilising action by acceleration of the compound motion very important. It is lost sight of by those who consider and criticise gyrostatic appliances from the usual and erroneous point of view. Also, I believe that it is by analogy a guide to the explanation of more complicated systems in the presence of energy-dissipating influences, and that the breaking down of stability or *death* of the system is due to the fact that energy can no longer be supplied from without in the manner prescribed for the system by its constitution.

I had just concluded this somewhat fragmentary address when the issue of NATURE for July 24 came to hand, containing a report of Sir Ernest Rutherford's lecture at the Royal Institution on June 6. The general result of Sir Ernest's experiments on the collision of α-particles with atoms of small mass is, it seems to me, a discovery of great importance, whatever may be its final interpretation. The conclusion that "the long-range atoms arising from the collision of α-particles with nitrogen are not nitrogen atoms, but probably charged atoms of hydrogen or atoms of mass 2," is of the utmost possible interest. The α-particle (the helium atom, as Rutherford supposes it to be) is extraordinarily stable in its constitution, and probably consists of three helium nuclei each of mass 4, with two attached nuclei of hydrogen, or one attached nucleus of mass 2. The intensely violent convulsion of the nitrogen atom produced by the collision causes the attached nuclei, or nucleus, to part company with the helium nuclei, and the nitrogen is resolved into helium and hydrogen.

It seems that, in order that atoms may be broken down into some primordial constituents, it is only necessary to strike the more complex atom with the proper kind of hammer. Of course, we are already familiar with the fact that radio-active forces produce changes that are never produced by so-called *chemical* action; but we seem now to be beginning to get a clearer notion of the *rationale* of radio-action. It seems to me that it might be interesting to observe whether any, or what kind of, radiation is produced by the great tribulation of the disturbed atoms and continued during its dying away. If there is such radiation, determinations of wave-lengths would be of much importance in many respects.

I may perhaps mention here that long ago, when the cause of X-rays was a subject of speculation and the doctrine that mainly found acceptance was that they were not light-waves at all, I suggested to the late Prof. Viriamu Jones that radiation of extremely small wave-length would be produced if atomic or molecular vibration, as distinguished from what in comparison might be called molar vibration, could be excited. An illustration that suggested itself was this:—Take a vibrator composed of a series of small masses with spring connections. If these masses are of atomic or molecular dimensions any ordinary impulse or impact would leave them unaffected, while vibrations of groups of them, depending on the connections, would result. But the impact on one of the masses of a hammer of sufficiently small dimensions and mass would give vibrations depending on the structure of the mass struck, and independent of the connections, just as the bars of a xylophone ring, while the suspended series of bars, if it swings at all, does so without emitting any audible sound. This is, I believe, in accordance with the theory now held as to X-rays. We now have some information as to the mode of producing a local excitement so intense as to cause, not merely atomic disturbance, but actual disruption of the atomic structure. Further developments of Sir Ernest Rutherford's experiments and of his theory of their explanation will be eagerly awaited.

SECTION B.

CHEMISTRY.

OPENING ADDRESS BY PROF. P. PHILLIPS BEDSON, D.Sc., PRESIDENT OF THE SECTION.

IN again taking up the work of this section, after an interval of three years, a discontinuity without parallel in the annals of the association, it is natural that our thoughts should turn to the past, and in so doing we are reminded of the gaps in the ranks of those who were accustomed to contribute to the work of our section. In 1916 we met under a shadow caused by the death of Sir W. Ramsay, whose genius added in so many ways to our science. And to-day we have to record the loss of one who in his long life contributed in a variety of ways to the advancement of chemistry, and to whom we owe an addition to the number of elementary substances in the discovery of thallium, one of the early fruits of the use of the spectroscope. The chemistry of the rare earths has been especially illumined by the researches of Sir William Crookes. With physicists we would join in a tribute to the memory of Lord Rayleigh, amongst whose experimental researches is one of special interest to chemists, namely, the revelation of the existence of argon, of which discovery Sir J. J. Thomson has recently written that it was not made "by a happy accident, or by the application of new and more powerful methods than those at the disposal of his predecessors, but by that of the oldest of chemical methods: the use of the balance."

In this connection it is but right that, despite the feelings engendered by the war, I should refer to the passing of two great chemists—Baeyer and Fischer. The former died some two years ago, and the latter within the past two months. Each of them advanced by his experimental researches the progress of organic chemistry, and brought illumination into many of the obscure departments of this branch of science. The field of investigation latterly cultivated by Fischer has revived an interest in the "vital" side of organic chemistry as distinguished from the study of chemistry of the carbon compounds. Moreover, there are many British chemists, amongst them some of the most distinguished, who, as students, received guidance and inspiration from the teaching of Baeyer or of Fischer, and with them we gratefully acknowledge our indebtedness.

Fifty years ago Mendeléeff communicated to the Russian Chemical Society a memoir which has exercised a profound influence on chemical philosophy, and continues to serve as a guide in the interpretation of research and speculations on the nature of the elements. Without entering on the somewhat vexed question as to whom should be assigned the credit of the discovery of the periodic law, I trust I shall not be considered unmindful of the claims of Newlands by adopting the traditional history, and, as is usual, associate this discovery with the name of Mendeléeff, and consequently we may look on this year as the jubilee of the periodic law. Although there is already abundant special literature dealing with this subject, and the periodic system has been assimilated into the teaching of the science, and is dealt with in the text-books of chemistry, in some of which it forms the basis of the system employed in the exposition of the facts and theories of inorganic chemistry, still it appeared to me that I might utilise this as an opportunity of passing in brief review some of the features of the rise and development of the "periodic law."

The memoir, made known to the non-Russian reader by the abstract in German, shows the principle of periodicity, viz. the recurrence of similar properties at regular intervals with increase in the magnitude of atomic weights, the possibility of utilising the atomic weights as a basis of the classification of the elements, the necessity for the revision of the values thus assigned to the atomic weights of certain elements, and finally that the scheme demanded for its completeness the existence of many new elements.

The later writings of Mendeléeff contain the mode of tabulating the elements in the form usually adopted in chemical text-books, portraying the principle of periodicity and showing the grouping of the elements into natural families. But undoubtedly the clearest demonstration of the association between the atomic weights and the physical properties of the elements is that exhibited by the curve of atomic weights and atomic volumes, which is an outcome of the independent studies of these relationships by Lothar Meyer, and, as is well known, shows the members of the natural families of elements occupying corresponding positions on the curve. This curve, with its undulations, corresponding with the series of the elements, has contributed to impress on the mind of the student the relationship between the properties of the elements and their atomic weights, and may have exercised an influence in directing attention to these relationships which the attempts of the earlier workers in this field were not successful in doing.

Mendeléeff's table of the elements was just beginning to figure in the teaching of chemistry in my undergraduate days, and, together with the speculations underlying it, aroused considerable interest and proved an incentive and inspiration for experimental inquiry. Foremost in this country amongst those who by their writings have contributed to spread a knowledge of Mendeléeff's speculations was my fellow-student, Carnelley. His experimental investigations added materially to our knowledge and definition of the physical properties of elements and compounds, which further emphasised the periodicity in the relation of the atomic weights to the properties of the elements, and have provided data from which curves, resembling in contour the atomic volume curve, have been set up.

A valuable guide in fixing the atomic weights of the elements has been the specific heat which, as the discovery of Dulong and Petit showed a hundred years ago, varies in the case of solid elementary bodies inversely with their atomic weights; or, as it is more usually expressed, the solid elements have the same atomic heat. The investigation of the exceptions to this empirical rule brought out the fact that the specific heat is influenced by temperature, and the study of the influence of low temperatures led Sir James Dewar to the discovery that at about 50° Absolute the atomic heats of the elements are a periodic function of the atomic weights. Further, the graphic representation of this relation gives a curve very similar in its course to that of the atomic volume curve. So that the specific heat is another of the physical properties to fit into the periodic scheme.

The necessity for a revision of the atomic weights of certain elements, as pointed out by Mendeléeff, has induced several workers to direct their energies to the solution of the problems indicated, so that in our present-day tables many of the anomalies of position and sequence which existed in the earlier schemes have disappeared. Tellurium has still resisted all attempts to bring it into order, with an atomic weight less than that of iodine, which its association with sulphur and selenium demands. The interesting attempts to decompound tellurium have so far remained unfruitful.

But undoubtedly the most fascinating feature of the periodic system is that "it allows the discovery of many new elements to be foreseen." This and the manner in which Mendeléeff, in full conviction of the truth of the "periodic law," boldly assigned properties to those elements required to fill the blank spaces in the table of the elements, and the verification within twenty years in three instances of these prophetic specifications have contributed to the recognition and firm establishment of the "periodic law" as an article of belief in chemical philosophy, and to make it the mainspring and inspiration of the greater part of modern inorganic research.

The discovery of argon, the announcement of which formed a notable feature in the proceedings of the association at the Oxford meeting in 1894, and the recognition in it of an element with an atomic weight of 40, raised doubts in the minds of some as to the validity of the scheme of the elements based upon the periodic law. It was indeed a time of testing the faith. The suggestion that argon would prove to be a modified form of nitrogen was brushed aside by the incontrovertible establishment of it as an element, endowed only with specific physical properties and distinguished from all known elements by its lack of any of those activities which characterise the remaining elements. But argon was not destined to enjoy a splendid isolation for long. The researches of Sir W. Ramsay soon brought helium to earth, and he and his colleagues provided a number of companions for argon. So, in a very short period, was recognised the existence of a group of gaseous elements forming a natural family, the molecules of which are monatomic, the members of which are distinguishable by their spectra and atomic weights, but are all in agreement in their unreadiness to take part in any chemical change. This inertness or nonvalence provided a simple means of reconciliation with the periodic scheme of the elements, as all that was required was simply to add to the eight groups of the table of elements a zero group containing helium, neon, argon, krypton, and xenon, and with niton, the emanation from radium, as a recent addition. If we are to accept Mendeléeff's suggestion, the zero group should contain a member lighter than hydrogen in series i., and in a zero series a still lighter representative of the elements of the zero group, which he has postulated as the "æther" of the physicist.

Thus the discovery of argon has formed a starting-point in the development and a justification of the natural system of the elements, but it still remains, to make the tabulation complete, that provision should be made for the accommodation of the rare earths. The paper published by Werner in 1905, under the title "A Contribution to the Development of the Periodic System," shows how this can be satisfactorily accomplished.

The elements of the argon group form a valuable extension to the periodic system, and the knowledge acquired in the investigation of these substances has proved serviceable in the solution of problems in the realms of science and of industry. The knowledge of the properties and behaviour of helium was destined soon to play a part in the solution of the riddle of the radio-active elements, whilst it is specially noteworthy that argon, the "idle one," should have been pressed into industrial service.

This fact suggests the thought that idleness has its uses, and at the present time how satisfactory would it be were we able to find useful application for a quality which appears to be plentifully and widely distributed in this country.

The history of helium is still more astonishing, for not until thirty years after its existence had been surmised from spectroscopic observations of the sun was this element found to have a terrestrial existence, and now, as one of the achievements of science during the war, we may look on its production in bulk as a commercial proposition. Moreover, we are told "that the advances made in the production of helium warrant the opinion that, had the war continued after November 11, 1918, supplies of helium at the rate of 2,000,000 cub. ft. per month would have been produced within the Empire and the United States, and helium-filled aircraft would have been in service" (NATURE, July 17, 1919).

Some of the speculations to which the periodic system of the elements has given rise have been the subjects of communications to this section.

At the Aberdeen meeting Carnelley, whom I have already mentioned as an ardent worker in this field, gave an account of a scheme based on the conception that the elements are composite, having relations similar to those exhibited by the paraffin hydrocarbons and the isologous series of radicals derived from them. He regarded the elements, other than hydrogen, as made up of two simple elements, A and B. A he identified with carbon, with the atomic weight of 12, and B was assumed to have a negative atomic weight of 2.

In the following year, at Birmingham, Sir W. Crookes devoted his address to this section to an exposition of his ideas of the "genesis of the elements," a subject to which he on many subsequent occasions returned, and amplified in the light of recent discovery. The process of evolution of the elements from a primal "protyle" is depicted as taking place in cycle after cycle, in each cycle the "unknown formative cause" scattering along its journey clusters of particles corresponding with the atoms of the "elements," forming in this way a series such as that beginning with hydrogen and ending with chlorine; a repetition of the movement under somewhat altered conditions giving rise to a series of similarly related elements, and thus homology, which is shown by the members of the natural families, is provided for.

The investigations of Sir J. J. Thomson on the discharge of electricity through gases have established the divisibility of the atoms, and in his "Corpuscular

Theory of Matter" he has given us conceptions of how atoms may be constituted to provide a series so related that they reflect, if not reproduce, many of the chemical characters of the elements and their periodic relation to atomic weights.

With the discovery of radium and its remarkable properties we have been brought in contact with an element undreamt of in our philosophy. The interpretation of the results of the investigation of this element has called for drastic changes in our conception of an element. The pursuit of the researches of the radio-active elements, guided by the theory of the spontaneously disintegrating atom propounded by Rutherford and Soddy, has served to reveal facts which lend a special emphasis to many passages in the address of Sir W. Crookes to which I have already referred.

For instance, the passage in which he said: "Should it not sometimes strike us, chemists of the present day, that after all we are in a position unpleasantly akin to that of our forerunners, the alchemists of the Middle Ages? The necromancers of a time long past did not, indeed, draw so sharp a line as do we between bodies simple and compound; yet their life-task was devoted to the formation of new combinations, and to the attempt to transmute bodies which we commonly consider as simple and ultimate—that is, the metals. In the department of synthesis they achieved very considerable successes; in the transmutation of metals their failure is a matter of history."

Or again, when he propounded the question: "Is there, then, in the first place, any direct evidence of the transmutation of any supposed 'element' of our existing list into another, or of its resolution into anything simpler?"—a question to which he, Sir William Crookes, was at that time forced to reply in the negative, whereas to-day many instances might be cited in support of an affirmative answer to this question. Radio-activity has supplied a method of analysis—radio-active analysis—surpassing in delicacy any of the previously known methods for the examination of material substance; the application of these methods has not only added to the list of elements, but also new classes of elements. First, elements indistinguishable and inseparable by chemical means, yet differing slightly but definitely in their atomic weights. The existence of these "isotopes," as Soddy styles them (a name giving prominence to the fact that such elements occupy the same place in the table of the elements), demonstrates that absolute uniformity in the mass of every ultimate atom of the same chemical element is not an essential, but that "our atomic weights merely represent a mean value around which the actual atomic weights of the atoms vary within certain narrow limits" (Crookes, Address to Section B, 1886).

Whether the possibility of separating isotopes, recently suggested by Dr. Lindemann and Dr. Chapman, will be found capable of experimental realisation, must be left to the future to decide; in fact, in this matter we must adopt the attitude, prevalent in other than scientific circles, of "wait and see."

The investigations in the field of radio-activity have further brought to light that identity in atomic weight may be associated with difference in chemical properties, revealing the existence of a further class of elements for which Dr. Stewart suggests the name "isobares." Further, Dr. Stewart considers that isobaric elements are to be found, not alone amongst the radio-active, but some of the normal elements exhibit properties which may be explained on the assumption that they are isobarics. Thus the compounds formed from iron are regarded as indicating the existence of three irons, all having the same atomic weight. One of these, termed ferricum, is tervalent; one, ferrosum, is divalent; whilst the third, ferron, is inert and takes no part in chemical changes. The three are, under certain conditions, mutually interconvertible. This last condition does not apply in the case of the radio-active isobares.

The elements are to be regarded as divisible into three classes:—(1) Isotopic elements, each set of which have different atomic weights but identical chemical properties; (2) isobaric elements which have identical atomic weights but different chemical properties; and (3) normal elements which differ from each other both in atomic weights and chemical properties.

The discovery of X-rays may be acclaimed as having added a new sense to aid us in our investigation of material objects, and among their innumerable services may be reckoned the results which have followed from the investigations of the X-ray spectra of the elements by the late Lieut. Moseley, whose death in Gallipoli in 1915 is one of the many tragedies of the war specially deplored in the scientific world. From the analysis of the X-ray spectra Moseley has shown that for each element a value can be deduced, which is styled the atomic number and represents the space in the atomic table the element should occupy. The researches of Rutherford and Andrade on lead and radium B have proved that "isotopes" have the same atomic number. Whatever may be the ultimate explanation of the meaning of the atomic numbers, their experimental determination has already proved valuable in the solution of some of the anomalies of the periodic table. In addition to the case of isotopes, just referred to, the number of elements between hydrogen and uranium is fixed by finding 92 as the atomic number for uranium, and, further, Moseley's work has revealed that the atomic numbers are in agreement with the order of the chemical sequence, rather than the order of the atomic weights, which is of special interest and value in the cases of tellurium and iodine, and of potassium and argon, the decision in each case proving a welcome support to the position in the table assigned to these elements on chemical considerations.

Again, Moseley's atomic numbers remind us of the arrangement of the elements adopted by Newlands in his communication to the Chemical Society of 1866, in which he set forth the "law of octaves," the precursor of the periodic law.

In concluding this brief sketch, cognisance should be taken of the speculations of physicists as to the structure of the atom. Already several models of the atom are in the field which leave the uncuttable Daltonian atom far out of view; still, in a measure they help to an understanding of some of those regularities exhibited by the elements, and set forth in the natural system. Valency and its vagaries, which we are accustomed to describe by phrases such as "variable valency," "selective valency," and the like, still call for a full explanation.

I purpose now to direct attention to matters of another nature, which appear to me of interest to chemists, and to that extent have a bearing on the welfare of chemistry in this country.

Among the numerous revelations and surprises of the past five years has been the realisation on the part of the public and the Government of the importance of the chemical industries to the national well-being. The apathy and indifference of pre-war times were replaced by an apparently lively interest in things chemical, and there was what in the religious world would be styled a revival.

Politicians, the Press in all its varied forms, daily, weekly, monthly, and quarterly, took up the subject of our industrial insufficiencies and emphasised in various ways the importance of research in connection with our industries. Again, the coal-tar colour industry furnished, as it had done again and again, some thirty to forty years ago, the text from which research and its importance was preached. This time the reiteration had the effect that the "aniline phantasm," as I have seen it described, was recognised as a "key industry," important to the vitality of the manufacture of textiles; with the result that the Government, discarding its fiscal policy, was induced to subsidise the enterprise for the manufacture of dyes and other coal-tar products. The negotiations preceding the formation of British Dyes, Ltd., have been remarkable as revealing that, in the eyes of some at any rate, special knowledge is a "dangerous thing," and, in fact, was deemed sufficient to exclude its possessors from a seat on the directorate. This is all the more remarkable, as the history of similar enterprises in Germany shows the *personnel* of the directorates to be made up of university trained men and, in not a few instances, of professors. So that in Germany academic distinction and theoretic learning are not considered as excluding the possession of commercial acumen and those other qualities needed in a successful man of business.

In the early stages of the war the demand for explosives was met by the expansion of already existing factories, the increase in staff of which called for many additional men with chemical training, a call which become unprecedented and insistent when the national factories were founded, so that men and women with a chemical training found an opportunity of putting their knowledge at the service of their country. And in not a few instances those who, for financial reasons, had at the close of their college career taken up a less congenial employment were able to return to the practice of chemistry, for which in their student days they had specially fitted themselves.

In the foreword of the publication "Reports on Costs and Efficiencies for H.M. Factories," issued by the Ministry of Munitions, we are told that only "when it was decided to commence the erection of new and national factories, and an attempt was made to collect from existing factories the necessary technical data and assistance, did it become evident that, due to the extraordinary demands of the war, there was —practically throughout the entire country—a regrettable lack of available accurate technical data, and an even greater lack of trained technical men, more particularly chemical engineers,"

To anyone acquainted with the conditions existing in this country in pre-war days, the lack of "trained technical men" is no matter of surprise. In fact, one cannot fail to be astonished at the remarkable development of chemical manufacture which has taken place under the directing influence of Lord Moulton in response to the call from Army and Navy. That men were found capable of taking a part in these varied undertakings cannot, at any rate, be credited to the encouragement which the teaching of chemistry or the students of the science had received from those directing industries which employ or should employ the services of chemists. It is no uncommon experience to find the chemist employed simply in the analytical testing of raw materials and manufactured products, and even in the working of processes under their control the potentiality of the chemist is not utilised to the full, as is evident from the following, which is a quotation from the preface to the brochure issued by the Ministry of Munitions to which I have already referred: "Since the beginning the policy of the Department with regard to our national factories has been to aim at maximum efficiency in respect of cost and usage of materials.

"For this purpose the greatest efforts have been made to place before all those who are in any way responsible for control full details concerning the working and costs of the factories. This was rather an innovation in the field of chemical manufacture, as until comparatively recently, either intentionally or through negligence, it was customary at many chemical plants to keep the chemists in complete ignorance, not only of the cost at their plants, but also even of the efficiencies.

"It is amazing that manufacturers can expect improvements in chemical processes when their chemists are kept in ignorance of such vital facts.

"It has happened very often that as soon as detailed figures were seen by chemists at a plant, important alterations and improvements have at once been suggested, the need for which would otherwise never have been noticed."

The condition of service indicated in the passage quoted, together with the low scale of remuneration which obtained hitherto in chemical industries, help to explain the scarcity of the kind of scientific labour referred to in the quotation I have made from the "Foreword."

But are we not told and invited to believe that all this is changed, that the records of the magnificent achievements of British chemists in the war have so educated the people, and may we say, the Government also, that the practitioners in chemistry will no longer find it essential that in describing their vocation they should be required to add, unless for special reasons, such prefixes as "analytical," "research," "scientific," or "engineering" to the word chemist, secure in the feeling that by describing themselves as "chemists" their standing, training, and profession will be correctly understood?

Still, a feeling akin to despondency, if nothing worse, is pardonable when, realising the fundamental importance of chemistry to our industries, and the thousand and one ways chemical research has ministered to the amenities of our everyday life, there should exist, not alone in the mind of the general public, but of the educated also, such a lack of information as has been revealed during the past few years—to wit, the myth woven into the history of the production of glycerine, the confusion in the minds of legislators between phosphates and phosgene. More serious, however, is the fact that the method of investigation employed by the chemist is so little appreciated or understood as to lead one to imagine that the discoveries and achievements are the results of a species of legerdemain. The production of new colours, a succession of happy thoughts, and that "by an accident the secret of synthetic indigo was unlocked." This last is a quotation from a review entitled "The Value of Scientific Research," published some three years ago, and is typical of much that passes muster in appraising the value of chemical research. That the unravelling of the constitution of indigo which occupied Baeyer and his pupils some thirteen years—the account of these investigations covers some 180 pages of Baeyer's collected works—should be summarised in this way appeared to me to call for a protest. My protest was made, and I attempted to put the matter in the correct light, showing the synthesis of indigo to be, indeed, a brilliant example of the value of theory and of a practical illustration of the importance of the chemist's conception of the architecture of molecules, as exemplified by Kekulé's theory of the constitution of benzene. The protestation evoked a reply from a correspondent signing himself D.Sc., Ph.D., who sought to justify the description of the revelation of the secret of synthetic indigo by reference to an accident which occurred in the investigation of the processes for the manufacture of phthalic acid and certainly greatly facilitated the production of this substance—an intermediate in the manufacture of artificial indigo. So, if the initiated emphasise the unessential, why should we blame the layman and be surprised that well-ordered and planned design should appear to be but the workings of chance, for every such achievement is a witness to the conquest of well-founded theoretical speculation?

But I do not wish to conclude on a despondent note, nor is it right that I should do so in view of the many activities operating for the promotion of scientific research, and of such evidence as that supplied by the magnificent endowment of the chemical department of the University of Cambridge, all of which are evidences of what we may reasonably hope to be a happy augury for the future of chemistry and chemists in this country.

NOTES.

The James Watt centenary celebrations in Birmingham were opened with lectures by Prof. F. W. Burstall and Prof. Hele-Shaw on Tuesday morning (September 16). In the afternoon there was a memorial service at Handsworth Parish Church, in which Watt, Boulton, and Murdoch were buried, an address being delivered by Canon E. W. Barnes, Master of the Temple. This was followed by a garden-party at Heathfield Hall, and a reception by the Lord Mayor at the Council House. On Wednesday morning, as we go to press, lectures are to be given by Sir Oliver Lodge, Prof. Alex. Barr, and Prof. J. D. Cormack, and in the afternoon visits will be made to some of Watt's engines. In the evening will be held the centenary dinner. On Thursday the University will hold a special Degree Congregation to confer honorary degrees on the American Ambassador (the Hon. J. W. Davies), Sir Charles Parsons, Vice-Admiral Goodwin, M. Rateau (of Paris), Sir George Beilby, Col. Blackett, Prof. Barr, and Mr. F. W. Lanchester. The response to the appeal for the memorial fund has up to the present been very meagre, and unless large additions are made to the subscription list the realisation of even one of the objects of the fund will not be possible. It is to be hoped that a marked improvement may be made during the week.

Summer time is to end this year at 2 a.m. on September 29. Each year the terminal dates of summer time have varied, and, though the dates will, of course, be known to our future compilers of natural phenomena, the use of summer time can scarcely fail to result in some errors. Even so simple a change as that of the Gregorian calendar has been attended by mistakes. Some years ago, for instance, the late Sir Edward Fry referred to some entries on British earthquakes in the diary of John Wesley (Nature, vol. lxxix., 1898, p. 98). He remarked that the London earthquakes of February 8 and March 8, 1750, which Wesley describes, are not mentioned in Mallet's Catalogue. Wesley's dates are correctly given, for the Gregorian calendar came into force after September 2, 1752. Mallet, however, gives the days in new style as February 19 and March 19. The error in this case is easy to detect; but, unless the letters "G.M.T." or the words "summer time" are added, it may be difficult to decide whether records of an earthquake at, say, 2.12 and 3.8 relate to the same shock at about 2.10 G.M.T. or to different shocks.

We regret to learn from Dr. G. C. Simpson, Director-General of Observatories, Simla, that Mr. W. L. Dallas, who was Scientific Assistant to the Meteorological Reporter to the Government of India from 1882 to 1906, passed away at Simla on August 5. Mr. Dallas's original meteorological work was devoted almost entirely to a study of the weather conditions over the Indian seas, although he published a few papers on more general subjects. He discussed for the Government of India the marine observations of the Indian seas collected by the London Meteorological Office during twenty years—1856–75. He also investigated the nature and causes of storms in the Arabian Sea, using all records available for the period 1648–1889, on which inquiry all later work undertaken by the India Meteorological Department for warning ships approaching India from the west was based. Mr. Dallas fittingly closed his long official connection with the India Meteorological Department by the compilation of a meteorological atlas of the Indian seas, which will be found in use on most ships visiting the East.

Mr. Edwin O. Sachs, whose death we announced last week, will be remembered mainly by his keen interest and untiring activity in relation to all questions regarding fire protection and fire prevention. The terrible holocaust of the Paris Charity Bazaar fire in 1887 led Mr. Sachs to form the British Fire Prevention Committee, of which he was the chairman and guiding spirit up to the time of his death. In his work with the committee Mr. Sachs was supported by a number of public men and professional friends. Thanks to his energy and devotion and his able leadership, the committee's work, from very small beginnings, soon covered a vast field of activity, which widened from time to time until the foundations of a comprehensive organisation were firmly laid. The large number of tests undertaken by the committee were made in a specially constructed testing station which Mr. Sachs designed, and to which he not only gave unstinted and devoted labour, but also largely financed. This testing station, which has been enlarged and improved from time to time, was the first of its kind, and has served as a model for similar centres of investigation throughout the world. The numerous activities of the committee—which during the war were greatly increased, and included arrangements for a voluntary fire survey force for more than two thousand war hospitals, camps, and factories, also research work of the highest importance to the nation—were initiated and guided by Mr. Sachs's unceasing energies, even during his latter years. All this work on the committee, as well as his other public activities, were rendered entirely voluntarily, and in all he did he was inspired by the highest ideals.

During the evening of September 11 an earthquake shock, causing considerable damage, was felt in the region of Monte Amiata, near Siena. At San Casciano several houses were wrecked. A slighter earthquake was also felt on September 12 at Ebingen (Würtemberg).

The *Times* correspondent at New York reports that on September 13 Mr. Roland Rohlfs, a testing pilot with the Curtiss Aeroplane Corporation, rose from Roosevelt Field, Long Island, to a height of 34,200 ft. This "record" is not officially confirmed, but Mr. Rohlfs will try on the first favourable day to make an authenticated attempt to exceed the altitude believed to have been reached by him.

On May 20 the volcano Kloet, in Java, discharged suddenly a great quantity of hot mud, which, spreading out in three streams, destroyed the town of Blitar and about thirty villages, and caused the death of several thousand persons. The place was visited by an exploring party two days later, and an interesting two-page reproduction of one of the photographs of the mud-stream is given in the *Illustrated London News* for September 13 (pp. 396–97).

AT a joint meeting of the Royal Asiatic Society, Société Asiatique, American Oriental Society, and Scuola Orientale of the University of Rome, recently held in London, Prof. A. T. Clay, of Yale University, described the efforts of American scholars to free themselves from dependence on Germany for research work in Asia. Several young Assyriologists in America are now devoting themselves to research work. Yale University has taken over the work of Sir W. Ramsay at Antioch, and the American School of Oriental Research in Palestine, which was closed on account of the war, is now to be re-opened on a more extensive scale. At least one professor and several students will be sent annually from Yale to direct operations, which will be carried out in co-operation with the British School, which will be founded on a more important basis.

STUDENTS of the mygalomorph spiders will do well to consult a critical systematic paper on South African species by John Hewitt in the *Annals of the Transvaal Museum* (vol. vi., pt. 3).

SOME results of a collecting expedition to Korinchi Peak, Sumatra, are published in the Journal of the Federated Malay States Museums (vol. vii., pt. 3, 1919). Descriptions, with excellent figures, of a number of Diptera, by F. W. Edwards, of the British Museum, are especially noteworthy.

WE have received the seventeenth Report of the State Entomologist of Minnesota. In addition to articles of economic interest, it contains several papers of systematic value, such as O. W. Oestlund's contribution to the classification of aphids and F. L. Washburn's summary of the Hymenoptera of the State. The illustrations in this Report are exceptionally praiseworthy.

DRS. S. HADWEN and A. E. CAMERON, working for the Canadian Department of Agriculture, have made a definite contribution to our knowledge of horse bot-flies (Bull. Entom. Research, vol. ix., pt. 2) by their observations on the eggs and early larvæ of *Gastrophilus haemorrhoidalis* and *G. nasalis* as compared with *G. intestinalis (equinus)*. The first-named species has stalked eggs which are laid on the hairs of horse's lips, while the second lays on the hairs of the intermaxillary space. It is possible that the newly-hatched larvæ may penetrate the horse's skin in these regions, as they were found to bore into the mucous lining of the mouth and also into the tongue of a recently killed calf.

THE possibilities of the manufacture of paper-pulp in Australia is the subject of a Bulletin (No. 11) issued by the Advisory Council of Science and Industry of the Commonwealth of Australia. The bulletin describes the results of some preliminary investigations of the native sources of wood-pulp and pulp from fibre-plants. The most satisfactory results have been obtained with karri and other species of eucalypts, and it is suggested that a thorough survey of the resources might indicate the possibility of building up a wood-pulp industry in Australia. As regards the fibre-plants, a number were found on testing to be unsuitable for paper-making. It is unlikely that either of the grasses Lalang or Marram, which have been used for pulping purposes, could be employed profitably in Australia, and negative results have also been obtained with prickly pear. A blend of 20 per cent. of a sedge (*Gahnia decomposita*) and 80 per cent. karri-pulp is reported as very satisfactory. The conclusion is that if Australia's demands for paper are to be supplied from native sources, the principal material to be used for some years to come must be straw, of which large quantities are produced within a hundred miles' radius of Adelaide.

VARIOUS memoranda and letters on "The Reconstruction of Elementary Botanical Teaching," which appeared in the *New Phytologist* during 1917–18–19, have been brought together in pamphlet form. As indicated by the letters, the teaching refers almost exclusively to the elementary university course, and the participants in the discussion are, with few exceptions, engaged in teaching of a university standard. The discussion originated from a memorandum by five botanists who pleaded for a more important place for plant physiology as compared with morphology in the elementary course. This was regarded by some eminent morphologists as a challenge, to which they replied with some vigour. The discussion brings out the fact that botany is a wide subject, attracting students of widely differing temperaments, and there is real difficulty in planning an elementary course which shall form an adequate introduction to the different branches in one or more of which the student may subsequently specialise. As regards the *motif* of the elementary course, it is important that the plant should be studied as a living organism and as part of a larger organisation which is closely associated with its environment. But present-day plant-life is not merely the expression of present-day environment, but largely the outcome of past history; and the neglect of the study of history may be disastrous. There is a considerable amount of elementary botanical teaching outside the universities, and the point of view and methods suitable for the university student are not necessarily those suited to boys and girls at school.

ALTHOUGH the statement is made quite definitely in many text-books that formic acid occurs in the stinging hairs of the common nettle (*Urtica dioica*), the proof has not hitherto been very satisfactory. In early experiments the nettles were cut up, distilled with water, and reactions of formic acid obtained on testing the distillate. Later observers, however, have found that various parts of plants yield formic acid when tested in a similar manner. Hence it was not certain that the acid in the earlier experiments had come from the stinging hairs; it might have been derived from the general plant tissues. Moreover, one of the chief chemical reactions of formic acid, namely, its power of reducing salts of silver and mercury, is not necessarily a conclusive proof of the presence of the acid under the particular conditions of these earlier experiments, since other "reducing" substances might also have been present. The question, however, appears to have now been definitely settled through some ingenious experiments devised by Dr. Leonard Dobbin (Proceedings of the Royal Society of Edinburgh, vol. xxxix., ii., No. 11). By pressing the leaves of growing nettles between dry filter-paper impregnated with barium carbonate, the contents of many thousands of hairs were absorbed without contamination by juices from any other part of the plant. After appropriate treatment the product yielded barium and lead salts, which were crystallised on glass slides, and the two formates identified under the microscope. Whether or not formic acid is the main cause of the intense irritation produced by nettlestings is a further question; the active irritant has been regarded by one investigator as being probably not formic acid, but an enzyme.

THE cause of the colours of "Blue John" and other varieties of fluorite has long been a matter of doubt and controversy. During the last two years Messrs. B. Blount and J. H. Sequeira have carried out an interesting investigation of the problem, and their results are now briefly described in the Transactions of the Chemical Society (vol. cxv., p. 705, 1919). They have carefully analysed blue and white varieties of the mineral, tested the powdered material by extraction with organic solvents, examined the gases occluded by "Blue John," and subjected several types of fluorite to "raying" by exposure to radium and X-rays. They conclude from their experiments that there is no substantial difference between white fluorite and the blue, green, and amethystine varieties, except in the presence of a small amount of organic matter to which the colours are ascribed. The state of dispersion of the organic matter is not discussed. It is already ascertained that the blue colour of certain varieties of rock-salt is due to a colloidal dispersion of sodium in sodium chloride, and the blue colours of sodalite and ultramarine are almost certainly due to a similar cause. To correlate the colours of fluorite with the presence of different amounts of organic matter therefore still leaves the core of the problem unsettled; and it is to be hoped that the authors will continue their work by applying methods of X-ray analysis and ultra-microscopy in the hope of demonstrating the degree of dispersion of the organic matter, molecular or colloidal, in each of the varieties of fluorite on which their present work has been conducted.

THE Union of Technical Men (*Bund technischer Berufsstände*), which has recently changed its name to the Imperial League for German Technology (*Reichsbund deutscher Technik*) is now publishing a regular weekly periodical, which reflects the opinions of the leaders of technical thought in the country. Questions affecting, in particular, the work of reconstruction find an important place in the journal. It is interesting to note that already more than one great conference or Technical Parliament has been held, and energetic measures are being taken with a view to ensure the adequate representation of scientific and technical thought on all public bodies. An announcement in the publications of the League states that a daily paper (*Die Arbeit*) will make its appearance as soon as the difficulties connected with the release of paper supplies are overcome.

WE have received recently a copy of *The Chemical Technology*, a monthly journal devoted to chemistry and chemical technology, published in Tokyo. It is printed chiefly in the Japanese language, but contains a section of about eight pages in English. This consists mainly of commercial notes upon chemical products, such as dyestuffs, alkaloids, wax, menthol, and peppermint oil. The Japanese columns contain a number of articles upon branches of technological chemistry, and some of a more general nature, including one on "Science and its Future," by Mr. S. Oguri. Judging by their titles, the articles cover a wide range of subjects, and indicate that chemists in Japan are quite awake to the importance of their science to the nation's industries. It may be noted, in passing, that the journal contains several American advertisements, but not a solitary British one.

FROM the director of the Wellcome chemical research laboratories we have received copies of sixteen scientific papers published during the last few years by the institution in question. They are chiefly accounts of investigations upon materials likely to be of value in medicine. On one hand, plants used as official or domestic remedies have been examined more thoroughly than hitherto; and, on the other, active constituents of drugs, such as alkaloids, have been investigated with the view of determining their constitution and facilitating the possible synthesis of similar therapeutic agents. The distribution of these memoirs to scientific institutions, formerly made periodically, was suspended during the period of the war, and is now being resumed. The results of the investigations, however, have already appeared in the Transactions of the Chemical Society and the *Pharmaceutical Journal*, so that they need not be mentioned here in detail. It will suffice to say that they form an important contribution to our knowledge of the medicinal plants examined, and are a testimony to the excellence of the work done at the laboratories.

THE importance of having a thoroughly trustworthy instrument for detecting and measuring the amount of any combustible gas present in the air at any time has led the Bureau of Standards at Washington to investigate the working of existing instruments and to design a further instrument depending on a new principle, which appears to have a great future before it. It depends on the combustion which takes place about a platinum wire in the mixture when an electric current is sent through the wire so as to heat it sufficiently. Three methods of measurement are adopted. The wire may form one arm of a resistance bridge and indicate the amount of gas by the rise of temperature, and therefore of resistance of the wire. Or the current in the wire may be increased until the wire just glows, the increase required being less as the amount of combustible gas increases. Or the heat generated by the combustion may be used to heat a bimetallic strip, the bending of which increases as the heat generated, and therefore as the amount of gas present. Full details of the instruments, with drawings, are contained in Scientific Paper No. 334, by Messrs. E. R. Weaver and E. E. Weibel, of the Bureau.

VOL. iii. of the Memoirs of the College of Science, Kyoto Imperial University, contains an account of a series of researches on the electrical resolution of spectral lines (Stark effect). The method employed was that originated by Lo Surdo, in which the intense electric field in the cathode dark space of a vacuum tube is utilised. The elements studied include H, He, Li, Ca, Mg, A, N, and O, and a number of new and interesting results have been obtained. The observations on the helium spectrum are particularly complete, and are summarised diagrammatically in a manner which brings out clearly most of the characteristic features of the effect. Special attention is given to the phenomenon of "isolated components," which only exist in sufficiently strong fields, and seem to be exclusively associated with a diffuse type of series. This latter property, together with other features of their observed behaviour, would suggest that it may be legitimate to regard them as a special class of satellite. Another observation of much interest refers to certain combination series lines which make their appearance only in intense electric fields. The examination of the secondary spectrum of hydrogen yielded fifty-four affected lines; these results, in conjunction with the Zeeman effects already on record, should be of material assistance in elucidating the structure of this spectrum. Among other conclusions of general interest may be mentioned the confirmation of the view, which previously rested on somewhat fragmentary evidence, that arc lines are affected by electric fields to a much greater extent than enhanced lines of the same element.

ALTHOUGH there is a general belief that underfed individuals are more susceptible to infection than well-fed persons, and that when the former contract a disease they show less resistance and are more prone to succumb to it, there is no definite scientific evidence even of a general character to support the theory. The study of the interesting question whether the immunity of an animal to disease is affected by a rigorous and prolonged dietetic deficiency is a natural outcome of the work on accessory food factors which has recently been carried out at the Lister Institute, and the current issue of the *Biochemical Journal* contains a suggestive paper on the subject by Dr. S. S. Zilva. Immunity is a complicated biological phenomenon which does not lend itself to quantitative estimation, but certain phenomena which accompany it, such as phagocytosis, complement fixation, and agglutination, can be estimated quantitatively for comparative purposes. Dr. Zilva has studied the effect on amboceptor and agglutinin formation and the complement content of the blood of rats, of diets deficient in (*a*) the elements calcium, iron, potassium, chlorine, phosphorus, and sodium; (*b*) certain amino-acids; and (*c*) the antiscorbutic, antineuritic, and fat soluble A accessory factors, the rat being the animal employed. The diets investigated were (1) those low in the elements mentioned; (2) those containing 12 per cent. and 8 per cent. of caseinogen as a source of protein; (3) those containing 18 per cent. of gliadin as the sole source of protein; and (4) those deficient in each of the three accessory food factors. As a result of several of the deficiencies the animals exhibited restricted growth and poor condition, but, except when the diet was deficient in phosphorus, no differentiation in the titres of the agglutinins and amboceptor could be recorded. Guinea-pigs, whether fed on an unrestricted mixed diet, quantitatively restricted mixed diet, or a scorbutic diet, showed no difference in the amboceptor and agglutinin titres or in the complement activity of their blood.

THE useful select list of scientific and technical books published in the Descriptive Catalogue of the British Scientific Products Exhibition, 1919, has, with the permission of the British Science Guild, been issued separately in pamphlet form by Messrs. A. and F. Denny, 147 Strand, London, W.C.2. The list gives in sixty pages the bibliographic particulars of standard books in the English language in sixteen branches of applied science, from aeronautics to wireless telegraphy. The date and price of the existing edition are shown in each case, and every volume in the list is on sale, so that any of the books ordered can be obtained without difficulty. Messrs. Denny will be glad to send a copy of the list to anyone who will apply to them for it.

THE following volumes are in active preparation for publication by the Hakluyt Society:—"The Chronicles of Muntaner," translated and edited by Lady Goodenough; "Jons Olafssonar Indiafara," translated by Miss B. Phillpotts, edited by Sir R. C. Temple, Bart., 2 vols.; "William Lockerby's Journal in Fiji, 1808," edited by Sir E. F. im Thurn and L. C. Wharton; "A Description of the Coasts of East Africa and Malabar in the Beginning of the Sixteenth Century," by D. Barbosa, translated by L. Dames, vol. ii.; and "Anales del Peru," by L. F. Montesinos, translated and edited by P. A. Means.

A LENGTHY and interesting catalogue (No. 181) has just been circulated by Messrs. W. Heffer and Sons, Ltd., Cambridge. The books (more than 1600 in number) are of a miscellaneous character, but there are sections devoted to archæology, folk-lore, anthropology, and kindred subjects; Irish literature, folk-lore, and archæology; and science and mathematics. In addition, Messrs. Heffer direct attention to collections of flint and bronze implements and of pottery which they have for disposal.

Messrs. George Bell and Sons, Ltd., have completed arrangements with Prof. Moureu for the publication of a translation of "Notions fondamentales de chimie organique." The translation is being made of the fifth French edition, in which additional space is devoted to a more extensive treatment of stereochemistry, and of the relations between chemical constitution and physical properties. There will also be an additional chapter on dyestuffs.

OUR ASTRONOMICAL COLUMN.

COMETS.—Miss Vinter Hansen and Mr. Fischer Petersen have deduced elliptical elements for the comet 1919*b* (Brorsen-Metcalf), and give the following ephemeris:—

For Greenwich Midnight.

	R.A. h. m. s.	N. Decl. ° ′	Log *r*	Log Δ
Sept. 19 ...	12 7 43	42 46	9·8967	9·5175
21 ...	12 1 24	38 54		
23 ...	11 56 36	35 30	9·8577	9·5935
25 ...	11 52 52	32 28		
27 ...	11 50 0	29 43	9·8168	9·6647
29 ...	11 47 50	27 11		

Prof. Wolf noted that at the end of August the comet was easily visible to the naked eye as a large, round nebula, with central condensation, and a tail. The theoretical brightness is now diminishing, but there is likely to be an increase in physical brightness as perihelion is approached (about October 17). The comet is in conjunction with the sun on September 22; after that date it may be observed to most advantage in the morning sky.

M. Ebell gives the following continuation of the ephemeris of Kopff's periodic comet 1919*a*:—

For Greenwich Midnight.

	R.A. h. m. s.	S. Decl. ° ′		R.A. h. m. s.	S. Decl. ° ′
Sept. 18	19 52 18	7 50	Sept. 26	20 2 12	7 45
20	19 54 40	7 49	28	20 4 51	7 43
22	19 57 6	7 48	30	20 7 34	7 41
24	19 59 37	7 46	Oct. 2	20 10 21	7 38

On September 24, $\log r = 0{\cdot}2755$, $\log \Delta = 0{\cdot}0740$, magnitude 11·7.

Continuation of the ephemeris of comet 1919*c*:—

For Greenwich Midnight.

	R.A. h. m. s.	N. Decl. ° ′		R.A. h. m. s.	N. Decl. ° ′
Sept. 18	14 49 5	16 0	Sept. 30	15 12 47	10 44
22	14 56 46	14 16	Oct. 4	15 21 8	8 57
26	15 4 40	12 30	8	15 29 42	7 10

The comet is brightening slowly, its magnitude on October 8 being 8·5.

THE BLINK MICROSCOPE.—Mr. R. T. A. Innes has an article on this subject in *Scientia* for September. He is one of the chief workers with this instrument, so he speaks with authority. It is unrivalled as the readiest means of picking out all the large proper motions on a pair of plates. Taking the smallest proper motion that can be detected in the case of plates taken twenty-five years apart as $1\frac{1}{4}''$ in this interval, or 5″ per century, Mr. Innes states that there are about three such stars in each square degree, or 120,000 in the whole sky. He estimates that the number of stars with sensible proper motion would increase as the square of the time-interval, so that with a century interval there would be 2,000,000 proper motions.

It is explained in the article that the proper motions found by photography are not absolute, since they take no account of the systematic drift of the region of the sky, due to the solar motion. At present photography does not appear to be capable of giving absolute proper motions without the aid of the transit circle. It is necessary to determine absolute places and proper motions of a sufficient number of reference stars on each plate to enable them to be deduced for the remaining stars.

IRRIGATION IN EGYPT AND THE SUDAN.

THE admirable record of agricultural progress achieved under British control in Egypt offers every incentive to further exertions, with a view to increase the productivity of a country so rich in latent possibilities. It is interesting, therefore, to note the resumption of irrigation undertakings, which have been temporarily suspended during the war. During the last generation the Nile has undergone drastic engineering treatment, and now, no longer free to give vent to irregular and wasteful discharges, its valuable waters, conserved and controlled by artificial works, are increasingly administered on systematic lines and directed to those localities where their beneficial influence can be most effectively exercised.

The pioneer dam of Mougel Bey, just below Cairo, restored and raised to a higher degree of utility by the late Sir Colin Scott-Moncrieff, the barrages at Asyût, Esna, and Zifta, and the bolder and more imposing structure at Aswân, are now being followed by other works which will, no doubt, produce results as noteworthy and important.

The schemes at present in hand include three separate projects relating to different sections of the river. There is a scheme for the development of the Gezirah plain of the Sudan on the Blue Nile, just south of Khartoum; another for the benefit of Egypt proper by utilising the flood-waters of the White Nile; and a third scheme of drainage improvement for the deltaic region included in the provinces of Gharbieh and Beheira, lying below Cairo.

The Blue Nile scheme consists of a dam at Makwar, about five miles south of Sennar and 175 miles south of Khartoum, with a canal, some forty miles in length, leading from just above the dam to the district to be irrigated, which is a remarkably level and treeless plain some 300,000 feddâns in extent (a feddân is 1·04 acre). The cotton, which it is capable of producing, will be raised as a winter crop, absorbing the river winter supply without interfering with the summer discharge. The dam will be a work of some magnitude, withstanding, when completed, a head of 40 ft. of water, and capable of coping with a discharge of some 1,250,000 gallons per second in a river subject to sudden and extreme fluctuations.

The White Nile scheme is, fundamentally, a development of the Aswân undertaking, which has now reached the limit of its effective utility. In 1916 the demands of the area under cultivation exceeded the available supply. It is, accordingly, proposed to construct an auxiliary reservoir dam at Gebel-el-Auli, or Gebel Aoli, on the White Nile, capable of impounding an adequate summer supply of water for Egypt, and at the same time reducing the excessive flood-waters of the main Nile. This scheme has been the subject of certain criticisms by Sir William Willcocks, whose own proposal was briefly referred to in the Notes column of NATURE for May 22 last. A subsidiary work is the formation of a channel from the Blue Nile above Sennar, so that the superfluous water from that reservoir may be conveyed to the Gebel-el-Auli reservoir. The Gebel-el-Auli dam will have a pressure-head of 23 ft.

The increased water supply to Lower Egypt, due to the Aswân reservoir, has severely taxed the drainage channels of the provinces of Gharbieh and Beheira, forming the alluvial plain between Cairo and the sea. It is necessary to find some measure of relief, and a solution of the problem is sought in the construction of large pumping installations on the borders of Lake Mareotis and Lake Borollos.

Interesting details of the engineering features of the various projects are given in a series of articles recently published in the *Engineer*, from which most of the foregoing particulars are taken.

BRYSSON CUNNINGHAM.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

STOCK of the value of 300,000*l.* has been presented to the University of California by Mr. E. F. Searles, of San Francisco.

IT is announced that Yale University will receive from the estate of the late Mr. J. W. Sterling approximately 3,600,000*l.*, or about 600,000*l.* more than had been anticipated.

ANNOUNCEMENT is made in the *Times* that Mr. Balfour is to be nominated for election as Chancellor of Cambridge University, in succession to his brother-in-law, the late Lord Rayleigh.

DR. T. STUART, formerly professor of mathematics in Hongkong University, has been appointed lecturer in mathematics, and Mr. G. Mavor, formerly of the Gillingham Technical Institute, lecturer in mechanical engineering at the Loughborough Technical College.

THE sum of 1000*l.* has been given to the applied science department of Sheffield University by Mr. J. D. Brunton, of Musselburgh, for the annual award of a medal and premium for the best metallurgical research work done at the University during the year.

DR. J. F. GEMMILL, lecturer in embryology, University of Glasgow, and in zoology at Glasgow Provincial Training College, has been appointed to the chair of natural history at University College, Dundee, in succession to Prof. D'Arcy W. Thompson.

THE Edith Barnard memorial fellowship in chemistry in the University of Chicago has been endowed through the gift of 600*l.* by the mother, brother, colleagues, and friends of Edith E. Barnard, a former instructor in chemistry in the University. The fellowship has been temporarily maintained since 1916, but it has now been placed upon a permanent basis.

THE Commission for the Relief of Belgium is placing at the disposal of the country the sum of 6,000,000*l.*, which is to be devoted to university education, and will facilitate access to the universities for children of the poorer classes. The Universities of Brussels, Louvain, Ghent, and Liège are each to receive 13 per cent. of the money, the School of Mines at Mons 3 per cent., and the Colonial School 6 per cent.

A COURSE of training in industrial chemistry will begin at the Northern Polytechnic Institute, Holloway, N.7, on September 22. The course is open to the general public, and is adapted to the requirements of demobilised men who desire to qualify for positions as analytical and works chemists. In addition to the usual training in chemistry and allied subjects, glass-working, instrument-making, and plumbing are also to receive attention. Detailed information may be obtained from the Principal.

UNDER the Government scheme of financial assistance for the higher education of ex-Service officers and men, the total number of grants awarded by the Board of Education now amounts to 9500, including 4000 officers and 5500 men. The courses in respect of which grants have been awarded include more than 2500 for engineering and technological subjects, between 800 and 900 for classics, philosophy, and literature, and about 1200 for pure science and mathematics. Applications are still being received in large numbers, and are being dealt with at the rate of more than 100 a day.

THE new session of the Sir John Cass Technical Institute will commence on Thursday, September 25. The courses of instruction provided are specially directed to the technical training of those engaged in chemical, metallurgical, and electrical industries and in trades associated therewith. Full facilities are provided for those wishing to carry out work associated with the industries in which they are engaged or to undertake special investigations and research. Special courses of higher technological instruction form a distinctive feature of the work of the institute. The curriculum in connection with the fermentation industries includes courses of instruction on brewing and malting, bottling and cellar management, and on the microbiology of the fermentation industries. A connected series of lectures in fuel and power, comprising liquid, solid, and gaseous fuels and their application, electrical supply and control, the transmission of power in works, fuel analysis and technical gas analysis is also included in the syllabus of the chemistry department for the forthcoming session. Full details of the courses are given in the syllabus of the institute, which can be had on application at the office or by letter to the Principal.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 1.—M. Léon Guignard in the chair.—A. **Lacroix**: The mineralogical and chemical constitution of the volcanic lavas of Tibesti. Fourteen complete rock analyses are given, together with a general account of the minerals present.—G. **Humbert**: The measurement of the *ensemble* of the positive classes of Hermite, of given discriminant, in an imaginary quadratic body.—E. **Cosserat**: Some stars possessing a total annual proper motion of more than 0·5″. The movements of stars mentioned by A. van Maanen in 1915 and 1917, and one pointed out by Wolf in 1916, have been studied by means of the photographic catalogue of the Toulouse Observatory. The positions of seven stars are provisionally given possessing a proper motion of more than 0·5″.—M. **Tilho**: The raw materials and railways of tropical Africa north of the equator. A discussion of the best railway scheme, taken in conjunction with existing railways, for opening up northern Africa.—E. **Kogbetliantz**: New observations on ultra-spherical series.—G. **Guillaumin**: Contact forces in heterogeneous solids, with special reference to reinforced concrete.—B. **Jekhowsky**: Orbit of Metcalf's comet 1919*b*. The calculations are based on observations made on August 21, 22, and 23.—C. L. **Charlier**: The spiral nebulæ. As a working hypothesis it is supposed that spiral nebulæ are formed by the collision of an extra-galactic body with the solar system. This hypothesis explains simply two well-established facts.—A. **Soret** and R. **Couespel**: A multiple-valve microphone.—A. **Boutaric**: The calculation between the ratio of the vapour-pressure of a solid and that of the surfused liquid at varying temperatures.—J. **Guyot** and L. J. **Simon**: The action of dimethylsulphate and the alkaline dimethylsulphates on dry alkaline bromides and chlorides.—J. **Delpech**: The pure "B" powders. These specimens were prepared by complete solution of the nitrocellulose, followed by a filtration through cotton-wool under pressure. The powder thus produced is transparent, and doubtful portions can be detected by inspection.—MM. **Vermorel** and **Dantony**: The comparative usefulness of ordinary Bordeaux mixtures and mixtures prepared with the addition of casein for the preservation of grapes. The addition of casein is very advantageous.—MM. G. **Bertrand**, **Brocq-Rousseau**, and **Dassonville**: The destruction of bed-lice by chloropicrin. Quite moderate amounts of chloropicrin suffice for the practical disinfection of beds.

THE MISSING THEME.

Wild Life of the World: A Descriptive Survey of the Geographical Distribution of Animals. In three volumes. By R. Lydekker. Vol. i., pp. xiv+472; vol. ii., pp. xii+440; vol. iii., pp. xi+457. (London: F. Warne and Co., 1916.) Price 4*l.* 4*s.* three vols.

IT is doubtful whether any modern naturalist other than the late Mr. Richard Lydekker could have written such a book as this. Endowed with a remarkable memory, boundless energy, and a facile pen, he spent his days in acquiring a perfectly unrivalled knowledge of natural history and in writing about it. No matter what aspect presented itself for discussion, it found Lydekker and his pen both ready and willing. A friend in common, writing for a newspaper, once confessed to Lydekker that he had great difficulty in finding themes for his weekly articles. "Pooh! I find no difficulty," said Lydekker. "I do not require a *theme*—I think of a *word.*" Using every possible moment and opportunity, and writing at incredible speed, Lydekker's literary output was enormous; it covered, moreover, the whole wide field between comparative anatomy, palæontology, and systematic work on one hand, and field natural history and sport on the other. While writing, at least, he was never filled with doubts or tormented by vain cares; whatever came into his head first he wrote, and what he wrote he printed light-heartedly as soon as possible. One scarcely likes to apply that harsh epithet "careless" to writing with so much good, solid work as its foundation, but the dangers of Lydekker's methods are obvious, and as a result one cannot place the normal degree of trust in any book that he wrote. Nevertheless, the fact that his books contain a huge store of real and valuable information is beyond all dispute and a testimony to the industry and genius of the author.

The three stately volumes now before us represent Lydekker's last effort. Well printed and beautifully illustrated, they appear unusually attractive. Opening them and reading at random, one is usually pleased and sometimes delighted with the text, and no doubt to many persons the book will be not only useful, but also a precious mine of information. Casual reading, however, is not the purpose of the book; it aims at being a descriptive survey of the geographical distribution of animals; but an attempt to read it as a whole proves to be a formidable and wearisome task, which one leaves sooner or later with a feeling of disappointment. From the title one expects a connected narrative in which there will be an attempt to expound, albeit in a popular manner, some of the principles underlying geographical distribution, to show how the present depends upon the past, and to bring home to the reader, however ignorant of zoology, the fundamental importance of such things as isolation—in its numerous forms—in the great scheme of evolution.

It would not matter at all what sort of view or theory the author developed in his narrative; he might have proceeded, with equal advantage, along the lines of his own "Geographical History of Mammals," or pursued the attractive, though totally divergent, courses of Scharff on one hand, or of Matthew on the other. Books with an endoskeleton are generally far better than those with a mere exo-skeleton. In one case the reader has something definite and more or less fascinating to follow; even when the writer's style is harsh and his phrasing none too happy, there is a plot which holds one fast while it gradually reveals itself in a well-connected stream of facts. In the other, the facts are disjointed and scattered—interesting and important in themselves, perhaps, but with little or no apparent bearing upon one another; in such a case the author may be endowed with superlative gifts of language and expression, enabling him to charm us on every page, perhaps, when taken in small doses, but he can never succeed in holding the attention of the reader from cover to cover. "Wild Life of the World" is in all essential respects a distinguished example of the books without endoskeletons. In this case, too, alas! Lydekker did not trouble to think of a theme—though he thought of a great many words.

The work calls for little more in the way of general criticism, but it may be worth while to direct attention to one or two specific matters. As an instance of the hasty selection of the facts dealt with, we may mention that, while more than two pages (vol. i., pp. 212–14) are devoted to a discussion of European field-mice (Microtus), no mention is made of the Orkney vole (*M. orcadensis*), which from the point of view of geographical distribution is one of the most interesting and important species; nevertheless, room is found for a whole paragraph dealing with the characters and habits of a phantom species, *M. campestris,* described from Brunswick long ago by Blasius, but generally admitted now for many years to be nothing more than a misidentification of the common Continental vole, *M. arvalis.*

In reading the book we have noticed few misprints. There is, however, an unfortunate transposition in the account of the cuckoo (vol. i., pp. 90–96) which may bewilder the reader. The matter from the word "moreover" in line 2 of p. 93 down to the end of the paragraph seems to be a misplaced continuation of paragraph 2 of p. 91, dealing with the colour and markings of the eggs. The name of the inventor of the harpoon-gun, Svend Foyn, has been converted into "Sven Foyle" (vol. iii., p. 310). It is with considerable satisfaction that we notice that Lydekker endorsed the view that whales and seals in southern latitudes are now in need of a measure of protection, and that our own Government has to bear the weight of direct responsibility in this matter. The quite indiscriminate and unscientific, though lucrative, slaughter which is at present happening in the southern hemisphere and elsewhere is rapidly leading both the larger Cetacea and a valuable industry to extinction.

Lydekker's remark that the Addo Bush elephants "are specially protected" causes a pang when we recollect that the statement is no longer true. No naturalist could hear of the recent decision to exterminate this most interesting herd without grief. One may be pardoned for wondering whether much more would be heard either of the damage done by these elephants or of the project to exterminate them if the authorities, in granting the licence to kill, were to stipulate that the whole of the profits of the chase should be expended upon obtaining such a series of specimens, photographs, and casts as would form an adequate memorial of the threatened race for the use of zoologists and comparative anatomists, and that the balance, if any, should be applied for the purposes of zoological research in Africa.

To conclude, we would reiterate that this book contains a vast amount of most interesting and valuable information brought together by a man of unrivalled experience and ability; this information is most lucidly conveyed throughout, and many passages in the work are quite charming. The illustrations, on the whole, are very good, and some of the coloured plates may fairly be called magnificent. Our sole regret is that Mr. Lydekker did not require a theme.

M. A. C. H.

WATER IN ACTION—CONTROLLED AND FREE.

(1) *Irrigation Engineering.* By Dr. A. P. Davis and H. M. Wilson. Seventh edition, revised and enlarged. Pp. xxiii+640. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1919.) Price 21*s.* net.

(2) *Shore Processes and Shoreline Development.* By Prof. D. W. Johnson. Pp. xvii+584. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1919.) Price 23*s.* net.

(1) AFTER passing through six editions, this work, originally composed by Mr. Wilson in 1896, has been recast and largely rewritten with extensive additions by Dr. A. P. Davis, whose own book on "Irrigation Works in the United States" was reviewed in NATURE for June 20, 1918. It speaks much for the merits of a technical work that it should reach a seventh edition, and the present issue will undoubtedly maintain the reputation gained by its predecessors.

The scope of the treatise is wide—admittedly too wide for complete treatment—and the object kept in view, and that very successfully, has been to present a general outline of the whole field of irrigation work, including its history, the chemistry of soils and soil treatment, sources of water supply, methods of application and measurement, construction of canals and dams, drainage and sewage disposal, water rights, surveys and preliminary investigations, and systems of operation and maintenance. It is obvious that, even in a volume of 600 odd pages, matters so many and so varied could not be treated exhaustively, and that some must receive less attention than, perhaps, is their due. The chapter on masonry dams, for instance, would, in our opinion, have admitted with advantage of some amplification in respect of the fundamental law of the middle third, and some account of the theory of vertical shearing stresses, especially as the book is intended primarily as a manual for engineers.

On the other hand, there are to be found on nearly every page practical notes of considerable utility. Moreover, at the end of the volume is the complete specification, running to fifty-six pages of small print, of the contract for the construction of the Arrowrock dam in Idaho. This, in itself, will prove of inestimable value to the practising engineer for reference purposes. There are also a number of tables with useful data, and computed results of various formulæ.

Another restriction, which must be noted and, perhaps, is inevitable, is that, with one or two rare exceptions, all the examples illustrated are chosen from American practice. It is true that the Assuan dam is mentioned, and that Indian irrigation is not without notice, but the book is written almost entirely from the American point of view. Possibly it gains in interest and value in this way, since the authors thus confine themselves to cases in which they speak with experience and authority.

The illustrations, both photographs and diagrams, are excellent throughout. It is a most valuable and informative book, in a comprehensive way, on a subject which materially affects farmers, geologists, meteorologists, engineers, chemists, and business men, as well as the highest interests of the State.

(2) A work of some 550 pages, in which a list is given of 416 authorities cited, and the references in one chapter alone amount to 187, cannot fail to impress the reader with the erudition of its author and the immense labour he must have taken to collect his data. We pay a tribute, in passing, to the unremitting zeal and perseverance which have produced so concise a compendium of opinion on a subject which, on account of its complexity, is little understood and yet is of the greatest scientific interest.

The book is compiled on methodical lines. Each chapter opens with an "Advance Summary" and closes with a "Résumé." The first and second chapters deal with waves and their work, the third with currents, and the fourth with shore classification. The ensuing six chapters contain an exposition of theories of shoreline development.

The earlier part of the volume is largely historical and retrospective; it reviews the data obtained by experimentalists in the past, with the conclusions based upon them. That there is a radical divergence of testimony is evident from the fact that by one school of thought coastal drift is attributed entirely to wave action, and by another to current flow. By the author no doubt is entertained that, as a whole, waves are the more important agency, and in this view of joint action we are disposed to concur.

In dealing with shorelines, the author rejects the German system of numerical notation, and classifies them broadly as submergent, emergent, neutral, and compound, with a cycle of development passing from young to mature and old. Each of the four classes is dealt with at length, and there are apposite examples, illustrated by photographs, charts, maps, and diagrams, which will repay study. Fjords are not recognised as an indication of land subsidence, but are attributed to glacial action, and it is interesting to note the author's opinion that "any careful analysis of the process of marine erosion must lead to the conclusion that marine planation is possible without coastal subsidence."

The book covers a fairly wide area, and is written with the intention of assisting the engineer, the geologist, and the geographer. As affecting the first-named profession, the difficulty of reconciling the conflicting views of so many eminent authorities seems to us almost insuperable. There is scarcely any problem which causes the harbour engineer more perplexity and anxiety than that of forecasting the effect on the shoreline of a structure projecting into the sea, and in the present state of our knowledge—or ignorance—the evidence available is often capable of quite contradictory interpretations. No doubt further investigation will throw more light on this baffling question, but, for the present, it is beset with obscurity.

The volume is an excellent addition to the literature of physiography, and it fulfils a special function in classifying much fragmentary and detached information not readily accessible.

BRYSSON CUNNINGHAM.

MAMMALIAN PHYSIOLOGY.

Mammalian Physiology: A Course of Practical Exercises. By Prof. C. S. Sherrington. Pp. xi+156+ix plates. (Oxford: At the Clarendon Press, 1919.) Price *12s. 6d.* net.

THE publication of Prof. Sherrington's practical course of mammalian physiology will surely be recognised as an event of first-rate importance for the teaching of physiology and for medical education.

Many teachers must long have felt the limitation imposed by the use of the frog for practically all class-work on living animal organs. The experiments possible to students were restricted to certain aspects of the subject; some were liable to be retained in the course which had mainly historical interest, and others were apt, in unpractised hands, to degenerate into exercises in fine dissection. Nor had the technical facility thus acquired much relation to the later requirements of the medical equipment.

The introduction into class teaching of the surviving carcass of the decerebrated or decapitated cat effects a great liberation. The student can observe for himself the main phenomena of mammalian function. The technique is in most cases relatively so simple that attention is concentrated on the observation of the result; at the same time, it has real value as an introduction to surgical manipulations.

The course opens with exercises on isolated mammalian plain muscle—intestine, spleen, and artery—and on the perfused heart of the rabbit. They involve no very new departure, but the methods given require simple apparatus only, and are admirably adapted to give successful results in the hands of students. Here, too, as throughout the book, each exercise is given the maximum educational value by the explanatory and historical comments.

From Exercise IV. onwards the decerebrated or decapitated carcass is used. Starting with relatively simple experiments on the arterial blood-pressure, the course leads to more elaborate demonstrations of the effect of nerve-stimulation on the vascular mechanism and the activity of the respiratory centre, of vascular and somatic reflexes, and ultimately, when the requisite dexterity has been acquired, to such relatively exacting experiments as that on the stimulation of pancreatic secretion by secretin. In each exercise the opportunities are fully used for incidental observation of important phenomena, not directly connected with the main object of the experiment.

The student who conscientiously follows this course must emerge with a wealth of experience in the methods of physiological observation, and a vivid apprehension of vital phenomena, which no amount of reading or even of witnessing prepared demonstrations could give. Prof. Sherrington himself points out that the method leaves to the individual teacher a wide choice of valuable exercises, beyond the representative series which he has been able to accommodate within the limits of his course. He opens, indeed, a new vista of possibilities to student and teacher alike.

The value of the book is greatly enhanced by the admirably clear drawings of dissections and apparatus. The records reproduced, nearly all taken from experiments made in the class, give convincing evidence that the exercises are well within the compass of the keen student. The last exercise of all, that on the determination of the opsonic index, seems to lie curiously outside the general scope of the course, and to have no clear connection with the opportunities offered by the brainless mammal. Doubtless experience has shown that its inclusion has some special advantage.

Not only students and teachers, but also those engaged in original investigation, have abundant cause for gratitude to Prof. Sherrington for the care and labour which he has expended on putting his methods and experience at their disposal.

H. H. D.

OUR BOOKSHELF.

Birds Beneficial to Agriculture: Economic Series No. 9, British Museum (Natural History). By F. W. Frohawk. Pp. vi+47. (London: British Museum (Natural History), 1919.) Price 2s.

It is important that attention should be focussed now and again on the benefits that accrue to farmer and gardener from the activities of birds, for too frequent reiteration of misdemeanours tends to produce an antagonism which the facts do not warrant; and there is greater danger in indiscriminate destruction than in indiscriminate protection. Recognising these facts, the Trustees of the British Museum have done good service, at once to the farmer and to the naturalist, in publishing this pamphlet, and in preparing the special exhibit to which it makes an efficient and attractive guide.

Of the birds the presence of which in Britain is of any importance in this connection, "120 species may be regarded as decidedly beneficial to agriculture generally," and of these Mr. Frohawk describes in detail a very fair sample of forty-four species, and adds besides two short general notices, necessarily somewhat perfunctory in treatment, on birds in their relation to injurious insects and to agriculture. Careful illustrations by the author make easy the task of identifying a large proportion of the species described. It is to be regretted, however, in a work dealing primarily with economic values that more space could not have been given to feeding habits and food statistics, even at the expense of specific characters and of habits of less immediate importance. Nevertheless, this latest addition to the "Economic Series" of British Museum Publications should help to awaken and broaden interest in the valuable heritage which Britain possesses in its birds.

Rudiments of Handicraft. By W. A. S. Benson. Pp. 40. (London: John Murray, 1919.) Price 1s. net.

This is a forty-page pamphlet, illustrated by fourteen pages of sketches, which attempts to set forth the principles and practice of manual training for children between the ages of eight and twelve, taking wood in the form of sawn laths 1⅛ in. wide and ¼ in. thick as the material to be used.

The idea of the use of strip wood manipulated by quite simple tools is by no means new, having been adopted in certain important educational centres more than twenty years ago. It is difficult to realise how some of the exercises figured in the book can be made into the substantial structures for which they are designed on the methods described, and many of the drawings leave much to be desired from both the technical and artistic points of view. It is just as important for the pupil to be taught to make an accurate drawing in plan elevation and section of the object he purposes to produce as it is for him to execute it.

The well-trained manual instructor who ought to find an honoured place in every school will search in vain for much that is really helpful to him in the pamphlet. The principle of hand and eye training and of its high and necessary educational value is now fully admitted by educationists and is well established, and a large body of capable men fully trained in teaching methods are now available who have formed themselves into an association and assemble in annual conference with the view of promoting the efficiency of their work.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can be undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

National Representation upon International Councils.

In the account of the meeting of the International Research Council (NATURE, August 14, p. 464) it is stated that "the United Kingdom" was "represented" on the council by "delegates." The explanation in the first paragraph of your Notes of September 4 of how the "delegates" were appointed shows that the words are the expression of an intention rather than of a fact. The council apparently wished that its decisions should have some authority other than that derived from the personal distinction of its members, but their wishes remained unfulfilled because there is in existence no machinery for selecting a delegation representative of the scientific workers of this country. It seems worth while, therefore, to inquire what characteristics such machinery must have in order that it should fulfil this purpose, and how such machinery could be set in action.

I suggest that the machinery necessary and sufficient would be such as secures that every professional scientific worker is informed of any action that it is proposed to take which may affect his work and that he has a constitutional means of expressing his opinion upon the proposal. It does not appear to be necessary that any attempt should be made to obtain the equality of voting power which is important in a representative body concerned with political and economic questions—so long, of course, as such questions are excluded from the domain of the body and its attention is confined to purely scientific matters.

The chief difficulty in establishing such machinery is that of defining the class of professional scientific workers. It ought to be overcome by the method used in defining the members of other professions. Lawyers, architects, actuaries, and medical practitioners are defined by membership of certain professional societies, of which the distinctive feature is that they admit to membership all who have undergone certain training and acquired certain experience. Societies having this feature already exist in the profession of science; the various scientific and engineering institutions and institutes are examples. They do not at present cover the whole field, but it will probably be agreed that it is desirable that they should. The best way of securing the representation of science would be to set up institutes for those branches of science which do not already possess them; to organise a small permanent secretariat supported by them all; and to charge this secretariat with the duty of bringing before the institutes any scientific matters likely to interest them. It should be made clear that this secretariat should be the means of communication between the scientific profession of this country and all outside bodies (foreign scientific bodies, Governments, commercial organisations, and so on); to discuss the questions submitted to it, the institutes would appoint delegates appropriate to the nature of each question.

But it is always desirable, if possible, to use existing machinery for such a purpose. It is possible that such an organisation as is required might be developed out of the Conjoint Board of Scientific Societies. The societies represented on it do not all conform to the type of institutes; some are barely scientific; some have no professional test for membership; some of them overlap and represent practically identical interests. But it is probably better to have some machinery at once rather than a perfect machine which will take long to get into action; probably also the machine will improve as it works; its defects will be apparent, and there will be a demand for their cure. I venture, therefore, to suggest respectfully that, unless anybody has a better plan to propose, the Conjoint Board should consider early and earnestly whether they cannot take upon themselves, permanently and consistently, the functions of a body representative of scientific workers in all purely scientific matters.

Hitherto these functions, in so far as they have been exercised at all, have been exercised by the Royal Society. While it was held that the proper spokesmen for science were its most eminent students, no body could have been more suitable for selecting them than that which annually selects for the coveted distinction of its membership the fifteen most eminent men of science still outside its ranks. (For it is obvious that no woman could be included in that number.) But if the spokesmen are to be representative delegates, no body could be less suitable. If the character of the society is to be maintained, exclusiveness must be as essential a part of its constitution as inclusiveness must be of any representative body. By its very nature the Royal Society can never represent any but a small fraction of scientific workers; it cannot represent the fraction which, because its work lies in the future rather than in the past, is most likely to be affected by any proposals for change. We all thank the society for what it has done; we can express our gratitude best by liberating its energies for those more important tasks for which its constitution is adapted.

Intravenous Injections of Gum Solutions in Cholera.

In Nature for June 5 Prof. Bayliss advocates, with good reason, in view of his valuable work on gum solutions in shock, that a trial should be made of their intravenous injection in cholera with a view to obtain a more prolonged maintenance of the blood-pressure than sometimes follows the use of hypertonic salines. Last year Prof. Bayliss kindly sent me a copy of his paper on gum solutions in shock, and in acknowledging it I informed him that I had previously read it, and been so struck with the possibilities of the method being of great value in the very severe cases of cholera which repeatedly collapse, and are sometimes lost in spite of hypertonic salines, that I had lost no time in trying it, but, unfortunately, with very disappointing results. This letter apparently did not reach Prof. Bayliss, probably on account of "enemy action."

With one exception, the cases in which I tried the gum solution were rather below the average severity, as is commonly the case in the rainy season, when the trial took place; yet several were lost which I should have expected to have recovered under hypertonic salines Still more striking was the fact that, instead of the great relief, often resulting in sleep before the hypertonic saline injection is finished, the gum solutions were followed by increasing distress, difficulty of breathing, and cyanosis, which soon compelled me to abandon their use. In view of the shortness of my trial, I decided not to publish my results at once, in the hope that others might be more successful, but I have now learned that my friend, Lt.-Col. A. Leventon, I.M.S., has extensively tried gum solutions in accordance with Prof. Bayliss's method at the Campbell Medical School Hospital, Calcutta, where well over one thousand cases have been treated in the first half of this year, and Lt.-Col. Leventon has authorised me to state that, with various strengths of the purest gum arabic up to 7 per cent., his results have been in entire agreement with mine, and he has also had to abandon the method. He, too, noted the same distress and cyanosis which I saw, and the unexpected loss of not very serious cases under the treatment—clearly indicating that gum solutions do not meet the physiological needs of cholera cases.

I confess that this failure has been a great disappointment to me, but I believe the explanation to be that the gum solutions lead to the retention in the circulation of the deadly cholera toxins, which are absorbed from the bowel in increasing quantities with the restoration of the circulation by intravenous injections of large quantities of salt solution, with or without gum, but which are usually sufficiently rapidly re-excreted through the kidneys and bowels after hypertonic saline to avoid dangerous accumulation in the blood. The fact that I found salines made up with freshly distilled water produced febrile reactions, indicating that the fever was due to toxin absorption, lends support to this view. There is still room for considerable improvement in the treatment of the most severe toxic cases of cholera, but the hopes which Prof. Bayliss's researches in shock led me to expect from gum solutions in cholera have been disappointed. I have for long thought that the most promising line of advance is the use of anticholeraic serums, such as those formerly made by Salimbeni in Paris and Schurupow in Russia, but which I have not yet been able to obtain facilities for making in Calcutta owing to the war. Perhaps one of the hill laboratories of India could take up this important line of work, and send the serum to be tested in Calcutta, in addition to my system of treating cholera.

Leonard Rogers.

I beg to thank you for your courtesy in permitting me to see the above communication from Sir Leonard Rogers. It is unfortunate that the letter to which he refers did not reach me, because it is evident that the effect of gum saline in states similar to that of cholera requires investigation. If the cases to which reference is made had been very severe, one might have supposed that an excessive viscosity was conferred on the blood by the addition of gum. I have made some experiments on this point, but have been unable to detect any serious result when gum saline has been injected after the blood has been concentrated by various means.

It is possible that the retention of toxins may be the explanation, and, of course, the object of any simple intravenous injection is merely to keep up a normal circulation until the remedial agents, such as the specific sera to which Sir Leonard Rogers refers, may be able to produce their effect. The symptoms mentioned, however, suggest to my mind rather some mechanical action of the gum, and it might perhaps be worth making a trial of a preliminary saline injection, followed later by one of gum saline, to avoid too rapid a loss of the fluid injected. In any case, I hope that the experiments now in hand may throw further light on the problem and lead to a means of avoiding the serious disadvantage. I may mention that in my experiments gum saline was found very effective in restoring the renal secretion, and I am convinced that if it should be found possible to use such solutions they would be more permanent in their results and lead to the more rapid elimination of the toxins, if this takes place through the kidney.

W. M. BAYLISS.

A Photoelectric Theory of Colour Vision.

READING in the *Irish Times* of to-day (September 11) a very brief reference to a paper communicated by Sir Oliver Lodge to the British Association, in which Sir Oliver suggests that light absorbed in the black pigment may stimulate certain atoms into radioactivity and so cause the sensation of light, I am reminded of a theory of colour vision which I endeavoured to investigate some years ago. The theory is that the emission of electrons, probably by the pigment layer under light stimulus, is responsible for light-sensation, and that where these electrons act upon the cones they excite colour vision. It is known that, in the photoelectric expulsion of electrons by light, the range of the electron increases with the frequency. Hence for violet light the cone would experience a different distribution of the stimulus from that for red light, and so on.

I endeavoured to detect a photoelectric effect by experiments of the usual sort, using a bullock's eye in which the pigment layer had been exposed. Although a fairly sensitive arrangement was ultimately arrived at, I failed to detect the sought-for effect. I put the matter aside, although urged by some physiologists to continue it.

That the photographic image is initiated in a somewhat similar manner seems very probable. On this view much has already been written.

J. JOLY.

Trinity College, September 11.

Mathematics at the University of Strasbourg.

I HAVE received the programme of the courses in mathematics at Strasbourg, which will undoubtedly stand second only to Paris among the French universities. The Institut de Mathématiques, which forms part of the Faculté des Sciences, is to have five titular professors and three "maîtres de conférences," and offers complete graduate and post-graduate courses. The professor of *analyse supérieure* and director of the Institut is M. Maurice Fréchet. MM. Valiron, Villat, and Esclangon occupy respectively the chairs of calculus, rational mechanics, and astronomy; the chair of geometry has not yet been filled.

While English mathematicians are fully appreciative of the work of their French *confrères*, the French universities, where students of the other nations of the world have flocked, have in the past been a little neglected by English mathematical students. An English student could not do better than spend one of his post-graduate years in France, where he will find every facility and encouragement, and a very warm welcome.

H. BRYON HEYWOOD.

The Magnetic Storm of August 11–12, 1919.

I OBSERVE in the issue of NATURE for August 21 an account of the magnetic storm of August 11–12, 1919, by Father Cortie, of Stonyhurst College Observatory, and note that he looked out for a possible display of aurora on the night of August 11. "But," he says, "the brightness of the moon effectually veiled any such appearance, even if it were present."

In these circumstances it may be well to record that a fine display of the Aurora Borealis was observed here, Cape Breton Island, Nova Scotia, on the night of August 11. The affected area extended far into the southern sky. Pulsations of light swept upwards to the zenith, resembling clouds driven before a heavy wind.

September 5.

THE WATT CENTENARY CELEBRATIONS.

THE Watt Centenary Celebrations in Birmingham last week were full of interest, and the presence of representatives from the United States of America, Australia, France, Japan, and Sweden, as well as a cordial message from Norway, bore testimony to the honour in which the memory of James Watt is held throughout the world. At the inaugural meeting on Tuesday, September 16, the Lord Mayor (Sir David Brooks), in welcoming the visitors (among whom were Mrs. Gibson Watt and Miss Boulton, direct descendants of James Watt and Matthew Boulton), said that it was fitting that Birmingham should wish to establish a permanent memorial to the man whose discoveries and inventions had done so much for the city of his adoption. He thought that the proposals as to the form which the memorial should take would commend themselves not only to Birmingham citizens, but to all who really appreciated the work which James Watt and his associates had accomplished. It was proposed to endow a "James Watt Chair of Engineering" at the University of Birmingham, for the prosecution of research in the fundamental principles underlying the production of power. He hoped that the success of this part of the scheme would early be placed beyond doubt. In addition to this it was very desirable to have in the city a suitable building to house examples of the work of Watt, Boulton, and Murdock, and the relics which these men had left behind—a building which might also be a suitable meeting place for scientific and technical societies.

An address on "The Rise of Engineering Manufacture" was then delivered by Prof. F. W. Burstall (professor of mechanical engineering in the University of Birmingham). Before the middle of the eighteenth century a high degree of skill in metal work had been attained, but lack of power restricted the scale on which work could be done. Prof. Burstall directed attention to the fact that Boulton and Watt were looked upon as the first builders of steam engines, but their work in starting a system of co-ordinated manufacture had generally been overlooked. He believed that both the conditions of work and the quality of the workmen to-day were considerably in advance of those of one hundred years ago. There was no likelihood that the highly-skilled worker would ever be replaced by a machine, but for the vast number of unskilled workers machinery meant monotonous work. For the latter the provision of means of healthy recreation was of vital importance.

Then followed a lecture by Prof. Hele-Shaw on "James Watt and Invention." The lecturer emphasised the importance of inventions, and remarked that in the late war the country was many times saved by our own inventions, which were brought into being under the stimulus of patriotism and the encouragement given by timely organisation. He made the suggestion that, as Watt was so pre-eminent as an inventor, the proposed James Watt chair should be a chair of invention instead of one of engineering. Such a chair would be unique and worthy of James Watt as a new and original departure.

In the afternoon an impressive memorial service was held at Handsworth Parish Church, where Watt and his associates worshipped and were buried. Adjoining the church is the memorial chapel in which stands the famous Chantrey statue of James Watt, and there, after the singing of the anthem "Let us now praise famous men," the Lord Mayor of Birmingham laid a laurel wreath at the foot of this statue. The address was delivered by the Rev. Dr. E. W. Barnes, Canon of Westminster, who claimed that "it was especially fitting that Birmingham should honour James Watt, for it was there that he perfected his steam-engine; there he found workmen of sufficient skill to carry out his designs; there he found in Boulton the friendly capitalist of whom he was in need; there his fortune was made; and there he died in honourable old age. Throughout his life Watt was a religious man. He had not the temper or interests of a theological partisan. His attitude was that of a philosopher, conscious of the complexities of social organisation and of the inherent difficulties of government—a man of science, fully understanding how immense were the distances that shut us in, and not unconscious of the danger of unduly dogmatic speculation as to the unknown." Dr. Barnes compared the good and evil resulting from Watt's genius: "We were, owing to Watt's inventions, using up coal at a dangerously rapid rate, and when it was gone the industry and the workers which the coal sustained must pass to other lands. The desire for more motion and for barren luxuries had crowded life and wasted toil, taking largely from man's mental freedom and physical rest. And of all barren luxuries by which man wasted Watt's legacy the worst was war. We could thank God sincerely for Watt's discoveries and the mechanical revolution to which they led, if we remembered that it was the political sagacity and moral wisdom of men that had been at fault. In the last century mechanical progress so outstripped spiritual growth that disaster resulted. In default of security gained by religious idealism, the better men and the best races would be eliminated by war, and we should be left with moral degenerates, clever, indeed, in the invention and control of machines, but destitute, and even contemptuous, of spiritual energy."

After the service the visitors were entertained at a garden party at Heathfield Hall by Mr. George Tangye, and much interest was shown in Watt's famous garret-workshop, which has been preserved in the condition in which he left it a century ago.

On Wednesday morning, September 17, the proceedings were presided over by the United States Ambassador (the Hon. J. W. Davies), and an address was given by Sir Oliver Lodge on "Sources of Energy." The lecturer, in his most attractive and vigorous style, dealt mainly with the possibilities of intra-atomic energy. The stock of energy of this kind is prodigious, but it is at present almost entirely inaccessible, and the lecturer speculated on the possibilities of its use in the future.

This was followed by Prof. J. D. Cormack, Regius Professor of Engineering in the University of Glasgow, with a paper (written in collaboration with Prof. Barr) on "The Model of the Newcomen Engine repaired by James Watt."

In the afternoon, visits were paid to some James Watt engines, one at Ocker Hill being shown in action. Here Watt's original indicator was seen at work, and indicator-diagrams taken on it were distributed among the visitors. The occasion was one of unique interest, vividly impressing the mind with the genius of the great engineer, and at the same time bringing home the vast developments which a century has seen in the applications of steam-power.

In the evening about 300 guests assembled for the centenary dinner at the Grand Hotel, the Lord Mayor presiding, and the American Ambassador and the Chancellor of the Exchequer being prominent in a gathering of distinguished men. In proposing the toast of the "Houses of Parliament," Sir Oliver Lodge insisted on the vital need of the encouragement of scientific research, not by an *ad hoc* bureau in London, but through the universities throughout the country. He coupled with the toast the name of the Chancellor of the Exchequer. "They in Birmingham had an affection for Mr. Austen Chamberlain, and they in the University of Birmingham regarded him with affection because when he last held his present office he increased to them a Government grant which subsequent occupants of the office had followed up. It would be wisdom for this country to lavish money upon the universities. Economy was necessary, but it did not pay to cut off the best part of the money granted to the universities."

Mr. Austen Chamberlain, in replying, spoke of the difficulties of a Chancellor of the Exchequer, especially at the present crisis; but he was sympathetic. University education was one of the things that seemed to him to require generous treatment, and he had endeavoured to ensure that university grants should be increased—not merely by a temporary increase which was given to repair the injury done by the war, but by a permanent increase. That expenditure would grow as they could afford it, but they must not expect the Government to move too far. People might be enthusiastic men of science and devoted sons of universities on Monday, but on Tuesday, when he presented the budget, they were taxpayers. ". . . The Government would do its share on one condition only—that the towns did their share also."

The toast of "The Navy, Army, and Air Force," proposed by Mr. Gilbert C. Vyle, was replied to by Admiral Sir G. G. Goodwin, who acknowledged the debt of the Navy to Watt, and by Colonel Barraclough (professor of engineering in Sydney University), the latter expressing the opinion that "if the agitator, the profiteer, the man who was inclined to relax his labours, could all come to Soho and live, as the visitors to that commemoration had done, with the memories of Watt and his co-workers, they would go away with a higher sense of their responsibilities to themselves and to the community of which they formed a part."

The American Ambassador proposed the toast of "The City of Birmingham" in an admirable speech, in the course of which he said that one date in the summary of the important events in the life of James Watt was that of the American Revolution. "The ideas that the revolution embodied had not lost their force. But, great as that revolution was, and important as Americans believed the date to be, he was reminded that it was the year of an even greater revolution—the year when James Watt made his invention a practical success."

The toast of "The Memory of James Watt" was proposed by Prof. Burstall, who emphasised the value to James Watt of the strength and co-operation of Boulton.

Prof. Rateau brought "a tribute of honour and appreciation from science and labour in France to the memory of the great man in whose honour they were met that day."

On Thursday, at a special degree congregation, honorary degrees were conferred by the University on the American Ambassador, M. Auguste Rateau, Prof. Archibald Barr, Sir George Beilby, Colonel Blackett, Engineer Vice-Admiral Sir George Goodwin, and Mr. F. W. Lanchester. It was much regretted that Sir Charles Parsons was unable to be present.

On Saturday representatives of the Chamber of Commerce, the University, and engineering workers in Birmingham formed an impressive procession headed by a model of a James Watt engine. The interest taken by the workers themselves in the memory of Watt is perhaps the most encouraging feature of the commemoration, for the future depends very largely on the attitude of organised labour, and there is no doubt that many of the leaders of labour take an enlightened view of the educational needs of the country.

PROF. J. W. H. TRAIL, F.R.S.

WE regret to record the death on September 18 of Prof. Trail, who for forty-two years held the Regius chair of botany in the University of Aberdeen. Carrying his sixty-eight years with uncommon vigour, he lectured twice daily to the overcrowded classes of the past summer, and he seemed in July to be in the enjoyment of his usual health, so that it was with a shock that his friends heard of a serious operation. At first he rallied, but then rapidly sank. Those who knew him could hardly imagine for him any other end than that he should thus die in harness.

Prof. Trail was a marked figure in Aberdeen. Orcadian by birth, he was the son of Dr. S. Trail, professor of systematic theology in Aberdeen, and moderator of the General Assembly in 1874. He graduated with highest honours in natural science in 1876, and took his M.D. in 1879. In 1873–75 he travelled in Northern Brazil as naturalist to an exploring expedition, and used this opportunity for making a special study of Palms, of which family he had an expert knowledge. His results were published in a series of papers "On the Palms of the Amazon Valley," contributed to the *Journal of Botany*. On his return at the age of twenty-six he was appointed to the chair of botany in succession to Dr. Dickie. He held that post till his death.

Prof. Trail's work was marked by extreme accuracy, and guided by a keen sense of duty. Once a specimen was collected, he felt the obligation to make the most of it. The result of such work, extending over so long a period, has been the amassing of an enormous record of facts relating especially to the native flora. The *Scottish Naturalist* was one of the chief channels of his publication. There he produced a series of papers on Scottish galls and on leaf-diseases, which will provide rich material for those who follow. His mind was attracted by fact rather than by theoretical construction. His knowledge of those details which he studied was singularly wide and exact. For instance, having noted the inconstancy of floral construction in *Polygonum aviculare*, he monographed a single plant, and found as many as 120 distinct variations in number and relation of the floral parts borne upon it. He was rather reluctant in publication, but he was most generous in imparting his knowledge by correspondence, thus suggesting the stores that lay behind. These were most readily revealed to the botanical visitor to his house.

Prof. Trail was thoroughly typical of Aberdeen, vigorous, self-reliant, with a strong sense of duty, and a touch of austerity in its performance. Brought up in the granite city, he took a large hand in the guidance of education there. Not only was he a leader in the University itself, but he also took part locally in directing that secondary education which forms the natural foundation for the higher learning. Himself son of a professor and moderator, he married a daughter of the late

Prof. Milligan, who was also moderator of the General Assembly, and clerk of senate in Aberdeen, and he leaves a son and three daughters. Thus truly the spirit of Aberdeen University was bred in his bones, and inspired him throughout his life. F. O. B.

NOTES.

SIR RICHARD GLAZEBROOK's appointment as Director of the National Physical Laboratory expired on September 17 on his attaining the age of sixty-five. Sir Richard had held the post with distinction for twenty years, having been appointed on the foundation of the laboratory by the Royal Society in 1899. For the first two years the work of the laboratory was carried out at Kew Observatory by the staff of the observatory with the addition of three scientific assistants. The income was approximately 5000*l*. per annum. Soon afterwards Bushy House became the home of the laboratory, and as its work extended additional buildings were erected in the grounds. At the present time these buildings probably provide a space twenty times that of Bushy House, and the staff now numbers about five hundred, nearly two hundred of whom are women. The ordinary expenditure of the laboratory just before the war was about 40,000*l*. per annum. During the war it rose to 110,000*l*. per annum. The rapid growth of the institution is the best proof that it met a real need, and that it met it efficiently. It owes its success to the administrative powers of the director and to the skill he exercised in his choice of the men to fill the earlier appointments. Without exception, these men have distinguished themselves by their scientific work and have contributed largely to the reputation the laboratory now enjoys. Eighteen months ago the laboratory was taken over by the Department of Scientific and Industrial Research, and, according to the report of that Department for 1918–19 just issued, 154,000*l*. is allocated to it for the current financial year Although the laboratory does not attain its majority under Sir Richard's directorship, he has had the satisfaction of rearing it to a vigorous manhood, and he will from his Cambridge home watch its growth under Government auspices with interest. He is succeeded by Dr. J. E. Petavel, professor of engineering in the Victoria University of Manchester.

CIRCULAR No. 39, dated September 1, issued by the Meteorological Office, mentions the retirement of Rear-Admiral Sir John F. Parry and the appointment of Rear-Admiral F. C. Learmonth, C.B., who succeeds as Hydrographer of the Navy, and consequently as an *ex-officio* member of the Meteorological Committee. A conference of meteorologists will be held in Paris on September 30 and subsequent days, following the conference in London of the meteorologists of the British Dominions from September 23 to 27. A note is given relative to the time of occurrence of minimum air-temperature on the grass. The observations at Cahirciveen have been handled to test a suggestion made that the grass minimum for the night is frequently reached between sunset and 21h. Since April 1, 1917, the grass minimum at Valencia has been set at 18h., and read daily without disturbance at 21h. Out of 850 observations made to June, 1919, the number of occasions on which the phenomenon was observed was 101, which seems to be accounted for by a cloudy to overcast sky setting in during the evening, followed by rain, mist, or drizzle, with a wind of moderate force having a southerly component, the sky previously, between 18h. and 21h., being comparatively clear. The effect of terrestrial radiation is clearly to be traced in the foregoing explanation.

FROM the September issue the *Technical Supplement to the Review of the Foreign Press*, formerly issued by the General Staff of the War Office, is to be known as the *Technical Review*. With the same organisation and staff it will continue to provide a digest of the technical Press of the whole world for the benefit of engineers and manufacturers. At present the articles in it consist either of abstracts or of titles, with occasional short accounts arranged under the heads:—Engineering construction and transportation, mechanical engineering, mining and metals, shipbuilding and marine engineering, electrical engineering, aeronautics, chemical engineering and industry, miscellaneous, recent publications, and engineering index. The review provides for engineering in general the information as to recent progress which has been available for electrical engineering for some years in *Science Abstracts*, and for chemical engineering in *Chemical Abstracts*, as well as in the abstracts published by the Chemical Society and the Society of Chemical Industry.

AN important collection of Lycænidæ and Hesperidæ has recently come into the possession of Mr. J. J. Joicey, and is now at the Hill Museum, Witley. This collection was made by Mr. Hamilton H. Druce, who is well known as one of our greatest authorities on the Lycænidæ and Hesperidæ. A great many types of species described by Mr. Druce, as well as many of the types of Semper, are contained in the collection. Entomologists desirous of comparing any specimens in this collection are invited to write to the Curator, the Hill Museum, Witley, Surrey.

THROUGH the courtesy of the Corporation of London, a series of fortnightly lectures on industrial problems will be delivered at the Guildhall at 4.30 p.m., commencing on October 7. The speakers will include Mr. E. J. P. Benn, Prof. Ripper, Dr. Russell Wells, the Right Hon. Sir Auckland Geddes, Sir George Paish, and the Right Hon. Lord Emmott. Tickets for this series can be had on application to the Secretary, Industrial League and Council, 66 Victoria Street, S.W.1.

THE New York correspondent of the *Daily Mail* announces that, on September 18, Mr. Roland Rohlfs reached an altitude of 34,610 ft. in seventy-eight minutes in a 400-h.p. Curtiss triplane. The flight was observed by officials of the Aero Club, who sealed Mr. Rohlfs's instruments, and, when he landed, sent them to Washington for verification. The previous record for altitude was that of 30,500 ft. attained by Capt. Lang and Lieut. Blowes in January last. (See NATURE, January 9, p. 369.)

IT was announced by Sir Robert Hadfield at the autumn meeting of the Iron and Steel Institute, which opened on September 18, that the Prince of Wales had consented to become an honorary member of the institute. Dr. Federico Giolitti, formerly professor of metallurgical chemistry and metallography at Turin, was presented with the Bessemer medal for 1919 in recognition of his services to the science of metallurgy.

A LARGE neolithic graveyard, of the La Tène period, has been found by Dr. B. Schnittger at Gestilren, in Vestrogothia. Two quadrangular and ten circular stone enclosures were set on a gravel esker and covered by smooth slabs. The bones were burned, and in hollows or urns. Similar graves are known at Halleby and other places in Ostrogothia, but these are the first discovered in Vestrogothia.

THE Scandinavian Association for a Tropical Biological Station has decided to send an expedition this autumn to select a site for a research station to study marine biology. Dr. Th. Mortensen, who is chairman and founder of the association, will lead a small party including probably Dr. Nils Holmgren and a botanist. They will visit Celebes, North Borneo, Amboina, and New Guinea.

PROF. G. T. MORGAN will deliver the Streatfeild memorial lecture at the Finsbury Technical College at four o'clock on Thursday, October 2, taking as his subject "Applied Chemistry in Relation to University Training." Admission will be free.

IN the *Canadian Field-Naturalist* (vol. xxxiii., No. 2, May, 1919), Mr. F. W. Waugh, of the Geological Survey, Ottawa, gives a careful account of Canadian aboriginal canoes. The types of these are found in separate regions—the Eskimo kayak and umiak in the north, and to the south that of the birch-bark canoe. The latter apparently reached its perfection in the Algonquian area, a region extending from round the Great Lakes and some distance westward, to the maritime provinces and the New England States. This distribution was largely determined by the range of the canoe birch (*Vetura papyrifera*), which extends practically from the Atlantic coast to the Rockies. The disappearance of the birch southward is indicated by the inferior canoes of elm, buttonwood, and basswood bark built by the Iroquois of Central New York State. This latter type was heavy, inconvenient for portaging, and usually short-lived. Practically everywhere within the region of Algonquian influence proper the birch-bark canoe was essentially the same, such differences as occur concerning mostly the shape of bow and stern, which has evidently been derived almost exclusively from a single pattern, with local variations in the amount of curvature or recurvature, and the method of decking over at the ends, where such a device was employed.

PROF. CHILTON has published some notes of interest on destructive boring crustacea in New Zealand (*N.Z. Journ. Sci. and Techn.*, vol. ii., no. 1). The well-known European *Chelura terebrans* (an amphipod) and *Limnoria lignorum* (the "gribble," an isopod) are active destroyers of pier-timber in the southern seas, and the latter devours also the insulating material of submarine telegraph cables. In addition, an Australian isopod, *Sphaeroma quoyana*, burrows into sandstone rock as well as into timber.

IN the Annals of the Natal Museum (vol. iv., pt. 1), among several interesting zoological papers, one on the wing venation and respiratory system of certain South African termites by Claude Fuller is worthy of special notice. Details are given of the relation between wing nervures and primitive air tubes in several genera of termites, and the student of insect transformations may obtain much instruction from Mr. Fuller's demonstration of the development and unfolding of the wings from the larval and nymphal rudiments.

DR. VICTOR E. SHELFORD writes in the *Scientific Monthly* of August last on the general question of the waste involved in the discharge of domestic and industrial sewage into the sea and rivers. Experimental methods for testing the effect on fishes of various substances in solution have been devised. The reaction employed was the turning away of various kinds of fish from the part of a large tank where the contents of the water in the toxic substance was above or below the normal amount. The sensibility of fish to such compounds as occur in waste material is thus shown to be greater than has hitherto been supposed, thus an increase in carbon dioxide of 2 c.c. in one litre above the normal caused the turning-away reaction. A low oxygen content was also detrimental, and this was usually found to accompany a high carbon dioxide content. The waste substances resulting from gas-production works and from munitions processes were also studied, and it was shown that these substances, though almost insoluble, had very marked effects on fish-life. References to papers published by the author and his colleagues are given.

VOL. xxv. of the "Rapports et Procès-Verbaux" issued by the International Council for the Exploration of the Sea deals with the administration for the years 1916–18. The usual financial contributions were made by the neutral countries, Denmark, Holland, Norway, and Sweden, and by Great Britain for the years 1916–17 and for 1918–19. Some fishery investigations were carried on in Scandinavian waters, and a hydrographical bulletin summarising the results so far obtained is being prepared. The influence of the war on the fish population of the North Sea is discussed, and the opinion expressed that the stock of certain kinds of fish is undergoing considerable changes. "It is even within the bounds of possibility that the previous indications of 'over-fishing' may be replaced by indications of 'over-population' of fish." The testing of such opinions is regarded as a matter of much importance. "New points of view even as to restrictive laws may be expected as a result of such investigations." There is, however, no indication that such work is being seriously undertaken, and the "accumulated stock," if it exists, must soon be seriously diminished by the intensive trawling which may be expected very soon.

A DETAILED report on fruit culture in Malaya by J. N. Milsum (Bull. Dept. Agr., Fed. Malay States, No. 29, Kuala Lumpur, 1919) has recently appeared. The story that is told here or written between the lines might be told of most countries of the eastern tropics, or, indeed, of most countries where the population that is likely to consume such fruit is small and migratory. The native of the country is content with the fruit that is easily produced there and already well known (in this case the durian, mango, sapodilla, mangosteen, jak, etc.), and has no desire for others. The migratory European planter does not think it worth his while to grow fruit that he may not remain to consume. And, lastly, and most important of all, the profits of the established industries (here largely rubber) are greater and more certain than those of fruit culture, so that no one is tempted to grow fruit commercially. The result is that the resident in the country is reduced in general to bananas, pineapples, mangoes, and a few more, and these usually not of the best quality. What is really required, and shows real possibilities, is the improvement of those fruits that are already cultivated rather than the introduction of new ones. The resident, too, must be prepared to pay a good price for a good article. A detailed account is given of many different fruits and how to cultivate them, but little attempt is made to discriminate between really first-class fruits, such as banana, mango, or pineapple, and inferior fruits such as rambutan or rose-apple—interesting fruit to taste once in a while, but not fruit that anyone is likely to wish to cultivate.

THE Memoirs of the Indian Museum (vol. vii., No. 2, July, 1919) contains an interesting paper entitled "Observations on the Shells of the Family Doliidæ," by E. W. Vredenburg. The memoir is illustrated by seven excellent plates reproduced from photographs, in which the features of four of the principal species of Dolium are well shown. The material dealt with is largely contained in the Indian Museum, and includes several species of Dolium and of Pirula. A very welcome and important feature is a review of the fossil occurrences of species belonging to these two genera, from which it appears that the genus Dolium is not known in formations older than the Oligocene, the greater number of fossil representatives being Upper Miocene and Pliocene; it seems to have reached the climax of its development at the present day. The genus Pirula, on the other hand, is known from Cretaceous times, and the fossil species are more numerous than the recent ones. In discussing the synonymy of certain of the species of Dolium, the author brings forward some excellent arguments in favour of the selection of specific names of long-established usage and tradition instead of the adoption of names which, though earlier, are not always to be trusted; for, as the author points out, there is always the risk of an industrious bibliographer discovering some forgotten monograph of earlier date than the one relied upon as final. This is only one of many cases, both of generic and specific names, which can be cited to show that a rigid application of the law of priority is not always to the benefit of science. As has been pointed out by others, it is for the International Zoological Congress to consider the adoption of a list of *nomina conservanda*.

CANADA and the Colonies of Bermuda and Newfoundland issue regularly a "Monthly record of meteorological observations" under the directorship of Sir Frederic Stupart. The record for March has just reached us, and it contains a mass of means for barometer, temperature, relative humidity, precipitation, wind direction and velocity, and cloudiness. For chosen stations the hourly readings are given which allow of minute examination of the climate. The detailed observations are "boiled down" to give a general synopsis of temperature and precipitation for the several districts and provinces. It is stated that under ideal conditions the means should be derived from stations uniformly distributed, but such ideal conditions are not only wanting in Canada, and it is a common failing elsewhere, if not everywhere. Maps are given showing difference of temperature from average, and total precipitation in inches. The temperature-map shows a deficiency of 14° F. around Alberta and an excess of 6° to the south of Hudson Bay. The precipitation is indicated by degrees of shading, the heavier falls being well shown over the parts bordering the Pacific and the Atlantic Oceans.

A MORE than usually interesting discussion of a typhoon in the Eastern seas by the Rev. José Coronas, S.J., the chief of the Meteorological Division of the Weather Bureau of the Philippine Islands, has been recently issued. The storm is called the "Quantico" typhoon, as it caused the total wreck of a large steamer of that name on the northern shore of Tablas Island. The storm is also known as "the Christmas typhoon of 1918," as it occurred on Christmas Day. The typhoon is carefully tracked throughout its course and maps are given at frequent intervals. Detailed observations are also given of the movement of the barometer and the direction and force of the wind. Several plates are given showing the damage caused by the typhoon. The track of the typhoon is said to be altogether abnormal, and this is probably the most interesting feature, as it contains a warning for both the seaman and the forecaster. The typhoon is shown to have first moved towards the west by north, then to have inclined northwards whilst to the east of the central part of the Philippines, and finally recurving backward not only to west by north, but to west by south, and even to west-south-west. The slow movement of the typhoon on December 23–24 is said, in 99 per cent. of the cases, to be a sign that the typhoon was recurving north-eastward, especially at the end of December, and to the east of the Philippines. Observations, however, prove most conclusively that the movement was in the opposite direction. The rate of progress of the typhoon was at first about 11 miles an hour, the rate afterwards decreasing to 4 miles an hour or less, whilst after recurving to the west-south-west the typhoon attained its former rate of progress. The vortical calm was probably 15–25 miles in diameter. The area of destruction whilst it was raging in or near Luzon was about 80–100 miles in diameter.

THE "Algebraic Cube" is a model illustrating the formula $(a+b)^3=a^3+3a^2b+3ab^2+b^3$. Imagine a cube of edge equal to $a+b$ cut by three mutually perpendicular planes each distant a from one of the sides. The eight pieces into which the cube is divided will consist of a cube of edge equal to a, a cube of edge equal to b, three blocks of base a^2 and height b, and three blocks of base b^2 and height a. Thus each piece represents a single algebraic term, which is engraved on the face of the block. The block a^3 is coloured blue, the three blocks a^2b are yellow, the three blocks ab^2 red, and the cube b^3 black. The model is the three-dimensional analogue of the well-known Euclidean construction showing the relation $(a+b)^2=a^2+2ab+b^2$, and should prove a very useful aid in teaching young pupils the foundation of the rule for the extraction of cube roots. The blocks are supplied in a neat cubical box, 10 cm. to the edge, by Messrs. Barnes and Morris, Ltd., scientific instrument makers, Audrey House, Ely Place, London, E.C.1.

WE learn from the *British Journal of Photography* of September 12 that Mr. Herbert A. Lubs, of the colour laboratory of the United States Bureau of Chemistry, has investigated the preparation of *p*-aminocarvacrol and its use as a developing agent in photography. It is conveniently prepared from carvacrol by the production of nitrosocarvacrol, and the reduction of this by ammonium sulphide. Five grams of the pure derivative were obtained from 10 grams of carvacrol. As a developer for prints *p*-aminocarvacrol was found to be as good as metol, *p*-aminophenol, or *p*-aminocresol, and the lasting quality of the mixed developer was superior to that of *p*-aminophenol, but not quite so good as that of the others. This work has been done particularly with the view of utilising the abundant source of carvacrol that may be prepared from cymene. Thymoquinol and *p*-aminothymol were also prepared, but they proved to be less satisfactory both with regard to yield and their behaviour as developing agents.

IN *Engineering* for September 12 Dr. W. C. Unwin gives an account of an investigation he has made on the results of notched-bar tests. Dr. Unwin has applied Prof. Martens's method of calculating the "mean error," which differs little from the probable error and is easier to calculate, and has taken the test results given in the paper on shock tests by MM. Charpy and Thenard (Iron and Steel Institute, 1917), and also those in the British Association report for 1918. Dr. Unwin finds that an empirical formula of the form: Work of rupture/area of fracture raised to a power n, gives closer agreement with the experimental results than other formulæ which have been employed. n ranges from 1·17 to 1·41 for the Charpy and Thenard results. Dr. Unwin considers, however, that the results are too few for a safe generalisation, and that further progress cannot be made until a greater number of careful tests have been made with bars of different sizes, the results of which are as consistent with each other as those of Charpy and Thenard, the value of whose 1917 paper it would be difficult to overrate.

AN interesting description, with working drawings, of a Michell thrust bearing appears in the *Engineer* for August 29. This bearing has been made by Messrs. Cammell Laird for H.M. destroyer *Mackay*, and was fitted to the port turbine, whilst the starboard turbine had a thrust bearing of the ordinary type. The pressures on these bearings were 549 lb. and 120 lb. per sq. in. respectively, and it is interesting to note that the oil discharged from the Michell bearing was about 18° cooler than that from the ordinary type. Another valuable point about the Cammell Laird design is in the form of a thrust-indicating device fitted to the bearing. This consists of a number of small hydraulic cylinders having rams which bear against the abutment ring which carries the thrust pads. By pumping oil into these cylinders the rams force the abutment ring off its seat, and the whole of the propeller thrust is then carried by the rams. Thus the pressure in the cylinders is a measure of the thrust. On the trials of the *Mackay* the thrusts registered were 59 tons and 56 tons respectively for the port and starboard engines, and varied to 61 tons and 47 tons when turning. Variations in speed were also recorded by the thrust indicator, and give fair curves on a graph. This device is likely to be extremely valuable in solving problems of propeller efficiency and resistance of ships by enabling experiments to be carried out on the ship itself as well as on tank models.

Messrs. George Bell and Sons, Ltd., announce for early publication a new "Card Test for Colour-Blindness," consisting of twenty-four cards devised by Dr. F. W. Edridge-Green. Mr. J. Reid Moir is publishing through *Mr. W. E. Harrison, the Ancient House Press, Ipswich*, a volume entitled "Pre-Palæolithic Man," in which will be given an account of the flint-implements discovered in certain Pliocene deposits in East Anglia. The book will also contain chapters dealing respectively with flint fracture, the ancestry of the Mousterian palæolithic artefacts, and the Piltdown remains. *Messrs. Hodder and Stoughton* announce for appearance in their New Teaching Series of Practical Text-Books "Chemistry from the Industrial Standpoint," P. C. L. Thorne; "The Natural Wealth of Britain: Its Origin and Exploitation," S. J. Duly; "Foundations of Engineering," W. H. Spikes; "Chemistry and Bacteriology of Agriculture," E. J. Holmyard; "Applied Botany," G. S. M. Ellis; "Everyday Mathematics," F. Sandon; "The Mathematics of Engineering," S. B. Gates; "Mathematics of Business and Commerce," O. H. Cocks and E. P. Glover; and "Geography of Commerce and Industry," R. S. Bridge. The list of announcements of the *Oxford University Press (Mr. Humphrey Milford)* has just been issued, and contains, among others, the following works:—"Medical Science: Abstracts and Reviews"; "Pathology of War Gases," Dr. M. C. Winternitz; "United States Forest Policy," J. Ise; "Fungal Diseases of the Common Larch," W. E. Hiley; "Effects of the Great War upon Agriculture in the United States and Great Britain," Prof. B. H. Hibbard; "Aristotelis Meteorologicorum Libri Quattuor," Recensuit Indicem Verborum Addidit, F. H. Fobes; "James Tod's Annals and Antiquities of Rajasthan," edited, with an introduction and notes, by Dr. W. Crooke; and "The Heart and the Aorta," Drs. Vaquez and Bordet, translated by Dr. Honeij. A new series of books is to be brought out by the *University of London Press, Ltd.*, entitled "The Education of the Future." It will be edited by Mr. Benchara Branford, who is writing an introductory volume on "The Modern Philosophical Basis of Education." Other volumes of the series will be "Psychology of the Class," F. Watts, and "The Teaching of Geography," Miss A. Booker.

READERS of NATURE interested in geology should see the latest catalogue (No. 88, new series) of Messrs. John Wheldon and Co., 38 Great Queen Street, W.C.2, which contains the titles of upwards of two thousand publications relating to geology and mineralogy, conveniently classified under the main headings of Geographical, General Geology, and Economic (Mineralogy, Metallurgy, and Mining). The catalogue is particularly strong in French and German works.

OUR ASTRONOMICAL COLUMN.

COMETS.—Mr. H. Vanderlinden has computed the following orbit of comet 1919*c* (Metcalf-Borrelly) from observations on August 24 and 30 and September 5. It differs considerably from that already published, but is evidently more accurate:—

$$T = 1919 \text{ Dec. } 7{\cdot}2721 \text{ G.M.T.}$$
$$\left.\begin{aligned}\omega &= 185^\circ\ 49'\ 37''\\ \Omega &= 120^\circ\ 59'\ 14''\\ i &= 46^\circ\ 23'\ 30''\end{aligned}\right\}1919{\cdot}0$$
$$\log q = 0{\cdot}046698$$

Ephemeris for Greenwich Midnight.

	R.A. h. m. s.	N. Decl. ° ′	Log r	Log Δ
Sept. 28 ...	15 12 8	10 50	0·1943	0·3221
Oct. 2 ...	15 21 18	8 50	0·1827	0·3173
6 ...	15 30 49	6 48	0·1711	0·3127
10 ...	15 40 41	4 43	0·1594	0·3083
14 ...	15 50 55	2 37	0·1478	0·3041

The magnitude is 8·8 on October 2; brightening slowly.

Many naked-eye observations of comet 1919*b* (Metcalf-Brorsen) are reported, so the brightness evidently exceeds the tabular value. No revised elliptical elements have yet been published. The errors of the Copenhagen ephemeris are now quite appreciable, so a little sweeping may be necessary to find the object.

THE FUTURE OF THE TRANSIT CIRCLE.—Mr. J. E. de Vos Van Steenwijk has a paper on this subject in the September *Observatory*. Some ardent supporters of photography think that our transit circles might be scrapped altogether. The paper reminds us that fundamental places of the sun and principal fixed stars are still needed, but they may safely be left in the hands of a few observatories. Reference stars for photographic plates must also be observed, but the number required may be greatly diminished if portrait lenses with a large field are used for the photographs. The paper suggests two other useful fields: (1) A meridian parallax Durchmusterung; while the individual results might not be very accurate, probably a good many stars would be found that would repay further research. (2) It is desirable to obtain accurate positions and proper motions of as many stars as possible of types M and N. Owing to their non-actinic colour, these stars are more suitable for visual than for photographic research.

HEREDITY AND EVOLUTION.

IN recent investigations on the subject of heredity much interest has centred around the question of the determination of sex. In this connection attention may be directed to a short but important paper by Prof. Jacques Loeb (Proc. Nat. Acad. Sci., Washington, vol. iv., 1918, pp. 60–2), in which he describes observations on the sex of frogs developed from parthenogenetic eggs incited to segmentation by the mechanical stimulus of puncture. Twenty of these creatures reached ages of from ten to eighteen months, several attaining the size of the full-grown, normal adult male, to which sex belonged seven of the nine the gonads of which were examined, the other two being females. Hence it appears that frogs of either sex may arise as the result of "artificial parthenogenesis." Cytological study demonstrated the presence of the full (diploid) number of chromosomes in these males, and Prof. Loeb infers that the female is probably heterozygous for the sex-character. But there seems to be good evidence for an "indifferent" condition as to sex in some immature frogs at least, as shown by the well-known researches of Prof. R. Hertwig and suggested by observations of Prof. Loeb in a former paper of his that the testes of a male just after transformation may contain a few eggs. It is doubtful, therefore, whether sex in frogs is absolutely determined by the nature of the germ-chromosomes.

Individual animals in which the secondary characters of the two sexes are combined afford a curious puzzle to students of this question. In the *Journal of Genetics* (vol. vii., No. 3) the Rev. J. E. Hull gives details of a few cases of such "gynandry" among spiders. In one case (*Œdothorax fuscus*) the specimen externally was "completely male on the left side and female on the right"; in another (*Maso sundevallii*) it was "male on the left side, but not quite female on the right," the apex of the right palp being somewhat swollen. A third spider (*Lophomma herbigradum*) was perfectly male on the right of the cephalothorax, with modified falx and palp, and female on the left, but the abdomen showed the characteristic female epigyne half-developed on the right, the left half of the abdomen being male. Such abnormalities, though highly interesting, are so rare that it will probably be long before they will yield much enlightenment on fundamental problems of sex. In the same issue of the *Journal of Genetics* Mr. D. W. Cutler describes the spermatogenesis of infertile hybrids between pheasant and Gold Campine fowl, and finds that the process is abnormal: "The failure of the synaptic threads to form bivalent chromosomes is evidently the cause of sterility in the hybrids." This result is compared with those derived from the study of the germ-cells of other sterile hybrids, in some of which the sex is apparently determined by the sex of one of the parent species.

A short but noteworthy contribution to this subject is Drs. L. J. Cole and W. A. Lippincott's paper on the relation of plumage to ovarian condition in a Barred Plymouth Rock pullet (*Biol. Bull.*, vol. xxxvi., No. 3). This bird assumed partially the male plumage, and the change was found to be due to a large ovarian tumour; though the abnormal feathers were like those of a male in shape and structure, they resembled hen feathers as regards "barring." This, the authors believe, differentiates "secondary sexual dimorphism from dimorphism caused through sex-linkage as illustrated by the barring." After an implantation of normal ovarian tissue, new feathers which were definitely female grew in a few weeks.

New subjects for hybridising experiments are afforded by the northern and southern forms of African ostrich, the results of crossing which are described by Prof. J. E. Duerden (*Journal of Genetics*, vol. viii., No. 3). These two species (or sub-species) interbreed freely, and the offspring are fertile among themselves and with the parent forms. "Everything points to the distinctive characteristics of the two species as having separate factorial representation in the germ plasm." The bald patch on the head of the northern race is dominant to the feathered condition of the southern, but in most features "blended" inheritance is apparent. None of the specific characters appear to have any adaptive value.

The application of Mendelian analysis to economic plant-breeding is well exemplified by A. St. Clair Caporn's studies (*Journal of Genetics*, vol. vii., No. 4) on early and late ripening in an oat-cross and on variation in glume-lengths of extracted parental types and the inheritance of purple colour in a wheat-cross (*Triticum polonicum × eloboni*). "Earliness" and "lateness" in oats are not sharply defined characters; they are spread over a period, though "the ripening times of the parents used did not overlap." The hybrids were more or less intermediate, while in the F_2 generation there was "evidence of early, late, and many intermediate forms." Some remarkable results were obtained from the wheat-crossing experiments. In the F_2 generation a marked change in the average length of the glumes in homozygous long-glumed plants "as compared with the average of the parent *T. polonicum*, under equal conditions, persists right through into the F_3 generation." The inheritance of purple pericarp colour "is distinguished by one cardinal and unaccounted for anomaly; segregations analogous to the F_2 segregation have not been found in the F_3 generation."

Most students of "Mendelism" would probably hold the opinion that little remains to be added to our knowledge of the classical case of the blue Andalusian fowl But Dr. W. A. Lippincott (*Amer. Nat.*, vol. lii., No. 614) gives reasons for believing that "the 1 : 2 : 1 ratio is in reality a combination of two 3 : 1 ratios," and that the condition in the blues is due to the combined action of two factors, one of which restricts the distribution of the black pigment within the feathers in such a way that it gives the characteristic blue-grey appearance, while the other extends the black pigment to every feather of the bird. Somewhat similar suggestions had previously been made by R. Goldschmidt and by A. L. and A. C. Hagedoorn. According to Dr. Lippincott, the birds usually defined as "white splashed with black" would be more correctly described as "blue-splashed." His theory seems largely dependent on the possibility of "crossing-over" of determinants in the chromosomes, for which no evidence is yet forthcoming, and he admits that "if these cross-overs should not be found, it might at first appear that the interpretation of the case of the blue Andalusian is in all probability exactly what has been suggested from the first, namely, that blue is a heterozygote intermediate between the parental types."

A noteworthy critical discussion on the factors of organic evolution has been contributed by Prof. L. B. Walton to the *American Naturalist* (vol. lii. Nos. 622–23). He believes that heritable characters in general arise from preformed unit factors that may have been in existence during long geological periods; the modern study of genetics gives no means of distinguishing a new factor from one long in existence. He suggests that the mutations studied by De Vries in plants, and the modifications obtained by Castle in mammals, are due to the combination of pre-existing factors, while the famous mutations in flies elucidated by Morgan "are in the nature of modal fluctuations having no definite cumulative value." Prof. Walton's own definite contribution in this paper is found in his summary of the direction of axial rotation in Euglena and other Protozoa which "is best explainable on the basis of the apparent east-west motion of the sun having influenced the movement of the organs of locomotion." This seems an insecure foundation for such a generalisation as the author's statement that "the primary factors in evolution are environmental, and thus dynamic."

G. H. CARPENTER.

CHEMISTRY OF "BURGUNDY MIXTURE."

THE chemistry of "Burgundy mixture" is practically important, because to give it the greatest efficiency it should possess a maximum fungicidal power and a minimum potentiality for injuring foliage. The reaction of sodium carbonate and copper sulphate solutions has been studied by Pickering and by Ravaz, but, according to a paper contributed to the August Journal of the Chemical Society by Messrs. Robert L. Mond and C. Heberlein, the problem is more complex than they considered. The latter authors have studied the reactions of copper sulphate with varying proportions of sodium carbonate and of sodium hydrogen carbonate; have determined the amount of absorbed sodium carbonate and the ratio of copper oxide to carbon dioxide in the various precipitates and the amount of basic copper sulphate in the mixtures; and have studied the solvent action of carbon dioxide and the change of the colloidal precipitate to a crystalline form. As a result of their experiments Messrs. Mond and Heberlein conclude that three distinct copper compounds are formed when sodium carbonate and copper sulphate solutions are mixed:—(1) Insoluble hydrated basic copper carbonate (the bulk of the precipitate); (2) insoluble hydrated basic copper sulphate; and (3) soluble basic copper sulphate in the form of a hydrosol; the proportions of which vary with the conditions of precipitation. One molecule of copper sulphate is completely transformed by 0·93 molecule of sodium carbonate instead of the one molecule theoretically necessary. In a 1 per cent. mixture of copper sulphate and sodium carbonate (in the proportion 1 : 0·93 mol.) made at 15°, 9·6 per cent. of the copper is present as soluble basic sulphate, the basic carbonate contains copper oxide and carbon dioxide in the ratio 2·2 : 1, the insoluble basic sulphate contains copper oxide and sulphur trioxide in the ratio 15 : 1, the precipitate contains absorbed sodium carbonate in the proportion of 1 part to 74 of copper oxide, and 52·4 per cent. of the carbon dioxide is evolved. At higher temperatures more carbon dioxide is evolved, all being expelled on boiling. The amount of basic sulphate formed decreases as the proportion of sodium carbonate increases, the proportion in solution (but not that of the basic carbonate) increasing with the amount of free carbon dioxide. At first the precipitate is wholly colloidal, but eventually it becomes crystalline, the colloidal condition apparently being conditional on the absorbed sodium carbonate. The transformation is accelerated by free copper sulphate, carbon dioxide, or sodium hydrogen carbonate, but retarded by sodium carbonate or 0·02 per cent. of glue.

ÆTHER AND MATTER: BEING REMARKS ON INERTIA, AND ON RADIATION, AND ON THE POSSIBLE STRUCTURE OF ATOMS.[1]

PART II.—THE POSSIBLE STRUCTURE OF ATOMS AND THEIR RADIATION.

HOW, then, are we to explain the different kinds of matter? Here we enter upon territory so recently annexed as to be still very debatable; but progress has been and is still being made, and it is only through the work of recent explorers that we can attempt to answer the question at all. It is invidious to select names, but I must mention Rutherford, Soddy, Barkla, Bragg, Moseley, Nicholson, and Bohr, among many others. Moseley—as brilliant as any of them, and patriotically self-sacrificing like all our splendid youth—was killed, alas! by a Turkish bullet at Gallipoli; though not before he had made an immortal discovery. How much more might he not have accomplished had it not seemed good to evil Powers to impose by force their dominance on the world!

To give a certain and definite answer to questions about the structure of the atom is premature. I can only state the answer which at present tentatively appeals to me and, I think, to others. Your professor of natural philosophy (Sir J. J. Thomson) is lecturing, I see, on Saturday afternoons concerning spectroscopic evidence on this great subject, and he will, no doubt, carry the matter further.

Meanwhile, and very briefly, the idea about the atom which at present seems most likely to be on the path towards truth is a central positive nucleus surrounded by a system of negative electrons—so much is pretty certain—while according to one theory the system is composed of revolving electrons moving under an inverse-square law in regular orbits, very like the sun and planets. The orbital movement is governed by electric force instead of by gravitation, but the laws of motion, and the perturbations which may be caused by outside forces, are very like those familiar to astronomers.

According to Moseley's experimental counting and Bohr's theory, hydrogen seems to be like a sun with one planet, just a positive and a negative electron, the two being equal electrically, but differing in inertia, the positive being the more massive, though probably for that reason the smaller or more concentrated of the two. Helium seems to have two central unbalanced positive charges and two revolving negative; lithium, three of each; beryllium, four; boron, five; carbon, six; nitrogen, seven; oxygen, eight, and so on, according to the number of the element in Mendeléeff's series—a number something like half the number expressing its atomic weight.

The number of positive atoms in the nucleus was counted for several elements by Rutherford, and the number of negative corpuscles in the orbit was counted by Moseley; the two numbers agree. Normal atoms are therefore electrically neutral, so that their external electric attraction at any reasonable distance is nil; but it is supposed that at atomic or molecular distances the outer or orbital electrons which can interlock with those of others determine the atom's chemical affinity and all the chemical behaviour of the substance. An atom with one or two outlying planets—let us surmise—would be an active chemical element, a monad or dyad perhaps. An atom with a close-grouped, self-contained system would be an inert element of the argon-neon-helium series. These

[1] Amplified from a discourse delivered at the Royal Institution on Friday, February 28, 1919, by Sir Oliver J. Lodge, F.R.S. Continued from p. 19 (September 4).

might exhibit chemical properties, perhaps, under enormous pressure. The heavier atoms contain the most particles, and must have the most complicated structure. There is every grade, from the simplest, hydrogen, with one electron, to the most complex, uranium, with ninety-two. There is room for ninety-two elements in the series, and no more. All these are actually known except five or six. There are only these few unfilled gaps in the chemical series of elements as thus planned.

Radio-activity.

A complicated atom has a certain amount of instability, and may fall down occasionally into the next simple grouping, flinging away one or more of its units. When this happens there is a sort of atomic cataclysm or explosion; a projectile and some quanta of energy are emitted. This is the phenomenon of radio-activity. Uranium after three (or possibly four) such eruptions becomes the element three (or four) steps down the series, viz. radium. Radium after five more explosions becomes apparently the well-known and stable element lead, or at least something chemically indistinguishable from it, though perhaps of slightly different atomic weight,—what has recently been called an "isotope" of lead. That is the kind of statement that without too much rashness can be cautiously and tentatively made.

At every serious cataclysm an α-particle or atom of helium is emitted from the nucleus, accompanied by a β-particle or negative corpuscle from somewhere, usually from the planetary system. A sympathetic æthereal gush of γ-rays accompanies the eruption. A definite unit of energy—a quantum or a simple multiple of it—is emitted at each explosion; and the remaining electrons then settle down into their new orbits, the element changing in character and chemical properties accordingly.

A catastrophe of this kind can be produced by a sufficiently rapid projectile, an α- or β-particle shot off, say, by radium; and a minor catastrophe or emission of a β-particle can also be produced by the accumulated energy of properly attuned X-rays. When an X-ray or ray of ultra-violet light agrees in frequency with the orbital frequency of an electron, we can suppose (not without a little difficulty) that its energy is absorbed until a quantum has been accumulated, and then a β-ray or excessively rapid electron is emitted.

Remarks on the Quantum.

In my view, it should not be thought that energy exists in numerical bundles or quanta; the discontinuity is not really in energy, but in the atom. Atomic properties are essentially numerical and discontinuous, and we ought not to be surprised at an equilibrium which needs a specific amount of energy to upset it. The energy must be supplied by the disturbing impulse; but in the case of ultra-violet or X-ray radiation the energy can only be attributed to the disturbing impulse on the principle of resonant or syntonic accumulation; for its intensity does not matter. Nor ought it to matter so long as the tuned impulse is repeated often enough—a repetition for which an extremely minute fraction of a second is ample. What matters is not the brightness or energy of the incident radiation therefore, but its frequency. On the other hand, a β-projectile cannot effect a real disturbance unless it possesses a minimum quantum of energy; for in that case there is no accumulation.

The quantum, considered merely as a finite store of energy, is susceptible of exceedingly elementary illustration. Here is a case of stable equilibrium (a simple pendulum or a round-bottomed flask loaded so as to oscillate stably) which responds to the slightest touch and returns to equilibrium. There is no quantum about that. But here is another case of stable equilibrium (a brick or block or pillar standing on end) which takes no notice of any but a finite force, and requires a finite amount of energy to upset it, viz. its weight multiplied by the elevation of its centre of gravity as it revolves round its lower edge; this being also the amount of energy emitted when it falls. Or there may be a union of the two kinds of equilibrium. This rounded rocking flask, for instance, or a rocking-horse, may accumulate oscillations until the energy reaches a sort of quantum, when it upsets and breaks or causes an accident. This last is the kind of stable equilibrium which we meet with in an atom.

A flying particle below a certain limit of energy can alter the eccentricity of an orbit, and may thus excite some simple radiations which continue until the orbit becomes circular again; but a synchronous X-ray disturbance, however intrinsically feeble, may precipitate a catastrophe; and simple facts of this kind seem to be, in the main, responsible for the general notion of quanta of energy. The really remarkable thing about a quantum, the thing which makes it so essentially worthy of attention, is the fact that it is a universal constant; the same amount of energy is found associated with every kind of matter—the same, or differing only by simple multiplication. Hence the notion at one time put forward that energy itself might be atomic and exist in indivisible packets, like cartridges.

Hypothetical Structure of Atoms.

The real facts concerning the quantum, which are the result of observation, suggest, when interpreted properly, that there are stable electronic orbits in an atom, and that these follow a regular law of succession, analogous perhaps to Bode's law of planetary distances in the solar system. Spectroscopic evidence —the so-called Balmer's series of lines—strongly bears out this idea. For there is what is called K radiation, of highest frequency, apparently due to perturbations of the innermost, the most rapid, ring; L radiation of lower frequency from the next outer ring; M radiation from a ring outside this; and recently there is talk of a J radiation of extra high frequency from a ring still closer to the nucleus—perhaps quite close to it, part of it perhaps—and, anyway, well within the K ring.

The frequencies adapted to bring about an atomic catastrophe, or which are emitted during perturbations, are usually high up in the series of X-ray series of vibrations, far above visible light. I assume that these frequencies correspond with the frequency of orbital revolution, and that the inverse-square law holds good. The more massive the nucleus, the greater must be the frequency of orbital revolution at a given distance, in accordance with Kepler's third law. The square of the frequency multiplied by the cube of the radius of the orbit will be constant for all the orbits of all the atoms of any given substance, and will give the attracting force of the nuclear centre for that substance.

In other words, this product (or, what comes to the same thing, the radius multiplied by the square of the speed) will correspond with the number of unneutralised positive charges which go to make up the nucleus. It will give, in fact, the number of the element in the Mendeléeff series. The K radiation frequency from uranium, therefore, must be exceptionally rapid, because the nucleus is so strong. For hydrogen, the nucleus of which is only 1/92nd of that of uranium, the orbital frequency might be comparatively slow, not higher than the ultra-violet; while the L radiation from hydrogen, it is now thought, may be within the limits of the visible spectrum, an M series being, perhaps, in the infra-red.

But how comes it that hydrogen, with only one electron, can have a K series and an L series and an M series at all? Bohr's theory suggests that even a single electron may have alternative orbits—not necessarily occupied; and the spectroscope strongly suggests that the radii of these alternative orbits run as the squares of the natural numbers

$$1 \quad 4 \quad 9 \quad 16 \quad 25, \text{ etc.}$$

The frequencies, or reciprocals of periodic times, would then be as the inverse cube of the natural numbers

$$1 \quad \tfrac{1}{8} \quad \tfrac{1}{27} \quad \tfrac{1}{64}, \text{ etc.}$$

and this is, approximately and roughly, what the K, L, M series of spectrum lines correspond with—with some exceptions.

When a cataclysm occurs and an electron is expelled, it is expelled, as I think, with the velocity which it possessed in the atom just before it burst its bonds and flew off. For the energy required to fling a planet to infinity, under an inverse-square law, is just double the energy with which it was already moving in its circular orbit. Its own orbital energy is, therefore, the quantum of energy that has to be supplied in order to get a satisfactory ejection. Some of it might be supplied by the falling in of other particles from their original orbits; for their kinetic energy therein would be inversely as the distance from the nucleus. Hence if K, L, M orbits have the radii 1, 4, 9, three units of L energy would represent the fall from L to K, and this added to the original L energy would give the quadruple L energy which is equal to the K energy, and able to eject a K particle. Similarly, a ninefold multiple of the M energy, eight units of which would be acquired by falling to K, would supply that particle with the ejection energy equally well.

Would an M particle falling to L be able to eject an L particle? $\frac{1}{4}-\frac{1}{9}=\frac{5}{36}$ of a K unit of energy would be acquired in the fall from M to L—that is, $\frac{5}{4}$ M units,—so altogether $\frac{9}{4}$ of M energy would be transmitted, and that, being equal to a unit of L energy, ought to be sufficient.

Hence, in general, particles may be ejected from any ring, either by direct impact from outside, or by accumulated disturbance of X-rays, or by a collapse of particles from one orbit to the next; and from an immense group of atoms, as in a visible speck of substance, all kinds of radiation can be emitted simultaneously.

Are we to suppose that there is only one electron in each orbit, or may several of them distribute themselves over a ring in accordance with some law of stability? Both alternatives are possible, and both are likely to be found in Nature. It seems scarcely likely that a uranium atom should possess ninety-two different orbits, although it does contain ninety-two electrons. Yet even this number of orbits is possible within the dimensions of an atom. We need not exclude the possibility as taking up too much room. For, given the size of the ultra-innermost or J orbit as 1, the outer orbit would, on Bohr's law pressed to extremes, be $(92)^2$ times that radius—say, 8464 times the size of the innermost orbit; but if this innermost orbit is near the uranium nucleus, which may be $\sqrt[3]{92}$, or, say, 5 times the radius of the hydrogen nucleus, the boundary or confine of the atom is some 10,000 times as far away; leaving, therefore, just room enough for the ninety-two Bohr orbits, though not much more than is required.

Hence, if there were any reason to desire them separate, they could be made room for, without endowing the atom with outlying or ever-ready electrons likely to confer upon it very active chemical properties. But, so far as I see, so many separate orbits are not likely; for there is every probability that periodically, as you ascend the series, the outer ring is not occupied by a single electron, but by a closed, compact sort of structure of many electrons, with very little outside affinity; so that we reach periodically an atom which is chemically inactive—helium, neon, argon, krypton, etc.—up to emanation, or what Ramsay called niton. So little cohesion holds between such atoms that they are able to exist as permanent gases, in spite of the high density of some of them. This, at least, appears to be the view of Rutherford and Soddy. Helium only condenses to a liquid when cooled down to near the absolute zero of temperature. Its cohesion or intermolecular attraction is nearly nil.

A Fanciful Analogy.

If I attempt to compare the supposed alternative orbits in an atom with the known orbits of the solar system, it is mainly to emphasise, provisionally and tentatively, and perhaps semi-humorously, the astronomical view of the atom, and to bring out still more strongly the resemblances whatever thorough differences there may be as well.

I write down the squares of the natural numbers, therefore, and underneath put the initial letters of the names of planets, with its real distance written under each in the same units.

Radii of Bohr's atomic orbits	1	4		9	16	25	36	49	64	81	100	121	144	169	196
		m	V	E	M	Asteroids		J			S				U
Planetary distances		3·9	7·2	10	15·2	20–35		52			95·4				192

The obvious suggestion is that asteroids should be looked for between Jupiter and Saturn, and between Saturn and Uranus; but I would not venture to predict the existence of any such bodies on the strength of this analogy, because you will doubtless have noticed that no analogue of the planet Venus appears in the list of atomic orbits; the scheme provides no place for her—a lamentable omission which must discredit and, I expect, condemn even the analogy. Nevertheless, I make no apology for introducing it in order to emphasise astronomical similarities in the possible structure of an atom.

QUANTITATIVE INTERPOLATION.

On Atomic Radiation.

Permitting ourselves this view of the atom as a working hypothesis, we have to picture each atom as an attracting centre or nucleus, with a number of alternative orbits in regular succession round it, but not all necessarily occupied by revolving electrons. The atoms of different elements differ in the number of positive units in the nucleus, and in the corresponding number of revolving negative units; in fact, the diverse chemical elements in their atomic constitution form a definite arithmetical series with common difference 1. There is a discontinuity or finite step in passing from one element to the next in the series; there is no continuous passage from one to another; hence if the physical transition or mutation ever occurs, it must be by some sort of sudden convulsion.

To extract laws for this hypothetical structure, suggested by the labours of many workers, we may attend to the different rings of one kind of atom, or we may attend to the corresponding rings in different kinds of atom. Each, for instance, has an innermost ring, which it is convenient at present to call the K ring because of the shortest wave-lengths, or so-called K spectrum, which its perturbations emit. And in ascending the series of elements, as the nucleus gets stronger by addition of units, the electron in this innermost or K ring must revolve faster and faster to counterbalance the greater attracting force. Its orbit will accordingly get smaller and smaller, in the proportion proper to the law of inverse square. And the frequency will increase for both reasons, *i.e.* for both the greater speed and the shorter journey. The spectrum accordingly, while preserving the same type, ascends the ladder of frequency.

Suppose the atomic number, or strength of the nucleus in atoms of successive elements, increases in arithmetical progression $N-1$, N, $N+1$, etc., then the radius of the given type of orbit may shrink in the same proportion, so that rN is constant; and the velocity v may increase in the same proportion, so that rv is constant; or, in other words, so that the moment of momentum in corresponding rings of different atoms is the same. There is good evidence that such is the case. The law, so far as it is a law, is styled by Prof. Millikan the atomicity of angular momentum. If the value of mvr or $mr^2\omega$ differs in different rings, it differs by finite steps.

The frequency of orbital revolution will depend on v directly and on r inversely, so the frequency $(v/2\pi r)$ will increase in the proportion of N^2; and this, in some form of other, is known as Moseley's law.

The energy, $\frac{1}{2}mv^2$ in a given type of ring, will also depend upon N^2 in different atoms, and is therefore simply proportional to the frequency. The orbital energy is half the energy with which a particle breaks loose (or is driven to infinity) whenever a convulsion occurs. The convulsion can be stimulated by X-rays or ultra-violet light of the right frequency; their energy appears to be stored by resonance until the critical breaking-up point is reached. The ratio of emission energy to frequency is a remarkable universal constant, and is called h, the quantum. It is not energy, but the accumulation or integral of energy for a certain time; and it is permissible to write $mv^2=2mu^2=hn$; because the emission velocity u (the velocity from infinity) is $\sqrt{2}$ times the orbital velocity v. But h, or rather $h/2\pi$, may also be taken as representing the orbital angular momentum mvr (more strictly, if the orbit is at all elliptical, mvp) for the ring whence the particle came. It would be rather convenient if the designation h were transferred to $h/2\pi$ before it is too late; but I must leave this minor change to the approval of leaders in this subject.

I may point out that this constancy of angular momentum in different orbits bears a curious analogy to Kepler's second law about rate of description of areas in the same orbit. And, if a coincidence, it is odd that the symbol h should have been used both for Kepler's $r^2d\theta/dt$ and for an atomic quantity which is also $r^2d\theta/dt$ multiplied by $2\pi m$.

Within each atom Kepler's laws must presumably hold; so r^3/t^2, or rv^2, is constant for the different circular orbits in each atom; whence the energy in successive rings of one atom is inversely as their radii; hence the ring most likely to eject a particle is the innermost or K ring.

This characteristic constant rv^2 of an element is proportional to the central attracting force, and therefore proportional to N. Hence it goes up step by step in the series of atoms, as N does.

Summary.

N is Moseley's atomic number, and equals the number of orbital electrons, or the number of unbalanced positive charges in the nucleus. The constant rv^2 is characteristic of all the rings in one atom (N being constant). The product rv is a constant characteristic of a given type of ring in the whole series of atoms (N going up step by step); but in any one atom this product rv ascends from ring to ring in regular arithmetical stages, the same stages as $\sqrt{r}$.

The product rv^2 is constant inside each atom, and proceeds by steps from atom to atom; while the product rv is the same for different atoms, but changes inside each atom and proceeds by steps from ring to ring. In fact, we may write:—

For all the Rings in One Atom.

Central force	rv^2 is constant.
Angular momentum for the rings in one atom ...	$rv \propto \sqrt{r}$
Energy for the same ...	$v^2 \propto 1/r$

For any Ring in any Atom.

Central force for any ring in any atom	$rv^2 \propto N$

For the same Type of Ring in Different Atoms.

Radius of given type of ring in any atom ...	$r \propto 1/N$
Orbital velocity in ring of that type	$v \propto N$
Moment of momentum in given type of ring ...	rv is const. as regards N.
Frequency in that type of ring	$v/r \propto N^2$
Energy in same	$v^2 \propto N^2$

So for a given type of ring in different atoms the orbital energy is proportional to the frequency; which is a curious result thoroughly consistent with Moseley's law, ascertained by experiments on emission, and true, at any rate, for emission energy. The ratio

$$\frac{\text{emission energy}}{\text{frequency}}=\frac{mv^2}{v/2\pi r}=2\pi mvr=2\pi.mr^2.2\pi r=2\pi I\omega$$

So if we call this h, or a multiple of h, then on our hypothesis $h/2\pi$ is the indivisible unit of angular momentum for an orbital electron.

The speed with which an electron is ejected is very high, something like 0·9 of light, so the increase of mass at high speeds must be taken into account in propounding a reason for the emission of corpuscles.

Radiation Heterodoxy.

In considering the radiation from an atom, I have virtually made the hypothesis that so long as orbits are circular they do not radiate, but that if perturbed into ellipses, with corresponding fluctuation of speed —as they would be by the influence of a flying charge passing through or near them—then they would radiate, with the proper orbital frequency, until the eccentricity disappears again and they resume their stable circular orbit once more, though, of course, they might be so much perturbed as to eject a particle. Any one of the rings, if perturbed at all, may radiate and give appropriate spectral lines. An external synchronous alternating field will also cause them to absorb energy, even though they were not radiating any until the extra energy arrived.

This hypothesis, if at all regarded, is equivalent to a request to mathematicians to reconsider their theory of electronic radiation. Radiation intensity is known to be proportional to the square of acceleration (Sir Joseph Larmor, and to some extent FitzGerald and Hertz, established this), and I must admit that the reasoning seems to make this law applicable to every kind of acceleration; but my rash suggestion is that it may be only speed-acceleration that is really effective, and not transverse or curvature-acceleration at constant speed. For this will not perturb the lines of force holding the electron to the nucleus, but will leave them in a constant condition so long as the orbit is circular and the speed therefore constant. There is a recognised difference of the same sort in connection with varying inertia; its value is not affected by transverse acceleration, with the speed left constant, but it is affected by longitudinal acceleration, which alters the speed.

So I am in hopes that it may be found that this latter or speed-acceleration is what is responsible for radiation, and that mere curvature at constant speed in a circular orbit need not radiate at all, provided always that the superposition of an external alternating field of the right frequency may cause absorption. Many of the difficulties connected with the stability of the astronomical atom would be evaded if the theory of radiation could be modified in this way, and the excitation of characteristic radiation by almost any kind of perturbation of the orbit would be intelligible.

Speculations on Radiation and Atomic Structure.

Bohr's remarkable theory of atomic structure does not pretend to be strictly dynamical; it is partly empirical, being based on the discontinuity signalised by Planck's constant, but it is very brilliant, and extensively justifies itself by agreement with facts.

His expression for the frequency of radiation emitted by any element is virtually, to a fair approximation,

$$n=\frac{2\pi^2 me^4}{K^2h^3}\cdot\left(\frac{E}{e}\right)^2\left(\frac{1}{p^2}-\frac{1}{q^2}\right)$$

where $\frac{E}{e}$ is Moseley's atomic number N, the number of unbalanced charges in the nucleus or the number of electrons in the atom, and where p and q are integers, of which p changes from series to series, while the lines in each series are given by the mutations of q. For heavy atoms the E in the above formula should be E *minus* a geometrical function of all the other electrons inside the radiating orbit, because they will affect the central attracting force. In this way outstanding discrepancies may plausibly be explained. But the remarkable thing is that the formula gives the frequencies, not merely relatively, but absolutely. For if the experimental values otherwise obtained for e, m, and h are inserted, the constant outside the brackets, called Rydberg's constant, which is spectroscopically determined and known to be the same for all elements, comes out right. A very notable fact!

The above expression for spectral lines not only agrees with the Rydberg-Balmer known spectroscopic series, and with the kind of formula given by many pioneer workers, but has been able to predict other series which have been afterwards observed. It also accounts for many extra-low-frequency lines which, though not obtainable in the laboratory, are observable astronomically by suggesting that they come from very large masses of highly rarefied gas. For under such conditions the atoms would have more room and could possess far outlying or ultra-Neptunian electrons, and yet have total substance enough to display their spectra.

To contemplate the emission of radiation, both waves and particles, we may picture one of the satellite electrons in a many-orbited atom struck or so thoroughly perturbed by the sudden arrival of a foreign charge as to precipitate it into the next inner ring, ejecting the constituent of that ring into the one below, and so on, after the manner of the "jack for mustard" game with a series of wooden bricks set up on end.

Wave-emission should accompany each transition. The effect of precipitating the innermost electron on the body of the nucleus is not clear; but a compound nucleus must be a strangely interlocked conglomerate, and an explosion seems not unlikely, especially if one of the supposed binding negative electrons were ejected. The potential gradient close to a nucleus is prodigious.

The effect of the arrival or departure of a charged particle at the nucleus would be suddenly to change its intrinsic attracting force; and this of itself would render all the orbits elliptical for a time, with eccentricity $\frac{1}{N\pm1}$,[2] thus exciting radiation of several frequencies. If the radiation ceased when the eccentricity was got rid of, a new circular orbit would be taken up; and thus perhaps discontinuities might be accounted for in a dynamical manner.

The effect of properly attuned X-rays or ultra-violet light, if it is to be accomplished through resonance—and it is difficult to account for its independence of intensity otherwise—seems to require a fair range of frequency in those rays; for their effect on a revolving electron would naturally be to increase its angular speed and so throw it out of tune with the particular disturbance to which it initially responded. The sectorial area swept out would increase, the radius vector would increase, the linear speed would therefore diminish in spite of the resonant effort to increase it—unless, indeed, under the peculiar conditions in an atom, there may be some compromise. The alternative would be for the electron to be constrained, under conditions of stability, to maintain its frequency unaltered, either proceeding in an outward spiral towards a position of Planckian instability, or trying still to obey the law of inverse squares by increasing the eccentricity of its orbit with given axis major until it becomes practically parabolic.

This could represent an inversion of the process by which the electron may have been originally bound, according to Bohr's theory of what happened before the atom became neutral. For it is to be presumed that a positively charged α-particle, after ejectment, neutralises itself by accretion and settles down.

CONCLUSION.

I have led you over a great deal of territory in a hurried manner, and occasionally have entered on regions where the ground is not yet solid and secure. Let it be granted that the chemist may naturally object to an astronomical atom and may prefer a more static or geometrical structure, although such a structure would have less clear and explicable properties. The static or Boscovich atom, with purely hypothetical interior fluctuations of force, leaves every-

2 This can be proved as follows:—

For a circular orbit

$$rv^2=\mu$$

and

$$r^2v^2=h^2=\mu r.$$

When μ suddenly changes to $k\mu$ (where k may be $\frac{N\pm1}{N}$) the velocity does not instantly change, but the orbit acquires an a and an e, such that

$$a(1-e^2)=\frac{h^2}{k\mu} \text{ or } e^2=1-\frac{r}{ka};$$

also

$$\frac{\mu}{r}=v^2=k\mu\left(\frac{2}{r}-\frac{1}{a}\right).$$

This last gives

$$\frac{r}{a}=2-\frac{1}{k},$$

so

$$e^2=1-\frac{1}{k}\left(2-\frac{1}{k}\right)$$
$$=\left(1-\frac{1}{k}\right)^2.$$

And the place where the sudden impulse occurred, becomes an apse of the new orbit, because $r=a(1\pm e)$. (See also Appendix I. in *Proc. R.I.*)

thing in the dark, and is therefore less tempting to a physicist, until some physical explanation of those fluctuations can be given. At present they seem to be postulated merely in order to secure positions of equilibrium in which an electron can settle down. Orbital revolution achieves the same end, in apparently a more complicated but really a more tractable manner. Moreover, it confers upon an atom the sort of energy and structural velocities which are conspicuous in the various types of radio-activity. True, it is a working hypothesis at present, and nothing more, but it seems likely to be a fruitful one; and that is its present justification.

The subject is in the nascent or rapidly growing stage; and, provided we refrain from dogmatism, it is legitimate thus tentatively to survey and explore the boundary between knowledge and ignorance, and to speculate as to what may be the next stages in the exhilarating pursuit.

The apparent resemblance between an atom and the solar system opens up extraordinary vistas for further inquiry. Optics and gravitation still have many secrets. The interactions between æther and matter are as yet barely understood. We know that the energy of an electric current is really in the æther, *i.e.* in the magnetic field surrounding the current; but we must admit that the electromagnetic explanation of inertia is no ultimate explanation; it is but relegating the property to some fundamental property of the æther, of which substance presumably matter itself may in some way be composed.

Evidence suggests that the æther is an excessively dense substance, and that it circulates slowly along lines of magnetic force.[3] But though so dense we have no means of apprehending it directly. Matter, though so comparatively filmy and fragmentary, yet looms large in our estimation because of our material sense-organs; its properties force themselves on our attention, because, in fact, our bodies are composed of matter. But underneath and behind all the known properties of matter lie the unknown properties of the æther of space; and if we are to create a true philosophy we must attend continually to æther as well as to matter in the physical universe. The æther makes no appeal to our senses, but it is none the less real for that. Sensation is no test of reality—many of the most important things are in the insensible universe; and he is the wisest man who shuts the door on no opportunity for investigation, but keeps his mind open and is ready to explore every avenue towards truth.

[3] This view of the energy of a magnetic field, that it is direct kinetic energy of the æther moving longitudinally, suggests a possible (or nearly impossible) experimental means of determining the real density of the æther of space—a subject on which I have much more to say. See *Phil. Mag.* for May, 1919.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

EDINBURGH.—Considerable developments have recently taken place in the departments of pure and applied mathematics of the University. Since 1914, the department of pure mathematics has occupied a separate building, the Mathematical Institute, in ground adjacent to the Arts Quadrangle. This building contains lecture-rooms large and small, mathematical laboratory, reading-room with students' library, research-room with a library of mathematical periodicals and advanced works, and rooms for the staff. The laboratory course comprises interpolation, construction of mathematical tables, numerical solution of algebraic and transcendental equations, numerical integration, least squares, graduation or adjustment, fitting of normal and skew frequency curves, correlation, practical Fourier analysis, spherical harmonic analysis, periodogram analysis, with drawing-board work in nomography, descriptive geometry, and cartography.

The most recent development is the institution of a diploma in actuarial mathematics. This is intended for students who are employed in the numerous life insurance offices in the city of Edinburgh, and are, therefore, only part-time students of the University, attending, however, day, not night, classes. The course, which covers two years, is conducted on the mathematical side by Prof. E. T. Whittaker, F.R.S., and on the actuarial side by Dr. A. E. Sprague, president of the faculty of actuaries. Students who obtain the diploma will be exempted from Part I. and Part II. of the faculty's examinations for fellowship.

The Mathematical Institute is the meeting-place of the Edinburgh Mathematical Society, and houses the library of the society.

In the department of applied mathematics, which is under the charge of Dr. C. G. Knott, arrangements have been made for the inclusion of special honours courses on wave-motion in matter and æther, kinetic theory of gases, and radiation. The former courses on dynamics, hydrodynamics, and elasticity have also been extended, one of the full-year courses being specially adapted to the needs of the student of engineering. There is also a post-graduate course on quaternion vector analysis.

MR. J. S. W. BOYLE has been appointed lecturer and assistant in chemistry in University College, Dundee, in succession to Dr. J. K. Wood.

THE Right. Hon. Christopher Addison, Minister of Health, will deliver the introductory address at the opening of the winter session of the London (Royal Free Hospital) School of Medicine for Women, University of London, on Wednesday, October 1, at 3 p.m.

THE ninety-seventh session at Birkbeck College, Breams Buildings, London, E.C.4, will commence on Monday next, September 29. Courses, day and evening, in the faculties of arts, science, laws, and economics for the examinations of the University of London begin on the following Tuesday. Full details of the courses are given in the syllabus of the college, which can be obtained on application to the secretary.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 8.—M. Léon Guignard in the chair.—L. **Mangin**: Notice on the work of the late William Gilson Farlow.—G. **Humbert**: The measurement of the classes of Hermite of given discriminant in an imaginary quadratic body, and on certain non-Euclidean volumes.—G. **Bigourdan**: The work of La Caille (conclusion) and his successors at the Mazarin College.—M. **Stuyvaert**: The elimination of one unknown between three algebraic equations.—N. E. **Nörlund**: The principal solution of a certain equation of finite differences.—G. **Guillaumin**: The transversal effects of contraction in reinforced concrete structures.—P. **Chofardet**: Observations of Borrelly's comet (1919*c*) made with the *coudé* equatorial at the Observatory of Besançon. Observations, with positions of comparison stars, are given for August 25, 27, and 28. The comet is of the 10th magnitude, is round, about 2′ diameter, with a central condensation. There is no tail.—J. **Guillaume**: Observations of Borrelly's, Kopff's, and

Metcalf's comets made with the *coudé* equatorial at the Observatory of Lyons. Observations of each comet were made on August 28.—G. **Sagnac**: The æther and the absolute mechanics of waves.—J. **Rey**: A lighthouse of great power, arranged with metallic mirrors. A description of the optical arrangements adopted at a lighthouse erected off the coast of Tunis. Metal reflectors only were used, without glass. Details of the photometric measurements and range are given.—Ch. **Mauguin** and L. J. **Simon**: Cyanogen chloride. A review of the methods suggested for the preparation of cyanogen chloride, including three new electrolytic methods, based on the electrolysis of a mixture of hydrochloric and hydrocyanic acids. The pure liquid chloride solidified at −6·5° C., and boiled at 12·5° C. The only other cyanogen chloride is the solid polymer melting at 145° C.—Ch. **Pussenot**: New observations concerning a recent submersion of the coasts of Morbihan.—M. **Leriche**: The fossil fishes of the coast region of the Congo, and on the presence of the Eocene in this region.—L. **Blaringhem**: Vigour of growth, compensating sterility, in the hybrids of species of Digitalis (*Digitalis purpurea*: *D. lutea*). The hybrids between species of Digitalis are absolutely sterile, but there is an excessive development of the plant-tissues with all the characters of young, super-nourished organs.—E. **Roubaud**: The antagonism of cattle and man in the blood nutrition of *Anopheles maculipennis*. The anti-paludic *rôle* of domestic cattle. When the mosquito has choice of man or domestic animals, it attacks the latter for preference. In order of preference, mosquitoes go first to pigs, then cattle and horses, then sheep, rabbits, and dogs. Fowls are not touched. When there are plenty of cattle adjacent to a house, the mosquito is not found in the house.—G. **Bertrand** and M. **Dassonville**: The treatment of scab in horses by the vapours of chloropicrin. Chloropicrin has been successfully applied to the cure of scab in horses; it possesses advantages over the sulphur dioxide treatment.

THE WASTE OF YOUTH.

Problems of National Education. By Twelve Scottish Educationists. With Prefatory Note by the Right Hon. Robert Munro. Edited by John Clarke. Pp. xxvi+368. (London: Macmillan and Co., Ltd., 1919.) Price 12*s*. net.

THE extension of the school age from fourteen to fifteen, with compulsory education in continuation classes to eighteen years of age, which is the main provision of recent educational legislation, adds four additional years of schooling at the most critical and formative period of life. It is to be hoped rather than expected that better use may be made in the future than has been made in this country of the school period in the past. One opens this book on "Problems of National Education," a collection of twelve essays by Scottish educationists, expecting some assurance at least that the stale old stock-in-trade of the schoolmaster derived from the Middle Ages had, in public education at least, been finally discredited. Then Latin was the universal written language, and it has been handed on as a ready-made means of disciplining youth to distasteful tasks, after all intelligible reason has ceased and the manifold activities of a rapidly expanding and luxuriant scientific civilisation have made it unsuitable. But, alas! in education the vicious circle besets one at every turn. It is idle to expect the child to be put *au fait* with the modern world, of which already he probably knows far more in certain ways than his teachers, until the latter have caught up with it and the subjects of their training in the ancient universities and the training institutions been fundamentally recast. But in this book every and any aspect of education is discussed exhaustively rather than this central problem.

The work of building up more and more elaborate superstructures on such false foundations meanwhile goes merrily on. Physical training, ethical, moral, religious, æsthetic, and civic education, anything rather than the intellectual foundations, are all explored in these centrifugal essays by experts in the vain hope of disguising the rottenness of the core. For, excellent and informative as are many of these discussions on the outriders and secondary consequences of national education, on the main theme, which is engaging the attention of the taught, if not the teachers, this volume is singularly vacuous.

Thus we read: "The new movement regards the purpose of education as primarily social efficiency and social progress rather than individual development and personal success," followed by the inevitable reference to Plato and Aristotle, which with unconscious and monotonous irony reiterates the fatal retrospective habit of mind. The future, if it learns from the past, will see to it that this type is put in charge of museums and cemeteries rather than of the growing child.

The main primary, as it was the original, purpose of the school is still to provide the child with a suitable intellectual equipment with which to face the world of the twentieth century. That is the weak spot, and it does not solve the problem to pretend that intellectual efficiency is Prussian and therefore to be shunned, or that preparation for the world of to-day is vocational and therefore no proper part of school work.

Principal Laurie contributes the most valuable and satisfying exposition of the position in his essay on "Technical Education." His statement—"To deal with the promotion of scientific research, I draw no distinction between pure and applied science, as no distinction can be drawn in practice. The first essential is the pursuit of science for its own sake as a pure branch of knowledge" (p. 249)—may be generalised. With regard to intellectual training, no distinction can be drawn between cultural and vocational training. The first essential is that the intellect must be trained for its own sake. The culture of a workman is the vocation of a scholar, and *vice versa*, though the scholar might not be sufficiently cultured to admit it. The educationist surely should use every means most calculated to develop the growing intelligence of a child and not scorn the new because they are, or may be, vocational.

Another remark from this essayist needs no comment:—"The love of knowledge for the sake of knowledge, which inspired the Greek civilisation, is not understood by the very men who have received a classical education. They do not see that the man of science is carrying on the tradition of Greek culture to-day."

As an example of how completely cut of touch a teacher may be with the psychology of modern youth, a passage from the essay on "Moral and Religious Elements in the School" may be quoted (p. 148):—"There seems to be no good reason why the narratives of the miracles in the Old Testament should be excluded. The wonderful and the miraculous are a source of great delight to young children and may be turned to good moral purpose. Provided that at some stage in the pupils' school career they are exhibited in their proper light, there is no reason to debar children from reading and enjoying these narratives." Possibly this may throw some light on the complaint (p. 110): "Little or no respect or consideration for older people is exacted from the young. It is not easy to detect in them the spirit of reverence either for institutions or individuals."

Classical education, according to Prof. Burnet, is about to achieve fresh laurels in the new era. "Humanity" its exponents call it—"that is to say, the literature, institutions, and thought of antiquity," thereby subtly suggesting that modern man is not humane, or humane by descent rather than by ascent, in conformity with the ancient, exploded Biblical myth, so harking ever backwards to the past rather than reaching out towards and apprehending the more glorious future.

"Now the first thing," he says (pp. 183–85), "we have to realise is that we are witnessing the dawn of a renaissance of humanism in Europe comparable only to that of the fifteenth century or to the magnificent expansion of science in the nineteenth. . . . Excavation, especially in Crete, and the recovery of papyri from the sands of Egypt have not only transformed our outlook upon the Mediterranean civilisation, of which our own is the lineal descendant, but has given us the inspiring feeling that some new truth of first-rate importance may come to light any day. . . . It is becoming plain that what we call science may be best described as *thinking about the world in the Greek way*." (Dr. Laurie's way of putting this has already been quoted.) "But there is another, and perhaps a deeper, reason for believing that a humanist renaissance is at hand . . . In the hard times ahead of us the greater number will turn rather to the poets, historians, and philosophers for solace and edification than to the austerer discipline of the exact sciences. That is for the few; the mass of men can hardly penetrate beyond its outer courts."

So, the classics are still for the many and science for the few! Nothing is incredible, not even that this and much more like it should actually be written as a contribution to "Problems of National Education" at the close of the great war. If these are the people to whom their children's educational destinies are to be committed for four further years, the Labour Party will do well to expedite its attainment of a minimum State subsistence. For, be they turned out from school with their physique, morals, and manners, religious and æsthetic perceptions, civic ideals, and use of the subjunctive mood in subordinate clauses in the ancient languages never so perfect, it is difficult to see what else can save them from starvation in the hard times ahead. Until something more in keeping with the age is substituted for the intellectual training of the school, the words in the opening essay (p. 39) will continue to be true: "They begin their course with keen interest and lively curiosity. Then shades of the prison-house seem gradually to close upon the growing boy."

FREDERICK SODDY.

BIOLOGICAL PROBLEMS.

Life and its Maintenance: A Symposium on Biological Problems of the Day. Pp. viii+297. (London: Blackie and Son, Ltd., 1919.) Price 5*s.* net.

DESIRE, want, pain, disease, and death, the tools used by Nature for fashioning the race, are equally efficacious for awakening the mental and bodily faculties of the individual. Under their goad the soldier has not only shown himself gifted with an unsuspected degree of intelligence, but, what is more important, has discovered how to use the intelligence of others, so that at the close of the war our scientific arms, creations of the war itself, were more efficient than the corresponding formations in the Army of a nation which had long prided itself on its thorough utilisation of all the means science placed at its disposal. Even among those compelled by age or infirmity to carry on their normal vocations at home, the trifling discomforts and privations to which they were subjected under war's constraints acted as hormones, as adequate stimuli for arousing their slumbering mental faculties, and disturbing for a while the hopeless incuria with which, to the detriment of the body politic, our upper and middle classes are afflicted. Any discomfort, whether it be the presence of a flea or the necessity of absorbing war bread, rouses an appropriate reaction and interest in its removal. Thus it came about that a sufficient number of persons, anxious to devote a certain time to learning about the world around them with special reference to the discomforts under which they were suffering, and willing to devote an hour in the week to this purpose, were found to justify the delivery at University College of a course of lectures which are reproduced in this volume under the general title of "Life and its Maintenance."

The first object of interest to every man is himself, and since at the time of the delivery of these lectures there was a certain amount of food shortage and a reasonable doubt as to the prospects of food supplies in the future, it is natural that most of these lectures are devoted to the subject of food, its effects on man, and the methods of increasing its production in this country.

Prof. Bayliss leads off with a clear, elementary account of the significance of food for the body. This is followed by a reassuring lecture on war bread by Prof. Hopkins. The third lecture, by Miss Hume, deals with accessory food factors, the importance of which was brought into unwelcome prominence by the outbreaks of beri-beri and scurvy among our forces abroad, and the consideration of which, in their relation to infant feeding, must always take an important place in our measures for ensuring the health of the community. Prof. Cushny contributes a judicious and well-balanced lecture on the subject of alcohol, and the various questions relating to the production of food by the improvements of farming methods are dealt with by Dr. Russell, Mr. Stapledon, Dr. Horne, and Profs. Hickson and Tansley.

The last five lectures are of a more miscellaneous import. The shortage of paper prompts Prof. Oliver, who was responsible for editing the whole series, to give a useful summary of the various materials used in the manufacture of paper and to describe certain new plants, notably a grass (*Spartina Townsendii*) growing on the mud flats of Southampton Water, which had been tried for this purpose. Dr. Vernon deals with the relations of industrial efficiency and fatigue. This subject is so closely connected with the question of hours of labour that no one possessed of a vote has a right to say that it does not concern him. This lecture, as indeed the whole collection, is an attempt to rouse the man in the street to take an interest and a part in the search for such knowledge and methods as by their generalisation may increase the efficiency and thereby the prosperity of the nation as a whole. The next few years will be marked by the introduction of one legislative measure after another directed to this end, but probably in many cases ill-conceived from lack of acquaintance among law-givers and people with the intimate character of the problems involved. To those problems which affect the life of the individual this series of lectures will serve as an interesting and authoritative introduction.

SOUTH AUSTRALIAN GEOLOGY.

The Geology of South Australia. (In two divisions.) Division 1, *An Introduction to Geology, Physiographical and Structural, from the Australian Standpoint.* Division 2, *The Geology of South Australia, with Notes on the Chief Geological Systems and Occurrences in the other Australian States.* By Walter Howchin. Pp. xvi + 543. (Adelaide: The Education Department, 1918.) Price 10*s.*

FOLLOWING the example of Mr. Chapman's Australian fossils—an outline of palæontology based on Australian examples for Australian students—Mr. Howchin, of the University of Adelaide, has prepared a general text-book of geology based on Australian illustrations, followed by an account of the geology of South Australia, with shorter summaries of that of the other Australian States. The book should be very useful, as it fills a gap in Australian educational literature, while it supplies geologists in general with an excellent and up-to-date compendium of the geology of South Australia. Mr. Howchin is exceptionally qualified for the work; he is well known for his discovery of the Australian Cambrian glacial deposits, his researches on fossil foraminifera, and his text-book on the geography of South Australia. The first division of the work gives a clear summary of the general outlines of geology; it is especially good in the physiographic portions. The petrology is comparatively elementary, since the book, being published by the South Australian Education Department, is probably intended more for secondary schools than for university students. Australian petrologists may consider that there is inadequate notice of the alkaline igneous rocks; and in an effort at simplification "pyroxene (augite)" is included in the hornblende group, a step which would lead students to overlook the important distinction between the pyroxenes and the amphiboles. The parallelism of these series is also not indicated in the statement as to the composition of augite. There is not much information about economic geology; for example, the author tells us nothing about the oil-fields of South Australia and their prospects. He follows those who extend the petrographic use of the word "mineral" for mineral species into general geology, although mineralogists, such as Miers, adopt the more commonsense practice which does not refuse the term "mineral" to most economic minerals. The author, of course, cannot be consistent, for the term is not used in the latter part of the book in accordance with the restricted definition. In regard to the Australian artesian water, the author adduces evidence that the supply is dwindling from the reduction in size of the mound springs; but those who hold that plutonic water is largely influential in the uplift of the water in the wells do not consider, as is twice stated, that most of the water is plutonic in origin.

Mr. Howchin makes the interesting suggestion that the word "scree," of which the etymology is doubtful, comes from "screed," a fragment; but is it not more probably from "screen," owing to the resemblance to the sloping sheet of angular fragments on a road metal screen? The most important chapter is that on the Lower Cambrian glacial deposits, which extend northward from Adelaide for about 450 miles to a latitude as low as 29½. The author, to whom is due most of the existing knowledge of these beds, shows that they were probably laid down at sea-level. The occurrence of this great sheet of subtropical low-level glacial deposits at the very beginning of the fossiliferous rocks is one of the most significant facts in geological history. Mr. Howchin also tells us the latest information from the trans-continental railway bores as to the extension into Australia of the Cretaceous sea, and shows that in all probability it did not extend across the continent. The book is illustrated by numerous well-selected and excellent illustrations.

J. W. G.

OUR BOOKSHELF.

Annual Reports on the Progress of Chemistry for 1918, issued by the Chemical Society. Vol. xv. Pp. ix + 240. (London: Gurney and Jackson, 1919.) Price 4*s.* 6*d.* net.

THESE important volumes have been issued annually by the Chemical Society since 1905. Their object is to present an epitome of the principal definite steps in advance which have been accomplished in the preceding year for the benefit of workers or students in pure or applied science. They are not popular in any sense of the word. During the war there was necessarily some slackening in the production of results bearing chiefly on purely scientific problems, and the volume for 1918 is somewhat thinner than the volumes issued in previous years. Nevertheless, some advances can be recorded. For very many years the mass of the atom has been regarded as determining its chief properties. This is embodied in Mendeléeff's periodic scheme familiar to every chemist. It is therefore not surprising to find that the new doctrine which assumes some knowledge of the internal constitution of the atom should be rather slowly accepted. But chemical physics or physical chemistry is a department of knowledge which is undergoing rather rapid and bewildering change consequent on advances in positive knowledge. Absorption spectra, the properties of colloids, ionisation and the nature of ions, the nature and source of osmotic pressure, and the relations of isotopes are all subjects of supreme interest, many of which have assumed a totally new form, or have even been recognised only within the last twenty years. The chemical student of the future will need to be a fairly good mathematician if he hopes to follow all that is going on in these several directions. Fortunately there are other large fields of work still open in which this is not an essential condition and where great successes continue to be scored, especially in constitutional and synthetic organic chemistry and its applications to problems in physiology, animal and vegetable. These are all dealt with under appropriate heads in this volume of reports.

Heredity. By Prof. J. Arthur Thomson. Third edition. (The Progressive Science Series.) Pp. xvi+627. (London: John Murray, 1919.) Price 15*s*. net.

The first edition of Prof. Thomson's "Heredity," which appeared in 1908, was reviewed at some length in Nature (vol. lxxviii., pp. 361–63). The book quickly became established as an introduction—at once trustworthy, impartial, and comprehensive—to the many problems that are presented to students of inheritance, and a second edition with some additions and revisions was published in 1912. The third edition is now before us, and the author has taken the opportunity of directing the reader's attention to some of the important advances that have been made by investigators during the last seven years. The size of the book has not been increased from the second edition, so that room for additions has been found by condensing the type-setting on certain pages; this involves a brevity of treatment disappointing to those who would have valued Prof. Thomson's judicious criticism of several recent theories. For example, the studies by T. H. Morgan and his fellow-workers on the inheritance of linked factors in the fruit-flies (Drosophila), and W. E. Castle's work on the relation between heredity and selection in hooded rats, are barely mentioned.

A short list of some important books and papers of the last few years has been added to the bibliography, but the subject and general indexes appear to have escaped a revision which would have greatly increased their value. The paragraph on "Militarism" in the concluding chapter has been rewritten in the light of the experiences of the last five years, and the author emphasises Dr. Chalmers Mitchell's contention that "the struggle for existence as propounded by Charles Darwin and as it can be followed in Nature has no resemblance with human warfare." Again, as one turns the pages of Prof. Thomson's familiar volume, one realises how the study of biology, wisely applied, may become an aid rather than a rival to that of "the humanities." G. H. C.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can be undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

A Photoelectric Theory of Colour Vision.

Referring to his letter under the above heading on p. 74 of Nature of September 25, I perceive that Prof. Joly has had ideas similar to mine about an electric stimulation of the terminals of the optic nerve through bombardment of corpuscles flung off under the stimulus of ordinary light.

My argument is strengthened by reflecting that this utilisation of atomic energy, emitted in *quanta* under the stimulation of accumulated almost infinitesimal vibrations of the right frequency, can account for the extreme sensitiveness of the eye and of the sensitive pigments known very low down in the scale of animal life. The great variation of brightness permissible, between wide limits, without much differential physiological result is also natural on this view; so is the fatigue of colour-sensation by temporary exhaustion of a specific potentially radio-active material, until renewed by living tissue.

I should suppose that on this trigger-like basis the eye can form very little estimate of absolute brightness inside the limits above spoken of, though the ear, having no explosive mechanism, might be able to form a scale of loudness. In the main, photometric observations must be comparative.

A pathological condition of the retina, when flashes are perceived without objective stimulus, may be accounted for by overinstability of material and consequent spontaneous emission of corpuscles.

The experiments which Prof. Joly began to try seem to have been just in the general direction which I wished to encourage some young physiological physicist to pursue, only he must be prepared to design or adjust his electrical detecting instrument for extreme sensitiveness. A frog's nerve-muscle preparation could scarcely be responsive without something analogous to rods and cones, or something like an electric organ, and without access to unsheathed terminals. If a mechanical electroscope is employed it must have minute capacity; a silvered quartz filament, with a minimum of attachments, in the field of a microscope may be suggested.

Oliver Lodge.

Reversed Pleochroic Haloes.

In a paper on "The Genesis of Pleochroic Haloes" (Phil. Trans. R.S., vol. ccxvii.) by J. Joly, a theory is advanced accounting for certain structural features of the halo on the assumption that reversal of the halo-image is possible, and may take place under conditions defined in the paper. In support of this a drawing of a halo is given in which an evident inversion or change from positive to negative has occurred, the inner region being light, the outer dark.

Recently, in examining the brown mica extracted from a granite, we have found quite a large number of these negative haloes. All internal features are gone, solarised out of existence; the wide outer band alone remains. They resemble negatives of a much-exposed halo. Their dimensions shows that they possess uranium-charged nuclei. When the nucleus is *very* minute there is no sign of reversal; the halo is normal.

It is possible that the frequency of reversal in this mica is to be ascribed more to special uranium-richness of the nucleus rather than to the antiquity of the rock. The rock is a biotite granite with a white and a yellow felspar. It is said to be from Sinai. One side of the specimen has been exposed to the weather, and the appearance of this side suggests desert conditions.

J. JOLY.
J. H. J. POOLE.

Trinity College, Dublin.

The Spectra of Isotopes.

SOME years ago I made an investigation of the spectra of ordinary lead and lead from pitchblende residues, but I was not able to detect any difference in the spectra. More recently Aronberg (*Astrophys. Journal*, February, 1918) has found a difference in the wave-lengths of the principal line in the spectra of ordinary lead and lead from Australian carnotite amounting to 0·0043 Å. I have made a fuller investigation of the problem by a method of experiment greatly superior to that which I had previously adopted, and the results show that there is a small but real difference in the spectra, which agrees closely with the value found by Aronberg. A difference has also been found between the wave-length of the principal line in ordinary lead and lead from Ceylon thorite.

These results at once suggest that the spectroscope will furnish a simple and comparatively rapid method of distinguishing isotopes, and some measurements have been made of the wave-lengths of the principal line in ordinary thallium and in thallium from pitchblende residues. It has long been suspected that, in addition to lead, some of the metals found in pitchblende may be of radioactive origin, and the results of the wave-length measurements, though for certain reasons they cannot be given the same weight as those relating to lead, suggest that the thallium in pitchblende is an isotope of ordinary thallium and more probably of greater atomic weight. It is hoped to publish shortly an account of the investigation.

THOMAS R. MERTON.

Balliol College, Oxford, September 15.

A British Imperial Antarctic Expedition.

MAY I, through the columns of NATURE, direct attention to the British expedition which I am at present organising and propose to lead to the Antarctic in June next year? The objects of the expedition are briefly as follows:—

(1) To ascertain the position and extent of the mineral and other deposits of economic value already known to exist in Antarctica (*vide* scientific reports of Bruce, Mawson, Scott, and Shackleton), and obtain data for the practical development as a further source of Imperial wealth.

(2) To obtain further evidence of the localities of whales of economic value, and to create British industries in this trade.

(3) To investigate the meteorological and magnetic conditions in the Ross Sea area and at Cape Ann (Enderby Land) in connection with their influence under similar conditions in Australasia and South Africa respectively. That such results are of great economic value has been proved by the station established by the Argentine Government for similar purposes in the South Orkneys.

(4) To circumnavigate the Antarctic continent.

(5) Generally to extend our knowledge of Antarctica, especially with the view of obtaining further scientific data of economic importance.

The expedition proposes to leave England in June, 1920, and to be away for a period of five years. During this period important scientific research will be undertaken on the lines briefly given above. Applications are invited from fully qualified men in the following branches of scientific knowledge:—Geology, meteorology, biology, surgery and physiology, photography, cartography, and hydrography.

The expedition has been well and strongly supported, and I shall be glad if all who are interested will communicate with me at the address given below.

JOHN L. COPE.

September 20.

Luminous Worms.

WHEN I wrote the letter which appeared in NATURE of September 11 (p. 23), I made no reference to my impression that a friend had seen luminous earthworms in Great Britain because I was not aware that he was still in England, and was consequently unable to give accurate details. I found afterwards that this friend, Dr. Edgar Newbery, recently appointed professor of physical chemistry in the University of Cape Town, had not yet left this country, and I was able to write to him for confirmation of the impression in my mind, and I have now received a reply. Writing from Byton Rectory, Presteign, Radnor, Prof. Newbery says:—

"I have seen luminous earthworms on more than one occasion on the grass of our lawn here. (We are really in Herefordshire, though our post town is in Radnor). The soil from which they emerged is a mixture of clay and gravel, but is very fertile. The luminosity was very weak, and gathered in spots or blotches over the body. Small luminous patches were left behind on the grass in the track of the worm, but these faded in a very short time (30 seconds or so). I have seen them both in warm weather and when a slight frost was on the ground, but a very dark night is necessary to render them at all conspicuous, as the luminosity is so weak."

That Prof. Newbery is not confusing luminous earthworms with luminous centipedes is concluded from the next paragraph in his letter:—

"On Tuesday, September 2, I saw a remarkably brilliant luminous centipede in a barley field 100 yards from here. The light was so vivid that it caught my attention at a distance of 12 yards, and the luminous trail left behind it was quite 12 in. long. . . ."

Suggesting the cause of luminosity, Prof. Newbery says: —

"I am inclined to believe that the luminosity of these centipedes and worms is due to slow oxidation of some excretion from the body which may well be affected in quantity and quality by the food available."

So far as centipedes are concerned, I think Dr. Brade-Birks and I shall be able to show, in a forthcoming paper on luminous Chilopoda, that atmospheric oxygen is not necessary for the production of light in the centipedes we have studied, but Prof. Newbery's suggestion about food supply may explain why some individuals of a species are luminous while others are not.

In Verhoeff's "Chilopoda" (Bronn's "Klassen und Ordnungen des Thier-Reichs") there is no reference in the bibliography to Dr. T. L. Phipson's "Phosphorescence, or the Emission of Light by Minerals, Plants, and Animals" (London: Lovell Reeve, 1862); I therefore conclude that this useful work is little known. Phipson cites the experience of Audouin in 1814. In August that year some persons came to him at Choissy-le-Roi, near Paris, where he was on holiday, and told him they had seen an immense number of luminous earthworms in a chicory field not far away. These earthworms turned out to be centipedes. In another chapter Phipson tells us that in 1840 Forestèr wrote to the Academy of Sciences recording luminous earthworms. When this letter was communicated to the Academy, M. Audouin rose and said that he knew of no authentic case of luminous earthworms, but that he could cite numerous cases where luminous centipedes and worms had been confused. Whereupon Duméril, to prove that earthworms sometimes are phosphorescent, quoted the experience of Flaugergues and that of the naturalist Bruguière. It seems that M. Audouin was afterwards convinced of the fact that earthworms were sometimes luminous by the experience of Saigey and Moquin-Tandon, who found them so at Toulouse in 1837. Phipson quotes other evidence, and closes an interesting chapter with words which may confirm Prof. Newbery's suggestion about the relation between the quantity and quality of phosphorescence and the food supply:—

"I may add here," says Phipson, "that I distinctly remember witnessing, when quite a child, the phosphorescence of the earthworm; the light appeared connected with the slimy matter that covers the animal's body. It was whilst digging at night, in a large dunghill, for worms to supply baits for a fishing excursion that my schoolfellows and myself turned up many hundred Lumbrics in a highly luminous condition; but I cannot recollect in what month this happened."

S. GRAHAM BRADE-BIRKS.

CATALYSIS IN CHEMICAL INDUSTRY.

THE catalytic agent is penetrating peacefully, yet effectively, into modern chemical industry. In explanation, to the lay mind, of the *rôle* of a catalyst in chemical reaction, comparison was recently cleverly drawn between the catalyst and the matrimonial agency. Both serve to bring together and to facilitate the union of others. Both are free after the consummation of the one process to renew their activities in like manner. The catalytic substance has played an important part in the many industries which have been necessary to the maintenance and equipment of the fighting Services with munitions of war. Not less distinctive a part has it played on the home front in the work of victory. The catalyst has been largely employed in the supply of margarine, to which we have grown accustomed. The soap with which we have been cleansed calls, in the process of its manufacture, for the assistance of the catalyst. The glucose which has helped to sweeten our lives, in time of a sugar shortage, is the resultant of yet another catalytic process.

Let us survey a few of the more striking applications of catalysis in industry. Glycerine for dynamite and nitroglycerine is obtained from fats by catalytic hydrolysis, using alkalis or acids as splitting agents. In the modern developments of fat-splitting the discovery of the Twitchell catalyst facilitated, owing to its combined acidic and fatty nature, the rapid working-up of low-grade fats and greases for glycerine and soaps. Sulphuric acid is made by one or other of two catalytic processes. The old or "lead chamber" process uses oxides of nitrogen to assist the process of oxidation of sulphur dioxide. For the stronger acid, the "oleum" or fuming sulphuric acid required in the nitration of toluene and phenol for high explosive, the modern "contact" process is more suitable. The sulphur dioxide and oxygen are caused to combine in the presence of solid contact agents such as platinum or oxide of iron. Chlorine, as well for poison-gas as for the more peaceful requirements of bleaching-powder of sanitation and water purification, is generated from hydrochloric acid by oxidation in the presence of copper chloride as catalyst. That very inert but plentiful constituent of the atmosphere, nitrogen, may now, with the assistance of a suitable catalyst, be caused to combine with hydrogen directly to form ammonia. This may be used for the production of ammonium sulphate for fertiliser, or oxidised in contact with a hot platinum gauze to form oxides of nitrogen, and thus lead to the manufacture of nitric acid or ammonium nitrate. The hydrogen which is necessary for ammonia synthesis is obtained most cheaply and effectively by another catalytic reaction, using water-gas and steam as the raw materials. Town gas and fuel gases generally are freed from obnoxious sulphur compounds present as impurities by catalytic processes of sulphur removal.

It is a matter of difficulty fully to characterise the developments which have attended in several instances the discovery of successful catalytic processes. Perhaps, however, an illustration involving the application of the researches of the brilliant French chemist, M. Paul Sabatier, will serve to demonstrate potentialities and possibilities inherent in academic research. M. Sabatier is the discoverer of the principle of catalytic hydrogenation, and has conducted an exhaustive series of researches into the phenomenon. The application of his results to industry has solved the century-old problem of the economic utilisation of liquid fats. During the last ten years, in ever-increasing measure, liquid fats and oils have been catalytically hydrogenated in presence of reduced nickel as catalyst to yield the more valuable hardened fats which are used in the soap and candle industry, as well as for purposes of food. The economic results of such application are tremendous. Whole tracts of tropical country are being opened up for the production of palm nut and other nut oils. Fish oils are being hardened and deodorised for use in the industry. New uses are being found for hardened cotton-seed, linseed, and similar largely available oils.

Catalytic hydrogenation has also been applied to the enrichment of gaseous fuels. The carbon monoxide of water-gas may be hydrogenated in presence of reduced nickel to give methane with consequent production of a gas of high calorific value and illuminating power. The production of hexahydro-benzol in bulk, by hydrogenation of benzene, is as yet in its infancy, but has a certain future owing to the utility of the product as a volatile fuel for internal-combustion engines. The fact that it is a single compound gives it marked advantages over petrol as a fuel for air transit, since the variability of petrol is a distinct drawback in the case of a fuel upon which such rigorous demands are necessary.

The development of the fine chemical industry in this country involves also an extended use of catalytic reactions. The successful production of synthetic indigo was facilitated by the discovery of the catalytic acceleration of the oxidation of naphthalene by mercuric sulphate, discovered owing to the breakage of a thermometer bulb in the reaction mixture. The production of dye intermediates involves, more and more, the aid of catalysis. Especially, however, in the large-scale preparation of solvents will catalysis contribute convincingly to success. Industrial alcohol may be cited in illustration. Every method by which this important solvent is produced is catalytic. The ordinary process of fermentation and distillation involves the participation of the living catalysts, the enzymes and ferments. The production of alcohol from potato and rice starch is a combined process of hydrolysis and fermentation with the catalytic action of acids followed by enzymes. Similarly, alcohol of the future will be obtained by catalytic degradation of the cellulose content of wood waste, or, synthetically, from acetylene and ethylene, by processes of catalytic hydration and hydrogenation. The potentialities of alcohol as a fuel in the future must not be forgotten, in view of the increasing consumption and prospective exhaustion of oil-fuel reserves. In the meantime these latter, as a result of more rigid scientific control, are being more economically utilised. The "cracking" of oils to yield the more volatile fractions usable in motor-engines is a modern development, the catalytic features of which have not, as yet, been completely realised.

From alcohol as starting-point, catalysis is involved in the production of acetic acid and acetone, the solvents largely required in the preparation of aeroplane dopes and varnishes. From methyl alcohol, a distillation product of wood, catalytic oxidation or dehydrogenation in presence of metallic copper yields formaldehyde, a powerful germicide and disinfectant, and itself the starting-point in the manufacture of bakelite, the artificial vulcanite or amber, a polymerised product formed under the influence of catalytic agents, and increasingly produced for use in electrical insulators and for fancy articles. The demand for formaldehyde is already so great that investigations are in progress with the object of production from sources other than methyl alcohol. The hydrocarbon methane has been suggested in this connection. A process of fractional oxidation of methane should yield formaldehyde. Alcohols and organic acids of varied complexity may be largely utilised in the production of synthetic essential oils and perfumes by processes of catalytic condensation.

The catalogue is not exhaustive, but sufficient has been said to show the paramount importance of catalysis in modern chemical industry. It is evident, therefore, that the modern curriculum of theoretical chemistry should concern itself largely with the scientific principles involved in catalytic reactions. An extended experience with catalysis, both pure and applied, has demonstrated that, from a complete realisation of the theoretical aspects of the problem, progress in the application follows the more rapidly and the more certainly. It is astonishing to note the facility with which new progress is attained by the employment of the scientific principles which have been acquired in a totally different application of catalysis to industrial progress. The records of certain of the Government Departments of investigative work, during the last few years, would be instructive in this regard. The need, therefore, is urgent for a well-trained force of young students, versed in the fundamentals of this modern branch of chemistry, and equipped to take their place in the further developments which lie so close at hand. There are manifold possibilities ahead—numerous processes and agencies catalytic awaiting the facile brain and hand of the investigator.

Hugh S. Taylor.

FROSTS AND AGRICULTURE IN THE UNITED STATES.

The United States Department of Agriculture has recently issued a publication on "Frost and the Growing Season." This consists of a series of maps in colours and some diagrams from which the probable date of the last frost in spring and the earliest in autumn may be seen at a glance. An article on a paper by Mr. W. G. Reed on this subject appeared in the issue of Nature for May 23, 1918, and the present publication is also by the same author.

Frosts are divided into three classes: "light," "heavy," and "killing." The first two terms apply to the amount of the deposit in the form of hoar-frost; the last only is dealt with in the paper, and is defined on an occasion on which the screen temperature fell below 32° F. In a country like the United States there is naturally great variation in the length of the period that is free from frost; not only is there variation in latitude from Florida to the Canadian border, but there is also much difference in the height above mean sea-level. The local topography is also important, for while, in general, frost is more prevalent at the greater altitudes, yet locally a small elevation will prevent a frost, and in enclosed valleys the hill-sides and the hill-tops may be less subject to frosts than the valley bottoms.

Frost records are available from about four thousand regular stations of the Weather Bureau, and of these about six hundred have a twenty years' record. The most noteworthy feature of the critical frost dates is their extreme irregularity. Thus at Peoria, Ill., with a fifty-nine years' record, the latest frost in spring covers a period of nearly fifty days, and the earliest in autumn a period of forty days. The maps are based upon the average dates.

The mountainous character of the country in the western portion of the United States, and the fact that the stations are mostly situated on the lower slopes of the mountains, make mapping very difficult, and it is pointed out that only a general idea of the conditions can be given. For practical purposes this position of the stations should not matter, as they would naturally be in those parts where cultivation was most prevalent.

It appears from the maps that there is no part of the United States except Key West where a frost may not occur, and the line showing a frost in half the years—that is, the line showing the position where a frost is just as likely to occur once in the winter as not to occur—excludes only a small part of Florida and reaches down to latiture 26° N. The line for the last frost before March 1 cuts off the peninsula of Florida and fringes the southern coast as far as New Orleans. In the north frosts are common until the middle of May or even June 1, and in the higher parts of the west, which are only used for grazing, they occur after June 1.

The earliest frost in autumn does not occur until after December 1 in Florida and in parts of the south-west. On the north-western frontier frost may be expected about the middle of September. About one-quarter to one-third of the whole country has a period of 210 consecutive days free from frost, but in the mountainous regions of the west there is a good deal of country in which the period is barely half as long.

Some smaller maps give information as to the frequency of frosts in the different districts one, two, or more weeks before or after the average dates. The whole paper is most interesting, and should be very useful to agriculturists in the United States.

W. H. D.

NOTES.

THERE was a certain inevitableness in the nomination of Mr. Arthur James Balfour for the Chancellorship of Cambridge University. The fact that Mr. Balfour has consented to be so nominated in succession to his late brother-in-law has everywhere been received with enthusiasm. In the history of Cambridge, statesmen, administrators, literary men, and philosophers have succeeded one after another in the roll of Chancellors, but in Mr. Balfour, the most celebrated of living graduates of Cambridge University, all are combined in one man. Mr. Balfour is one of the two honorary fellows of Trinity College, the other being the Right Hon. G. O. Trevelyan. Mr. Balfour was educated at Eton, and entered Trinity College in the late 'sixties. He took his degree in the Moral Sciences Tripos of 1896, in the same year as Dr. Percy Gardner, now the professor of archæology at Oxford. The Balfour family has been most intimately associated with Cambridge; his younger brother Francis, who unhappily perished in the Alps in 1882, was a man of the highest scientific distinction, one who was leading zoologists along new lines of thought; another brother, Gerald, was a fellow of Trinity; one of his sisters married Prof. Henry Sidgwick, and was for many years Principal of Newnham College; and another sister married Lord Rayleigh, whose recent death has deprived the University of a generous Chancellor and a great pioneer in modern physics. A reference to "Who's Who" will show not only the list of honorary degrees, too long to be quoted here, which have been conferred upon Mr. Balfour, but also that he has constantly taken the lead on various boards and committees connected with education. He has been Lord Rector of St. Andrews University, Lord Rector of Glasgow University, and he is Chancellor of Edinburgh University. The announcement that so distinguished a man and scholar has consented to be nominated for the post of Chancellor has met with widespread sympathy and hope amongst the members of the Senate.

ENTOMOLOGISTS, it appears, have not yet solved the problem of what becomes of the house-fly in wintertime. The popular idea that when the cold season comes the house-flies, or such of them as do not die off, retire to some quiet nook or cranny in the house and, like dormice, sleep undisturbed through the winter is still entertained in some scientific and other respectable quarters, although no trustworthy evidence has been found to support it. There are flies and flies; and, as Dr. L. O. Howard was, we believe, the first to suggest, no evidence relating to the hibernation of the house-fly can be trusted until it has first been submitted to expert examination. Since that suggestion was made, a large amount of evidence has been submitted to experts, and now they are almost unanimously agreed that the hibernating house-fly is a wholly mythical creature. But the house-fly must get through the winter somehow, and if not in its perfect state as a fly, then in some other stage or stages of its life, or else we should not be troubled with the pestilent brood year after year in succession. Before the entomologist can tell us exactly how, it looks as if he will need the help of the sanitary officer, the stable-boy, the farm labourer, or even of the Boy Scout, rather than that of the ordinary householder. The search for larvæ and pupæ of the fly is not an easy one, and often involves a great amount of physical labour. In summer-time the pupæ are frequently to be found living at a depth of 2 ft. under the surface of the soil within half a yard of a manure heap. Dr. Gordon Hewitt has searched for them in such places, and in every other likely place, in wintertime, and has never succeeded in finding any alive. But because he, and possibly a few others, have made it and failed, it can scarcely be said that a search of that kind has been exhausted, and that we must fall back upon the hibernating adult fly as the only alternative. There may be no definite hibernating stage in the life of the fly. The insect may continue to breed in the winter, not exactly as it does in the summer or autumn, but at a greatly retarded rate, each stage being more or less prolonged. This probably does not happen to any extent under natural conditions in this country, but the number of places in which it can happen, and probably does happen, under special conditions may be quite sufficient to account for the perpetuation of the fly.

THE officers and other members of council of the Röntgen Society for the session 1919–20 are as follows:—*Pesident*: Dr. Sidney Russ. *Hon. Secretaries:* Dr. Robert Knox and Dr. R. W. A. Salmond. *Hon. Treasurer:* Mr. Geoffrey Pearce. *Hon.*

Editor: Major G. W. C. Kaye. *Council:* Mr. W. E. Schall, Dr. G. H. Rodman, Mr. C. Howard Head, Mr. C. R. C. Lyster, Dr. J. Metcalfe, Mr. E. P. Cumberbatch, Dr. A. E. Barclay, Mr. F. J. Harlow, Dr. W. Makower, Dr. E. A. Owen, Mr. J. Russell Reynolds, and Mr. R. S. Wright.

A congress attended by 350 persons met at Marseilles in January last, under the auspices of the local Chamber of Commerce, to discuss and emphasise the rights of France over Syria. The discussions of the congress were divided into four sections:—Economics, archæology and history, education, and medicine and hygiene. A summary of the main papers of geographical interest is given in *La Géographie* (vol. xxxii., No. 5). M. E. de Marbonne contributed a paper on the geographical unity of Syria, in which he showed that Syria cannot be divided latitudinally, but that the natural divisions of the country extend from north to south, and are separated approximately by meridians from the Mediterranean to the valley of the Euphrates. Various papers of considerable value, although from a distinctive point of view, dealt with the trade and ports of Syria.

At the instigation of the Admiralty, the Royal Geographical Society has taken steps to form a permanent committee on geographical names, on which the Admiralty, War Office, Foreign Office, Colonial Office, India Office, Post Office, Board of Trade, Board of Agriculture, and the Royal Geographical Society are represented The chairman of the Committee is Major-Gen. Lord Edward Gleichen, and Mr. A. R. Hinks is acting povisionally as secretary. The Committee hopes eventually to examine all cases of doubtful nomenclature and spelling in the place-names of the British Empire, accepting, wherever possible, official name-lists such as those provided by the Gazetteer of India, the Board of Geographic names of Canada, etc. Place-names of the British Isles are outside the scope of the Committee, as they are dealt with by the Ordnance Survey. Lists of names will be published at intervals after they have been submitted for approval to the authorities of the country concerned. Correspondence regarding confused or doubtful place-names of which the writer has personal knowledge is invited, and should be addressed to the Secretary, Committee on Place-Names, c/o Royal Geographical Society, Kensington Gore, London, S.W.7.

The Journal of the Royal Microscopical Society for June (part 2, 1919) contains an important paper by Mr. J. Bronté Gatenby on the identification of intracellular structures. Considerable difficulty is often experienced in distinguishing several categories of cell elements. The Golgi apparatus, mitochondria, yolk, and fat are, or contain, substances often identical and generally chemically allied. For this reason care must be exercised in any attempt to identify a given cell body, and it is clearly recognised that the mixture of two or more of the above-mentioned elements may lead to confusion. The characteristics of the various elements of the cell which the zoologist may meet with, and the manner in which they may be distinguished by staining methods and microchemical tests, is indicated in tabular form.

The Review of Work in 1918 of the Rockefeller Foundation has recently been issued. The activities of the foundation include a campaign against tuberculosis in France, which is mainly engaged in coordinating the various agencies already in existence for combating this disease. Demonstrations to test the possibility of ridding a community of malaria by anti-mosquito measures have been carried out in Arkansas with considerable success, and an epidemic of yellow fever in Guatemala has been stamped out. Measures for the control and prevention of hookworm disease have been undertaken in many tropical countries. Medical education is also encouraged by the foundation; the Pekin Union Medical College is being built under its auspices, and grants are made to many missionary hospitals. The total disbursements of the foundation for 1918 amounted to more than 15,000,000 dollars, and war-work expenditure during the war totals nearly 22,500,000 dollars.

In an article published in a recent issue of the *North China Daily News* Mr. Austin J. Clements estimates that to maintain the trade in musk which passes across the Szechuan-Tibetan border, about 100,000 musk-deer must be captured and killed each year. The quantity of musk brought into Tachienlu, the chief centre of the trade, shows no sign of diminution, so that apparently the annual drain, large as it is, has so far had no noticeable effect on the musk-deer population of Eastern Tibet. Mr. Clements thinks it may be feasible to rear musk-deer in semi-captivity, and to collect musk from the animals without killing them. The wholesale slaughter which now goes on is largely unnecessary, since the snaring methods employed lead to the destruction of large numbers of females and immature males, whereas only male deer more than three years of age secrete musk. The article contains a good deal of information regarding the trade in musk, not the least interesting item being the statement that one firm in Tachienlu devotes itself solely to the manufacture of an adulterant, which resembles true musk in all respects save smell, the latter being provided by the addition of a small quantity of genuine musk. In coping with this and other less ingenious forms of sophistication the Chinese merchant is accustomed to rely on his personal judgment of the appearance, taste and smell, etc., of the article offered to him, so that it is not surprising that some authorities believe that all the musk exported from Tachienlu is more or less adulterated.

In connection with the Rat Exhibition held a few months ago in the gardens of the Zoological Society of London, special investigations were made into the various methods of rat destruction. Mr. E. G. Boulenger was placed in charge of this research, and on September 26, in a lecture presided over by Prof. E. W. MacBride, and attended by a large gathering of medical officers of health, sanitary officers, and rat officers, he gave an account of the results obtained. He stated that in the course of his investigations it was ascertained that, not only had the common brown rat very greatly increased in numbers in recent years, but also that the old English black rat, or ship's rat, which was supposed to have been practically exterminated in this country by the commoner species, and to be restricted to ports and ships, had become much more abundant, and the two species of rats were now found in various parts of London living together in harmony. Where rats were present in large numbers, and where it was not practicable to use gas, poisoning was found to be the best and cheapest method to adopt for their destruction. Of all the poisons experimented with, squill, the extract of the bulb of the Mediterranean plant *Scilla maritima*, gave the greatest satisfaction. Good results were also obtained with barium carbonate. Both these poisons, Mr. Boulenger said, were, in the small quantities required to kill rats and mice, more or less harmless to domestic animals. The destructive power of virus was found to be more untrustworthy than that of some poisons. The most successful form of trap consists of a tunnel-shaped cage with open doors at each end, which shut when the rat treads on a platform in the centre of the passage. The common steel gin-trap was specially successful when covered with wire tunnels. A large number of experiments were conducted in order to ascertain whether there was any truth in the statement that rats are influenced by human odour. As a result of these experiments it was found that it was superfluous to avoid handling traps on the assumption that rats are detracted by the odour of man. Sulphur dioxide was found to be the most effective gas, and was recommended for killing rats on ships and in confined spaces. When driven off under pressure, the gas could be used with success in fumigating rat-holes in the open. Details of the research will be found in a "Report on Methods of Rat Destruction," by Mr. E. G. Boulenger, shortly to be published by the Zoological Society, price 6*d*.

THE Proceedings of the United States National Museum (vol. lvi., No. 2288) contains an interesting paper entitled "Descriptions of New Species of Molluscs of the Family Turritidæ from the West Coast of America and Adjacent Regions" by Dr. W. H. Dall. In all, somewhat more than 200 species are considered, of which 181 are new. Of this large number 93 belong to the fauna of the western coast of the United States from the Arctic Ocean to San Diego, California, including one species from Hawaii. Eleven species appertain to the west coast of South America, including the Galapagos Islands; 89 belong to the Panamic fauna and its extension into the Gulf of California. The new species are well figured on twenty-four plates reproduced from excellent microphotographs.

DURING the early days of rubber-planting, seed was put in regardless of its origin, whether from trees yielding large or from trees yielding small quantities of latex. Now, however, so much rubber is planted that there is danger of over-production, and for further plantations (now that capital costs have increased) to have much chance of success they should be planted with seed from the best bearers. Selection of seed is already in progress in Ceylon and elsewhere, and a paper by Whitby ("Variation in *Hevea brasiliensis*," *Ann. of Bot.*, vol. xxxiii., 1919, p. 313) provides useful data which give an idea of the possibilities of improvement in average yield. A large number of trees were tapped on a uniform system (in Malaya), and it was found that nearly 10 per cent. yielded twice the mean or more. If, then, the method of selection indicated in Lock's "Rubber and Rubber-Planting" (p. 101) were adopted, there seems good reason to hope that new plantations might be made yielding much more rubber per acre than the old.

THE possibilities of camphor cultivation in the West Indies has recently been discussed in the *Agricultural News* for May 31 last. The decreasing amount of camphor available for export from Japan, which has hitherto been the main source of supply, has led to experimental growth of the camphor-tree in various West Indian Islands. It has been found that some varieties of the tree yield oil only, while others yield camphor and oil, and this important botanical aspect of the question is being investigated at Kew. With the right variety, the leaves and twigs, as well as the wood and roots, are found to yield camphor on distillation, and the trees will bear severe pruning with little apparent injury. Camphor production appears to be an industry which might profitably be developed in several West Indian islands, where climatic and soil conditions are suitable; for instance, Jamaica, Trinidad, Dominica, and others. Camphor hedges as wind-breaks to lime or cacao plantations might be experimented with, even if extensive areas were not devoted entirely to camphor plantations.

AMONG recent publications of the Board of Agriculture is the first annual report of the Flax Production Branch—a branch formed in 1917 to arrange for the growth of at least 10,000 acres of flax in Great Britain. It is estimated that the 1918 crop will yield about 26,500 tons of straw and seed. The cost of production has been enormous, chiefly owing to the great difficulty in obtaining the large amount of labour necessary for harvesting the crop. Pre-war experiment stations proved the possibility of flax production on a small scale in Great Britain, but it would be obviously unfair to take last year's experience as a guide to the possibility of a large-scale flax industry. The latter will depend on foreign imports and prices, on the development of flax-growing in other countries, and also on the hitherto unattacked problem of the reduction of costs in all the stages of production. Improvements already in sight are the increased straw yield from selected strains, and the progress made with the threshing attachment which makes deseeding on the farm possible. Also, it must be remembered that, failing the large-scale establishment of the flax industry, considerable loss will be sustained in the disposal of the machinery which has been put up during the past year.

THE recently issued volume of the Journal of the Royal Agricultural Society (vol. lxxix., 1918) contains several papers of great interest in connection with the food production campaign carried on during the war. Prof. Bryner Jones describes the results of breaking up grass-land in 1918. This will always rank as one of the most remarkable achievements of British agriculture, contributing as it did so largely to the food-supply of the country in times of great need. It was fitting, therefore, that the technical problems should be recorded and discussed. Teachers and experts will hope that an even fuller account may be published eventually, giving details of soil formations and conditions that will add to its usefulness. Mr. Garrad describes the work of the tractor on the farm. This implement is rapidly revolutionising farm conditions, and is greatly increasing the efficiency of the farm-worker. The defects of present types are set out and suggestions made for the consideration of engineers. Unfortunately, the great enemy of the tractor is the weather; in Mr. Garrad's opinion, it is essentially a fine-weather machine, and has to be laid up in winter. But it works so quickly that it enables a farmer to do much of his work during the fine periods. Mr. J. R. Bond gives an account of modern haymaking machinery, and Mr. Arthur Amos discusses the difficulties of growing red clover.

THE REV. M. SADERRA MASÒ, who has studied the seismic and volcanic phenomena of the Philippine Islands for many years, has recently published the catalogue of earthquakes for the year 1918 (U.S. Weather Bulletin for December, 1918). Excluding after-shocks, the total number of earthquakes is 167, three of which were recorded all over the world. The most important earthquake was that which occurred in Southern Mindanao on August 15 at 12.20 p.m., G.M.T., its epicentre being in 5·5° N. lat. and 124·5° E. long. This shock, the intensity of which reached the highest degree (10) of the Rossi-Forel scale, was followed by thousands of after-shocks (some of them of degrees 7 and 8) during the months of August, September, and October. It was followed by a sea-wave, which swept over the southern coast of Catabato, causing great damage and loss of life. About a month later, on September 13, there were two violent shocks in the Batanes Islands, the first of intensity 8 at 6.56 a.m., the second of intensity 9 at 11.5 a.m., by which the towns of Sabtan and Ivana were destroyed.

THE Bulusan volcano rises on the south-east end of the island of Luzon to a height of about 5000 ft. For centuries—indeed, so far back as the historic record extends—it has been dormant, only occasionally ejecting small jets of steam from numerous vents around its breached and nearly filled-up crater. A few light outbursts with ejection of ashes are reported as having occurred in 1852, 1889, and 1894. Far more important were the eruptions which took place in January, 1916, and October, 1918, and are briefly described by the Rev. M. Saderra Masò in the U.S. Weather Bulletin for January last. The first began on January 16, 1916, and lasted five days, with numerous earth-tremors and rumbling noises and small explosions. The eruption of October, 1918, was more violent, and at the end of December incandescent lava began to pour down a deep ravine on the south-south-west side of the mountain, continuing until the end of March, 1919. The damage caused by the eruptions is of little account; indeed, the plantations on the lower flanks of the volcano have been benefited by the small falls of ashes.

Symons's Meteorological Magazine for September inaugurates the passing of the magazine from the British Rainfall Organisation to the Meteorological Office as a part of the unification of the British Meteorological Services. The Thames Valley rainfall map for August shows the general rains to have ranged during the month from 2 in. to 4 in., the rains being heaviest in the southern districts of Hampshire and Sussex. In London and over a large part of Middlesex the rains measured about 2·5 in., the least rains amounting to 2 in. and less over the estuary of the Thames.

THE Monthly Meteorological Chart of the North Atlantic Ocean published by the Meteorological Office, in addition to the usual information dealing with matters of especial interest to the seaman, has on the face of the chart a note on the increasing storm tendency during the autumn. Attention is directed to the fact that during the winter half of the year both anticyclones and cyclones are of greater intensity than those of the quieter months of summer, the barometer during the winter season both rising higher and falling lower, which accounts for the greater severity of the wind. As an illustration of the irregular track of storms at times, attention is directed to a storm experienced by H.M.S. *Caesar* in the neighbourhood of Bermuda during the early days of September, 1915, when the storm's path seems to have nearly completed a circle and then to have doubled back over a considerable area. To confirm so erratic a path, a minute discussion of neighbouring and surrounding observations seems desirable. Autumn is referred to as the most stormy period for hurricanes in the tropical belt, but the accumulated data for many years show August as the most stormy month for West Indian hurricanes. Charts are given of the North Polar seas for the months from April to August inclusive, taken from the "State of the Ice in the Arctic Seas, 1918," published by the Danish Meteorological Institute.

THE developments of aerial photography during the war seem likely to be put into practical use in peacetime in connection with surveying and cartographic work. In *La Nature* for September 6, P. Dautriche expresses the opinion that the field of application for aero-photography seems to comprise (1) land cartography (revision and explorations); (2) marine cartography or charting; (3) the preparation of large-scale maps and plans for various public works enterprises; and (4) control work (forest sections, the traffic of ports, stations, etc.). His article develops the subject in an elementary way by simple examples of the method of procedure.

A WRITER in *La Nature* (September 6) sketches the development of the French Ministry of Inventions from its inception in 1915. The Department has been responsible, like the British War Inventions Department, for carrying out numerous investigations related to matters of artillery, small arms, lorries, tanks, aircraft, and shipping. One of the most useful inventions which was the outcome of much experiment by Prof. Perrin and his collaborators is a method of acoustic signalling by means of a compressed-air trumpet. The apparatus, which is quite portable, comprises two clarions or bugles having different notes and a compressed-air cylinder. It has a range of several kilometres. Much valuable work was done, too, on the photography of projectiles at extra high speeds. Mention is also made of Prof. Rothé's method of recording wind velocity by means of small anemometers and mills attached to captive balloons, the anemometers closing an electric circuit at intervals of 10 m. of change in wind force.

AN interesting pamphlet has been issued by the Niagara Falls Chamber of Commerce relating to the electro-chemical industries established at the Falls. The power at present utilised amounts to 605,000 h.p., whilst schemes in process of development will absorb a further 420,000 h.p. It is estimated that a total of 2,500,000 h.p., equivalent to more than 16,000,000 tons of coal per annum, may be obtained without impairing the natural beauty of the Falls. The substances produced by the various companies cover a wide range, and include abrasives, refractories, fertilisers, metals and alloys, inorganic compounds, and a variety of organic substances such as chloroform, methyl alcohol, and formaldehyde. When cheap power is available, electro-chemical methods of production often prove cheaper than alternative processes, and to this fact may be attributed the rapid development of hydro-electric schemes in all countries where water-power is available on a sufficiently large scale. The policy of the United States is to utilise water-power to the fullest extent, thereby conserving fuel; and it is worth while considering whether the British Empire could not act as a whole in this connection, particularly in view of the present situation in relation to coal supplies. Judging from the success already achieved at Niagara, it appears probable that a continuously increasing proportion of chemical and metallurgical products will emanate from water-power centres in the future.

WE have received a copy of an interesting pamphlet (obtainable from the editor of the *British Baker*, Messrs. MacLaren and Sons, Ltd., 38 Shoe Lane, E.C., price 1s.) by Capt. Robert Whymper on "The Conditions that Govern Staleness in Bread." For the greater part the report deals with work carried out by Capt. Whymper himself as Assistant Inspector of Bakeries with the Army in France, and it extends over far too large a field for complete abstraction here. The questions studied include the estimation and location of losses occurring in the manufacture of bread, the conditions that govern staleness in bread, changes occurring in bread with age, and the colloid nature of bread-crumb. The conclusions arrived at are as follows:—(1) The cooling of bread takes place in three stages: a steam period, a condensation period, and a drying period, the rate of loss of moisture of the first being four times as great as that of the drying period and five times that of the condensation period. (2) No marked loss of moisture from the centre of the loaf occurs until after 100 hours, and within the latter period the zone of drying is a layer only 1 in. thick adjacent to the outer crust. (3) The loss of water from a loaf on keeping is not responsible for staleness. (4) As the loaf becomes stale there is a fall in the amount of soluble extract of the bread-crumb, followed by a rise, the soluble starch falling rapidly between six and twenty-four hours' cooling. This supports Lindet's view that staleness is due to the retrogression of soluble starch. A similar fall and rise of soluble extract has been observed with starch pastes. Capt. Whymper considers that staleness may be attributed to (i) deposition of solid starch in the bread-crumb by change of temperature and accelerated by the pre-existence of solid starch particles; and (ii) partial polymerisation of starch independent of the deposition mentioned, which tends to crumble the gelatinous nature of the bread-crumb. Changes occurring in the proteins of the bread may also be a cause of staleness.

Messrs. Baillière, Tindall, and Cox have in the press for appearance in their Industrial Chemistry Series:—"Explosives," E. de Barry Barnett; "The Industrial Gases," Dr. H. C. Greenwood; "Animal Proteids," H. G. Bennett; and "The Carbohydrates," Dr. S. Rideal. The following volumes are in preparation for the same series:—"Fats, Waxes, and Essential Oils," W. H. Simmons; "Silica and the Silicates," J. A. Audley; "The Rare Earths and Metals," Dr. E. K. Rideal; "The Iron Industry," A. E. Pratt; "The Steel Industry," A. E. Pratt; "Gas-works Products," H. H. Gray; "Organic Medicinal Chemicals," M. Barrowcliff and F. H. Carr; "The Petroleum Industry," D. A. Sutherland; "Wood and Cellulose," R. W. Sindall and W. Bacon; "Rubber, Resins, Paints, and Varnishes," Dr. S. Rideal; and "Economic Fuel Production in Chemical Industry," Dr. H. S. Taylor.

Erratum.—On p. 84 of Nature of September 25, in the Table in column two, 95·4 appeared under S(aturn) in some copies as 5·4, the 9 having been broken off during printing.

OUR ASTRONOMICAL COLUMN.

The Twenty-four-hour Day.—The spirit of standardisation and unification is abroad, and one of its latest manifestations is the attempt to reduce the various methods of time-reckoning to a single system. Astronomers have made an important contribution to this end in deciding to commence the astronomical day at midnight instead of noon. This reform will commence in the year 1925, an earlier date being inconvenient for the various nautical almanacs. While astronomers will gain, on the whole, by the change, yet in some respects, notably in the case of sets of observations extending on both sides of midnight, it will cause inconvenience; this gives them a certain claim to ask for some sacrifice on the part of the general public in order to achieve the further unification which is now desired; this is the substitution of 24-hour reckoning for the present system of a.m. and p.m.

Twenty-four-hour time has long been used in Italy; it was introduced into the British Army last year, and a few railway companies already use it in their time-tables, where its convenience is so manifest that it is surprising that its introduction has been so tardy. The majority of social functions take place in the afternoon or evening, and it undoubtedly is somewhat more troublesome to say seventeen than five, or twenty-one than nine. *Punch* made some amusing play on this subject when the reform was suggested in 1885; possibly this had something to do with the failure to carry it at that date. However, the fact that astronomers could not then agree to alter the astronomical day deprived the scheme of its driving-power. The auspices are now more favourable, and the report of the Committee, consisting of seven members, just appointed by the Home Secretary will be awaited with interest.

Comets.—Using observations made on August 21, 29, and September 7, Messrs. Braae and Fischer-Petersen have deduced the following elliptical orbit of the comet 1919*b*:—

T = 1919 Oct. 16·861 G.M.T.	log a = 1·23860
ω = 129° 32·11′ } 1919·0	log e = 9·98767
☊ = 310° 43·41′ } 1919·0	log q = 9·68544
i = 19° 11·45′ } 1919·0	Period 72·095 years

The elements are extremely close (within about 5′ in each case) to Gould's elements for 1847 when corrected for precession. The error of the middle place in longitude (great circle) is −0·50′, in latitude +0·51′. The period adopted is simply the observed interval between the two perihelia, uncorrected for perturbations.

Ephemeris for Greenwich Midnight.

	R.A. h. m. s.	N. Decl. ° ′	Log r	Log Δ	Mag.
Oct. 1 ...	11 46 46	25 14	9·7836	9·7184	6·8
5 ...	11 45 19	20 52			
9 ...	11 46 13	16 46	9·7130	9·8392	7·3
13 ...	11 49 41	12 49			
17 ...	11 55 30	8 55	9·6856	9·9440	7·9

The comet will be observable as a morning object in Europe until early in December; after that it will pass to the south of the sun, and will be better placed for southern observers. It is very desirable to observe it as long as possible, in order to place the elliptical character of its orbit beyond a doubt.

The physical appearances of the three visible comets are discussed in *L'Astronomie* for September. 1919*a* (Kopff) appeared as a circular nebulosity some 3′ in diameter, gradually increasing in brightness towards the centre, where there was a nucleus of the 12th mag.; no trace of a tail. 1919*b* (Metcalf-Brorsen) was visible to the naked eye on September 5, in spite of strong moonlight. In the telescope it appeared as a large nebulosity, with eccentric condensation, and a short but broad tail pointing S.W. 1919*c* (Metcalf-Borrelly) appeared early in September as a pale nebulosity, 2′ in diameter, with slight central condensation; observation difficult owing to moonlight.

Minor Planets.—A sixth member of the interesting Trojan group of planets (the mean motion of which is the same as that of Jupiter) was found in March last, and provisionally designated 1919 FD. Its mean longitude is 60° greater than that of Jupiter. Prof. Cohn gives the following elements:—

Epoch 1919 March 19·5 G.M.T.

M_0 = 88° 48′ 18·9″
ω = 78° 46′ 7·8″ }
☊ = 336° 55′ 10·5″ } 1919·0
i = 21° 56′ 49·8″ }
ϕ = 4° 55′ 43·4″
μ = 303·190″
log a = 0·712194

Four of the Trojans have longitude 60° greater than Jupiter, and two 60° less.

FLORA OF MACQUARIE ISLAND.

THE recently issued part of the Scientific Reports of the Australasian Antarctic Expedition, 1911–14 (series iii., vol. vii., part 3), entitled "The Vascular Flora of Macquarie Island," by T. F. Cheeseman, contains some important conclusions on the origin and distribution of the southern floras. Macquarie Island is situated on a narrow submarine ridge, surrounded by water more than 2000 fathoms deep, about 600 miles to the south-west of New Zealand. Its greatest length is barely twenty-one miles, and its greatest breadth under four miles. The island is little more than a range of mountains, the exposed ridges bare and wind-swept, while in the hollows are numerous shallow lakes, and the coastal hills are deeply scored by ravines. The climate is marked by a low summer temperature, much cloud and fog, and constant high winds. Dr. J. H. Scott, who visited the island in 1880, describes the landscape as barren in the extreme. There is not a tree or shrub, but long stretches of yellow tussock are varied with patches of the bright green *Stilbocarpa polaris*, the Macquarie Island cabbage, a plant resembling very fine rhubarb in growth, and of Pleurophyllum, a handsome Composite, with long, sage-green leaves and purple flowers. On the hillsides are globular masses of Azorella, forming dense, solid cushions often 4 ft. across. Near the hilltops is an abundant growth of rich brown mosses. Hooker ("Flora Antarctica") mentions seven species of flowering plants and one fern as known from the island. Mr. A. Hamilton, on whose collections the present account is based, spent nearly two years in the island, and Mr. Cheeseman now enumerates thirty flowering plants and four ferns. Of these, three grasses are endemic, while of the remaining thirty-one species eighteen extend to New Zealand, and eleven of these are found in no other country. A remarkable fact is that fifteen, or practically one-half of the non-endemic plants, are also found in Fuegia or the South Georgia to Kerguelen groups of islands. Fuegia lies 4600 miles east of Macquarie Island, with no trace of land between, and South Georgia, further east, at about 5800 miles. Westward there is open sea until Kerguelen Island is reached, about 3250 miles distant. The extraordinarily scanty flora of the South Georgia-Kerguelen-Macquarie areas, which lie between parallels roughly corresponding with the north of England and the centre of France, is probably due mainly, as Prof. Rudmose Brown has suggested, to the short summer with its comparatively low temperature; but the almost continuous westerly gales must also act adversely on plant growth.

After a brief comparative review of the vegetation of the various land areas of the sub-Antarctic zone, Mr. Cheeseman concludes that during Tertiary times there have been only two directions in which the vegetation of the rest of the world can have approached the sub-Antarctic zone and Antarctica itself, or along which an interchange of species could take place, namely, the direction of New Zealand and that of South America. The rich and varied flora of New Zealand, in addition to its obvious Australian, Pacific, and Malayan alliances, has also an evident Andine and Fuegian affinity, which is still greater in the New Zealand sub-Antarctic islands. These islands in early Tertiary times were part of a greater New Zealand, and a northward extension of Antarctica might have reduced the distance between it and the New Zealand area to one capable of being passed by plants and animals. An indication of a former continuous or broken land connection between Antarctica and South America, presumably in Oligocene times, is found in the comparatively shallow bank which curves round by way of the Falkland Islands and South Georgia. The fossil Tertiary flora discovered by Dr. Andersson in Graham Land, comprising species of well-known recent South American and New Zealand genera, is of interest from this point of view. It suggests an Antarctica largely free from ice and snow, and supporting a numerous flora along the shores of the continent. We may imagine a regular exchange of species between Antarctica and Fuegia, and also a passage of species between New Zealand and Antarctica. In this way we may account for the presence of a New Zealand element in the South American flora and a South American element in New Zealand.

The subsequent Glacial epoch caused much extinction of species in the southern flora. At its close Macquarie Island had lost its higher plants except the few grasses which now constitute its endemic flora, Kerguelen had suffered almost as badly, and in South Georgia the whole of the vascular flora had perished. With the advent of a milder climate only two sources of supply remained, Fuegia and the New Zealand area. South Georgia and the Kerguelen group, both favourably placed in the line of the constant westerly winds, received almost the whole of their new flora from Fuegia, while Macquarie Island obtained a large proportion from the comparatively close New Zealand sub-Antarctic islands.

EDUCATION IN BRITISH INDIA.

THE Bureau of Education, India, has issued an interesting quinquennial review of the progress of education in British India for the period 1912–17. The facts are set forth in a statistical abstract covering 100 folio pages. They deal with all forms of education, primary, secondary, professional, and university, under various heads, such as the number of institutions public and private, the scholars in attendance, local and State expenditure, number and qualifications of the teachers, and cost of education in elementary and secondary schools and in professional and university colleges. The statistics differentiate between the various races, together with Europeans and Anglo-Indians, and between the different creeds, including Hinduism, Mohammedanism, and Buddhism. The returns refer only to British India, with an area of 1,034,716 square miles and a population of about 244,000,000, of which number 124,747,805 are males and 119,273,295 females. The Hindus number 163,611,094, Mohammedans 57,419,309, Buddhists 10,642,812, Parsis 86,155, Europeans and Anglo-Indians 265,254, Indian Christians 2,226,464, others 9,989,185—figures of much interest in view of the present Indian unrest. Of this vast number only 7,851,946, in which is included 1,230,419 females, are under instruction in all types of educational institutions, or about 3 per cent. of the population. In 1906–7 only 5,388,632 were under instruction, and in 1911–12 6,780,721.

The number of arts colleges in 1916–17 was 134 with 47,135 students; of professional colleges, 61 with 11,504 students; of special schools, inclusive of training, medical, agricultural, and other technical schools, 4861 with 143,604 students; of secondary schools, 7693 with 1,186,335 pupils; of primary schools, 142,203 with 5,818,730 pupils. In addition to these there were 37,803 private institutions, 3009 of which were advanced with 60,618 pupils, and 34,794 were elementary with 584,020 pupils. The total expenditure on public instruction in 1916–17 was 7,525,537*l*., of which sum there was spent on administration, inspection, scholarships, buildings, furniture, apparatus, etc., 2,239,749*l*. On the arts colleges there was spent 473,583*l*., on the professional colleges 239,961*l*., on the training schools 190,920*l*., on all other special schools 298,474*l*., on the secondary schools 2,128,612*l*., and on the primary schools 1,954,236*l*. There was a total income from fees in 1916–17 of universities, professional colleges, and special technical schools of 107,453*l*., and of secondary schools of 242,620*l*. In 1917 14,799 students matriculated, 4209 qualified for the B.A. examination, 440 for B.Sc., 555 for M.A., and 152 for M.Sc. An elaborate census of education such as this for the United Kingdom would be a welcome contribution to our knowledge of educational affairs.

THE BRITISH ASSOCIATION AT BOURNEMOUTH.

SECTION C.

GEOLOGY.

Opening Address (Abridged) by J. W. Evans, D.Sc., LL.B., F.R.S., President of the Section.

One of the most striking features of our science is the need in which it stands of a large and widely distributed body of workers, and the opportunities it affords to every one of them of making important contributions to scientific knowledge.

Everywhere someone is needed who will devote his spare time to the examination of the quarries and cliffs, where the materials that build up the solid earth are exposed to view, and who will record the changes that occur in them from time to time; for a quarry that is in work, or a cliff that is being undermined by the sea, constantly presents new faces, affording new information, which must be recorded if important links in the chain of evidence are not to be lost. It is equally important that someone should always be on the look-out for new exposures, road or railway cuttings, for instance, or excavations for culverts or foundations, which in too many instances are overgrown or covered up without receiving adequate attention. It is, again, only the man on the spot who can obtain even an approximately complete collection of the fossils of each stratum, and thus enable us to obtain as full a knowledge as is possible of the life that existed in the far-off days in which it was laid down. In his absence, many of the rarer forms which are of unique importance in tracing out the long story of the development of plants and animals, and even of man himself, never reach the hands of the specialist who is capable of interpreting them. It was an amateur geologist, a country solicitor, who saved from the road-mender's hammer the Piltdown skull, that in its main features appears to represent an early human type, from which the present races of man are in all probability descended. Another amateur, who was engaged in the brick-making industry near Peterborough, has provided our museums with their finest collections of Jurassic reptiles. A third, a hard-worked medical man, was the first to reveal the oldest relics of life that had at that time been recognised in the British Isles; and many more examples could be instanced of the services to geological science by those whose principal life-task lay in other directions.

Such workers are, unfortunately, all too few—fewer, I fancy, now than they were before the pursuit of sport, and especially of golf, had taken such a hold upon the middle classes and occupied so considerable a portion of their leisure hours and thoughts. One might hope that the extended hours now assured to the working classes for recreation would lead to a general increase of interest in science among them, if it were not that the students of that admirable organisation, the Workers' Educational Association, seem almost invariably to prefer economic or political subjects to the study of Nature. In a large county in which I am interested the number of those in every condition of life who are able and willing to take part in geological research might be told almost on the fingers of one hand, and, so far as I am aware, there has not been a single recruit in recent years from the ranks of the younger men or women.

It might be suggested that the prevailing indifference to the attraction of geological research was due to a conviction that after eighty years of work by the Geological Survey, as well as by university teachers and amateurs, there was little left to be done, and that all the information that could be desired was to be found in the Survey publications. Such a belief can scarcely be very widespread, for, as a matter of fact, comparatively few of the general public realise the value of the work of the Geological Survey, and still fewer make use of its publications. Municipal libraries, other than those of our largest provincial centres, are rarely provided with the official maps and memoirs relating to the surrounding areas, and in the absence of any demand the local booksellers do not stock them. This cannot be attributed to the cost, for, though most of the older maps are hand-coloured and therefore expensive, the later maps—at least, those on the smaller scales[1]—are remarkably cheap, and the memoirs are also issued at low prices. The true explanation appears to be that a geological map conveys very little information to the average man of fair education who has received no geological instruction. This is certainly not the fault of the Survey maps, which compare very favourably with those of other countries, and have been greatly improved in recent years. In particular, the introduction of a longitudinal section on each map and the substitution of the vertical section drawn to scale for the old colour index must greatly assist those into whose hands it comes in obtaining a correct view of the succession of the strata and the structure of the country. Some of the maps are, it is true, so crowded with information—topographical and geological—that it is frequently difficult, even for the trained geologist, to read them without a lens. This is largely due to the fact that they are printed over the ordinary topographical maps in which there is a great amount of detail that is not required in geological maps. In India the Trigonometrical Survey are always ready to supply, as a basis for special maps, copies of their own maps printed off plates from which a portion of the topographical features have been erased.

The best remedy, however, would be to extend the publication of the maps on a scale of 6 in. to a mile (1 : 10,560). For many years all geological survey work has been, in the first place, carried out on maps of this scale, but they have not been published except in coal-mining areas. There the geological boundaries are printed, but the colouring is added by hand, which makes the maps comparatively expensive. In other localities manuscript copies of the geological lines and colouring on the Ordnance Survey maps can be obtained at the cost of production, which is necessarily considerable. There is, I believe, a wide sphere of usefulness for cheap colour-printed 6-in. geological maps, especially in the case of agricultural and building land, for which the 6-in. Ordnance maps are already in demand. They afford ample room for geological information, and, accompanied by longitudinal sections on the same scale without vertical exaggeration, their significance would

[1] 1 in. to the mile, 1 : 63,360; ¼ in. to the mile, 1 : 253,440, and 1 in. to 25 miles, 1 : 1,584,000.

be more readily apprehended than that of maps on a smaller scale.

It would be of great advantage if there were a uniform usage by which the position in the stratigraphical series of rock outcrops were indicated by colour and their lithological character by stippling (in black or white or colour), following the ordinarily accepted conventions. This course has been pursued by Prof. Watts in the geological map prepared by him to illustrate his "Geography of Shropshire."

Some explanation, apart from the maps themselves, is, however, needed if they are to be rendered, as they should be, intelligible to the general public. The official memoirs which deal with the same areas as the maps do not afford a solution of the difficulty. Excellent as they are from the technical point of view and full of valuable information, they convey little to the man who has not already a considerable acquaintance with the subject. What is needed is a short explanatory pamphlet for each map, presuming no previous geological knowledge, describing briefly and in simple popular language the meaning of the boundary lines and symbols employed, and the nature and composition of the different sedimentary or igneous rocks disclosed at the surface or known to exist below it in the area comprised in the map. A brief account of the fossils and minerals visible without the aid of a microscope should also be included. The probable mode of formation of the rocks and their relation to one another and the subsequent changes they have undergone should be discussed, and at the same time their influence on the agriculture value of the land and its suitability for building sites, as well as on the distribution and level of underground water, pointed out. Some account, too, should be given of the economic mineral products and their applications. These pamphlets should be illustrated by simple geological sections, views of local quarries and cliffs showing the relative positions of the different rocks, figures of the commoner fossils at each horizon, and, where they would be useful, drawings of the forms assumed by the minerals. Each pamphlet would be complete in itself. This would involve a considerable amount of repetition, but it must be remembered that different pamphlets would have, as a rule, different readers.

During the war publications containing desirable information were circulated widely and gratuitously by the authorities to all public bodies concerned, and there seems no reason why the information laboriously gathered by the Geological Survey in the national interests and paid for out of the public funds should not now receive the same treatment. All municipalities, district councils, public libraries, colleges and schools, both secondary and elementary, should receive free copies of the Geological Survey publications dealing with the area where they are situated or with those immediately adjoining it.

Every facility should, of course, be afforded to the public to make use of the Survey publications. They should not only be on sale at the post offices in the areas to which they relate, but it should also be possible to borrow folding mounted copies of the maps as well as bound copies of the explanations and memoirs, on making a deposit equal to their value. When they were no longer required, the amount of the deposit, less a small charge for use, would be repaid on their return to the same or any other post office and the production of the receipt for cancellation. It would thus be possible, when traversing any part of the country, to consult in succession all the Geological Survey publications of the districts passed through. This system would also enable the permanent residents to refer to the more expensive hand-coloured maps, including the 6-in. manuscript maps, at a comparatively small cost.

The Survey publications should be illustrated in every museum and school in the districts with which they deal by small collections showing the characters of the local rocks, and of the minerals and fossils that occur in them, and care should be taken to see that these collections are maintained in good order and properly labelled.

It would be a good plan for the Survey to appoint a local geologist, an amateur or member of the staff of a university or college, in every area of twenty or thirty square miles to act as their representative and as a centre of local geological interest. He would be expected to given his assistance to other local workers who stood in need of it. He would receive little official remuneration, but inquirers in the neighhood would be referred to him, and where commercial interests were involved he would, subject to the sanction of the central office, be entitled to charge substantial fees for his advice. He would report to the Survey any event of geological importance in the area of which he was in charge—whether it was the discovery of a new fossiliferous locality, the opening of a new quarry,[2] the sinking of a well, or the commencement of boring operations. Many of these matters would be adequately dealt with by local workers, but in other cases it might be desirable for the Survey to send down one of their officers to make a detailed investigation.

One of the most important duties of the Survey, or of its local representative, would be to see that the records of well-sinkings and borings are properly kept, and that where cores are obtained the depth from which each was raised is accurately recorded. At the present time the officers of the Survey make every effort to see that this is done, but they have no legal power to compel those engaged in such operations to give the particulars required. Equally important is a faithful record of the geological information obtained in prospecting or mining operations. This is especially necessary where a mine is abandoned. If care is not then taken to see that all the information available is accurately recorded, it may never be possible later to remedy the failure to do so.

Probably these objects would be much facilitated if engineers in charge of boring or mining operations had sufficient knowledge of geology and interest in its advancement to make them anxious to see that no opportunity was lost of observing and recording geological data. This would be in most cases ensured if every mining student were required to carry out geological research as part of his professional training. It is now recognised that no education in science can be considered to be up to university standard if it is limited to a passive reception of facts and theories without any attempt to extend, in however humble a way, the boundaries of knowledge. In the case of geology such research will naturally in most cases take the form of observations in the field. The important point is that the work must be original, on new lines, or in greater detail than before, and not a mere confirmation of published results. It is only by the consciousness that he is accomplishing something which has not been done before that the student can experience the keen pleasure of the conquest of the unknown and acquire the love of research for its own sake.

There is one respect in which geological workers

[2] It is very desirable that arrangements should be made for the co-operation of the Geological Survey or their local representatives with the Inspectors of Quarries appointed by the Home Office, and that the annual official list of quarries should describe the rocks which are worked, not only by their ordinary economic designations, but also by their recognised geological descriptions.

suffer a heavy pecuniary handicap—the cost of railway fares. This affects both the staff and students of colleges, as well as local workers who are extending their radius of work—an inevitable necessity in the investigation of many problems. It also seriously interferes with the activity of local natural history societies and field clubs, the geological societies and associations of the great provincial towns, and, above all, that focus of amateur geological activity—the Geologists' Association of London. It is difficult to exaggerate the importance of these agencies in the promotion of geological education. Both professional and amateur geologists are deeply indebted to the excursions which are in most cases directed by specially qualified workers, with whom it is a labour of love. At the same time one of their most valuable results is the creation of interest in scientific work in the localities that are visited. Now that the railways are, if report speaks truly, to be nationalised, or at any rate controlled by the State, the claims of scientific work, carried out without reward in the national interest, to special consideration will surely not be ignored. All questions as to the persons to whom such travelling facilities should be extended and the conditions that should be imposed may safely be left to the decision of the Geological Survey, which has always had the most friendly and sympathetic relations with private workers and afforded them every facility and assistance which their comparatively limited staff and heavy duties permitted.

There is at the present time a very urgent need for the provision of further facilities for the analysis of rocks and minerals to assist and complete the researches both of the official surveyors and of private persons engaged in research. The work is of a very special character, and the number of those who have given sufficient attention to it and understand its difficulties and pitfalls is very limited.

The analytical work of the Survey is organised on a very modest scale in comparison with the *personnel* and equipment of the laboratory of the United States Geological Survey, though the quality of the work has been, as a rule, in recent years quite as high. There are two analytical chemists attached to the Geological Survey, and some of the other members of the staff are capable of doing good analytical work. The demand, however, for analyses for economic purposes is so great that it is impossible to carry out all the analyses that would be desirable in connection with the purely scientific work of the Survey itself. There is, consequently, no possibility of their being able to assist private investigators.

In the absence of facilities for obtaining rock analyses, petrological work in this country is at present seriously handicapped. A striking illustration of the inadequate provision for analyses is revealed in the fact that for the whole of the early Permian granitic intrusions in the south-west of England, covering nearly two thousand square miles, and including numerous different types and varieties, there are only four analyses in existence, and of these two are out of date and imperfect. This is all the more remarkable in view of the fact that these rocks are closely connected with the pneumatolytic action that has given us almost all the economic minerals of the south-west of England.

Another direction in which the work of the Survey could with advantage be extended is in the execution of deep borings[3] on carefully thought out schemes by which a maximum of information could be obtained. Both in Holland and Germany borings have been carried out to discover the nature of the older rocks beneath the Secondary and Tertiary strata, and Prof. Watts in his presidential address to the Geological Society in 1912, dwelt on the importance of exploring systematically the region beneath the wide spread of the younger rocks that covers such a great extent of the east and south of England. Prof. Boulton, my predecessor in this chair, has endorsed this appeal, but nothing has been done or is apparently likely to be done in this direction. It seems extraordinary that no co-ordinated effort should have been made to ascertain the character and potentiality of this almost unknown land that lies close beneath our feet and is the continuation of the older rocks of the west and north to which we owe so much of our mineral wealth. It is true that borings have been put down by private enterprise, but, being directed only by the hope of private gain and by rival interests, they have been carried out on no settled plan, and the results, and sometimes the very existence, of the borings have been kept secret. The natural consequences of this procedure have been the maximum of expense and the minimum of useful information.

Unfortunately, in recent years percussion or rope-boring, which breaks up the rock into fine powder, has more and more, on account of its cheapness, replaced the use of a circular rotating drill, which yields a substantial cylindrical core that affords far more information as to the nature of the rocks and the geological structure of the district. If private boring is still to be carried on, the adoption of the latter procedure should be insisted on, even if the difference of cost has to be defrayed by the Government. It is quite true that a considerable amount of useful information can be collected by means of a careful microscopic examination of the minute fragments which alone are available for study, so that the nature of the rocks traversed can be recognised: but the texture of the rock is destroyed, as well as any evidence which might have been available of its larger structures and stratigraphical relations, and almost all traces of fossils. It is, too, impossible to tell with certainty the exact depth at which any particular material was originally located, for fragments broken off from the sides of the bore may easily find their way to the bottom.

A good illustration, and one of many that might be cited, of the misdirected energy that is sometimes expended in prospecting operations was afforded a few years ago by a company that put down a boring for oil through more than a thousand feet of granite without being aware of the nature of the rock that was being traversed. In this case a percussion drill was employed, but a few minutes' examination of the material should have enabled the engineer in charge, supposing he had even an elementary knowledge of geology, to save hundreds of pounds of needless expenditure. The sum total of the funds which have been uselessly expended in this country alone in hopeless explorations for minerals, in complete disregard of the most obvious geological evidence, would have been sufficient to defray many times over the cost of a complete scientific underground survey.

If research is to be carried out economically and effectively, it must be organised systematically and directed primarily with the aim of advancing knowledge. If this aim be well and faithfully kept in view, material benefits will accrue which would never have been thought to be sufficiently probable to warrant the expenditure of money on prospecting.

It is, however, not only in the areas occupied by Secondary or Tertiary rocks that systematic boring is urgently needed. There are many other localities where important information as to the structure of

[3] I have not space to deal here with the shallow borings in soft strata which have been so successfully conducted on the Flanders front during the war by Capt. W. B. R. King, of the Geological Survey.

the rocks could probably be obtained in this manner. Opinion is very much divided as to the relation of the Devonian to the older rocks in South Devon and Cornwall, but there is little doubt that a series of judiciously placed borings would solve the problem without difficulty. In North Devon and West Somerset the question as to whether the Foreland Grits are a repetition by faulting of the Hangman Grits could also be settled at once by borings in the Foreland Grits and in the Lynton beds.

It is not, however, on *terra firma* alone that such investigations may be usefully carried out. The floors of the shallow seas that separate these islands from one another and from the continent of Europe are still almost unknown from the geological point of view, although their investigation would present no serious difficulties. Joly has described an electrically driven apparatus which, when lowered so as to rest on a hard sea-floor, will cut out and detach a cylindrical core of rock, and retain it until raised to the surface. Afterwards he invented a still more ingenious device, in which the force of the sea-water entering an empty vessel is substituted for electrical power, but, unfortunately, neither the one nor the other has actually been tried or even constructed.

Meantime, however, vertical sections up to 80 cm. of the mud of the deep seas have actually been obtained in iron tubes attached to sounding apparatus employed in the course of the voyage of the *Gaussberg*. These reveal a succession of deposits of which the lower usually indicate colder water conditions than the upper.

In many places rock fragments are dredged up by fishing-boats. These should, of course, be used with caution in drawing conclusions as to the distribution of rocks *in situ* on the sea-bottom, as such fragments may have been transported when embedded in ice-sheets or in icebergs or other forms of floating ice, or entangled in the roots of floating trees; but where the rock fragments can be shown to have a definite distribution, as in those described by Grenville Cole and Thomas Crook from the Atlantic to the west of Ireland, and by R. H. Worth from the western portion of the English Channel, they may be regarded as affording trustworthy information as to the geology of the area.

There seems every reason to believe that advances in submarine geology will not be only of scientific interest, but will bring material benefits with them. It seems quite possible that off the shores of Northumberland and Durham there are, in addition to extensions of the neighbouring coalfield, Permian rocks containing deposits of common salt, sulphate of calcium (gypsum and anhydrite), and, above all, potash salts comparable to those at Stassfurt, which have proved such a source of wealth to Germany.

No less important than the work of the Geological Survey is that of our great national museums. I have already alluded to the need for local collections to illustrate the geology of the areas in which they are situated. The museums of our larger cities and our universities will naturally contain collections of a more general character, but it is to our national museums that we must chiefly look for the provision of specimens to which those engaged in research can refer for comparison, and it is imperative that they should be maintained in the highest state of efficiency if the best results are to be obtained from scientific investigations in this country. The ability and industry of the staff of the mineral and geological departments of the Natural History Museum are everywhere recognised, as well as their readiness to assist all those who go to them for information, but in point of numbers they are undeniably insufficient to perform their primary task of examining, describing, arranging, and cataloguing their ever-increasing collections so as to enable scientific workers to refer to them under the most favourable conditions.[4] Even if the staff were doubled, its time would be fully occupied in carrying out these duties, quite apart from any special researches to which its members would naturally wish to devote themselves. The additional expense incurred by the urgently needed increase of the museum establishment would be more than repaid to the country in the increased facilities afforded for research.

There is room, too, for a considerable extension in the scope of the activity and usefulness of our museums in other directions, and more especially in the provision of typical lithological collections illustrating the geology of different parts of the British Empire and of foreign countries.

So far as the United Kingdom is concerned, this requirement has been admirably fulfilled in the museums attached to the Survey headquarters in London, Edinburgh, and Dublin, and there is a smaller collection of the same nature, excellent in its way, at the Natural History Museum. But to obtain a broad outlook it is essential that the attention of geological workers should not be confined to one country, however diversified its rocks may be, and it is impossible to assimilate effectively publications dealing with the geology of other parts of the world without being able to refer to collections of the rocks, minerals, and fossils described.

Such collections should include not only rock specimens in the ordinary sense of the term, but also examples of metalliferous veins and other mineral deposits which present important distinctive features.

The lithological and palæontological collections which I am now advocating should be arranged so that each group of specimens illustrates an area possessing distinctive geological features. Little has hitherto been done in this direction. The mineral department of the Natural History Museum possesses a large and extensive collection of foreign and Colonial lithological specimens arranged according to localities, which is too little known, but it is naturally very unequal and incomplete, some countries being comparatively well represented and others scarcely at all. The geological department of the museum is well provided with palæontological specimens, but these are arranged according to their biological affinities, and they might well be supplemented by a series of typical collections illustrating the fauna and flora of the more distinctive horizons in different areas. This is all the more important, as the mode of preservation may be very different in different places. The provision of such facilities for the study of the geology of other lands is especially desirable in London in view of the number of students of mining and economic geology who receive their training in this country and ultimately go out into the world to find themselves face to face with problems in which a true understanding of the local geology is absolutely essential.

* * * * * *

It is more difficult to arrive at the true interpretation of the phenomena presented by the endogenetic rocks[5] which have come into existence by the action of the forces of the earth's interior, for the conditions of temperature and pressure under which they were formed, whether they are igneous rocks in the narrower sense, or mineral veins, or metamorphic in

4 Even the number of skilled mechanics is quite insufficient, though their work is urgently needed. In the Geological Department provision is made for two only, and at present but one is actually at work.
5 T. Crook, *Min. Mag.*, vol. xvii., p. 87, 1914.

origin, were widely different from those with which we are familiar. In such circumstances the ultimate physical principles are the same, but the so-called constants have to be determined afresh, and a new chemistry must be worked out. It is necessary, therefore, so far as possible, to reproduce the conditions that prevailed—a task which has been courageously undertaken and, to a considerable extent, accomplished by the geophysical laboratory of the Carnegie Institution of Washington.

By artificial means temperatures and pressures have been already produced far higher than those that were in all probability concerned in the evolution of any of the rocks that have been revealed to us at the surface by earth-movements and denudation, for it is unlikely that in any case they were formed at a greater depth than five or six miles, corresponding with a uniform (or, as it is sometimes termed, hydrostatic) pressure of 2000 or 2400 atmospheres, or at a greater temperature than 1500° C. Indeed, it is probable that the vast majority of igneous and metamorphic rocks, as well as mineral veins, came into existence at considerably less depths, and at more moderate temperatures. It is true that most of the rock-forming minerals crystallise from their own melts at temperatures between 1100° C. and 1550° C., but they separate out from the complex magmas from which our igneous rocks were formed at lower temperatures.

It has been found possible at the geophysical laboratory to maintain a temperature of 1000° C. or more under a uniform pressure of 2000 atmospheres for so long a time as may be desired, and, what is equally important, the temperature and pressure attained can be determined with satisfactory accuracy, the temperature within 2° C., and the pressure within 5 atmospheres.

It has been ascertained that such uniform pressure as would ordinarily be present at the depths mentioned does not directly affect the physical properties of minerals to anything like the same extent as the difference between the temperature prevailing at the earth's surface and even the lowest temperature at which igneous rocks can have been formed. It has, however, a most important indirect action in maintaining the concentration in the magma of a considerable proportion of water and other volatile constituents[6] which have a far-reaching influence in lowering the temperature at which the rock-forming minerals crystallise out—in other words, the temperature at which the rock consolidates—and in diminishing the molecular and molar viscosity of the magma, thus facilitating the growth of larger crystals and the formation of a rock of coarser grain. They must also be of profound significance in determining the minerals that separate out, the order of their formation, and the processes of differentiation in magmas.

It is, therefore, obvious that any conclusions derived from the early experiments which were carried out with dry melts at normal pressures must be received with very considerable caution. Nor does much advance appear to have been made, even at the geophysical laboratory, in experiments with melts containing large amounts of volatile fluxes, and yet, if we are to reproduce even approximately natural conditions, it is absolutely necessary to work with magmas containing a proportion of these constituents, and especially water, equal in weight to at least one-third or one-half of the silica present. This will obviously present considerable difficulties, but there is no reason to doubt that it will be found possible to surmount them.

A much more formidable obstacle in realising the conditions under which rocks are formed is the small scale on which our operations can be carried on. There are important problems connected with the differentiation of magmas, whether in a completely fluid or partly crystallised state, under the action of gravitation, for the solution of which it would seem for this reason impossible to reproduce the conditions under which Nature works. Instead of a reservoir many hundreds of feet in depth, we must content ourselves in our laboratory experiments with a vertical range of only a few inches. There are, however, other phenomena that require investigation and that involve a great difference of level in their operation, but do not take place at such elevated temperatures. Such are some of the processes of ore deposition or transference, especially secondary enrichment. Here, with the friendly assistance of mining engineers, but at the cost of considerable expenditure, it might even be possible to experiment with columns several thousand feet in vertical height.

In any attempt to reproduce the processes of metamorphism other than those of a purely thermal or pneumatolytic character, or to imitate the conditions that give rise to primary foliation, we must consider the effects of non-uniform or "directed" pressure involving stresses that operate in definite directions and result in deformation of the material on which they act. Unlike uniform pressure, which usually raises the crystallisation point, directed pressure may lower it considerably and thus give rise to local fusion and subsequent recrystallisation of the rock. At the same time it profoundly modifies the structure, resulting in folds and fractures of every degree of magnitude. One of the most pressing problems of geology at the present moment is to determine the effects of directed pressure in its operation at different temperatures, and in the presence of different amounts of uniform pressure, a factor which has probably an important influence on the result, which must also depend on the proportion and nature of the volatile constituents which are present, as well as on the time during which the stresses are in operation.

The time elements in the constructive or transforming operations of Nature cannot, of course, be adequately reproduced within the short space of individual human activity, or, it may be, that of our race; but I am inclined to think that, even in the case of metamorphic action, the importance of extremely prolonged action has been exaggerated.

In attempting to imitate the natural processes involved in the formation and alteration of rocks and mineral veins, we require some means of ascertaining when we have approximately reproduced the conditions which actually prevailed. It is not sufficient to bring about artificially the formation of a mineral occurring in the rocks or mineral deposits under investigation, for the same mineral can be reproduced in many ways. It is, however, probable that a mineral produced under different conditions is never identical in all its characters. Its habit, or the extent to which its possible faces are developed (a function of the surface tension), the characters of the faces which are present, its twinning, its internal structure, inclusions, and impurities, all vary in different occurrences, and the more closely these can be reproduced the greater the assurance we obtain that an artificial mineral has been formed under the same conditions as the natural product.

For this purpose it is, above all, necessary that there should be in the first place a systematic comparative study of these characters and of the association in which they are found. The results thus obtained should be of the greatest value in indicating the directions along which experimental work would

[6] John Johnston, Journ. Franklin Inst., January, 1917, pp. 14–19.

be most probably successful. They should be supplemented by laboratory studies of the relations of such subsidiary crystallographic characters to the environment in the case of crystals which can be formed under normal conditions of temperature and pressure, and therefore under the immediate observation of the experimenter. Some work has, in fact, already been done on the effects on these characters of the presence of other substances in the same solution.

In the study of the secondary alterations of metalliferous deposits, especially those which consist of the enrichment of mineral veins by the action of circulating solutions, either of atmospheric or intratelluric origin, the study of pseudo-morphs gives, of course, valuable assistance in determining the nature of the chemical and physical changes that have taken place.

The problem of the structure and nature of the earth's interior, inaccessible to us even by boring, would seem at first sight to be well-nigh insoluble, except so far as we can deduce from the dips and relations of the rocks at the surface their downward extension to considerable depths. We can, however, gain important information about the physical condition of the deeper portions from the reaction of the earth to the external forces to which it is subjected, and still more from a study of the "preliminary" earthquake tremors that traverse it, the time occupied in their passage, and the difference in intensity of those that follow different paths. These methods are, however, not applicable to the earth's crust. Its physical characters appear to be distinct from those of the interior, but very little is as yet definitely known about them, except, of course, in the neighbourhood of the surface, and for this reason they are usually ignored in calculating the paths of tremors traversing the earth. It seems to be separated from the deeper portions of the earth by a surface of discontinuity at which earthquake vibrations travelling upwards towards the surface may be reflected. Calculations based on the total time taken by these reflected waves to reach the surface after a second passage through the earth's interior appear to indicate that this surface of discontinuity, whatever its nature may be, is at a depth of about twenty miles, though there can be little doubt that this depth varies considerably from point to point.

There must be numerous surfaces of discontinuity in the earth's crust in addition to that forming its lower limit. Such would be the boundaries between great tracts of granite or granitoid gneiss and the basic rocks that in all probability everywhere underlie them; the surface dividing gneisses and crystalline schists from unmetamorphosed sediments overlying them unconformably; that between hard Palæozoic rocks and softer strata of later age; and the surfaces of massive limestones or sills.

It deserves consideration as to how far it may be possible to add to our knowledge of the earth's crust by experimental work with a view of the determination of surfaces of discontinuity by their action in reflecting vibrations from artificial explosions, a procedure similar to that by means of which the presence of vessels at a distance can be detected by the reflection of submarine sound-waves. The ordinary seismographs are not suited for this purpose; the scale of their record, both of amplitude and of time, is too small for the minute and rapid vibrations which would be expected to reach an instrument situated several miles from an explosion, or to distinguish between direct vibrations and those that may arrive a second or two later after reflection at a surface of discontinuity. As the cylinder on which the record is made would be only in motion while the experiment was in progress, there would be no difficulty in arranging for a much more rapid movement. At the same time it would be desirable to dispense with any arrangement for damping the swing of the pendulum, which would be unnecessary with small and rapid vibrations, and would tend to suppress them. It is possible that it might be better to employ a seismograph which records, like that devised by Galitzin shortly before his death, variations of pressure expressing terrestrial acceleration, instead of one which records directly the movements of the ground. It would, however, probably be found desirable to substitute for the piezo-electric record of pressure employed by Galitzin a record founded on the effect of pressure in varying the resistance in an electric circuit. This is, in fact, the principle of the microphone and most modern telephone receivers, but quantitatively they are very untrustworthy. This would not matter so much for the present purpose, where the time of transmission is the most important feature in the evidence.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—Mr. B. M. Jones, Emmanuel College, has been elected to the Francis Mond professorship of Aeronautical Engineering at the University, founded by Mr. Emile Mond in memory of his son, who was killed in the war. This is the first professorship in aeronautics which has been filled in this country. Mr. Jones entered Emmanuel College as an Exhibitioner in 1906. He afterwards became a scholar, and obtained First Class Honours in the Mechanical Sciences Tripos of 1909. From 1910 to 1912 he was employed on aeronautical research at the National Physical Laboratory, and held a research scholarship from the Imperial College, London. In the capacity of an assistant he continued in this work until May, 1913, when he left the National Physical Laboratory to take up the design of rigid airship construction and other aeronautical work for the firm of Sir G. W. Armstrong, Whitworth, and Co. In September, 1914, Mr. Jones joined the Royal Aircraft Establishment, and remained there, carrying out aeronautical research and experimental work until May, 1916. He was then transferred to the Armament Experimental Station, Orford Ness, with the rank of captain, R.F.C., eventually rising to the position of Assistant Controller of Experiment and Research with the rank of lieut.-colonel. His chief activities were directed towards aerial gunnery and aerial bombing, and in order to gain first-hand experience of fighting conditions he qualified as a pilot and served with No. 48 Squadron, R.F.C., in France during the early months of 1916. On being demobilised in March last, Mr. Jones was elected a junior fellow of Emmanuel College, with the post of director of engineering studies at the college.

Sheffield.—The council has received with much regret the resignation of Prof. J. O. Arnold, dean of the faculty of metallurgy and professor of metallurgy in the University since 1889. Steps will shortly be taken to appoint a successor.

Dr. J. G. Stewart has been appointed lecturer in engineering at University College, London.

A chair of laryngology has recently been established in the University of Paris, the first occupant of which is to be Dr. Sebileau.

The sum of 400,000*l*. has been bequeathed to the University of Sydney by Sir Samuel McCaughey.

The University of Brisbane will receive 250,000*l*. from the same source.

PROF. ALEX. FINDLAY desires it to be known that after October 1 his address will not be the University College of Wales, Aberystwyth, but the Chemistry Department, the University, Marischal College, Aberdeen.

THE School of Librarianship, instituted at University College, London, will be opened by Sir Frederic Kenyon on Wednesday, October 8, at 5 p.m. Cards of invitation and particulars of the work of the school may be obtained from the Secretary, University College, Gower-street, W.C.1.

THE programme of University Extension lectures for the coming session has now been issued by the University of London. Central courses are to be held in the University buildings and in the City, while local courses, at some sixty local centres in and around London, will prove of value to the student in the suburbs. The subjects treated cover a wide range, but science occupies a minor position among them. There are to be about ninety courses in all, and these are mainly on literature, economics, history, and architecture, progressive science being represented by two courses only on scientific discoveries and their practical application. Either the local committees of London University Extension centres are not interested in scientific subjects, or the Board is unable to offer a strong panel of science lecturers for their selection.

SOCIETIES AND ACADEMIES.

MELBOURNE.

Royal Society of Victoria, July 10.—Mr. J. A. Kershaw, president, in the chair.—H. G. **Smith**: The essential oil of *Boronia pinnata*, Smith, and the presence of elemicin. The plants were collected at Longwarry, where it grows in great profusion, and the distillation was carried out by Mr. P. R. H. St. John. The product consists largely of elemicin, which has previously occurred only in the order Burseraceæ (Protium, elemi resin), whilst Boronia belongs to the Rutaceæ.—J. T. **Jutson**: The "clawing" action of rain in sub-arid Western Australia. The author describes the erosion on ground generally covered by hard capping due to surface deposits of hard mineral matter. When this capping is broken, miniature waterfalls are formed, and at lower levels basins with crenulated edges, with a gradual reduction of rock material from high to low levels. The "clawing" action of the rills is so marked as to deserve special notice.—J. T. **Jutson**: A striking example of rock expansion by temperature variation in sub-arid Western Australia. This note puts on record an instance of a thin slab of granite parting from the main mass and rising convexly 7 in. from its base before cracking and breaking up.—E. O. **Teale**: The diabase and associated rocks of the Howqua River, near Mansfield, with reference to the Heathcotian problem in Victoria. A study of this interesting area of the Howqua district with its Lower Carboniferous, Upper and Lower Ordovician, and older rocks throws much light on the sequence of the Lower Palæozoic series in other areas. Cherts and bedded ash with radiolaria and sponge-remains are found, similar to those of Heathcote, and an interesting phosphate-breccia with trilobite remains is described, which is closely associated with Upper Ordovician rocks.—F. **Chapman**: An Ostracod and Shell-marl of Pleistocene age from Boneo Swamp, west of Cape Schanck, Victoria. This deposit of marl, which does not now appear to be subject to tidal influence, contains an interesting fauna of fresh- and salt-water Ostracoda, and swamp, land, and marine shells. Two of the Ostracods are new, *Cypris tenuisculpta* and *Limnicythere sicula*. It is probable that in late Pliocene and on to Pleistocene times this area was connected with N.W. Tasmania, as an emergence of Bass Strait of 40 fathoms would show the earliest land connection at these points. This theory is supported by the occurrence of Limnicythere both at Boneo and Mowbray Swamps.

(4) *Dynamics. Part II.* By R. C. Fawdry. (Bell's Mathematical Series.) Pp. viii+179–355+vii. (London: G. Bell and Sons, Ltd., 1919.) Price 2*s.* 6*d.*

(5) *Solid Geometry, including the Mensuration of Surfaces and Solids.* By Prof. R. S. Heath. Fourth edition. Pp. iv+123. (London: Rivingtons, 1919.) Price 4*s.*

(1) ONE of the most important activities of the practical, as well as of the theoretical, man of science is the discovery of laws. Given a number of observations, the problem is to correlate them in the form of a single analytical expression. The basis of such discovery is the recognition of a curve as being one the equation of which is known. But, strictly speaking, there is only one curve that is really recognisable, and this is the straight line. A piece of a circle can easily be mistaken for a piece of an ellipse, and a parabola for a catenary; but if a sufficiently long piece of a curve is straight, then the curve can be pronounced to be a straight line. If, then, it is possible to plot the results of observation in such a way that the resulting points lie on a straight line (even if there are some casual, experimental errors and consequent deviations), then we can at once deduce the law.

This fact underlies the major part of Prof. Running's monograph. The author summarises the most useful types of laws that are reducible to straight-line laws by means of simple transformations. He also gives practical rules for deciding whether such a law is correct for the given data and for the determination of the constants. Nineteen laws are discussed, and illustrated by means of numerical examples, whilst curves are drawn to show graphically the types of relations given by these laws.

A twentieth law is the Fourier expansion. Chapters are added on the method of least squares, interpolation, and numerical integration. The result is an eminently useful handbook for the scientific researcher and the practical engineer, and a highly commendable adjunct to the more theoretical study of mathematics.

The pedagogy is, however, somewhat defective. It is difficult to imagine such a book in the hands of a student. The philosophy of the subject is scarcely entered into at all, and in places, where an attempt at justification is made, the result is not satisfactory. Also, one question remains unanswered: How is one to guess which law to try? Is one to try them all one after the other until the right one is reached? And what if none of those given is correct? Information on this and other points is very desirable, but none is offered.

One or two definite criticisms must be made. The different schemes in the chapter on Fourier series are not always consistent, and some are incomplete. No explanation is given of the meaning of "weights" in the method of least squares. In the chapter on interpolation the difference formula is proved only for integral values of the argument, and then applied to fractional values. In addition, there are a few misprints and some evidences of carelessness. The book thoroughly deserves a second edition, in which, it is hoped, these and other faults will be rectified.

(2) This is a very good book on the calculus, written in the old style with which we have been familiarised by writers like Edwards and Williamson. It is very well written and compact in form; the diagrams are good, and the exercises excellent. Particular attention is paid to questions of a practical nature. The student who has worked through this book conscientiously will have a good, if dull, appreciation of the subject and its manipulation. A few of the pages are headed "Unconventional Methods," but the thrill one gets on seeing this only leads to disappointment. There is nothing unconventional in an involute or in a parabola rotating about an axis.

The second part (which is also issued separately) includes the usual chapters on differential equations and the usual box of tricks.

This book, like so many others, gives the student the impression that there is just one particular integral of a linear differential equation in which the right-hand side is a function of the independent variable. It is more useful to inform the student that there are, of course, an infinite number of particular integrals, but that one of them is obtainable most readily and directly.

In Ex. 3, p. 10, of the second part it would have been more reasonable to put a negative sign to indicate the retarding effect of friction.

(3) Dr. Milne and Mr. Westcott have given expression to an important and fundamental principle in mathematical pedagogy—namely, the secondary nature of the manipulative art, and the first-rate importance of the ideas and methods of mathematics. They have recognised that the main part of the essence of the calculus, and even the most important practical applications of its processes, can be taught and learnt without using anything but the simplest of all functional types —namely, x^n and combinations of powers of x. When once the student has learnt to differentiate x^n, he is ready for much of the mysterious dis-

cipline that constitutes the black art of the calculus method. He can do dynamical problems without the aid of confusing formulæ; he can measure the volume of a tree; he can enclose land economically; he can draw tangents and normals; he can find radii of curvature; he can even solve differential equations. The authors, having recognised this fact, have acted upon it boldly and frankly, with the result that they have produced a book of a peculiarly suggestive and persuasive kind. Both authors are experienced teachers of mathematics, and the practical touch introduced by the physical propensities of one of them is everywhere noticeable. It is also refreshing to see $dy/dx=f(x)$ treated as a differential equation.

The merit of the book is somewhat marred by a few faults, and especially by the mediocre diagrams. Some are not well produced, whilst others are not even well drawn. The authors, or their artistic representative, seem to have an unfailing belief that a circle in perspective can be represented by two circular arcs intersecting at sharp angles. This is a gratuitous trap for the unwary.

The style is splendid. The preface is worth reading for its own sake, whilst the historical sketch with Isaac Barrow's prayer will interest even such students as are not excited by Guldinus's and Pappus's theorems.

(4) Many teachers have experienced the want of books on mechanics more advanced than the easy text-books used in schools, and not so advanced as the larger treatises intended for specialists in mathematics. Mr. Fawdry's books are supplying this want, and the present volume is a further contribution to the author's series of books on mechanics. This volume forms the second part of his "Dynamics," and discusses such subjects as differentiation and integration as used in dynamics, harmonic motion, and easy two-dimensional rigid dynamics. The work is well done. The experimental hints, the numerical illustrations of dynamical laws and results, and the very practical examples all help to make the subject attractive and intelligible. There is some lack of logic in the arrangement, and the impression one gets is that of scrappiness. The chapter on harmonic motion, *e.g.*, seems out of place in the middle of a discussion of rigid dynamics.

Mr. Fawdry wastes time in proving that the acceleration d^2x/dt^2 can be written vdv/dx. Surely it must be a part of fundamental dynamical doctrine that:

Number of units of force = time rate of momentum;

Number of units of force = space rate of kinetic energy.

This saves much trouble and memory-searching. One cannot feel angry with a student who forgets the trick of "multiplying by twice the velocity" to get the energy equation.

The figure on p. 271 is unfortunate: when a spiral spring is stretched, the pitch is increased.

One can heartily recommend this as a sound book that will be found very useful both in itself and as an introduction to the larger treatises on the subject.

(5) The fact that a new edition is called for of Prof. Heath's "Solid Geometry" proves that it has been found to serve its purpose as an introduction to those parts of the subject that are required for their practical usefulness. The book, while making no pretence to pedagogical originality, is a very good collection of the most useful theorems and problems in solid geometry. It includes the geometry of the regular solids, spherical geometry, and the mensuration of the sphere. There are a large number of examples with some hints for their solution.

S. BRODETSKY.

VAGUENESS AND DISCRIMINATION.

(1) *The Intuitive Basis of Knowledge. An Epistemological Inquiry.* By Prof. N. O. Lossky. Authorised translation by Nathalie A. Duddington. With a preface by Prof. G. Dawes Hicks. Pp. xxix + 420. (London: Macmillan and Co., Ltd., 1919.) Price 16*s*. net.

(2) *Cultural Reality.* By Dr. Florian Znaniecki. Pp. xv + 359. (Chicago: The University of Chicago Press; London: Cambridge University Press, 1919.) Price 2.50 dollars net.

IT is extraordinary how difficult it seems to be (and how fearfully long the argument is) to convince a man that what he is quite ready to believe, until you make him doubt it, is true. Natural realism—the theory that the objects of knowledge are in themselves what they are represented to be in our knowledge, that knowledge is the discrimination by the mind of a reality awaiting discrimination—is, I suppose, the philosophical theory of knowledge we all hold until we are philosophers consciously philosophising. Tables and chairs are just tables and chairs, and would be such, so far as their essential form and matter are concerned, were there no mind, or, as the realist prefers to say, were there no act of discrimination, in the universe. We all believe it, but let us once challenge a realist philosopher to prove it—he may be able to, but, unlike the Rabbi called on to expound the whole of the law and the prophets, not while you stand on one foot.

(1) Prof. Lossky's "Intuitive Basis of Knowledge" is admirably translated and very clear and easy to read. The translator, Mrs. Duddington, is eminently qualified for the work, not merely by her knowledge of the original language, but also by what is far more important, her complete sympathy with the philosophical view of the author. The book is prefaced by a particularly lucid "Introduction" by Prof. G. Dawes Hicks, who, though not in entire agreement with the author, is very sympathetic towards his point of view. Prof. Hicks expresses surprise that a professor in a Russian university should have reached conclusions so strikingly in accord with his own, but, though Petrograd may be a long way from London, it is no further from

Berlin and the German universities than London is, and Prof. Lossky is known to many of us by his part in the International Congresses of Philosophy. He is, in fact, thoroughly cosmopolitan so far as his qualifications in philosophy are concerned. The title of his book might lead the reader to expect a theory in accord with some of the more noticeable modern developments, such as Bergson's doctrine of instinct or Croce's æsthetic activity, but intuition has not any such distinctive meaning for Prof. Lossky. He means by the intuitive basis of knowledge merely the vagueness with which the object of knowledge exists undiscriminated, before it is discriminated. This, of course, is the crucial point of realist theory. What it has to account for primarily is "vagueness," in the precise and not vague meaning of the term. According to the realist theory, tables and chairs are, so far as their basis in reality is concerned, the same for men and for guinea-pigs. Apart from acts of discrimination, men and guinea-pigs are on one level of knowledge. What is that? Well, the answer is what the realists are trying to give us, and perhaps if we are patient and allow them time enough they will succeed.

(2) It is not easy to indicate any particular connection between Prof. Lossky's book and Dr. Znaniecki's "Cultural Reality." Their names might suggest that they share an Eastern European viewpoint, if such there be. But, as Dr. Znaniecki is lecturer in the University of Chicago, it is not surprising that the philosophy of the New World—Pragmatism and New Realism—mainly occupies his attention. "Culturalism" is the thesis that there are an objective reality and a subjective adaptation that both change, and change more profoundly than can be expressed by the advance of knowledge by discrimination. It is an attempt to blend the realist theory that there is an object on which the only mental work is discrimination with the pragmatist theory that we make truth. The idea apparently is that from the two separate worlds of things and values there arises a third reality, which is irreducible to either—cultural reality *sui generis*. The primitive material is not conceived as vague, but as a "concrete chaos of historical reality."

IRON AND STEEL PRODUCTION IN GREAT BRITAIN DURING THE WAR.

The Iron and Steel Industry of the United Kingdom under War Conditions: A Record of the Work of the Iron and Steel Production Department of the Ministry of Munitions. By Dr. F. H. Hatch. Pp. xii+167. (London: Privately printed for Sir John Hunter by Harrison and Sons, 1919.)

On account of the vastness of the field covered, the variety and complexity of the technical problems involved, and the far-reaching industrial questions raised, the activities of the Iron and Steel Production Department of the Ministry of Munitions during the war form a subject of surpassing interest and importance. The history of this great work has been written by Dr. F. H. Hatch, himself a member of the Department.

The narrative falls naturally into two divisions, namely, (1) that of the small Steel Department which was formed as a branch of the Materials Department, of which Sir Leonard Llewelyn was director, and (2) that of the much larger organisation formed by Sir John Hunter when he became Director of Iron and Steel Production in August, 1916.

Sir John Hunter was confronted with a very difficult task. The demand for various types of steel for munitions and shipbuilding was growing rapidly while the supply of raw materials essential for their manufacture was threatened with curtailment, if not complete suspension, so far as foreign sources were concerned, by the activity of German submarines. The only sound remedy was the development of home resources, but the substitution of lean phosphoric ironstones such as constitute the main portion of British iron ores for the rich ores imported principally from Spain and the Mediterranean, involved such sweeping changes in plant, supplies, inland transport, labour, etc., that it could only have been carried out with difficulty even in peace-time. Under war conditions it was evident that the problem would require the most skilful handling by a carefully organised department. In spite of difficulties which at times appeared to be almost insuperable, Sir John Hunter's "Basic Iron Program" obtained a high measure of success, and enabled the urgent and incessant calls of the great Service Departments for ship plates, shells, and other munitions requiring steel in their manufacture to be punctually and duly met.

It is a remarkable tribute to the inherent but not always obvious organising power of the nation that under the adverse conditions of a great war it should have been possible to raise the steel production of the country to the highest point it has ever reached in the history of the industry. Under the stress of necessity raw materials which had been allowed to lie dormant in this country were rapidly developed and brought to the producing stage. Iron ores in Oxfordshire, coking coal in Scotland, ganister for silica bricks, moulding sands for foundry work, and refractory sands for open hearth furnace bottoms, are instances in point. Whereas in 1913 and 1914 the total steel output was 7·66 and 7·83 million tons respectively, it had risen in 1917 to 9·71 million tons, and during the first half of 1918 it was at the rate of close on 10 million tons per annum. The plans of the Department provided ultimately for an increase to 12 million tons annually. Dr. Hatch suggests two main reasons for the success obtained; these are (1) the trust reposed by Sir John Hunter in the members of his staff, which was entirely reciprocated, and (2) the fact that manufacturers cordially co-operated in the plans of the Ministry and loyally concentrated on war work. According to him, many firms readily fell in with the suggestions of the Department to depart from routine practice and embark on experimental work, often at a considerable financial loss to themselves.

OUR BOOKSHELF.

Pre-History in Essex, as Recorded in the Journal of the Essex Field Club. By S. Hazzledine Warren. (Essex Field Club Special Memoirs, vol. v.) Pp. vii+44. (Stratford, Essex: The Essex Field Club; London: Simpkin, Marshall, and Co., Ltd., 1918.) Price 2*s*. 6*d*. nét.

THE title "Pre-History in Essex" would suggest that the subjects treated in this special memoir are entirely prehistoric. But we find mentioned papers such as "Fifty Years Ago in Essex," "Tree-Trunk Waterpipes," "The Coming of Age of the Essex Field Club" (1901), etc. Indeed, the number of papers on various subjects mentioned is such that in most cases two or three lines comprise all the explanation of their nature.

Among the few subjects to which more space is given are the Deneholes of Hangman's Wood. Mr. Warren does not take the view given in the report on the Denehole Exploration at Hangman's Wood (*E. Nat.* 1, 1887), but considers that "they possess in every way the normal character of comparatively modern chalkpits" (p. 34). Now about half a mile west of Hangman's Wood is the eastern margin of an area of bare chalk extending thence to Purfleet, besides much smaller exposures of chalk near Little Thurrock and East Tilbury, with modern chalkpits in each place mentioned. Hence modern chalkpits at Hangman's Wood, where the chalk is about 60 ft. beneath the surface, where each pit occupies a very small horizontal space, and is separated from the other pits, and shaped so as to show intended separation, are surely incredible. And the evidence is surely in favour of the E.F.C. Exploration view that these deneholes were family stores. Then the notion of the E.F.C. explorers that *dene*holes meant *den*holes was considered by that eminent philologist, the late Sir J. A. H. Murray, to be incorrect, *dene*holes being *Dane*holes.

However, "Pre-History in Essex" will form a decidedly useful list of the papers published by the Essex Field Club since 1880.

T. V. HOLMES.

The Chemists' Year-Book, 1918–19. Edited by F. W. Atack, assisted by L. Whinyates. Vol. i., pp. vi+422; vol. ii., pp. iv+423–1146. (London and Manchester: Sherratt and Hughes, 1919.) Price 15*s*. net 2 vols.

THE chemical pocket-books used in this country before the recent war were chiefly of German origin. Mr. Atack brought out the first edition of his "Year-Book" in 1915: its appearance indicated that, as with sundry other chemical products and adjuncts, we were quite capable of supplying our own requirements in this respect.

A large amount of information has been packed into the two small volumes. Much of the space is devoted to tables showing the chief physical and chemical properties of numerous organic and inorganic substances—their formulæ, molecular weights, boiling-points, and so on. There are also the ordinary tables of specific gravity, solubility, etc., and much useful matter of a miscellaneous kind, including historical references, mensuration data, and lists of scientific journals. In addition, the volumes include a number of short articles which summarise the theory and practice of various branches of chemical technology. Thus, to mention only a few by way of examples, there are sections on electro-chemical analysis, fuels, dairy products, brewing materials, textile fibres, dyestuffs, tobacco, and photography. These condensed accounts serve to furbish up the reader's acquaintance with branches of work in which he may have become "rusty."

Several new sections have been added to the present edition. They include one on agricultural chemistry by Dr. E. J. Russell, and one on the analysis of ceramic materials by Dr. Mellor. Other parts of the work have undergone a general revision, and chemists will find the "Year-Book" a convenient and useful *vade mecum*.

The Geographical Part of the Nuzhat-Al-Qulūb. Composed by Hamd-Allāh Mustawfī of Qazwīn in 740 (1340). Translated by G. Le Strange, and printed for the Trustees of the "E. J. W. Gibb Memorial." Vol. xxiii. Pp. xix+322. (Leyden: E. J. Brill; London: Luzac and Co., 1919.) Price 8*s*.

WE have here an English translation of the original Persian text of the "Nuzhat-Al-Qulūb" published in this valuable series three years ago. The author, Hamd-Allāh, was a man of note in his day, holding the post of Mustawfī, or State Accountant, to Abu Sa'īd, the last of the decadent Ilkhan dynasty, the first Mongol rulers of Persia, and great-grandson of Hulāqu, the conqueror of Baghdad. The author must have been in possession of much geographical and statistical information, and in many ways his account of Persia and Mesopotamia in the middle of the fourteenth century is valuable; but he depended largely on materials collected by other writers, much of which is now available in published texts. The book takes the form of a gazetteer, but, except as regards places like Qazwin, the author's native city, little new information is forthcoming. Perhaps the best chapter is that describing the mines of western Asia producing metals, precious stones, and other minerals. His science is that of his own day, that of the scriptures and traditions of Islam, as when he tells us that one of the chief values of mountains is that they prevent the ground from moving. But the treatise abounds in miracles and folklore. Mr. Le Strange's special local knowledge is well exhibited in his identification of many of the obscure places mentioned in the text. The volume is in every way creditable to the editor and to the trustees of the E. J. W. Gibb Memorial Fund.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Temperature in the Sun.

WHENEVER a spell of hot weather occurs it is common to see published accounts of the "temperature in the sun." These sun-temperatures have little meaning unless the other surrounding conditions are also stated.

Comparatively few people realise that a thermometer indicates nothing except the temperature of the fluid in its bulb, and that to draw any useful inference from that temperature it is necessary to know how the heat which produced it was supplied.

Heat may enter a thermometer from the air by conduction, aided by convection currents and wind, and also by radiation from distant objects. In general, both these sources contribute to the total.

The true temperature of the air is indicated only when the thermometer is screened from the radiation of any body which is not at that temperature, and the ventilated shelters in which meteorologists place their instruments are intended to secure this condition. In ordinary cloudy and windy weather they answer the purpose, but in sunshine and calms the whole shelter becomes heated, and the thermometer readings are too high.

When a thermometer is fully exposed to the sun a large part of the heat received is supplied by radiation, and the apparent temperature will vary with the character of the surroundings, including the nature of the glass of which the bulb is made.

Of the total radiant energy falling on the bulb part is regularly reflected and the remainder scattered or absorbed, but it is only the energy absorbed during its passage through the glass of the bulb which raises the temperature of the contents—at any rate, in mercury thermometers. The limiting temperature is reached when the surface of the bulb loses, by conduction and dark radiation, as much heat as will balance the supply.

If the bulb is smoked there is scarcely any reflection, and thus a bulb coated with lampblack will reach a higher temperature than a black glass bulb, and this, in turn, will be higher than if the glass is transparent, and if the exterior of the bulb is silvered there will be an even greater difference.

Thus, in the same place and in the same sunlight, four different temperatures might be indicated by accurate thermometers, each reading differing from the others by several degrees, the differences depending on the different absorptive and emissive qualities of the glass and its surface.

The actual difference between the apparent "temperature in the sun" and the air temperature may in this country be as great as 50° F. In the tropics I believe it may be considerably more.

Darwin, when in the Galapagos Islands, wrote:—"On two days the thermometers in the tent stood for some hours at 95°, but in the open air in the wind and sun at only 85°. The sand was extremely hot; the thermometer placed in some of a brown colour immediately rose to 137°, and how much above that it would have risen I do not know, for it was not graduated any higher. The black sand felt much hotter. . . ." The true air temperature was probably about 80°, so that the sun's radiation heated the ground 60° or 70° more than air.

I remember seeing in a sunny window in January the thermometer standing at 108° when the room temperature was about 60°; and in the recent warm weather, when the air temperature was about 80°, a thermometer shielded from draught by a thin smoked glass tube indicated 128°.

These facts show how little meaning can be attached to "temperatures in the sun" unless all the conditions are stated.

If a blackened thermometer is enclosed in a good vacuum chamber of transparent glass, and is carefully screened from all ground radiation, its readings in the sun will give a good comparative measure of the transparency of the air to radiant heat; but if the true temperature of the air is required, the thermometer should be surrounded by two or more concentric silvered glass tubes through which a rapid draught is maintained. In this way the effects of radiation are almost eliminated, and all the heat received is supplied by conduction.

6 Cresswell Gardens, South Kensington.

Percussion Figures in Isotropic Solids.

THE accompanying photographs are of interest as illustrating the manner in which an isotropic solid breaks down under the stresses set up by impact when these exceed the limits of perfect recovery, and have a bearing on the theory of the collision of elastic solids developed mathematically by Hertz.

Figs. 1, 2, and 3 are pictures of the percussion figure, taken from three different points of view, produced on the surface of a thick glass plate by the impact of a polished hard steel ball. Near the centre of the region of contact between the sphere and the plate the stresses are mainly in the nature of a volume-compression, and fracture accordingly does not originate there, but occurs at or near the *margin* of the compressed area in the form of a fine circular crack which spreads inwards into the plate obliquely in the form of a surface of revolution. This is clearly shown in Fig. 1, which is a front view of the percussion figure by reflected light, the dark circle in the middle being the uninjured area of contact between ball and plate. The circular interference-rings seen in the picture are a measure of the separation of

FIG. 1.

FIG. 2.

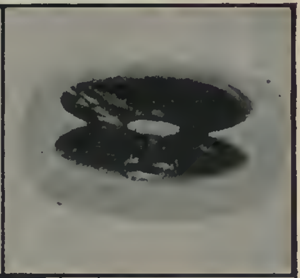

FIG. 3.

the surfaces of the internal fracture within the plate.

Fig. 2 is a side view, and Fig. 3 an oblique view, of the internal fracture seen through the edge of the plate, the lower half of each picture being the image of the upper half formed by the reflection of light at the interior surface of the plate. The circular area of contact from the margin of which the fracture starts appears in Fig. 3 as an elliptic white disc at the centre. It seems clear that the internal fracture practically occurs along the surface of maximum *shearing* stress set up during the impact. C. V. Raman.

210 Bowbazaar Street, Calcutta, August 18.

The Rigidity of the Earth.

An account of an experiment to determine the rigidity of the earth was published in the *Astrophysical Journal* and in the *Journal of Geology*, March, 1914. This gave the ratios of the amplitudes of tides observed in N-S and E-W pipes to the amplitudes computed for the same pipes on the assumption of a perfectly rigid earth as 0·523 and 0·710 respectively.

The work of reducing a new set of automatically recorded observations made by an interference method, which was interrupted by the war, was recently resumed, and it was found that the N-S and E-W ratios were very nearly equal to each other.

It was then noted that $0·523/0·710=0·7366$, and that the cosine of the latitude of Yerkes Observatory, where the experiment was performed, is 0·7363. It seemed highly probable, therefore, that $\cos\phi$ had been introduced erroneously into the computed formula for for N-S tides.

We have just been informed by Prof. Moulton that he has gone over the old formulæ used, and has found that the computer introduced the factor $\cos\phi$ erroneously into the N-S computation.

The N-S ratio should therefore have been $0·523/0·7363=0·710$, which, oddly enough, is exactly equal to the E-W ratio.

The new observations point to a value of about 0·69 for both E-W and N-S ratios.

The "Flying Gallop" in Art.

In Nature of August 21 (p. 489) reference is made to a popular article by Mr. C. W. Bishop on "The Chinese Horse," and to the distribution of the artistic motive of the flying gallop dealt with in it. It may be of interest to remark that this problem was first studied and discussed by the famous French archæologist S. Reinach in his "La représentation du galop dans l'art ancien et moderne" (Paris, 1901), and was afterwards expanded by me in my book, "Chinese Pottery of the Han Dynasty" (Leyden, 1909), where also many illustrations of the motive from Chinese art-works are given.

Curator of Anthropology.

Field Museum, Chicago, September 10.

MUSEUMS, EDUCATION, AND THE BOARD.

For many years a number of our provincial museums have striven to make their collections of educational value, both to the ordinary citizen through their exhibits and guides, and to the schools through their exhibits and special circulating collections, as well as by talks to the teachers or pupils. The response of the education authorities long continued disappointing, but some eight or ten years ago things began to move more rapidly. Certain pure educationists began to see that there was something of value for them in the museums, and in 1913 the Educational Science Section of the British Association appointed a strong committee to report on the question. The war, though unfortunately preventing the publication of that committee's lengthy report, and hindering museum activities in many directions, has had the result in some towns, notably Manchester, of inducing the schools to lighten their own troubles by seeking the aid of the museums and their staffs.

So well had the movement progressed, thanks mainly to the insistent propaganda of museum officials, individually and through the Museums Association, that at last the Education Act of 1918 and the draft suggestions for the arrangement of schemes thereunder (Circular 1096) took museums into serious account as an educational factor. Museum enthusiasts were delighted. But now comes a move which gives them pause. The Adult Education Committee of the Ministry of Reconstruction has issued an interim report (Cd. 9237) recommending that public libraries and museums should be placed under the control of the local education authorities, and administered by special committees of those bodies, and urging "that the powers and duties of the Local Government Board regarding public libraries and museums should be transferred forthwith to the Board of Education." So reasonable a recommendation would, it is doubtless expected, be welcomed effusively by the institutions concerned. The contrary is the case. The protests of the librarians are quoted—and dismissed—in the interim report itself. They have just been repeated at the meeting of the Library Association in Southport, but we cannot consider them here. As already reported (Nature, July 17, 1919, p. 394), the Oxford meeting of the Museums Association raised so many objections that it appointed a committee to prepare a statement. And now, in a discussion of the Educational Science Section of the British Association, the opposition of the museums found vigorous expression, and such support as the proposal received from one or two curators was only half-hearted. It may be well, therefore, to summarise the arguments.

The Adult Education Committee holds its opinion so strongly that it has condescended to very little argument. We gather more from a paper laid before Section L by Prof. J. A. Green. This assumes that museums are "fundamentally educational in character," and infers that they should form part of the educational machinery of the country. This machinery should be controlled by one authority, and its parts adapted to a common aim. This would change the outlook of the museums and lead them to display their collections in such a way as to dispel "museum headache." The responsibilities of the Education Committees have been extended to adult education, and they would be better able to bring museums into touch with universities and other of the higher educational establishments. Where a museum does not exist already, as in certain towns and in country districts, a live education authority would set one up, so that the number will be increased. Museums suffer from want of funds because few are supported by more than a ½*d.* rate, some not even by that; they would receive grants in aid directly from the Board of Education.

To this the museums reply that they recognise the argumentative force of a pecuniary bribe; but if their work is worthy of this reward, why should it not be given? For the rest, they dispute the premisses. A museum is *not* fundamentally an educational institution. It exists primarily for the collection and preservation of the works of nature or of man, and its highest aim is the advancement of science or of art. The needs of the researcher must never be sacrificed to those of the elementary student or the public. Even the smallest local museum has a duty in this direction, and it is this spirit which keeps the museum alive. Museums which themselves chart the unknown seas of knowledge can best pilot the learners. Organised education is the vehicle of established knowledge, is necessarily limited in scope, and must move on the rigid lines of a syllabus; but the museum must respond to new influences, must extend knowledge, and assemble material for future research. The existing museum committees are not ideal, but neither are the education committees. The curator knows his men, has been moulding their ideas, and has generally found a chairman with large views. He does not wish to see either himself or his chairman controlled by a body the scope of which embraces but a subsidiary part of his museum's activities. If his means of support are to come solely through educational channels, results will be expected through those channels alone. The others will gradually be blocked, the level of aspiration and accomplishment will be lowered, the living water will stagnate. Museum officials, from experience or observation, distrust bureaucratic government; they want men whom they can approach, not an anonymous Board.

Compromise, however, may be possible. Cooperation is desired, though not subordination. Let the education authority advise upon the public exhibition series, and support financially the educational work of the museum in proportion as it approves. But hands off the unseen activities of the museum! Provincial museums may be linked up with one another and with the national museums above and the minor museums below, but the linking should be through a body representative of their own committees and curators. If the source of money must be the Board of Education, so be it; but let it flow to these committees through a separate museum department of the Board. Museums here, as in the United States, have shown what good educational work they can do on their own initiative. Recognise that initiative, and they will respond with more abundant and more fruitful efforts.

THE COALFIELDS OF SPITSBERGEN.

Coal is not a new discovery in Spitsbergen. It has been known for more than 300 years, and about a century ago small cargoes were even brought to Norway. But mining on a serious scale did not begin until some fifteen years ago, while its rapid extension is due to the high price and comparative scarcity of coal during and after the war. There are now at least four mines in Spitsbergen exporting coal in large quantities during the summer months, and several others which will soon reach the export stage.

Coal of at least three ages occurs—Carboniferous, Jurassic, and Tertiary. It is difficult to give the total content, but it may safely be said that Spitsbergen coalfields do not contain less than 5,000,000,000 tons. Bear Island, in addition, has a content of some 8,000,000 tons. The occurrence of drowned fault valleys in the plateau of almost horizontal strata has made the coalbeds easily accessible in most places, and greatly facilitates loading by reducing land transport to a minimum. Practically all the valuable coalbeds lie around the two great inlets on the west coast—Icefjord and Lowe Sound—except a small outlier of Tertiary coal in King's Bay, near the north-west corner of Spitsbergen. The Tertiary coal has attracted most attention, and for the present at least provides most of the export coal. At Longyear City, the prosperous Norwegian mine in Advent Bay, several seams have been located at 755 ft. above sea-level; a 3½-ft. seam is now being worked, and at 815 ft. a 4½-ft. seam is being opened; another seam occurs at 640 ft. The same coal is being worked in Lowe Sound and in Braganza Bay. In the latter place Swedes are exporting large cargoes from their mine in the 3½-ft. seam at a height of 245 ft. It is also being mined successfully by Russians in Green Harbour.

The Tertiary coal has been proved to be a good steam coal of high calorific value, and fairly free from dirt. An average of the analysis of several samples gives about 79 per cent. carbon, 2 to 6 per cent. water, less than 2 per cent. sulphur, and about 4 per cent. ash. The calorific value averages about 7800. The seams appear to maintain a fairly consistent thickness and uniformity in quality over wide areas. Other seams of Tertiary coal also occur, notably a 7-ft. seam of bituminous coal in Advent Bay at a height of 1900 ft. This seam, which is now being mined, shows a slight tendency to pass to lignite, an unusual feature in Spitsbergen Tertiary coal.

The coal of Carboniferous age occurs in the culm beds near the foot of the Carboniferous system. The deposits are very extensive, but have been investigated only recently, and so have attracted less notice than the Tertiary seams. Moreover, the outcrops of these coal seams are generally obscured by enormous screes and slip masses, so that their examination entails a good deal of serious work, including boring operations; but this is well repaid, as the seams are thick, and extend over wide areas round the northern and eastern bays of Icefjord. In the Klaas Billen district valuable seams have been opened up at various heights. Varying from a few inches to about 3 ft. in thickness, they total 6 ft. Early analyses of Carboniferous coal were vitiated by the samples being taken from weathered slip masses, in consequence of which they showed a high proportion of ash. Now, however, that the coal has been reached *in situ*, it proves to be of high quality, clean and lustrous, and, unlike the Tertiary coal, fit for coking. Projects are on foot for extensive mining operations in these fields.

Jurassic coal is widely spread, but less accessible than the other kinds. It was the first coal to be mined, but turned out to be of relatively poor quality, and is now no longer worked.

Mining is continued throughout the year, although the export season at present extends only from June to September. The miners winter in comfortable timber houses, and are well supplied with fresh food, brought from the European mainland in the autumn. There is wireless communication throughout the winter. The restriction of export to four months in the year necessitates good storage facilities for the winter coal and rapid loading in summer both from the dump and direct from the mine, but these problems are being satisfactorily solved. The total coal export of Spitsbergen, which in 1913 was 35,000 tons, rose last year to 65,000 tons, and this year must have reached about 100,000 tons. These figures are, of course, comparatively small, but they will be much increased as several new mines get into working order. The shortage of labour, material, and tonnage still affected the output this season, but it may be said that the prejudice against mining in the Arctic has now been overcome, and Spitsbergen will soon take its due place as one of the important coal-producing countries of Europe.

R. N. R. B.

NOTES.

The Ministry of Munitions has published as a confidential document a highly interesting report of the Commission appointed to visit the iron and steel works of the occupied areas of Germany, also of Lorraine, Luxemburg, and certain portions of Belgium and France. The object of the Commission was to ascertain what developments in iron and steel manufacture have taken place during the war, the present condition of the plants, the future prospects of these areas, and to what extent fuel economy has been advanced therein. As regards the last-named item, Messrs. Cosmo Johns and Lawrence Ennis communicated to the recent autumn meeting of the Iron and Steel Institute a report on the present status of fuel economy in the German iron and steel industry of the occupied territory. This report is now public property, and contains very much interesting material; it may be taken as an indication of the importance of the valuable information which the Commission itself has collected. It is to be hoped that the Ministry of Munitions will see its way to publish the entire report as an ordinary Government publication purchasable in the usual way, so that it may be known by all engaged in the iron and steel industries in this country, as there is no reason why our industries should not be allowed the benefit of the careful studies of this Commission. Such an important document should be made available as widely as possible to all those interested in the subject-matter.

The future of the Royal Botanic Society at Regent's Park has for long been a matter of anxiety, and the recent appointment by Lord Ernle, when President of the Board of Agriculture and Fisheries, of a strong Committee to inquire and report as to what steps should be taken to render the work of the society as useful as possible, from the scientific and educational points of view, was a most welcome step. The Committee, under the chairmanship of Sir David Prain, Director of Kew Gardens, has taken evidence from representative botanists and others, and its report is now available. Apart from the establishment of the gardens at Regent's Park, the primary object of the society, which was incorporated in 1839, was "the promotion of botany and its application to medicine, arts, and manufactures." It is interesting and satisfactory, therefore, to note that the Committee is of the opinion that the usefulness of the work of the society would be enhanced by the organisation and development of botanical work essentially economic in its bearing. The chief suggestions made by the Committee are:—(1) The establishment of a school of economic botany at which a knowledge of economic plants and their products could be obtained; (2) an institute which might be made a centre for research, especially in plant physiology; and (3) a centre for teaching practical horticulture. The first is the most notable and valuable recommendation. The establishment of such a school would supply an undoubted want in this country, where organised instruction in economic botany, especially as regards tropical crop plants, is almost impossible to obtain. The Committee is to be congratulated on so accurately judging the need of the situation. It is greatly to be hoped that the financial means necessary for the successful carrying out of the Committee's recommendations will be forthcoming.

A meeting of the Executive Committee of the United States National Research Council was held at the National Research Council Building, Washington, on April 15 last, and according to an abstract, 21 pages in length, of the minutes, which appears in the July issue of the Proceedings of the National Academy of Sciences, the Council has already made great progress in initiating and co-ordinating research in pure and applied science in the States. It has organised divisions for physical science, chemical science, geology and geography, biology and agriculture, engineering, industrial, educational, and State relations. Each division is presided over by a man of note, and on it there are many representatives of scientific and other societies. The Council will have ample funds at its disposal, the Rockefeller Foundation alone having undertaken to provide 100,000*l.* during the next five years for the promotion of fundamental researches in physics and chemistry primarily in educational institutions. The chairman of the Council receives 2000*l.*, and chairmen of divisions 1500*l.*, per annum, with travelling expenses. The Council is to be congratulated on the speed with which it has accomplished so much.

Dr. Theodore W. Richards, professor of chemistry at Harvard University, has (*Science* announces) been elected president of the American Academy of Arts and Sciences.

The Secretary of the Department of Scientific and Industrial Research informs us that a British Association of Research for the Cocoa, Chocolate, Sugar, Confectionery, and Jam Trades has been formed in accordance with the Government scheme for the encouragement of industrial research. The secretary is Mr. R. M. Leonard, the Manufacturing Confectioners' Alliance, Ltd., 9 Queen Street Place, E.C.4.

A committee has been formed to raise a fund by public subscription for the purpose of establishing a memorial to perpetuate the memory of the eminent services, particularly in the fields of economics and science, rendered to Tasmania by the late Mr. R. M. Johnston, for many years Government Statistician and Registrar-General of that State. Subscriptions are now invited, and should be sent to Mr. T. A. Tabart, jun., honorary treasurer, Cathedral Chambers, Murray Street, Hobart, or Mr. Clive Lord, honorary secretary, c/o Museum, Macquarie Street, Hobart.

By the untimely death of Prof. F. J. Haverfield, Camden professor of ancient history, the University of Oxford has lost a valued member and the first living authority on Roman Britain. Early in life Prof. Haverfield devoted himself to this, his special subject, and his reputation caused Mommsen to entrust to him that portion of the "Corpus Inscriptionum" which dealt with Great Britain. Not only was he a master of the literature of the Romano-British period, but he gave much assistance to excavations at Silchester, Caerwent, and the Roman Wall. He was an admirably stimulating lecturer, and was interested in town-planning in ancient times, on which he wrote a valuable book. Late in life he devoted himself to the question of university finance. It may be said that the Camden chair was never more worthily held by a scholar and practical archæologist. It is a matter of deep regret that ill-health prevented Prof. Haverfield from preparing the authoritative work on Roman Britain which he had planned, and alone could have accomplished.

With the mathematician Philip Edward Bertrand Jourdain there died on October 1 a truly remarkable character. Jourdain lived only thirty-nine years, but the amount and value of the work that he accomplished, considering the disabilities under which he laboured, are almost incredible. He was weakly from infancy, and as a child developed symptoms of the progressive paralytic condition known as Friedreich's ataxia. In spite of his unsteady gait and constant ill-health, he early showed great mathematical and mechanical capacity. He went up to Cambridge in 1898, then already a cripple. During his course at Cambridge he spent some time in Germany and became a fluent and scholarly linguist, speaking and reading several European languages. In 1904, though now physically quite incapacitated, he was awarded the Allen mathematical scholarship for research, and throughout the remainder of his short career his main activities were directed to the prosecution of mathematical investigations. His most important work was the discovery of certain series of infinite numbers. Working with Russell and Whitehead, he showed that certain arithmetical processes could be applied to them, and thus he obtained new and interesting results. He continued on this line of research, and even a few days before his death, of the imminence of which he was fully aware, he succeeded in demonstrating the existence of a previously unsuspected series of infinites. His very last work was the discovery of a formula for the well-ordering of *any* aggregate. Notes of this work are now, we understand, in the hands of Prof. Love. Jourdain contributed extensive mathematical articles to the last edition of the "Encyclopædia Britannica." He founded and edited the *International Journal of Ethics*. He was for some years the English editor, and since the death of Carus in 1918 the chief editor, of the *Monist*. He also made a number of translations of scientific works for the Open Court Publishing Co. Jourdain took the liveliest interest in the movement for encouraging the history of science. He was a contributor to *Isis*, and at the time of his death he had in preparation an article for the "Studies in the History and Method of Science" which it is hoped he may have left in a state ready for publication.

In *Man* for September Col. de Guérin, of Guernsey, expresses the opinion that the megaliths in that island may be much more recent than they were hitherto supposed to be. This view is based on the important discovery of traces of a rudely sculptured human figure on a capstone of the great chamber of the dolmen of Déhus. The relationship of this figure to similar anthropomorphic sculptures in Guernsey and France is obvious, and as these latter, according to Déchellete and others, date at earliest from late in the Neolithic, at the verge of the Æneolithic period, the dolmen of Déhus must be of this age or later. This is confirmed by the discovery in 1847 of a copper knife-dagger in the great chamber of this dolmen. Col. de Guérin fixes also the statue Menhir at the Câtel Guernsey in the first Bronze age. He lays special stress on the evidence of a still earlier sea-borne trade with Brittany in the numerous celts of jadeite and other foreign rocks found in the island.

In the nineteenth volume of *Natural History* (Nos. 4–5, April–May, 1919) Mr. I. M. Clarke describes, with numerous excellent photographs, the new Gaspé bird sanctuaries established by the Canadian Government on Percé Rock and Bonaventure Island, off the Gaspé Peninsula, and, further out in the Gulf of St. Lawrence, the Bird Rocks of the Magdalen Islands. The efforts of ornithologists for bird-protection have at last proved successful with the support of the Hon. Honoré Mercier, Minister of Colonisation, Mines, and Fisheries for the Province of Quebec. In another article on the same subject Mr. A. M. Bailey describes the Hawaiian Island Reservation, which was established in 1909 by Executive Order as a sanctuary for the millions of sea-birds and waders which return there annually to raise their young or to rest while migrating. For this and other generous measures to preserve bird-life, science is indebted to the late Theodore Roosevelt.

Natural History (vol. xix., Nos. 4–5, April–May, 1919) publishes a series of articles on zoological sculpture in art and architecture. Mr. S. B. P. Trowbridge, dealing with architecture, beginning with the palæolithic horse frieze at Cap-Blanc and the horse painting from Altamira, reproduces photographs of the bas-reliefs of Assyria in the British Museum and the Rostra at Rome. In regard to modern art, he accounts for the comparative failure of modern attempts on the ground that "in the art of sculpture, as in all art, there must be sincerity and truth, accuracy in delineation and fidelity in modelling, and the suppression of every detail unnecessary to expression." This idea is pursued in Mr. C. R. Knight's account of the work of contemporary American artists dealing with animal life. The black rhinoceros and African buffalo by Mr. J. L. Clark have some impressive vigour; but the zoological statuary at Washington, described by Mr. R. W. Shufeldt, shows little dignity or power of expression.

The lions, tigers, and buffaloes are distinctly inferior to the Nineveh hunting scenes described in the previous article.

Mr. V. Stefansson describes his successful method of Arctic exploration in an interesting article entitled "Living Off the Country" in the May issue of the *Geographical Review* (vol. vii., No. 5). Mr. Stefansson's well-known adoption of Eskimo habits and diet have enabled him to travel with very light loads and to penetrate far into the unknown for long periods without any anxiety. He contends that from experience he has found that a diet of flesh or fish is quite sufficient to sustain a person in good physical and mental condition, and that salt is not necessary for health. White men whom he has known to have lived for a year or more on an exclusive meat diet have shown no desire to return to the varied and elaborate diet of civilisation. So convinced is Mr. Stefansson of the abundance of food in the Arctic lands and seas he knows that he asserts that any man conversant with the ways of wild animals and the hunting and living methods of the Eskimo can load on one dog-team all the equipment he needs for a journey of several years. Where previous explorers had carried food and fuel, Mr. Stefansson carried neither, choosing to adapt himself to his environment rather than fight it. Instead of taking food and fuel he carried merely the instruments for obtaining them. By economy in the use of ammunition one can obtain as much as two tons of food for a pound of ammunition, or, in other words, ammunition is several thousand times as economical to carry as the most condensed kind of food. The paper deals at length with the methods of Arctic hunting, particularly seal-stalking.

In his presidential address to the seventeenth meeting of the South African Association for the Advancement of Science, held in July last, the Rev. Dr. W. Flint discussed the thorny problem of "Race Consciousness" in the light of modern scientific opinion. He regarded "national consciousness" as a mental tendency which had been fostered among the peoples of Europe, by territorial and linguistic boundaries, and by the propagation of a community of ideas. "Race consciousness," as seen in South Africa and in the Southern States of America, on the other hand, was an inherent proclivity or "property of human nature," and demanded the closest scrutiny and most accurate study on behalf of all men of science if political bankruptcy was to be avoided. In Spanish America racial animosities had been dissolved by miscegenation, but that method was unthinkable as a solution of South African racial difficulties. There was also another plan, the proposal to segregate native races in demarcated territories, but in practice that proved an impossible working policy. There was a third proposal which had been debated, the frank recognition of racial antagonism and the resolution on the part of each race to live within its own armed camp. The solution advocated by Dr. Flint was none of these, but the cultivation and recognition of an "international consciousness," which could be fostered by education and by the recognition on the part of "superior" peoples that every race has its rights, economical, political, and social. Dr. Flint holds that "racial consciousness" can be uprooted and replaced by an intellectual "interracial consciousness," and that racial conflicts can be avoided only by education—of whites as well as of blacks. On the biological significance of "race consciousness" Dr. Flint did not attempt to throw any light; that is a matter which still awaits patient investigation. Everyone interested in the problems of racial contact will find food for thought and subjects for observation in Dr. Flint's presidential address.

The Board of Agriculture has received the following information from the International Agricultural Institute at Rome:—The yield of wheat in Spain, Scotland, Italy, Canada, the United States, India, Japan, and Tunis is estimated at 929,525,000 cwt., or 5·6 per cent. below the 1918 crop, and 1·1 per cent. below the average yield of the five years 1913–17. The estimated production of rye for Italy, Canada, and the United States is given as 48,274,000 cwt., or 7·1 per cent. below last year's production, but 67·3 per cent. above the average crop for the years 1913–17. The barley crop for Scotland, Italy, Canada, the United States, Japan, and Tunis is estimated at 159,397,000 cwt., or 15·1 per cent. below last year's production, and 4·1 per cent. above the average production of the years 1913–17. The estimated production of oats in Scotland, Italy, Canada, the United States, Japan, and Tunis is 491,933,000 cwt., or 18·4 per cent. below the 1918 yield, and 7·2 per cent. below the average yield of the five years 1913–17. The maize crop in Italy, Canada, and the United States is estimated at 1,473,592,000 cwt., or 10·2 per cent. above the 1918 production, and 3 per cent. above the average yield of the years 1913–17.

The flora of Aldabra and other small islands of the western Indian Ocean is the subject of an article by Dr. Hemsley in the Kew Bulletin (No. 3, 1919). Aldabra is an atoll, similar in size to the Isle of Wight, 220 miles north-west of Madagascar, and about 600 miles from the Seychelles Archipelago. Assumption, the nearest island, is about twenty miles distant. Aldabra is densely clothed with vegetation, which is unusually rich for an atoll flora, comprising herbaceous, shrubby, and arboreous species. Excluding species introduced by human agency, the flora comprises more than 170 species of flowering plants, representing 127 genera and 54 families, proportions which are characteristic generally of insular floras. Grasses number 14 species, Rubiaceæ 15, and Leguminosæ 12. The Rubiaceæ constitute the predominating element in the woody vegetation, both as to number and diversity of genera and number of species, but are less conspicuous in the scenery than the mangroves, the figs, and a species of Euphorbia. The vegetation consists of four types:—(1) Mangrove swamp, which fringes the lagoon. (2) Pemphis bush, a dense growth of the hard-wooded *Pemphis acidula* (Lythraceæ), a widely distributed sea-coast plant. (3) Open bush, mostly of low trees and bushes, which are usually leafless in the dry season and flower at the beginning of the rains; herbaceous plants are scarce, and only found in the wet season. Almost all the Aldabra plants are to be found in this type of country. (4) Shore zone, extending round the atoll, varying much in width and supporting some widely distributed littoral species. The coco-nut, of which there are conspicuous plantations, is regarded as an introduced plant. Dr. Hemsley is convinced that this palm is a native of South America, the home of all the numerous species of the genus, and that its present wide distribution is due to human agency. Some particulars are also given of the floras of other islands in the western Indian Ocean, and of their relations with the flora of Aldabra. The data collected point to the common origin of the flora of Aldabra and the neighbouring islands, and indicate that the flora is essentially African and almost without any infusion of a Malayan element, such as exists in the Seychelles and the Mascarene Islands.

OCTOBER is a transition month so far as winds and distribution of atmospheric pressure are concerned in the East Indian Seas, and the Monthly Meteorological Chart published by the Meteorological Office shows that a considerable change is taking place in the general meteorological conditions. To the north of the equator northerly winds are decidedly asserting themselves and the south-west monsoon of the summer months is giving way. In the Bay of Bengal and in the Arabian Sea, October and November are the most stormy months of the year, and cyclones are more numerous than at any other period. The low barometric pressure which has prevailed over the land to the north of India is giving place to higher barometer readings, which causes a diametrically opposite wind circulation. The chart contains an interesting note of sea phosphorescence in the vicinity of Madras on July 3. At 2.10 a.m., in latitude 12° 43′ N., longitude 30° 34′ E., the steamship *Clan Ogilvy* (Capt. W. M. Porterfield) passed through what appeared to be a gigantic wheel, with many "curved" spokes, revolving the same way as the hands of a clock. The phenomenon lasted quite ten minutes, and is said to have been caused by phosphorescence. The wheel was travelling to the eastward. As each "spoke" passed, the ship was lit up.

THAT the war has done a great deal to show the value of the spectroscopic examination of metals and alloys is proved in an article on the subject in *La Nature* (September 6). Considerable information was gleaned regarding the composition of secret German alloys which were investigated by A. de Gramont by his method, and the same remark applies to the composition of the metal used by the enemy in the manufacture of the long-range shells fired upon Paris. The spectroscopic method would seem to be of particular value when applied to the examination of the constituents of alloy steels and commercial alloys, and, as the writer states, is capable of great expansion in this direction.

MESSRS. LEVER BROS., LTD., Liverpool, have lately published an interesting "Cattle Food Calendar" for 1919–20. This contains articles on the scientific side of agriculture written by men competent to speak on their respective subjects. Further, it is illustrated by photographs and pictures of many of the important operations in agricultural science. Among the articles we note "How Mendelism May Help the Stockbreeder," and shorter, but equally interesting, articles on "The Work of the Board of Agriculture," "Plant Diseases," "The Relation between Skin-temperature and the Fattening Quality of Cattle," "The Official Seed-testing Station at the Food Production Department," "The Work of the Rothamsted Experimental Station," "The Breeding of New Wheats," "Warble Maggots in Cattle," "Investigation and Research in Dairying," "Contagious Abortion in Cattle," "Horticultural Research," "The Cheshunt Experimental and Research Station," and "Forestry." The list covers a wide field, and the articles give brief, but useful, summaries of the application of science to agriculture.

OUR ASTRONOMICAL COLUMN.

COMET 1919*c*.—The following is a continuation of the ephemeris of comet 1919*c* (Metcalf-Borrelly) for Greenwich midnight:—

	R.A. h. m. s.	N. Decl. ° ′		R.A. h. m. s.	S. Decl. ° ′
Oct. 9	15 38 25	5 11	Oct. 21	16 10 14	1 17
13	15 48 38	3 4	25	16 21 39	3 30
17	15 59 14	0 54	29	16 33 30	5 43

Log *r* and log Δ on October 9, 0·1574, 0·3052; on October 25, 0·1106, 0·2884. The comet is an evening object, and is getting inconveniently near the sun.

A FAINT NOVA.—Miss Mackie announces that she has discovered a nova from a study of the Harvard photographs (Harvard Bulletin 691). Its position is R.A. 20h. 3m. 4s., N. declination 17° 24·3′ (1900). It follows a 14th magnitude star by 0·2s. It reached its maximum, 7·2 magnitude, on November 22, 1913, and has now sunk to below 14·5. The position is in Sagitta, within the limits of the galaxy; it is only about 26° from Nova Aquilæ.

HINDU SPHERICAL ASTRONOMY.—Mr. G. R. Kaye has published a paper on "Ancient Hindu Spherical Astronomy" in the Journal and Proceedings of the Asiatic Society of Bengal (vol. xv.). In this he summarises, with the aid of modern mathematical formulæ, the fundamental portions of the principal classical astronomical texts, which date from between A.D. 498 (the *Aryabhatiya*) and about A.D. 1000, when the redaction of the *Surya Siddhanta* now extant was written. Indian trigonometry is, like Indian astronomy, of Greek origin, but the Indians developed the methods received from the Greeks in various ways. There seems to be no doubt that the Indians were the first to introduce the use of sines instead of chords, and to compute tables of sines. But they never went further, and did not make use of the tangent function. They never give a proof of any rule they enunciate. The title of Mr. Kaye's paper refers to spherical astronomy only, but the author also gives a short account of the Hindu notions of the motions of the planets, though this has been done by several previous writers. The Hindu planetary theories differ in several details from those of Ptolemy, and were probably mainly derived from Alexandrian writings from the period between Hipparchus and Ptolemy, now lost. Though there is nothing particularly new in Mr. Kaye's paper, it gives a convenient summary of the principal doctrines taught in the great Indian astronomical text-books.

STELLAR CLUSTERS.—Dr. and Mrs. Shapley contribute another paper to the *Astrophysical Journal* for July on stellar clusters. They give a table of forty-one clusters, of which thirty show ellipticity, eleven are sensibly circular, and one is unsymmetrical. The most elliptical cluster is Messier 19, in which the greatest diameter is about twice the least; this is a much lower degree of flattening than that in the galaxy or the spiral nebulæ. In the case of the circular clusters, the form may be real or it may be due to our being situated near their polar diameters. There is some evidence that clusters near the galactic plane tend to have their equatorial planes parallel to it. At a distance from the galactic plane this no longer holds.

THE AURORA OF OCTOBER 1.

THERE was noteworthy auroral activity on the night of October 1. The display started in the early evening and lasted until well after midnight. As seen in the south of England, the aurora was generally of the glow type. The absence of streamers, etc., was commented on by Mr. W. H. Dines, of Benson Observatory, but Capt. J. E. Cowper noted streamers at Shanklin, Isle of Wight, soon after 22h. 15m.[1] The colour of the glow, which was comparable in effect with bright moonlight, was reported as "pale white" at Benson, "greenish-yellow" at

[1] According to the *Times* of October 3 there was a brilliant display with streamers seen from Worcester Park about 1 30 on October 2. "Curtains" were seen at Newport between 21.30 and 23 on October 1.

Shanklin and also at Ross-on-Wye, and "reddish-yellow" at Newquay.

The display was first noticed at Bristol at 9.15, and the final traces of it disappeared $5\frac{3}{4}$ hours afterwards, viz. at 15h. G.M.T. The appearance was that of a band of luminosity lying just over the northern region of the sky and extending over about 70° from nearly north-west to north-east. From this intense glow streamers occasionally shot upwards, but these quickly broadened and disappeared. They showed a reddish tint, and in several cases could be traced nearly to the altitude of Polaris. The stars of Ursa Major were deeply involved in the aurora, but shone conspicuously amid the light surrounding them.

At first sight a person might have mistaken the aurora for the reflection of a widespread conflagration, but a little watching revealed the precise nature of the event. Clouds covered a large portion of the sky at times, but it seemed curiously to avoid the region affected by the phenomenon, and there were showers of rain at intervals. The brilliancy of the northern light and the darkness of the clouds in other parts offered a striking contrast. Several meteors were seen during the night radiating from a point at $355°+40°$.

A letter from the Isle of Man describes a brilliant aurora visible there at 8.45 G.M.T. on the same night, and continuing with various modifications for several hours.

Dr. C. Chree has supplied the following note on the simultaneous magnetic storm as recorded at Kew Observatory, Richmond:—

"A smart magnetic storm was simultaneously experienced in connection with the aurora. As recorded at Kew Observatory, it began with a well-marked S.C. (sudden commencement) about 16h. 12m. G.M.T. on October 1, and continued until 4h. on October 2. The approximate ranges were 32′ in D, 280γ in H, and 170γ in V. The extreme westerly position was reached at the end of the S.C. about 16h. 16m., the extreme easterly position about 23h. 25m. on October 1. Between 22h. 18m. and 22h. 50m. there was a swing of 29′ to the east. The maximum in H appeared about 17h., the minimum shortly before midnight. After the minimum there was a rapid recovery from the depression. As usual in storms, V was enhanced in the afternoon, the maximum appearing about 19h. 10m. There was, however, a second approximately equal maximum about 22h. 15m. This was preceded and followed by somewhat rapid movements. After $23\frac{1}{2}$h. there was depression in V, the minimum appearing shortly after midnight. The element remained depressed until 4h. on October 2. The curves were fairly quiet for the next twenty-four hours, but disturbance began again about 4h. on October 3, and was active when the sheets were changed about 10h. It may be noted here that the storm itself was quite secondary as compared with the big one in August last, and so, from the purely magnetic point of view, the interest is very moderate."

THE SUDAN IRRIGATION WORKS.

It is an unfortunate circumstance when a controversy respecting the merits of rival schemes for Imperial development works is embittered by charges impugning the good faith of either side, and it is particularly painful when an accusation of this kind is levelled by a Government official of high standing and repute against his colleagues in the Department with which he was formerly associated. We do not propose to discuss the ethical question (it has already been the subject of inquiry by a Foreign Office Committee), but it is unavoidable to mention it as indicating the ground upon which Sir William Willcocks has published his brochure on "The Nile Projects" and the acutely critical spirit in which it is written.

We have already outlined in NATURE for September 18 (p. 67) the schemes actually adopted by their respective Governments, and now in course of execution, for the development of irrigation in Egypt and the Sudan, comprising the formation of a dam on the Blue Nile at Makwar, near Sennar, and of a reservoir at Gebel-el-Auli, on the White Nile; and in the "Notes" columns of the issue for May 22 last (p. 233) we briefly alluded to the alternative proposal advocated by Sir W. Willcocks and designated by him "the Sudd reservoir." The following additional particulars gleaned from the pamphlet before us may be of some interest.

The Blue Nile project, for the irrigation of the Gezirah plain in the Sudan, involves the storage of 463,000,000 cubic metres of water for distribution during the winter season to 300,000 feddâns (acres) about to be exploited in cotton-raising. To meet this requirement a supply of 120–150 cubic metres per second will be necessary at the canal head throughout the winter up to the end of March, although in an occasional year the supply may have to be continued to the middle of April. This would leave three months for the gathering of the crop and the preparation of the ground prior to the next sowing. It is essential to have this period as dry as possible in order to root out the old stalks, which otherwise tend to sprout, as, indeed, happens when the rains supervene. Sir W. Willcocks expresses the apprehension that irrigation supplies will have to be given much later than April 15, and that the sources for Egyptian use will be seriously depleted in consequence.

The White Nile reservoir at Gebel-el-Auli, proposed to be formed by an earthen bank across the river at a point some 50 km. above Khartoum, comes in for the criticism that it will flood a considerable tract of country, disturbing the inhabitants and necessitating their transfer elsewhere, and that the stagnant pools left when the reservoir is low will lead to an increase in mosquitoes. Both these objections were before the Foreign Office Committee, but were not held to be vital. Another point made by Sir W. Willcocks is that a work so remote from Egypt might in the hands of a hostile Power become a serious menace to that country. "An enemy getting possession of the dam and filling it brimful to the height of the earthen bank in a high flood could sweep the Nile Valley as thoroughly as Noah's deluge swept the Euphrates Valley."

Pursuing a trenchant criticism of the estimated cost of the foregoing schemes, Sir W. Willcocks compares them very unfavourably with his own project of utilising as a reservoir the vast tract of swamp known as the Sudd region, where, owing to the dense growth of papyrus and aquatic vegetation, there are "a score of milliards of cubic metres of water standing well above the level of the flat plain as though they were congealed." Such a region, Sir William contends, could be laid under contribution for practically inexhaustible supplies of water more effectively and at less cost.

BRYSSON CUNNINGHAM.

COLLIERY BOILER-PLANTS.

A REPRINT of articles on the performance of colliery steam boiler-plants and the saving to be obtained by their reorganisation, which appeared in *Engineering* for July 25 and August 1 last, has been sent us by the author, Mr. D. Brownlie. The discussion in the articles is based upon results of tests carried out by the author, and a valuable feature is a large table giving details of these results for 100 boiler plants, chiefly of the Lancashire type. Mr. Brownlie's figures indicate that the average net working efficiency of colliery steam-boiler plants is only about 55·5 per cent. By carrying out a re-organisation of such plants on modern scientific lines it is possible to obtain 70 per cent. efficiency, and Mr. Brownlie estimates that about 6,600,000 tons of coal per annum could be saved by the adoption of scientific methods and by more extensive use of refuse coal.

The 100 boiler plants tested have a total of 570 boilers, 500 of these being Lancashire, 2 Cornish, 37 egg-ended, and 31 modern tubular boilers. The average efficiency of the egg-ended boilers is less than 35 per cent., and there appears to be still a fair number of this type at work, in spite of it being hopelessly out of date. It is also of interest to note that the few modern tubular boilers installed are, on the average, giving no better results than the Lancashire boilers, which average 55 per cent. efficiency. This fact obviously indicates improper arrangements in the installation or bad methods of working, or both.

Another point of importance to which Mr. Brownlie directs attention arises from the Final Report of the Coal Conservation Committee, which states that "the policy of collieries has been to set free the best qualities of coal for the market, and to retain for colliery consumption the poorest quality. The returns show that the quantity of ash in some of the fuels used ranges from 50 per cent. to 80 per cent." Mr. Brownlie actually finds an average of 15·5 per cent. ash and coal of 10,500 B.Th.U. used at colliery boiler plants, and most people will support him in his statements that he has never heard of a case of 50–80 per cent. ash; that such instances must be rare; and that the statement in the report is most misleading. In actual fact, 52 per cent. of the coal employed at collieries is high-grade coal; of the remainder, 32 per cent. could be used economically in industry for steam generation, and only 16 per cent. is definitely unsaleable. The highest ash-content of this refuse coal was 35 per cent. Mr. Brownlie maintains that these results are typical of the colliery industry, and the idea that collieries burn chiefly refuse and unsaleable coal is a complete fallacy.

As a matter of fact, there are millions of tons of refuse coal lying unburnt at collieries, and a very large proportion of this refuse could be utilised for steam generation, as has been proved by Mr. Brownlie's firm on a number of colliery plants. The carrying out of this proposition would result in a very large saving in the coal consumption, even after ample deduction for the cost of extra boilers and plant necessary because of the low calorific value. A fair average price for the whole of the coal burnt on colliery boiler plants is to-day about 20*s*. per ton; making allowance for extra labour, plant, and depreciation, and taking 3 tons of refuse coal as equal in practice to 1 ton of saleable coal, the value of refuse coal to-day would be about 8*s*. per ton.

Mr. Brownlie's pamphlet is to be welcomed, partly on account of the strong case for reform presented in view of the need for national economy, and partly on account of the large number of test results which he gives in a form suitable for easy comparison. The pamphlet may be obtained from Messrs. Brownlie and Green, Ltd., 2 Austin Friars, London, E.C.2.

THE BRITISH ASSOCIATION AT BOURNEMOUTH.

SECTION D.

ZOOLOGY.

Opening Address by Dr. F. A. Dixey, M.A., F.R.S., President of the Section.

One of the results of the great war now happily at an end has been its effect upon science. On the one hand it has checked the progress of scientific investigation; it has done much to destroy international co-operation and sympathy; it has removed from our ranks, temporarily or permanently, many admirable workers. On the other hand it has acted as a great stimulus in many departments of scientific inquiry, and it has given the general public an interest in many scientific questions which have hitherto met with little recognition or encouragement from the people at large. It was perhaps inevitable, but at the same time, as I venture to think, rather to be deplored, that that interest has tended to concentrate itself upon applied more than upon abstract science; that it has been concerned chiefly with the employment of natural knowledge in devising and perfecting new methods of destruction. Terrible as is the power which the present-day engines of warfare have attained, it may be reasonable to hope that some compensation for the mischief and suffering which they have caused may eventually be found in peaceful directions; that the submarine, the aircraft, and even the high explosive may cease to be a terror to civilisation, and in spite of their past history may after all become agents in the advancement of the general welfare:

Hoc paces habuere bonæ, ventique secundi,

will, let us hope, be a legitimate reflection in later times. But for the true scientific worker, I think I may safely assert, the primary object of his studies is the attainment of knowledge for its own sake: applications of such knowledge may be trusted to follow; some beneficial, some perhaps the reverse. Still, whether they do or do not so follow is less a concern of the scientific man than whether his labours have resulted in a fresh advance into the realms of the unknown. I confess to some sympathy with the feeling which is said to be expressed in the regular toast of a certain scientific gathering:—"Pure mathematics, and may they never be of any use to anybody."

For genuine enthusiasm in the cause of science for its own sake, I think that we zoologists may claim a good record. We are by no means unmindful of the great benefits to humanity which have taken their rise more or less directly from zoological science. I need do no more than mention the services to medicine, great at the present and destined to be greater still in the future, that are being rendered by the protozoologist and the entomologist. We may look forward also to results of the highest practical importance from the investigations into the laws of heredity in which we are engaged with the co-operation of our allies the botanists. But what we are entitled to protest against is the temper of mind which values science only for the material benefits that may be got from it; and what above all we should like to see is a greater respect on the part of the public for science purely as science, a higher appreciation of the labours of scientific men, and a greater readiness, in matters where science touches on the common affairs of life, to be guided by the accumulated knowledge and experience of those who have made such matters the subject of constant and devoted study. If the war leads to any repair of the general deficiency in these respects, it will to that extent have conferred a benefit on the community.

Regarding, as I do, my present position in this Section as a great honour and privilege, especially in view of this being the first meeting of the British Association to be held after the war, I hope I may be allowed a few preliminary remarks of a somewhat autobiographical character. As far back as I can remember, zoology has been a passion with me. I was brought up in a non-zoological environment, and for the first few years of my life my only knowledge of the subject was gained from an odd volume of Chambers's "Information for the People." But on being asked by a visitor what I intended to do with myself when I grew up, I can distinctly remember answering, with the confident assurance of seven or eight, "Zoology suits me best"—pronouncing the word, which I had only seen and never heard, as *zoo*logy. By the time I went to school, my opportunities had increased; but I soon found myself engaged in the classical and mathematical routine from which in those days there was little chance of escape. In due course I went to the University with a classical scholarship, which necessitated for the time an even more rigid exclusion of scientific aspirations than before. I mention this because I wish to pay a tribute of gratitude to the College authorities of that day, to whose wise policy I owe it that I was eventually able to fulfil in some measure my desire for natural, and especially biological, knowledge. After two years of more or less successful application to the literary studies of the University, I petitioned to be allowed to read for the final school in natural science. The petition was granted; my scholarship was not taken away, and was even prolonged to the end of my fifth year. This I think was an enlightened measure, remarkable for the time, more than forty years ago, when it was adopted. I only hope that we have not in this respect fallen back from the standard of our predecessors. The avidity with which I took up the study of elementary chemistry and physics, and the enthusiasm with which I started on comparative anatomy under the auspices of George Rolleston are among the most pleasant recollections of my youth. But from the force of circumstances, though always at heart a zoologist, I have never been in a position to give myself unreservedly to that department of biology; and even now, in what I must call my old age, I fear I cannot regard myself as much more than a zoological amateur. My working hours are largely taken up with serving tables.

What moral do I draw from this brief recital? Not by any means that I should have been allowed to escape a grounding in the elements of a literary education, though I think it quite possible that the past, and even the present, methods of school instruction are not ideally the best. My experience has led me to conclude that much of the time spent over the minutiæ of Greek and Latin grammar might, in the case of the average boy, be better employed. But I do not agree that a moderate knowledge of the classics, well taught by a sensible master, is useless from any reasonable point of view. To those of my hearers who appreciate Kipling, I would call to mind the vividly truthful sketch of school life called "Regulus." Let them reflect how the wonderful workmanship of the inspired and inspiring Ode of Horace, round which the sketch is written, must have sunk into the mind of the apparently careless and exasperating "Beetle," the "egregious Beetle" as King calls him, to bear such marvellous fruit in after years. Beetle, as we all know, is no professional scholar, no classical pedant, but a man of the world who has not forgotten his Horace, and upon whose extraordinary literary skill those early school-tasks must have had, whether consciously or not, a dominating influence. How else could he have written "Regulus"? "You see," says King, "that some of it sticks." So it does, if it is only given a fair chance; and in the skirmish between King the classical and Hartopp the science master, both right up to a point and both wrong beyond it, I give on the whole the palm to King. To revert to my own case. I do not regret a word of either the Latin or the Greek that I was obliged to read, nor even the inkling of the niceties of scholarship to which I got, I hope, a fair introduction. But I do think that I might have been allowed to start on scientific work at an earlier period, and that a good deal of the time spent, say, on Greek and Latin prose and verse writing, might in my case have been well spared for other objects.

To generalise what I have been saying. Start teaching your boy or girl on a good wide basis. Nothing is better for this than the old school subjects of classics, history, and mathematics, with the addition of natural science. In course of time a bent will declare itself. Encourage this, even at the expense of other studies desirable in themselves. But do not allow any one subject, however congenial, to usurp the place of a grounding in those matters which are proper to a general education. The time for specialising will come; and when it has arrived do all you can to remove obstacles, pecuniary and other. Do not hamper your historian with chemistry or your zoologist with the differential calculus. If they have a taste for these things by way of diversion or recreation, well and good. But let their action be voluntary.

This, however, is not a fitting occasion for propounding my views on the question of education, and it is time to turn to the immediate object of my address. And here I think I cannot do better than bring before your notice certain facts which have a bearing on the subject of insect mimicry; a subject which for many years past has engaged much of my attention. The facts on all hands are allowed to be remarkable. As to their interpretation there is much diversity of opinion; and indeed, until complete data are forthcoming, this could scarcely be otherwise.

In the first place let us glance at a certain assemblage of butterflies that inhabits New Guinea with some of the adjacent islands. These butterflies, though belonging to different subfamilies, present a resemblance to each other which is too strong to be accidental. Three of them belong to the Pierines, the group which includes the common white butterflies of this country; the fourth is a Nymphaline, not widely removed from our well-known tortoiseshells, red admiral and peacock. The resemblance on the upper surface between two of the three Pierines is not especially noteworthy, inasmuch as they present in common the ordinary Pierine appearance of a white or nearly white ground colour with a dark border somewhat broadened at the apex. But this, an everyday feature in the Pierines, is almost unknown in the very large subfamily to which our present Nymphaline belongs. Still, though sufficiently remarkable to arrest the attention of anyone familiar with these groups, the Pierine-like aspect of the upper surface of this Nymphaline, which is known as *Mynes doryca*, would not by itself have seemed to call for any special explanation. The resemblance would pass as merely an interesting coincidence. But the under surface of the three Pierines, known respectively as *Huphina abnormis*, *Delias ornytion*, and *Delias irma*, presents a striking combination of colour very unusual in their own group; and this peculiar character of the under surface is shared by the Nymphaline *Mynes doryca*. The "long arm of coincidence" could scarcely reach so far as this. Whatever might be said about the likeness seen from above, that the wings beneath should show virtually the same unusual pattern in the Mynes as in the Pierines seems to call for some explanation other than an appeal to chance or accident. Moreover, with regard to the Pierines themselves, the two members of the genus Delias are, of course, fairly closely related; but the Huphina belongs to an entirely distinct genus, separated from Delias by many important structural differences. The two species of Delias perhaps depart less widely in aspect from their nearest congeners than does either the Huphina or the Mynes. The under surface of the Huphina is unexampled in its genus, but the upper surface is quite ordinary. The Mynes, as we have seen, stands alone among its nearest relatives not only in the character of its under surface, but also in the Pierine-like character of its wings above.

We will now turn to another assemblage, which presents us with the same problem from a somewhat different point of view. In south-eastern Asia, with certain of the adjacent islands, is found a genus of large butterflies, called by Wallace Prioneris from the saw-like front margin of the forewing in the male. More than fifty years ago it was remarked by Wallace that the species of Prioneris in several cases seem to mimic those of the genus Delias, and that "in all cases the pairs which resemble each other inhabit the same district, and very often are known to come from the same locality." The parallelism is even stronger than was stated by Wallace, for there is not a single known member of the genus Prioneris which does not resemble a species of Delias, so that Prioneris cannot really be said to have an aspect of its own. *Prioneris clemanthe* and *Delias agostina* form a pair inhabiting the Himalayas, Burma, and Further India. In the same region occur *Prioneris thestylis* and *Delias belladonna*, the striking similarity of which species, especially on the underside and in the female, drew the special attention of Mr. Wallace. A still more remarkable instance is that of *Prioneris sita* of southern India and Ceylon, the likeness of which to the common Indian *Delias eucharis* is spoken of by Wallace as "perfect"; while Fruhstorfer, a hostile witness, testifies to the fact that the Prioneris always flies in company with the Delias, and rests just like the latter with closed wings on the red flowers of the Lantana. *Prioneris hypsipyle* of Sumatra and *P. autothisbe* of Java are like *Delias egialea* and *D. crithoe* of the same two islands. Here again Fruhstorfer says of *Prioneris autothisbe* that it visits the flowers of the Cinchona, "always in company with the similarly coloured *Delias crithoe.*" Wallace remarked on the close similarity between *Prioneris cornelia* of Borneo and *Delias singhapura* of the Malay Peninsula; in this case, it will be noted, the localities, though not far distant from each other, are not identical. But a Delias form which was unknown at the date of Wallace's paper has since been found in Borneo, and this latter butterfly, known as *D. indistincta*, is even more exactly copied by *P. cornelia* than is the *Delias* which first drew Wallace's attention. *Prioneris vollenhovii* of Borneo is a kind of compromise between *Delias indistincta* and, on the underside, *D. pandemia* of the same island, and it may be added that another Bornean Pierine, *Huphina pactolica*, is a good copy of *Delias indistincta*, therefore resembling also the Bornean *Prioneris cornelia* and *P. vollenhovii*.

The memoir, published in 1867, in which Wallace remarked on the parallelism between Prioneris and Delias, contains a noteworthy prediction by the same author. Speaking of *Pieris* (now called *Huphina*) *laeta* of Timor, he says that it "departs so much from the style of colouring of its allies and approaches so nearly to that of *Thyca* (*Delias*) *belisama* of Java, that I should almost look for an ally of the last species to be discovered in Timor to serve as its pattern." Thirty-four years after the expression of this anticipation, Mr. Doherty discovered in Timor an ally of *Delias belisama* which at once suggests itself as the model from which the peculiar and brilliant colouring of *Huphina laeta* has been derived. Fruhstorfer, who is by no means friendly to the theory of mimicry, says of this Delias, which was named splendida by Lord Rothschild, that beneath it is "deceptively like *Huphina laeta.*" But here comes in a curious point. The black forewing with its yellow apex and the orange-yellow hindwing with its scarlet black-bordered costal streak are present on the underside of both the Delias and the Huphina; but the latter butterfly possesses, in addition to these features, a row of scarlet marginal spots on the hindwing which are not to be found on the Delias. In spite of this discrepancy, the likeness is sufficiently striking. But from the same island of Timor, Doherty sent home another Delias which, besides resembling *D. splendida*, possesses a row of scarlet patches in the corresponding situation to those of *H. laeta*. In this latter Delias, however, named *dohertyi* by Lord Rothschild after its discoverer, the brilliant scarlet costal streak is completely absent. The Huphina, therefore, is more like either species of Delias than they are like each other, forming, as it were, a link between them. So that, adopting Professor Poulton's terminology, we may say that, if this is a case of mimicry, one form may possess at the same time the aposemes belonging to two distinct models. I will not now stop to discuss the bearing of this case on current theories, but will only remark that, granting mimicry, the whole assemblage, *D. splendida, H. laeta, D. dohertyi*, may be expected to gain advantage from the blending action of the intermediate *H. laeta*. This I think would happen whether *laeta* is a "Batesian" or "Müllerian" mimic, but the gain to the association in the latter case is certainly the more obvious.

This state of things would be sufficiently curious if it stood by itself. But it does not stand by itself. In Lombok, Sumbawa, and Flores there occurs another member of the peculiar group of Huphina to which *H. laeta* belongs. This butterfly, known as *H. temena*, resembles *H. laeta* in many respects; possessing on the underside of the hindwing a scarlet costal streak and a row of scarlet marginal spots like those of that insect. The forewing, however, differs from that of *H. laeta* in having its ground-colour not uniformly black, but divided between a dark shading to the veins, a dark submarginal band, and series of pale streaks and patches in the interspaces between the veins. The question at once suggests itself: Is there a relation between *H. temena* and one or more species of Delias corresponding to that between *H. laeta* and *D. splendida* and *dohertyi?* The answer to this question is in the affirmative. *Delias oraia*, together with *Delias sumbawana*, both species inhabiting the same three islands as *H. temena*, form with it an assemblage quite comparable with the former triad from Timor. Further, the points in which *H. temena* differs from *H. laeta* have their counterpart in the distinctions between *D. oraia* and *D. splendida* on the one hand, and *D. sumbawana* and *D. dohertyi* on the other. These points are chiefly, in the *temena* assemblage, the less definitely black-bordered costal streak, the more strongly-marked black bordering to the submarginal scarlet spots, and the diversely-coloured as compared with the uniformly black forewing of the Timor insects.

Again, in the island of Bali, *Huphina tamar* would seem to combine certain features of two species of Delias in a similar manner to the cases of *laeta* and *temena* just considered. The underside as a whole, is reminiscent of *D. periboea*, a member, like *D. dohertyi* and *D. sumbawana*, of the eucharis or hyparete group of the genus; while the red costal streak suggests the influence of a representative in Bali of the belisama group, like *D. splendida* and *D. oraia* in the other islands.

Finally, in the island of Sumba we have another member of this remarkable group of Huphinas. *Huphina julia*, the butterfly referred to, so closely resembles *Delias fasciata* of the same island, that even the sceptical Fruhstorfer is constrained to speak of it as a "faithful copy" of that insect. But here once more it is noticeable that one of the most conspicuous features of the Huphina is absent from the Delias. This time it is not, as in the case of *D. splendida*, the submarginal row of scarlet spots on the underside of the hindwing, but it is the scarlet costal streak that is wanting. *Huphina julia* was discovered by Mr. Doherty in the year 1887, and described in 1891. It is interesting, in the light of what is now known of the butterfly fauna of the Lesser Sunda islands, to read what Doherty has to say about the mimicry question in relation to the Delias and Huphina forms that have just been mentioned. Speaking of *H. julia*, he says, "If it stood alone, I should certainly suppose it to be a mimic of some form of *Delias hyparete* yet undiscovered in the island. But both *H. laeta* and *H. temena* require to be accounted for in the same way, and while it is possible that some Timorese Delias may resemble *H. laeta*, I feel sure that *H. temena* can have no such original. It must then be assumed that this group is less pressed by its enemies in the Timorian Islands, and has therefore been able to acquire more brilliant colours than its allies." So far Doherty.

Whatever may be the value of this last hypothesis, we have just seen that the supposed facts on which it rests are non-existent, for (1) the "form of *Delias hyparete* as yet undiscovered" has actually turned up in the person of *D. fasciata*; (2) it is not only possible, but actually the case, that "some Timorese Delias may resemble *H. laeta*"; (3) Mr. Doherty "feels sure that *H. temena* can have no such original," but *Delias oraia* and *Delias sumbawana* have just the same relation to *Huphina temena* as *D. splendida* and *D. dohertyi* to *H. laeta*. In view of these facts it may be not rash to suppose that the apparent absence of a model for the red costal streak of *H. julia* may hereafter be accounted for.

Of the three instances of possible mimetic association which have now been mentioned, I think that only one, viz. the first, has previously been treated in detail. The numbers of cases more or less similar to these three might be very largely extended, but for our present purpose it will be sufficient to confine our attention to those already given. It is probable that to some minds the facts adduced are simply curious coincidences, needing no explanation; but it can scarcely be wrong to suppose that to most students of nature the observed phenomena do call for some attempt at interpretation; and on a review of the evidence it seems clear that the geographical element must enter largely into any explanation that may be offered. On the whole, it is certainly the case that the forms which are supposed to be related by mimicry do inhabit the same localities; the continental Prioneris, for example, is like the continental Delias, and the island Prioneris recalls the island, not the continental, Delias. Moreover, we find the differences between the Delias of Timor, of Sumbawa and Sumba reflected in the associated Huphinas of the same islands. If it be granted that the geographical element is a factor, it is natural to inquire how it works.

It is no doubt true that external geographical conditions are occasionally capable of producing, whether directly or indirectly, a community of aspect in the animals or plants exposed to their influence. The prevalence of a sandy coloration in the mammals and birds of a desert, and of whiteness in the inhabitants of the arctic snow-fields, the spiny character so often assumed by the plants of arid regions, and the general dwarfing of the vegetation that grows close to the sea, may be given in illustration. At first sight these phenomena may seem to be of the nature of direct effects of the environment; quite possibly some of them are so, but I think few observers would deny that they are at least largely adaptive, being used for purposes of aggression or defence. Still, even if we allow the direct effect of the environment, as perhaps we may do especially in the case of the plants, can we frame any hypothesis of the action of geographical conditions which shall lead directly to the assumption of a common pattern in the case of the three or four butterflies from New Guinea? I confess that I am quite unable to do so. If the climate, or the soil, or any other geographical condition in New Guinea is capable of directly inducing so remarkable a combination of colour as we see in these Pierines and Nymphalines, why does it not affect other organisms in a similar way? Why do not other Pierines, for instance, closely related to ornytion and abnormis, share in the same coloration? And considering the characteristic aspect of the underside, which is supposed to be called into being by some unexplained condition peculiar to New Guinea, we may well ask, Why should its most conspicuous features belong in the one case to the forewing and in the other to the hindwing, and *vice versa*, the general effect being the same?

Fruhstorfer, we may note, does not feel these difficulties. "Many Pierids," he says, "present typical examples of that resemblance to other butterflies which has been named mimicry. The origin of this resemblance, however, is now explained by the supposition that the mimics were modified by the same (as yet unknown) influences under which the colouring of the models, mostly Danaids, developed." I think it will be generally agreed that this reference to "unknown influences" is no explanation at all.

It is necessary to take into account the fact that the resemblances of which we are speaking are independent of structural differences, being, in fact, merely superficial. This is a point which is capable of much wider demonstration than I am giving it to-day. But even from the instances now before us I think there cannot be much difficulty in coming to the conclusion that the resemblances are an appeal to vision. They are meant to be *seen*, though by whom and for what purpose may be open to question. Speculations as to recognition and sexual attraction may, I think, in these cases be put out of court; but there remains the theory of warning colours assumed in reference to the attacks of vertebrate enemies. From the fact that the most striking and most conspicuous of these common aposemes or danger-signals belong to the under surface—that is to say, the part chiefly exposed to view during rest—it may be inferred that the enemies to be guarded against are mainly those that attack butterflies, not on the wing, but when settled in repose. Both birds and monkeys are known to feed on butterflies, and there is a good deal of evidence as to their preference for one kind of food over another. I will not stop to give details, but anyone who wishes to study the evidence may be referred especially to the memoirs of Dr. G. A. K. Marshall, Mr. C. F. M. Swynnerton, and Capt. G. D. H. Carpenter.

If the warning-colour interpretation of these resemblances be the true one, we see at once why they are so largely independent of structure and affinity. Being meant to catch the eye, they ride rough-shod, so to speak, over inconspicuous features, such as venation; nor do they respect more than the nature of things obliges them to do the ties of blood-relationship. Then, again, it is obvious why they occur in the same and not in widely different localities; in some instances, as we have seen, their bearers actually flying in company and frequenting the same flowers; for the common aspect, supposing it to be in any sense protective, would only take effect when the sharers in it were exposed to the attacks of the same body of enemies; that is to say, when they inhabited the same locality. And this would be equally true, whether the warning colours are shared between distasteful forms, or whether they are deceptively adopted by forms unprotected by inedibility; whether, in Prof. Poulton's terms, they are synaposematic or pseudaposematic. I do not enlarge upon this part of the question, or upon the theories which are known under the names of Bates and Müller respectively, because these theories have been fully dealt with elsewhere, and I think I may assume that they are familiar to the greater part of my hearers. But that mistaken ideas as to what is really meant by protection and mimicry still prevail in some quarters, is evident from certain remarks of Fruhstorfer in dealing with the genus Prioneris which we have just been discussing. "Wallace," he says, "regards the 'rarer' Prioneris as a mimetic form of the 'commoner' Delias. But I cannot accept his view, since mimicry among the in all respects harmless Pierids appears no sort of protection, and, properly speaking, the smooth-margined Delias should rather copy the armed Prioneris if there is assumed to be mimicry at all." If anyone has no better knowledge than this of what is meant by the theory of mimicry, it is not wonderful that he should consider the subject unworthy of serious attention.

The warning-colour theory, then, gives a rational explanation both of the superficial character of the resemblances and of the geographical factor in their occurrence. But it obviously involves the reality of natural selection; and it is here that some are disposed to part company with the upholders of the theory. I have already referred to the fact that much positive evidence now exists both that butterflies are eaten and that preferences on the part of their enemies exist between one kind and another. I will only remark in passing that the objector on this score sometimes adopts an attitude which is scarcely reasonable, and, perhaps, on that very account is somewhat hard to combat. The kind of objector that I mean begins by saying that the destruction of butterflies by birds and other enemies is not sufficient to give play for the operation of selection. You beg his pardon, and produce evidence of considerable butterfly destruction. To which he replies, "Oh, they *are* eaten, are they? I thought you said they were protected." This is a good dilemma, but the dilemma is notoriously an unconvincing form of argument. If a reply be called for, it may be given like this: "Butterflies are either preyed upon or they are not. If they are, an opening is given for selection; if they are not, it shows the existence of some form of protection." The essence of the matter is that both the likes and dislikes of insectivorous animals, and the means of protection enjoyed by their prey, are not absolute, but relative. A bird that will reject an insect in some circumstances will capture it in some others; it will, for instance, avoid insect A if it can get insect B, but will feed on A if nothing else is to be had; and it is probable that scarcely any insect is entirely proof against the attack of every kind of enemy. The relative nature of protection is readily admitted when the question is not one of mimicry or of warning colours, but of protective resemblance to inanimate objects. All degrees of disguise, from the rudimentary to the almost perfect, are employed; the lower degrees are allowed to be of some service, and, on the other hand, a disguise that is almost completely deceptive may at times be penetrated. This consideration applies also to the objection that the first beginnings of mimetic assimilation can have no selective value. If the rough resemblance to an inanimate object affords some amount of protection, though that amount may be relatively small, why should not the same apply to the first suggestion on the part of a mimic of an approach to the aposeme or warning colour of its model? The position that neither kind of assimilation is of service is intelligible, though not common; but there is no reason why benefit should be affirmed in the one case and denied in the other. There are further considerations which tend to deprive this latter criticism of force; the fact, for instance, that a resemblance to one form may serve as a stepping-stone for a likeness to another; or, again, the existence of clusters, as they may be called, of forms varying in affinity, but embodying a transition by easy stages from one extreme to another. In a case of this sort the objection that may be felt as to two terms in the series arbitrarily or accidentally picked out is seen to be groundless when the whole assemblage is taken together.

Much attention has lately been given to the fact that of individual variations some are transmissible by heredity and some are not; under the latter heading would generally fall somatic modifications directly induced upon the individual by conditions of environment. Whether any other kind of variation belongs to the same category need not for the present purpose come into discussion. But with regard to the undoubtedly transmissible variations, or mutations if we like to call them so, there is, I think, a fairly general consensus of opinion that they need not necessarily be large in amount. A complete gradation, in fact, appears to exist between a departure from type so slight as to be scarcely noticeable, and one so striking as to rank as a sport or a monstrosity. And we know now that where the Mendelian relation exists between two forms, no amount of interbreeding will abolish either type; intermediates, when formed, are not permanent, and if one type is to prevail over the other, it must be by means of selection, either natural or artificial.

In view of all these considerations, I venture to think that there is no reason to dispute the influence of natural selection in the production of these remarkable resemblances. Other interpretations may no doubt be given, but they involve the ignoring of some one or more of the facts. It may fairly be claimed that the theories of Wallace, Bates, and Müller, depending as they do on a basis of both observation and experiment, come nearer to accounting for the facts than any other explanation yet offered. It will, of course, always be possible to deny that any explanation is attainable, or to assert that we ought to be satisfied with the facts as we find them without attempting to unravel their causes. But such an attitude of mind is not scientific, and if carried into other matters would tend to deprive the study of Nature of what, to most of us, is its principal charm. It is quite true that before the validity of any generalisation is accepted as finally and absolutely established, every opportunity should be taken of deductive verification. This has been fully recognised by the supporters of the theory of mimicry, and much has been done to test in this manner the various conclusions on which the theory rests. The verification is not complete, and perhaps never will be, but every successive step increases the probability of its truth; and probability, as Bishop Butler taught, is the guide of life. Meantime it is, one may say, the positive duty of everyone who has the opportunity, to fill up, so far as is in his power, the gaps that still exist in the chain of evidence. Here is an especially promising field for naturalists resident in tropical regions.

Before concluding this address there are two points on which I should like to lay some special emphasis. One is the undesirability—I had almost said folly—of undervaluing any source of information or any particular department of study which does not come within the personal purview of the critic or commentator. "I hold," says Quiller-Couch, "there is no surer sign of intellectual ill-breeding than to speak, even to feel, slightingly of any knowledge oneself does not happen to possess." This is a temptation to which many of us are liable; and falls, I fear, are frequent. It was a matter of sincere regret to me to find one of my most valued scientific friends speaking publicly of the Odes of Horace as a subject comparatively devoid of interest. I can only confess my utter inability to sympathise with my friend's point of view. If he had merely said, "Excellent as those works may be, I have other things to do than to attend to them," I could approve; but that is a different matter. The failing that I speak of is, unfortunately, by no means unknown among scientific men, and is perhaps rather specially prevalent when such subjects as those of my present address are in question. I can recall a very eminent man of science, no longer living, speaking with scarcely veiled scorn of those who occupied themselves with "butterflies in cases." This was in a presidential address to a section of this association. If so little respect is paid by a leader of science to work done in another part of the field, it is perhaps not to be wondered at that one of his Majesty's judges should speak of the formation of a great collection of butterflies—a most valuable asset for bionomic research—as the "gratification of an infantile taste." This or that collector may be an unscientific person, but it would be easy to show that the study of insects in general, and of butterflies in particular, is one of the most efficient of the instruments in our hands for arriving at a solution of fundamental problems in biology.

My second and final point is this: I have not hesitated to affirm my conviction of the importance in evolution of the Darwinian doctrine of natural selection. This necessarily carries with it a belief in the existence and general prevalence of adaptation. I am willing to admit that at times too much exuberance may have been shown in the pursuit of what Aubrey Moore called "the new teleology." "Men of science," it has been said, "like young colts in a fresh pasture, are apt to be exhilarated on being turned into a new field of inquiry; to go off at a hand-gallop, in total disregard of hedges and ditches, to lose sight of the real limitation of their inquiries, and to forget the extreme imperfection of what is really known." This is not the utterance of some cold outside critic, but of a great exponent of scientific method—no other than Huxley himself. It may be true of some of the wilder speculations of Huxley's date. I am by no means sure that there is not truth in it as applied to some of the developments of a later time. But however wide of the mark our suggested explanations and hypotheses may be, the net result of all our inquiries, after the gradual pruning away of excrescences and superfluities, will be a real advance into the realms of the unknown. We may feel perfectly assured that the objections so far brought against our own interpretations are null and void, but we may yet have to give way in the light of further knowledge. "Let us not smile too soon at the pranks of Puck among the critics; it is more prudent to move apart and feel gently whether that sleek nose with fair large ears may not have been slipped upon our own shoulders."[1]

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BRISTOL.—Under the will of the late Dr. Joseph Wiglesworth, whose interest in bird life is widely known, his ornithological library passes by bequest to the University. This library of more than 1000 volumes, including finely-bound copies of the works of Gould, Seebohm, Dresser, Lilford, Levaillant, and other leading authorities, is probably one of the best in the kingdom. It will be housed in a separate room in the new University buildings, and will be kept up to date. Dr. Wiglesworth gave the residue of his estate to the University after his widow's death for the furnishing and maintenance of this special library. The advantage to a university of facilities for prosecuting specific lines of research can scarcely be overestimated. Situate, as is Bristol, in a district rich in birds, it is to be hoped that the studies to which Dr. Wiglesworth devoted so large a portion of the little leisure obtainable in a busy and fruitful life will be stimulated by a bequest which will serve to keep his own work in remembrance.

CAMBRIDGE.—Dr. A. E. Shipley, Master of Christ's College, has resigned the office of Vice-Chancellor and been succeeded by Dr. Peter Giles, Master of Emmanuel. During his period of office Dr. Shipley devoted himself consistently to progressive measures, and was most active in furthering schemes of scientific importance. He has had two years of very strenuous work under abnormal conditions, and members of the University are grateful to him for the devoted attention he has given to all matters affecting their best interests.

GLASGOW.—During the summer an unusually large number of university lecturers have been promoted to professorial chairs at Glasgow and elsewhere. Prof. Henderson, formerly assistant, and lately professor, at the affiliated Royal Technical College, has been appointed to the Regius chair of chemistry in the University; Dr. T. S. Patterson, Waltonian lecturer, to the Gardiner chair of organic chemistry; Dr. E. P. Cathcart, formerly Grieve lecturer, to the Gardiner chair of physiological chemistry; Dr. C. Browning, formerly lecturer in clinical pathology, to the Gardiner chair of bacteriology; and two other lecturers in the arts faculty have also been promoted to chairs in the University.

The Queen's University of Belfast has elected Dr. A. W. Stewart, lecturer in physical chemistry at Glasgow, to its chair of chemistry, and Dr. T. Walmsley, lecturer in embryology at Glasgow, to its chair of anatomy. Dundee University College (St. Andrews) has appointed Dr. F. J. Charteris, lecturer in pharmacy at Glasgow, to its chair of materia medica, and Dr. J. F. Gemmill, research fellow and formerly lecturer in embryology at Glasgow, to its chair of natural history. Dr. Shaw Dunn, lecturer in clinical pathology at Glasgow, has been appointed professor of pathology in the University of Birmingham. Dr. W. E. Agar, lecturer in zoology and heredity at Glasgow, has been appointed professor of biology in the University of Melbourne. Dr. Leonard Findlay, Gow lecturer in medical diseases of children, has also been

[1] Dowden.

appointed Director of Child Welfare to the International Red Cross organisation at Geneva. Three lecturers in the departments of economics, history, and modern languages have received professorial appointments in other universities.

London.—A course of lectures on "A General Survey of the Globe and its Atmosphere," with practical work, will be given at the Meteorological Office, South Kensington, by Sir Napier Shaw, reader in meteorology in the University, on Fridays at 3 p.m. during the second term, beginning on January 23 next. The informal meetings at the Meteorological Office for the discussion of important contributions to current meteorology in Colonial or foreign journals will be resumed at 5 p.m. on Monday, November 3, 1919, and will be continued on alternate Mondays until March 22, 1920, with the exception of December 29. Students wishing to attend should communicate with the Reader at the Meteorological Office. The lectures are addressed to advanced students of the University and to others interested in the subject. Admission is free by ticket, obtainable on application at the Meteorological Office.

The academic teaching of military science as a subject of curricula for degrees of the University is to be resumed in the session now opening. Some years before the war military science was introduced as an optional subject for the Intermediate and Final Courses for the B.A. and B.Sc. degrees. The syllabuses have recently been revised by the Senate in the light of experience gained during the war, and it is expected that, in view of the large number of students who have gained practical military experience during the war, the subject will attract an increased number of students. The subject can be studied in the University both as a branch of general education and, in the case of candidates for University commissions in the Regular Army, as a preparation for their profession. Both classes of student will be able to obtain practical military training in the University Contingent of the Officers Training Corps. The post-war conditions under which commissions in the Regular Army may be obtained by University candidates have not yet been published.

Sheffield.—Prof. J. O. Arnold, who recently resigned his position as professor of metallurgy and dean of the faculty of metallurgy in the University of Sheffield, has been in failing health for some time, and, much to the regret of the University authorities, he has found himself unable to continue his work. Prof. Arnold was appointed in 1889 professor of metallurgy in succession to the late Prof. W. H. Greenwood at the technical department of the Firth College, which afterwards became a constituent part of University College, Sheffield, and later of the University of Sheffield. The applied science department of the University has kept pace with the applications of science to the steel industry, and taken a prominent part not only in the supply of trained men to these industries, but also in producing in rapid succession a number of valued contributions to the science of metallurgy. Prof. Arnold himself has been an active contributor for many years of valuable papers and researches carried out in the laboratories of his department. In 1912 he was elected a fellow of the Royal Society, and in 1916 a member of the council of the Iron and Steel Institute. He lectured before the British Association during its visit to South Africa in 1905, and he became the first dean of the faculty of metallurgy recently established in the University. His colleagues and friends wish him renewed health and vigour, which they trust may come to him now that he has allowed himself to relinquish some of the strenuous duties which he has performed so successfully for many years.

Dr. Edward Hindle, Kingsley lecturer and Bye fellow of Magdalene College, Cambridge, and assistant to the Quick professor of biology, has been elected to the chair of biology in the School of Medicine, Cairo, Egypt.

Dr. R. H. A. Plimmer, reader in physiological chemistry, University College, London, has been appointed as head of the biochemical department of Craibstone Animal Nutrition Research Institute, which is under the direction of Aberdeen University and the North of Scotland College of Agriculture.

Mr. J. R. Taylor has been appointed to the newly-created post of director of humanistic studies in the Huddersfield Technical College. Mr. Taylor is a graduate of the University of Edinburgh, and for several years past has occupied the position of lecturer to University tutorial classes under the University of Leeds.

News has just reached us of munificent bequests made to educational institutions in the Commonwealth of Australia by the late Sir Samuel McCaughey. Bequests made to the Sydney University, the Brisbane University, soldiers and their dependents, and the Presbyterian Church in New South Wales and Queensland are proportions of the residue of the estate, and the amounts are, therefore, contingent upon the sum realised by the estate. The estimated value of the estate is 1,750,000*l.*, and it is believed that, after certain legacies, amounting to about 230,000*l.*, and the other specific bequests are provided for, the residue of the estate will amount to 1,394,000*l.* Among the specific and the residuary bequests based on this estimate for educational, religious, and charitable purposes, the following are mentioned in the *Sydney Morning Herald*:—Sydney University, 465,000*l.*; Brisbane University, 232,000*l.*; Scots College, Sydney, 20,000*l.*; Sydney Grammar School, 10,000*l.*; North Sydney Church of England Grammar School, 10,000*l.*; Cranbrook Church of England Grammar School, 10,000*l.*; Newington College, 10,000*l.*; and King's School, Parramatta, 10,000*l.* The university bequests are unconditional. The gift to the University of Queensland (Brisbane) will enable that institution to do what it has always wanted to do, and never had the chance of doing: become a university, and more than a place for imparting a certain amount of (chiefly) technical instruction. The political world is rather a troubled one, and the type of Labour Party in power has not taken much interest in higher education. So the University has been cramped for funds, and unable to get much past its initial stage. With the gift to Sydney it is hoped that in a few years' time this institution will be a far bigger force for good than it now is. State education policy has brought secondary education to the people, with the natural result that the University is thronged, and that the buildings have been taxed to the limit of their capacity, the staff, especially on the scientific side, being far too heavily burdened. Now there is a prospect of an end to that condition of affairs, and, as the State will doubtless add to the buildings, the new revenues can go to strengthen the staff and bring in a number of leading men. A great increase in the graduate travelling scholarships is also desired, so that more of the best men of the University may spend some years in England and elsewhere. It is hoped that Cambridge will soon allow a Sydney B.Sc. to enter for the Tripos without making him pass the Little-go.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 15.—M. Léon Guignard in the chair.—E. **Goursat**: Remarks on a problem of vectorial geometry.—H. **Le Chatelier** and B. **Bogitch**: Refractory properties of aluminous materials. In spite of the high melting point of alumina, it has proved in practice to be an unsatisfactory refractory material. Measurements of the resistance to crushing at varying temperatures of alumina bricks, made up in different ways, are given, and it is shown that all become plastic at temperatures between 1200° C. and 1500° C. This explains their failure in steel furnaces, where the temperature exceeds 1600° C. In special types of laboratory furnace, where the material is not required to bear pressure, alumina can be used with advantage, and details are given of the method of building such a furnace capable of sustaining a temperature of 1600° C.—H. **Le Chatelier**: The development of scientific research in the United States.—A. **Foch**: Concerning the period of water-mains with a unique characteristic, furnished with an air-chamber.—L. **Picart** and F. **Courty**: Observations of the Metcalf and Borrelly comets made at the Bordeaux Observatory (38-cm. equatorial). Details of observations made on August 23 (Metcalf), August 31, and September 1 and 4 (Borrelly).—L. **Picart** and F. **Courty**: Further observations on these two comets. Measurements are given for September 5, 9, 10, and 11.—H. **Vanderlinden**: Elements of the comet 1919*c* (Borrelly).—L. **Guillet**, J. **Durand**, and J. **Galibourg**: Contribution to the study of the tempering of certain aluminium alloys. The alloys studied were of the duralumin type, containing about 3·7 per cent. of copper, 0·6 per cent. of manganese, 0·25 per cent. of zinc, and 0·43 per cent. of magnesium. The breaking strain, elastic limit, and hardness all increase with the time after tempering, a remarkable property shown by this alloy alone. The hardness was measured at varying intervals of time after tempering at temperatures of 300° C., 400° C., 450° C., and 500° C., and the transformation point found to lie between 400° C. and 450° C. The increase of hardness with time was only shown when the tempering temperature was above 400° C.—A. **Carpentier**: The fructifications of *Sphenopteris herbacea*.—L. **Daniel**: The stability and heredity of the Cratægomespilus and the Pirocydonia.—V. **Galippe**: The resistance of living intra-cellular agents to the action of certain chemical substances. The microzymas of tissues are not destoyed by glycerol, alcohol, chloroform, or by lapse of time.—M. **Herlant**: New researches on the inhibiting action exercised by the sperm of the mollusc on the fecundation of the egg of the sea-urchin.

THE BANTU LANGUAGES.

A Comparative Study of the Bantu and Semi-Bantu Languages. Sir Harry H. Johnston. Pp. xi+815. (Oxford: At the Clarendon Press, 1919.) Price 3 guineas net.

THE comparatively small number of people in this country who care in the slightest degree about the Bantu languages must long have been aware that this volume was in preparation, and have regretted scarcely less keenly than the author himself the innumerable difficulties which have conspired to keep it from the public. It is to be hoped that the obstacles to the production of the second volume will speedily disappear, as without it a right estimate of the whole work is impossible. It is to contain "an analysis and comparison of the phonology and word-roots, and a comparative examination of the syntax of the Bantu and semi-Bantu languages," and until these are available we shall be compelled to suspend our judgment on many important points.

Even a cursory survey of the first volume, however, fills one with astonishment (when one remembers the author's multifarious activities in other directions) at the amount of patient labour involved in the compilation and arrangement of the 274 vocabularies and the tabulation of prefixes and concords following each group. The three preliminary chapters likewise represent an amount of research out of all proportion to their length, and should be studied by all who wish to become acquainted with Bantu comparative grammar; while even those who want to acquire only some particular Bantu language will find their horizons enlarged and their grammatical path smoothed. That these pages contain some highly controversial—and controverted—propositions does not lessen their value. Bantu studies advance, as did the scholastic learning (no further parallel is intended) by means of continual disputations.

Perhaps the most important of such questions concerns the difference between the prefixes and pronouns, which, though in some cases identical, in others diverge so considerably (*e.g.* *m-* and *yu-* or *a-*, *omu-* and *gu-*) as to make the term "alliterative concord" largely a misnomer. Connected with this is the phenomenon of the initial vowel, or article, which Sir Harry Johnston prefers to call the "preprefix." This, he thinks, has given rise to the pronoun, therein agreeing with Meinhof, but—so far as we can make out—with this difference: Meinhof holds that the prefixes, probably excepting the tenth, consisted of one syllable only—*mu-*, *mi-*, *li-*, *ma-*, etc. To these was prefixed a demonstrative particle of the hypothetical form *γa*, which, through vowel-assimilation and modification or dropping of the consonant, produced in time such forms as *gumu-*, *kumu-*, *umu-*, *gimi-*, *imi-*, *gama-*, *ama-*, etc. (In some cases the consonant, as well as the vowel, was assimilated, giving such forms as *baba-ndu*, *bibi-ndu*, etc.) This "article," or "preprefix," became the pronoun prefixed to the verb.

Sir Harry Johnston's view seems to differ from the above in assuming that the original prefix consisted of two syllables, of which the first afterwards became the subject-pronoun, while the second supplied the object—thus explaining the difference between these in the cases where it exists. But, taking into consideration such a sentence as this, from his *Encyclopædia Britannica* article, "It is possible that some of these prefixes resulted from the combination of a demonstrative pronoun with a prefix indicating quality or number," it is really difficult to distinguish his explanation from Meinhof's.

We must leave to phonetic experts the discussion of the passages with which their science is more immediately concerned—viz. pp. 36–41 and 44; they will probably dissent from some of the author's statements. Even the lay mind is inclined to doubt whether *u* in "but" is the short sound of *a* in "father"; whether the German "ich-Laut" is "almost English *sh*"; and whether the Polish velar *l* ( ) can properly be described as dental. By the "indeterminate labial" (p. 39), bi-labial *f* and its corresponding voiced sounds are probably meant—and these can scarcely be said to result from "indecision on the part of the individual speaker or the tribe as to the utterance of *b* or *w*." Or are we to suppose that the whole Spanish nation halts between two opinions as to the *v* in *huevo* and that in *viejo*? But Sir Harry Johnston has seemed to us, of late, to exaggerate his revolt against pedantry into a too indiscriminate contempt for recent developments of phonetic science, and to fall back on "individual vagaries" or carelessness of pronunciation, somewhat as Socrates accused Anaxagoras of falling back on the *νοῦς*. At the same time, he credits "certain German philologists" with the theory "that we should attribute to the old Bantu some degree of vagueness in consonantal utterance." It is difficult to discover this theory in Meinhof's simple statement that primitive Bantu probably had three stops, all voiceless (*k*, *t*, *p*), and three fricatives, all voiced, *γ*, *l*, *v*. All analogy makes it probable that *γ*, for instance (which still exists in Shambala, where other languages have *g*, *j*, *dz*, *z*, or *y*), should be "the parent of the modern *g*" and some other sounds, but what vagueness of utterance is implied here, more than in any other sound-shifting that could be mentioned? (Meinhof, by the by, nowhere claims *χ*, or in Sir Harry's notation *x*, as "the parent of *k*," though he gives an example of the reverse relation.)

The paragraphs on p. 41 dealing with stress and pitch require some notice. Leaving aside the somewhat confused terminology ("accent *or pitch* of the voice"), we think the statement that the penultimate stress is the "prevailing rule in Bantu" requires some qualification. In Yao and Luganda the accent is on the stem-syllable, not shifting forward when terminations are added (*e.g.* *wángula*, not *wangúla*). The same seems to be the case in Konde and Sango. Again, it is not quite accurate to say that "the use of the high and low tones of the voices for purposes of etymological distinction is not common in Bantu, and is only observable (perhaps) in the Becuana group, and most markedly in the Pañwe languages of the north-west Bantu area." Tones are exceedingly important in Shambala, as Archdeacon Woodward discovered, once they had been pointed out to him; also probably in Konde and Sango; and they certainly exist (no doubt to a greater degree than has yet been observed) in Zulu and Nyanja, to name no others.

The summary, "History of Research into the Bantu Languages," given in chap. i., is exceedingly valuable, and the generous appreciation of work done by predecessors and contemporaries renders it very pleasant reading.

OUR LEGACY OF HOPE.

The Century of Hope. A Sketch of Western Progress from 1815 *to the Great War.* By F. S. Marvin. Pp. vi+352. (Oxford: At the Clarendon Press, 1919.) Price 6*s.* net.

THIS is a historical sketch of the last hundred years, distinctive in its insight and grip and in the place it gives to the development of science and its reactions. The new birth of humanity at the Revolution brought with it a legacy which has been especially expressed in the growth of knowledge and in the growth of freedom. These have had manifold social reactions, as in the political revival of 1815–30, with its increased realisation of the principles of freedom in both domestic and foreign affairs; the socialistic agitation which led on the Revolution of 1848; the practical applications of science, from railways and the telegraph onwards; the diffusion of biological and evolutionist ideas; the demand for schools for all; the increased liberation of religious activity; and the adoption of social reform as a primary objective of government. These are some of the subjects with which Mr. Marvin deals in his vivid and convincing book, and he leads us in conclusion to the international progress which is promised, he thinks, even in the decade of the greatest of wars. "If the war was the greatest, so also was the world-alliance for humanity and international law which brought it to a victorious conclusion. So also, we believe, will the world-union be the greatest, and most permanent, which will arise from the devastated earth and the saddened but determined spirits who are now facing the future with a new sense of hope, which enshrines our sorrows and has overcome our most oppressive fears." Belief in the desirability and practicability of any development is certainly a factor making for its realisation, and "The Century of Hope" shows that this faith is reasonable.

The fine chapter on mechanical science and invention enforces many useful lessons. "The sciences have, broadly speaking, become applicable to useful ends in proportion to the degree in which they have become exact." "Practical applications of science have become more and more abundant in proportion to the mutual aid of the sciences among themselves." The steam-engine "was the fruit of abstract thought applied to practice, and, in its turn, paid back its debt to science by leading to the greatest and most fruitful generalisation which had yet been reached. This was the principle of the conservation of energy, arrived at in 1848." "Society has become, in all these countries where industry has been organised and developed by science, a far more united and stable thing than it was before, or than it is in other regions less advanced in this respect." These sentences illustrate the insight and grip that mark the book. In a few pages Mr. Marvin sketches the development of the evolution-idea from Goethe and Lamarck to Darwin. "The organism in all its parts and with all its instincts was for the first time seen fully as an historical being." "No other part of science, no other episode in the story which we have to trace, affected so powerfully as did the theory of evolution the development of the historical spirit which we distinguished at starting as one of the characteristics of the age. The body of a man is like every social institution, history incarnate, and to Darwin more than to any other the world owes its overwhelming bent for the historical point of view, the desire to know the origins of things, the conviction that it is only by studying their steps that we can arrive at a true comprehension of their nature."

We cannot do more than refer to the lucid chapter on the new knowledge which centres around the discovery of radio-activity, and the inspiring discussion on social and international progress. The book begins and ends with emphasis on the truth that "not economic conditions nor geography nor the ambition of governments is the *primum mobile* in human affairs, but the spirit of man itself seeking greater freedom and expansion." "The spiritual forces are the supreme factors, both in building the individual soul and in giving a common soul to all humanity." "In the history of science and its applications we have the most perfect example of a growing human product in which the diverse races of mankind have all taken a proportionate share as they advanced in civilisation." This is a book that everyone should read, for it shows that from the real world with all its "Hearts of Darkness" we may not unreasonably augur the rising of a Heart of Light.

OUR BOOKSHELF.

Australia: Problems and Prospects. By the Hon. Sir C. G. Wade, K.C. Pp. 111. (Oxford: At the Clarendon Press, 1919.) Price 4*s.* net.

Sir Charles Wade, Agent-General for New South Wales, was Premier of that State during three years especially eventful in the effort to establish State control of wages and industrial unions. His pessimism as to the future of that policy and of the trend of government in this country may be due to the insuperable difficulties he then encountered. The book is based on a series of lectures on the resources and on the industrial and political problems of Australia. The author writes on political questions with expert knowledge. The chapter on the resources of Australia is less trustworthy; thus it says that there is little evidence of a diminishing flow from the artesian wells, in spite of the conclusive evidence to the contrary on the maps of the Queensland Water Supply Department. The exaggerated expectations based on the artesian water near Lake Eyre are also based on incomplete information.

The chapter entitled "Industrial and Social Problems" is probably the most important; it, however, deals only with the attempt to settle some of them by legislation. The author represents the New Zealand attempt to regulate wages by a special law court as a complete failure. He commends the wages boards of Victoria, but considers that system inapplicable where labour is aggressive. The attempt of New South Wales to enforce its labour laws by imprisonment or other penalties he regards as hopelessly impracticable. He shows, on the other hand, that the Australian system of land settlement has been remarkably successful, and the State expenditure on railways and public works a profitable investment. He predicts that the Constitution will be greatly modified in 1921, but does not expect that Australia will accept unification.

The book is a very valuable, up-to-date summary of the trend of industrial legislation in Australia, though the war has so disturbed its development that the conditions now are abnormal. A weighty preface by Sir Charles Lucas refers to the difficulties in the British and Australian comprehension of each other's points of view, and welcomes the book as helpful to that fuller knowledge and closer sympathy which are indispensable for permanent Imperial union.

Resources and Industries of the United States. By Prof. E. F. Fisher. Pp. ix+246. (Boston and London: Ginn and Co., 1919.) Price 3*s*. 9*d*. net.

Prof. Fisher's book is illuminating in that it presents the United States to the reader in such guise as to emphasise the greatness of the progress and the healthiness of the growth of the country. It is addressed to American secondary-school pupils, but merits a much wider public; it is knit together by a doctrine which is new to geography books — the doctrine that human energies should be conserved. The pupils are stimulated to visualise not only the resources and industries, but also the means whereby these may be conserved and made of most use to the community. For example, the United States, which produces two-thirds of the world's petroleum, uses more than it produces because it wastes half the oil that comes from the earth by allowing it to run to waste or to evaporate in open storage tanks. Petroleum is needlessly used to drive engines over 32,000 miles of railroad where electricity could be utilised. The pictures and maps are effective.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.]*

Colloid and Saline in Shock and Cholera.

The two letters by Sir Leonard Rogers and Prof. Bayliss in Nature of September 25 are of interest and importance, not only to physiologists and physicians, but also to physical chemists. The two series of observations are not contradictory of each other, but complementary.

There exists in blood plasma and in all living cells a delicate labile balance between the salines or crystalloids and the colloids. These two types of dissolved substances are not present in free condition, but in colloidal adsorption, the one with the other, forming a crystallo-colloidal complex.

This delicate balance is upset in opposite directions in wound-shock and in cholera respectively, saline being in excess relatively to the colloid in the former, and colloid of toxic origin in excess in the latter.

Hypertonic saline is efficacious in cholera because it replaces a defect, and combines with colloids of cells and with toxins which otherwise would combine with each other. In addition, it confers osmotic pressure on the poisonous toxins and hastens them out through the excretory cells. It is, indeed, because of this latter action that its concentration has become subnormal during the attack of cholera.

A colloid like gum-acacia is of no service in cholera, but rather the reverse, because it is an additional claimant for the denuded salines.

On the other hand, after hæmorrhage, as in wound-shock, both colloid and crystalloid are at first diluted, but saline is more fully restored from tissues than the protein colloids. In such circumstances there is no colloid available to hold any hypertonic or isotonic saline which may be injected, and this saline is promptly ejected by the excretory mechanisms; so saline alone is not efficacious. But a colloid of such a type as protein, gelatine, or gum-acacia possesses too great a molecule (or solution aggregate) to be excreted until it is broken down by metabolism, and, in addition to not being able to go out, it anchors salines by passing into labile adsorption with them, and so holds fluid in the vessels, raises pressure, assists the heart by giving fluid to fill it, and saves the cells from denudation of their crystalloids, which beyond a certain point always leads to change in colloidal aggregation and death.

It may be pointed out that such crystallo-colloidal adsorption is likewise the explanation of the important discovery of Ch. Richet, Brodin, and Saint-Girons at Paris that anaphylactic shock can be completely prevented by hypertonic saline. Here also lies the explanation for the prevention of hæmolysis by an active hæmolysin in presence of hypertonic saline as shown some years ago by McCay and Sutherland.

The saline locks up by adsorption the toxin or the immune body, and this can then no longer attack nerve-cells or blood corpuscles.

Under physiological conditions it is this adsorption of saline by colloid which determines the concentration of saline in circulation and cells. This regulation is one of the most ancient in evolution, far more so than regulation of body-temperature, for it holds sway from the teleostean fish to man. Whatever the concentration of the fluid of the external medium in salines from pond-water to sea-water, the salinity of the intimate medium bathing the living cells is always regulated to correspond with between 0·7 and 0·9 per cent. of sodium chloride.

It is strange that the mechanism governing this vital regulation should not have been grasped before. The cells and circulating medium are saturated with colloids, and this amount of 0·7–0·9 per cent. of saline is just the amount the colloids are capable of holding in crystallo-colloidal adsorption. Any more is at once filtered away; any less, and life ceases.

There are many other applications in biology and medicine, but they cannot be treated within the compass of a letter. BENJAMIN MOORE.

14 Frognal, Hampstead.

The Audibility of Thunder.

It has been stated that thunder is not usually heard at a greater distance than about twelve miles. This may be so during the day, but at night it can frequently be heard at a much greater distance from its point of origin. Some years ago I timed an interval between flash and sound over the sea, and found it to be more than two minutes. During the storm of September 5 last my son, Lieut. F. O. Cave, and I timed an interval by a method of counting seconds often adopted by photographers, with which method we were both familiar; one of us made it 140 seconds, the other 141 seconds. The flash was a particularly bright one; we had previously heard fainter thunder corresponding with less bright flashes, which were presumably a good deal further away.

On the night of October 1–2 a thunderstorm passed up-Channel to the south of this locality; any rainfall must have been beyond the Nab and the Warner lightships, as both lights were plainly visible; their distances are 17¾ and 16½ miles respectively if they are in their pre-war positions. With the help of an electric clock, which moves on every half-minute, supplemented by counting seconds, I made one time-interval 120 seconds and another 170 seconds; then with a stop-watch I timed an interval of 189 seconds.

During the storm of October 1–2 the pheasants crowed much more loudly than usual, especially at the early rumbles of thunder, or else the audibility was exceptionally good; probably the latter was the case, as the night was very clear and the air in the valley from which the crowing came would have been colder than the air here, a condition which would probably be favourable for good audibility of sounds coming from the valley, though it would scarcely account for the audibility of the much more distant thunder. It may be worth noting that the false cirrus above the thunder-cloud was lit up by light reflected from the aurora which was extremely brilliant at the time. C. J. P. CAVE.

Ditcham Park, Petersfield, October 6.

OPEN-AIR NATURAL HISTORY.[1]

MR. LOVELL'S book is the outcome of years of patient study, and will be welcome to botanists, entomologists, and bee-keepers. It deals with the inter-relations of flowers and insects, especially as regards pollination; it "treats of plants alive and in the midst of their home surroundings"; it justifies the author's prefatory remark that "the identification of a species should be regarded merely as an introduction and the beginning of a friendship long to be continued." The book is written with enthusiasm and popularly, but it is a scientific record of personal observations of great interest, and it includes some notes on modern theories which should be carefully considered. It is illustrated with conspicuously successful photographs, which have been taken on panchromatic plates to preserve in monochrome the proper colour values.

Beginning with a short historical sketch, in which tribute is paid to Sprengel, Hermann Müller, and Darwin, the author discusses wind-pollinated flowers, the *rôle* of hive-bees especially in relation to blue flowers, the humble-bee's favourite flowers which are mostly irregular in shape, the short-cuts taken to the nectaries, the crab-spiders which lurk in flowers and pounce on the insect-visitors, the "oligotropic" bees that rarely visit more than one kind of flower, the predominantly reddish butterfly-flowers like pinks and some Compositæ, the work of nocturnal moths in relation to flowers like evening primrose and honeysuckle, the fly-flowers like *Linnaea borealis* which is visited by the dance-fly (*Empis rufescens*), and those with nauseous odours like the carrion-flower and the skunk-cabbage, the usually injurious visits of beetles, flowers like wild roses, mulleins, and poppies which are visited for pollen, not nectar.

Mr. Lovell discusses the experimental evidence of the value of having conspicuous flowers and of colour-discrimination on the part of bees. In regard to the latter, however, the discussion is inadequate, for no experiments are conclusive that do not distinguish between colour as such and differences in intensity of illumination. A very interesting general chapter deals with the colours of flowers. Of the 4020 flowering plants in north-eastern America, the greens, whites, and yellows number 3001, while the reds, purples, and blues amount to only 1019. The latter are, on the whole, of more recent origin, and have evolved from the others, the selective agency of insects playing its part. In conclusion, the author discusses the value of bees in connection with fruit-growing, and notably in securing cross-fertilisation, the importance of which is very strongly emphasised.

The author has written a fine book on a fine subject, and his treatment should stimulate further study. We wish that he had been able to devote a special chapter to theoretical considerations, for, though he believes in the transmission of acquired characters, in the efficacy of insects as selective agents, in orthogenesis carrying plants beyond the limits of the advantageous, and in the evolutionary importance of crossing, he says tantalisingly little on these subjects. From an observer of Mr. Lovell's experience we should like to hear more.

(2) Mr. Step has written a delightful book on the industries of insects, which he arranges under headings corresponding with human occupations. He directs attention to the interesting fact that

[1] (1) "The Flower and the Bee: Plant Life and Pollination." By John H. Lovell. Pp. xvii+286. (London: Constable and Co., Ltd., 1919.) Price 10s. 6d. net

(2) "Insect Artizans and Their Work." By Edward Step. (Hutchinson's Nature Library.) Pp. x+318. (London: Hutchinson and Co., n.d.) Price 7s. 6d. net.

(3) "The Seashore: Its Inhabitants and How to Know Them." By F. Robson. Pp. 111. (London: Holden and Hardingham, Ltd., n.d.) Price 1s. 6d. net.

many of the activities are very specific and very intricate, yet there can be no help from parental instruction. "In the vast majority of species the parent is dead long before the daughter comes to that stage of existence when the necessity for making provision for her progeny arises, so the knowledge has to pass by way of transmitted memory. Somewhere in the minute speck of protoplasm constituting the egg of one of the solitary bees there is an infinitesimal particle of nerve matter which contains the secret of how to cut accurate circles and ovals of rose-leaf so that a number of them will overlap and curve into a perfect cylinder. During the greater part of its life the creature that hatches out from that egg will have no need of the secret, but the germ of it will go on developing, and when the insect has attained to the complete bee form there is the idea in the memory cells ready to instruct the nerves that govern the action of wings and legs and cutting jaws." We have quoted this at length, for it expresses Mr. Step's view of the big riddle that lies behind his book. Unfortunately, we do not know how the secret is kept in the egg before there is any particle of nerve matter, or how the insects get the knowledge which forms the contents of the transmitted memory, or whether they really have an idea which instructs the nerves. But the author usually chooses the wise path of keeping to the facts, and gives us a charming account of spinners and weavers, miners and masons, carpenters and wood-workers, upholsterers, wax-workers, paper-makers, tailors, horticulturists, sanitary officers, musicians, burglars, and lamp-bearers. The book is fresh and competent, and the illustrations (two of which are here reproduced) deserve high praise, both the photographs by the author and the drawings by Mr. Carreras.

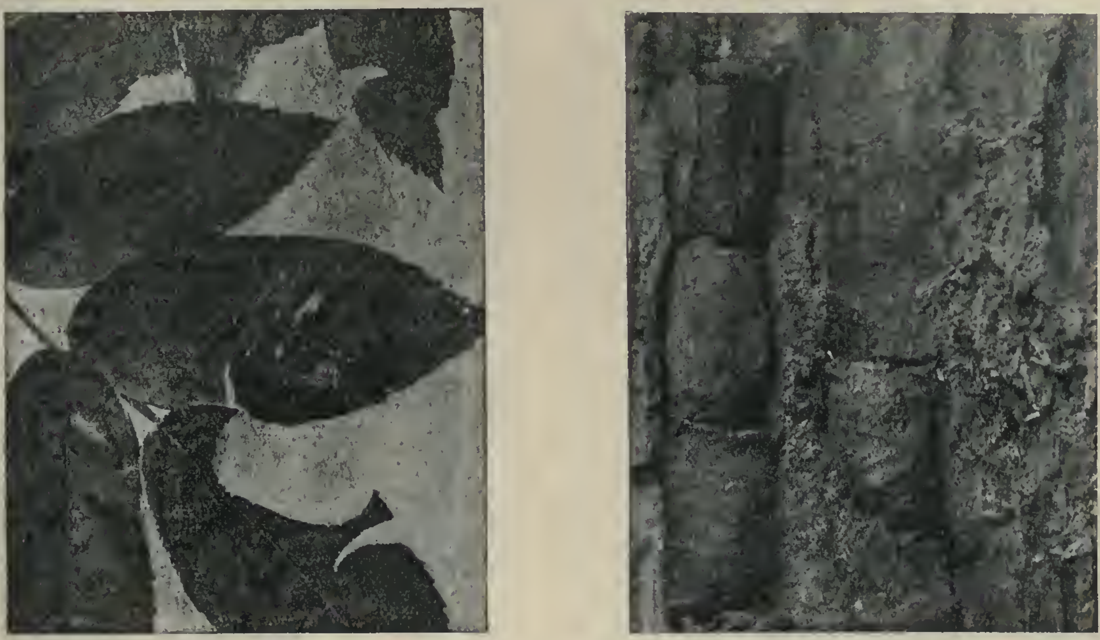

FIG. 1.—Leaf-cutter Bee. The left photo shows the bee at work. The right photo is a section of an old post and shows the thimble-shaped cells made from the cut portions of leaves. From "Insect Artizans and their Work."

(3) Mr. Robson's little book attempts the impossible, and does not succeed. The space is, indeed, inadequate for an interesting account of the inhabitants of the seashore, but it might have been used more skilfully; the illustrations are not very happy; there are several inaccuracies in the brief text; and there are far too many misprints. Several excellent inexpensive guides to the seashore, as much within children's compass as this book is, are readily available.

THE RECONSTRUCTION OF THE FISHING INDUSTRY.

IN November of last year the National Sea Fisheries Protection Association made proposals for a unification of fishery administration, and it embodied these in a "Memorandum" (which was referred to in NATURE of November 28, 1918, p. 248). The memorandum was submitted to Mr. Prothero, who doubtless acquainted the Cabinet with its provisions, but that was all that happened. Eight months afterwards the Government introduced a Bill for the establishment of a Standing Fishery Advisory Committee, and for the removal of the statutory limitation of the salary of the President of the Board of Agriculture and Fisheries!

The 1918 memorandum recommended the creation of a United Kingdom Ministry of Fisheries, but its authors found that they were "up against" the opposition of the Scottish industry. So when a special joint committee of the association prepared a scheme for fishery research, statistics, education, and propaganda they took care to avoid this and other obstacles. They recognised that the only logical way of co-ordinating all British agencies for fishery development was by the setting-up of an Imperial authority; but they also recognised that this ideal was unattainable. Some other statutory body for the co-ordination of research and education would have been agreed upon by the various sections of the British industry, but the committee then found that the fishery Departments were "unlikely to acquiesce in the formation of any central authority other than a Ministry of Fisheries, to be superimposed upon them from without." In the face of *this* formidable opposition the committee had to do the "next best," and, abandoning any really comprehensive way of making use, to the greatest advantage, of all fishery workers, they have made a compromise that may be practicable. In order that as few people as possible may object, they do not recommend the formation of anything in the way of a "Super-Department." Assuming that the existing fishery authorities are to be properly financed and organised as permanent secretariats, and that each of them will then proceed to set up a scientific branch with a director of scientific work, they propose that the three permanent secretaries shall then sit as a joint research board, with such official and non-official assessors as they may nominate. The hope (uncoloured by conviction) is then expressed that the assessors may form the means of communication between the officials, the industry, and the non-official investigators.

The joint research board, so constituted, is not to be, in general, an executive body controlling research. Obviously not, for agreement could not be obtained on points of difference between officials, and departmental privilege would be too great a factor. It is to deliberate on schemes of research and transmit plans and estimates prepared by the departments. But it is recommended that it shall control the collection of fishery statistics, set up a joint editorial board which will publish all results—administrative, statistical, and scientific—in uniform style and with promptitude, and establish and carry on (through an editorial staff) a Fisheries Journal which will be, in the main, popular in character. A strong plea is made for some reform in the manner of publication, for speedy production, for some relief from the exceeding dulness and clumsiness of governmental Blue Books, and for a "break away" from the methods of H.M. Stationery Office.

Considering the things to be investigated, the Committee recognise five categories of research, and set these out in detail: (1) Practical administrative problems to be studied by the departmental staffs; (2) fish culture; (3) industrial research; (4) speculative research; and (5) oceanography. Fish culture is obviously work for the departments, and, since the fishing industry does not seem likely to undertake industrial research itself, this must be done by the Government. Speculative research—a very large category of investigations—ought to be relegated to the universities and marine biological stations, with some other subjects included in the category of industrial research and in that of oceanography. Since the departments must possess and equip sea-going vessels for their practical administrative investigations, it is obvious that they should also carry out the oceanographic observations at sea, but the working up of these should be done by the unofficial State-aided institutions. And so, it is hoped, everybody will be satisfied, and the best use possible made of all the talents.

A provisional scheme for fishery education, training, and propaganda is appended. This includes the training of administrative and scientific officers, and of men occupying responsible industrial posts, by the provision of Government fellowships tenable as post-graduate studentships at the universities; fishery colleges at Liverpool and Aberdeen; fishermen's classes carried on locally and a scheme of fishery apprenticeship. The latter proposals are most interesting. Immediately upon the outbreak of war hundreds of vessels and thousands of men were placed at the disposal of the Admiralty, and, without any special training, the duties of mine-sweeping, patrolling, and escorting were carried out in such a way as to earn loud expressions of admiration and gratitude. There were exceptional losses due to war risks and natural decrease; the training of lads largely ceased during the period of war; the old system of apprenticeship has become obsolete and, in view of naval defence and in the interest of the industry itself, a better class of lad is now desirable. The interesting suggestion is made that a number of the trawl-vessels built during the war by the Admiralty be detailed and equipped as training-vessels, and a scheme of apprenticeship is recommended.

This scheme was worked out in detail by the industry as soon as it was seen that peace was assured. It is an integral part of any attempt at fishery reconstruction and naval defence. It was submitted to the Government nearly a year ago, and it has been "under consideration" ever since then! Meanwhile the Admiralty trawlers are being offered for sale.

Summary of Main Recommendations.

(1) That the Government be requested to provide funds for a comprehensive scheme of research statistics for the fisheries of the United Kingdom on the lines set forth in this report.

(2) That each Fishery Department be provided with a suitable scientific staff under a scientific director with well-equipped laboratories, and with sufficient steamers for research work and for the exploration of our fishing grounds.

(3) That the Fishery Departments be requested to adopt the best means they can devise for securing the uniformity of fishery statistics, and the co-ordination of research work throughout the United Kingdom.

(4) That the Fishery Departments make suitable provision for the publication of scientific reports which

are of importance to the industry, and in particular for the publication monthly of a fishery journal containing all information in regard to scientific results, statistics, statutes, orders, foreign intelligence, commercial information, and all other information likely to be of benefit to those carrying on the industry.

(5) That the Fishery Departments and the Education Departments of the three kingdoms be requested to co-operate in providing a scheme of education on the general lines laid down in the report.

NOTES.

The British Association, as an outcome of the comprehensive review of scientific work during the war, which formed a conspicuous part of the programme of the recent meeting in Bournemouth, has addressed the following resolution to the Prime Minister and the Treasury:—"The British Association for the Advancement of Science, in reviewing the results of scientific method applied to military and other practical arts, recognises that the successful issue of the war has sprung from the efforts of scientific men concentrated on those problems, and with the conviction that the well-being and security of the nation are dependent on the continuous study of such matters, would urge on H.M. Government the necessity for apportioning an adequate sum from that allocated to home administration and the upkeep of the fighting forces for the purpose of a definitely organised scheme of research, as, for example, on problems connected with health, food, and commerce, on explosives, on chemical warfare, and on physical and engineering problems bearing on military work." Similar resolutions, in varying terms according to the special cases, have been forwarded to the First Lord of the Admiralty, the Secretary for War, the President of the Board of Trade, and the Ministers of Health and Food.

The appointment, as recently announced, of Prof. S. J. Chapman to be joint Permanent Secretary of the Board of Trade, owing to the transfer of Sir William Marwood to the Ministry of Transport, will be welcomed by all who know him. Prof. Chapman, who had held the professorship of political economy at Owens College, Manchester, since 1901, acted during the war as head of the temporary Industrial (War Inquiries) Branch of the Board of Trade, and in 1918 was appointed head of a new General Economic Department created for the purpose of assisting the Permanent Secretary in relation to questions involving economic policy. He is a fellow and member of council of the Royal Statistical Society, to the Journal of which, and to that of the Manchester Statistical Society, he has made numerous contributions bearing mainly on the cotton industry of Lancashire.

In the *Times* of October 11 is a letter from Prof. J. Johnstone on the subject of the extension of territorial waters in relation to deep-sea fishing. It is pointed out that the information at present available is not sufficient to enable satisfactory regulations to be drafted, and that, therefore, administrative authorities should not be given legislative powers which they cannot exercise properly. Prof. Johnstone also states that scientific investigation of our sea fisheries has never been properly organised and supported, and is in a worse condition now than it ever was. We agree with him that fishery investigations in this country have been quite inadequate, and we hope in the near future to see the establishment of an organisation for the comprehensive scientific study of the sea, so important for a great maritime nation, on a scale proportionate to the magnitude of our interests.

Changes in the Meteorological Office staff have recently been made, and the following appointments have been announced:—Mr. R. G. K. Lempfert becomes assistant director, and takes general oversight of observations and stations contributing observations to the Office. Mr. Lempfert entered the Meteorological Office in 1902, and has been superintendent of the Forecast Division since 1910. Lt.-Col. E. Gold becomes assistant director, in charge of forecasting. Col. Gold graduated as Third Wrangler in 1902, and was elected Fellow of St. John's College, Cambridge, in 1906; he was Schuster reader in dynamical meteorology from 1907 to 1910, and he then became superintendent of statistics at the Meteorological Office. On the formation of the meteorological section of the Royal Engineers in 1915 he was appointed to the command of the overseas contingent at G.H.Q., France. Capt. D. Brunt is made superintendent of the work for Army services. Capt. Brunt was in the meteorological section of the Royal Engineers during the war, and acted under Col. Gold. Mr. Carle Salter becomes superintendent on the staff of the Meteorological Office for the British Rainfall Organisation. Mr. Salter has recently been assistant director of the British Rainfall Organisation, which has now come under the control of the Meteorological Office.

In connection with the International Meteorological Committee, appointed by the International Conference at Innsbruck, 1905, a meeting of available members was held at the Meteorological Office, London, on July 3–9 last, and a copy of the minutes which have been printed has reached us. Since 1905 the committee has met in Paris (1907), Berlin (1910), and Rome (1913). The July meeting was of a semi-official character, and was really to prepare the way for the Paris meeting, which commenced on September 30. The president, Sir Napier Shaw, in his introductory statement directed attention to the changes caused by the great war, and especially to the new meteorological organisations developed. It was felt that the extent and detail of international co-operation must be much greater in the future than it had been in the past, but the problems are essentially of the same nature as formerly. The great development of aviation has introduced new requirements in respect of information concerning the upper air obtained by pilot-balloons or in other ways. The hours of observation for Europe were considered; 1h., 7h., 13h., and 18h. have become general, but it has been suggested that preference might perhaps be given to 3h., 9h., 15h., and 21h. Consideration was given to North Polar investigation in co-operation with Amundsen's expedition, and there was a proposal for the establishment of a meteorological station in the Island of Jan Mayen for observations from the summer of 1920 to the autumn of 1922. Necessarily much attention was devoted to the coding of messages and to the method and nature of the observations.

The Harveian Oration will be delivered at the Royal College of Physicians by Dr. Raymond Crawfurd on Saturday, October 18, at 4 p.m.

We regret to record that *Engineering* has suffered a severe loss in the death of Mr. B. Alfred Raworth, who had long been a member of the staff, and taken a prominent position in the editorial management during the past thirteen years. Mr. Raworth was a trained engineer, and had considerable experience prior to joining the staff of *Engineering* in 1882. He was a member of the Institution of Mechanical Engineers, of the Iron and Steel Institute, and of the Institute of Metals.

THE *Engineer* for October 16 records the death of Sir Charles Chadwyck-Healey, who had been intimately associated with our contemporary throughout the greater part of his life. Sir Charles was the only son of the founder of the *Engineer*, and was trained for the Bar, from which he retired after a successful career in 1893. During the war he performed a national service of great utility in fitting out at his own expense the hospital ship *Queen Alexandra*, and commanded her until she was discharged a few months ago.

WE regret to record the death, on October 5, of Mr. G. W. Palmer, who was appointed senior mathematical master and master of the Royal Mathematical School at Christ's Hospital in September, 1911. Educated at Dover College and Trinity College, Cambridge, Mr. Palmer did valuable work as mathematical master first at the Royal Naval School, Eltham, and afterwards at Clifton College, where he became head of the military side. An enthusiast in all matters educational, and a prominent member of the Mathematical Association, he kept in close touch with the best modern ideas on the treatment of his subject. Owing to his strong influence, more time was given to important principles and fresh ideas, while elaborate development in any one direction was avoided or postponed. The result has been that Christ's Hospital boys have shown increased interest in their mathematical work and a high general level of achievement—and this, too, without affecting the standard attained by boys preparing for the universities. During a brief reign of eight years Mr. Palmer accomplished a notable and valuable work of lasting benefit to Christ's Hospital. His death is a very severe loss to the school.

THE Society for the Prevention and Relief of Cancer has issued a pamphlet, "Cancer Research and Vivisection," summarising in tabular form the number of experiments returned by cancer institutes in the last fourteen years. The author holds that animal experiment in cancer is a futile waste of money, and ought to be stopped. Illustrations are reproduced showing infiltrative growth and metastasis-formation in experimental cancer, but the author suggests that experiment can throw no light on these conditions in the human subject. The aims of the society include the provision of hospitals for cancer patients, the statistical study of cancer, and legitimate (*sic*) experiment. No indication is given of what kind of experiments are contemplated, although needles and syringes for animal inoculation are figured in the book. Pamphlets have also been published on the use of violet-leaves and on the influence of tea-drinking. The society has been in existence for seven years, but its efforts seem to have had no effect on cancer mortality.

THE September–October issue of the *Scottish Naturalist* contains some extremely interesting notes by Mr. Donald Guthrie on the birds of South Uist. Among these, Mr. Guthrie remarks of the greylag goose that its wariness baffles description, yet goslings of this species which he hatched out from a clutch of eggs placed under a hen proved as amenable to domestication as ordinary tame geese. In their second year two females of this brood bred near the house without the slightest sign of shyness. A third disappeared for several weeks, then returned with a brood of goslings, and took up her place, accompanied by her family, with the fowls round the house. Her mate, who accompanied her, for a day or two held aloof, but on the third day took his place with the rest and stayed there. Having regard to the interest attached to the oft-discussed theme as to the origin of our domesticated geese, this case is worthy of note.

IN Report No. 1 of the Industrial Fatigue Research Board Dr. H. M. Vernon describes "The Influence of Hours of Work and of Ventilation on Output in Tinplate Manufacture." The tinplate industry is a very strenuous one, especially as concerns the millmen, for they are responsible for rolling out the red-hot tinplate "bars" into thin sheets of steel, which are afterwards tinned. The tinplate mills run continuously from Monday morning until Saturday afternoon, and, as a rule, the men work in eight-hour shifts. If there is a breakdown of machinery or shortage of material, the men are often put on to six-hour shifts instead, and sometimes even on to four-hour shifts, so as to give them all some employment. Consequently one is able to obtain trustworthy evidence as to the effects of such shortened hours on output. Arguing from numerous statistical data collected at a number of tinplate works, Dr. Vernon found that when the men were transferred to six-hour shifts their hourly output went up about 10 per cent., and when to four-hour shifts, it went up 11·5 per cent. This improvement is not so great as would be brought about by a thoroughly efficient system of ventilation, for it appeared that in works without artificial ventilation there was a marked seasonal variation of output, and in the hottest weeks of the year the output was 11–18 per cent. smaller than in the coldest weeks. In the ventilated factories the seasonal variation was much less, but even in them there was plenty of room for improvement. The report is illustrated by photographic reproductions of the millmen under working conditions.

ONE of the commonest and most disfiguring abnormalities of the modern mouth is a forward protrusion of the upper incisor teeth, with which is usually combined a retraction of the chin and a crowding of the lower incisor teeth. On this condition Mr. D. M. Shaw, curator of the Prosthetic Laboratories, Royal Dental Hospital of London, has recently thrown quite a new light (*Lancet*, August 23). He has shown that a certain "perverted functional activity" of the tongue will produce the series of anomalies which dentists have so often to correct in the mouths of modern children—forward protrusion and obliquity in the upper incisors, with retraction and uplift of the lower incisors. Mr. Shaw directs the attention of dentists to the strength with which the tongue can be made to press against the anterior part of the roof of the mouth, particularly behind the upper incisors, thus exerting a much greater power to produce deformity than is used by dentists to correct malposition of the teeth. Tongue-pressure of this nature is particularly common among children, especially when eating soft or pulpy food, being really a form of tongue mastication. This form of mastication appeals to children because it yields a fuller sense of taste if the food is sweet or agreeable than the legitimate use of teeth and gums. The point which is quite new in Mr. Shaw's demonstration is that during the palate-pressure action of the tongue the genio-glossus muscle exerts a retracting action on the chin region of the lower jaw.

A USEFUL article on "The Climate of Liberia and its Effect on Man," by Mr. Emory Ross, appears in the *Geographical Review* for June last. The passages on "European life on the West Coast" in general, on "tropical hygiene," and on "the nervous strain of the tropics" offer conclusive advice to those who may, in an idle moment, have thought of emigration. By immense efforts acclimatisation of the white man might be rendered possible, but at present his relation to the African West Coast "can be only one of tolerance."

THE manganese ores of the Shimoga and adjacent districts are interestingly described by Mr. B. Jayaram, Senior Geologist to the Department of Mines and Geology of Mysore (Records, vol. xvi., part 2, 1917). The author suggests that percolating waters have brought the manganese, and the iron with which it is always associated, from the silicates of the basic chloritic schist series, and have deposited the ores as a replacement of the limestones and grits in which they are now found. The rocks termed limestone and grit are not true sediments, but secondary products of an igneous complex.

ATTENTION was directed to the magnesite deposits of Canada in NATURE, vol. c., p. 490, 1918. Those of Bulong, north-east Coolgardie goldfield, are now described by the Geological Survey of Western Australia (Bulletin 82, 1919). The magnesite, which is in numerous veins a few inches wide, has arisen from the decomposition of a great band of serpentine, and it is suggested that augite as well as olivine has supplied the magnesium required for its formation. The silica set free is probably responsible for the capping of "siliceous laterite, usually opaline in composition," which is stated to occur in the magnesite areas. The value of the magnesite is estimated at *1l.* per ton on the ground, the export value being nearly *4l.* per ton.

ONE of the means by which supplies of potassium compounds were eked out during the war period was the recovery of potassium salts from the flue-dust which occurs as a waste product in the manufacture of Portland cement. The principal methods employed depended upon treatment of the flue-gases by water-sprays or by a process of electrical precipitation. An account of the various installations devised for the purpose has been published by the Department of Mines, Ottawa (Bulletin No. 29, "Potash Recovery at Cement Plants"). It contains descriptions of the recovery systems developed at a number of cement factories in the United States, together with an historical review of the whole question and full references to the literature of the subject.

ATTENTION may be directed to a useful series of articles on the mechanical handling of chemical materials, by Mr. G. F. Zimmer, which have recently appeared in the *Chemial Age* (Nos. 10 to 15). It has been remarked that chemical works in this country are rather poorly equipped with labour-saving machinery. In present circumstances, when the cost of manual labour has increased so greatly, it may be necessary to pay more attention than formerly to devices which will reduce this cost. The articles in question will help to show how this may be done. They are illustrated, and well worth consulting by chemists in charge of factories.

MESSRS. LUMIÈRE AND SEYEWETZ have published in the *British Journal of Photography* (October 3, Colour Supplement) a simplified method for the development of autochrome plates. The developer is prepared of two degrees of concentration, so arranged that if the weaker is applied first to the plate, the time that is taken in producing the first outlines of the image (neglecting the sky) will be exactly the time that the stronger solution will require to complete development. Although a watch or clock may be used for the timing, a simple sand-glass has many advantages. The sand is started running when the weaker solution is applied, then on the first appearance of the image the glass is put on its side; the weaker solution is poured off and the stronger poured on, and the sand-glass put upright. When the sand has flowed back again the development is complete. In the formula given the concentrations of the developers are as 1 to 10.

SIR CHARLES BRIGHT read a paper on "Inter-Imperial Communication, through Cable, Wireless, and Air Methods," before the Section of Economic Science and Statistics at the Bournemouth meeting of the British Association. He pointed out that it is conceivable that national and imperial interests can be adequately provided only by the State controlling at least one complete cable to all points of the British Empire, supplemented by an all-British wireless chain. The recently established Telegraph Communications Board, first urged by the author seventeen years ago, is intended for generally controlling and developing inter-imperial telegraphic and aerial communication in national and public interests. By this scheme all the Government departments concerned (strategic as well as civil) are represented by delegates, who meet periodically to discuss and settle all matters germane to the subject. This should do much towards improving the previously existing arrangements by which the Post Office alone represented the Government. Besides increased cable and wireless facilities being necessary and the war devastations made good, it is highly desirable that improved methods of message condensation should be introduced so as to get the best results from existing facilities. The field open to inter-imperial air communication is considerable; air organisation and air routes are amongst the important questions of the day, and it is suggested that all aerial mail communications should be rationed.

AN important paper on the theory and use of radio-direction-finding apparatus by Capt. A. S. Blatterman, of the U.S. Army, appears in the Journal of the Franklin Institute for September. It is known that in radio stations it is sometimes possible to hear signals when the antenna is disconnected from the apparatus. Hence the passing waves induce sufficient electromotive forces in the coils of the receiver to produce audible signals. An investigation was therefore carried out in the U.S. radio laboratories in 1917 and 1918 to find out the most efficient shape of coil to receive signals directly. As the loudness of the signals varies with the position of the coil, an investigation was also made of the most efficient shape of coil for direction-finding. Elementary theory would lead us to suppose that the coil would be more effective the larger its cross-section and the greater its time-constant. It would also appear that the loudness of the signals is inversely proportional to the square of the wave-length. This, however, is not the case. The experiments recorded in this paper prove that there is a certain size of coil which gives the best results for a given wave-length. This was traced to the fact that the resistance of the coil varies with the wave-length. For very long wave-lengths the resistance has its ordinary value. As the wave-length is shortened, and therefore as the frequency is increased, the resistance increases slowly until it is two or three times its ordinary value, and it then increases with great rapidity. This effect makes the reception bad at high frequencies. There is, therefore, a certain sized coil which produces the best effects. The results of the experiments described prove this conclusively. A thorough investigation is also given of the directional characteristics of this type of receiver, and many curious properties depending on its height above the ground were discovered. Using a properly constructed coil in an ordinary room and a seven-stage amplifier, the signals issued by all the high-power European stations could easily be heard.

OUR ASTRONOMICAL COLUMN.

Ephemeris of Comet 1919*b*.—Messrs. Braae and Fischer Petersen give the following continuation of this ephemeris (for Greenwich midnight) in *Ast. Nach.*, 5008:

	R.A. h. m. s.	Decl. ° ′	Log *r*	Log Δ
Oct. 17 ...	11 55 29	8 55 N.	9·6856	9·9440
21 ..	12 3 20	5 10		
25 ...	12 12 36	1 36 N.	9·7225	0·0289
29 ...	12 22 44	1 43 S.		
Nov. 2 ...	12 33 18	4 47 S.	9·7962	0·0932

The comet is in perihelion October 16·9, so it should still be an interesting object, though its distance from the Earth has greatly increased. It is rather inconveniently placed in the morning sky, but observations of position are much desired.

The Albedo of Saturn's Rings.—The *Astrophysical Journal* for July contains a paper on this subject by Mr. L. Bell. It is considered that the very high albedo of the brighter parts of the rings indicates that much of the matter forming them exists in the form of optical dust of dimensions comparable with a wave-length of light. Mr. Bell quotes the familiar fact that many substances appear of a lighter colour when powdered than when in large blocks. He gives 15 km. as the thickness of the main parts of the rings, slightly greater at the outside of ring B and the inside of ring A. He suggests that there are dust-clouds of exceedingly small density on each side of the ring-plane, to explain the nebulous patches seen when the ring is edgewise. He points out that light-pressure would come into play in the case of this fine dust, and help in its diffusion. It is supposed that there are some larger lumps in the main rings, and by a combination of dynamical and optical arguments he fixes their diameters as being of the order of 3 metres. Mr. Bell makes use of Prof. Barnard's photographs, and also of those of Prof. Wood in monochromatic light.

The Selection of Sites for Astronomical Observatories.—The importance of studying atmospheric conditions before choosing sites for observatories intended for work of a delicate character on the sun or planets is becoming increasingly recognised. Prof. W. H. Pickering gives some interesting details of the station established by the Harvard Observatory at Mandeville, Jamaica, altitude 2000 ft. (*Popular Astronomy*, August–September). The air is of such extraordinary clearness that the star γ Volantis, magnitude 3·7, is frequently visible to the naked eye, although its maximum altitude is 1° 40′. A photograph is reproduced, taken with a small stationary camera, which shows a very clear trail of β Carinæ, altitude 2° 40′.

Prof. Pickering's experience, contrary to the impression of many astronomers, is that the seeing is at its best when the air is heavily charged with moisture. It will be remembered that much work on Mars has been done at Mandeville in recent years.

FORTHCOMING BOOKS OF SCIENCE.

Agriculture and Horticulture.

Edward Arnold.—Gardens: Their Form and Design, Viscountess Wolseley, illustrated. *Cassell and Co., Ltd.*—The Garden Month by Month, H. H. Thomas, illustrated; Garden Handbook for Beginners, H. H. Thomas, illustrated. *Constable and Co., Ltd.*—Forests, Woods, and Trees in Relation to Hygiene, Prof. A. Henry, illustrated.—*Hodder and Stoughton.*—Chemistry and Bacteriology of Agriculture, E. J. Holmyard, illustrated (The New Teaching Series of Practical Text-books). *Hutchinson and Co.*—Gardens of Celebrities and Celebrated Gardens, J. Macgregor, illustrated. *Macmillan and Co., Ltd.*—Science and Fruit Growing: Being an Account of the Results Obtained at the Woburn Experimental Fruit Farm since its Foundation in 1894, the Duke of Bedford and S. Pickering. *John Murray.*—Conifers and their Characteristics, C. C. Rogers. *Oxford University Press.*—Effects of the Great War upon Agriculture in the United States and Great Britain, Prof. B. H. Hibbard; United States Forest Policy, J. Ise.

Anthropology and Archæology.

W. E. Harrison (Ipswich).—Pre-Palæolithic Man, J. Reid Moir. *Hutchinson and Co.*—The Ruined Cities of Northern Africa, Dr. R. Sturzenbecker, illustrated. *Macmillan and Co., Ltd.*—An Introduction to Anthropology: A General Survey of the Early History of the Human Race, Rev. E. O. James; The Ila-Speaking Peoples of Northern Rhodesia, Rev. E. W. Smith and the late Capt. A. M. Dale, 2 vols., illustrated; Among the Natives of the Loyalty Group, Mrs. E. Hadfield, illustrated. *John Murray.*—Travels in Egypt and Mesopotamia in Search of Antiquities, 1886–1913, Dr. E. A. Wallis Budge, 2 vols., illustrated. *Oxford University Press.*—James Tod's Annals and Antiquities of Rajasthan, edited with an introduction and notes by Dr. W. Crooke, 3 vols., illustrated.

Biology.

A. and C. Black, Ltd.—Outlines of the History of Botany, Prof. R. J. Harvey Gibson. *Cassell and Co., Ltd.*—Under-water Glimpses of Animal Life, Dr. F. Ward, illustrated. *Constable and Co., Ltd.*—The Sea Fisheries, Dr. J. T. Jenkins, illustrated. *Hodder and Stoughton.*—Applied Botany, G. S. M. Ellis, illustrated (The New Teaching Series of Practical Text-books); The Book of a Naturalist, W. H. Hudson; The Mason Wasps; The Sacred Beetle; The Story Book of Birds and Beasts; and The Story Book of Science, each by J. Henri Fabre, translated by A. Teixeira de Mattos. *Henry Holt and Co. (New York).*—The Development of the Chick, Prof. F. R. Lillie, new edition. *J. B. Lippincott Co.*—In Monographs on Experimental Biology and General Physiology: The Nature of Animal Light, Prof. E. Newton Harvey; The Chromosome Theory of Heredity, Prof. T. H. Morgan; Inbreeding and Outbreeding: Their Genetic and Sociological Significance, E. M. East and D. F. Jones; Pure Line Inheritance, Prof. H. S. Jennings; The Experimental Modification of the Process of Inheritance, Prof. R. Pearl; Localisation of Morphogenetic Substances in the Egg, Prof. E. G. Conklin; Tissue Culture, Prof. R. G. Harrison; Permeability and Electrical Conductivity of Living Tissue, Prof. W. J. V. Osterhout; The Equilibrium between Acids and Bases in Organism and Environment, Prof. L. J. Henderson; Chemical Basis of Growth, Prof. T. B. Robertson; and Co-ordination in Locomotion, A. R. Moore. *Longmans and Co.*—A Naturalist's Sketch Book, A. Thorburn, illustrated. *Methuen and Co., Ltd.*—Iron Bacteria, D. Ellis, illustrated. *Oxford University Press.*—Fungal Diseases of the Common Larch, W. E. Hiley, illustrated. *Bernard Quaritch, Ltd.*—Essays in Early Ornithology, J. R. McClymont, illustrated. *G. Routledge and Sons, Ltd.*—The Wonders of Insect Life, J. H. Crabtree, illustrated. *S.P.C.K.*—Joseph Dalton Hooker, Prof. F. O. Bower (Pioneers of Progress: Men of Science). *Witherby and Co.*—A Geographical Bibliography of British Ornithology, H. Kirke Swann, W. H. Mullens, and F. C. R. Jourdain; A Handbook to the Vertebrate Fauna of North Wales, H. E. Forrest; The Birds of France, C. Ingram; A Practical Handbook of British Birds, in parts; Monograph of the Pheasants, W. Beebe, vol. ii.

Chemistry.

Baillière, Tindall, and Cox.—In the Industrial Chemistry Series: Explosives, E. de Barry Barnett; The Industrial Gases, Dr. H. C. Greenwood; Animal Proteids, H. G. Bennett; The Carbohydrates, Dr. S. Rideal; Fats, Waxes, and Essential Oils, W. H. Simmons; Silica and the Silicates, J. A. Audley; The Rare Earths and Metals, Dr. E. K. Rideal; The Iron Industry, A. E. Pratt; The Steel Industry, A. E. Pratt; Gas-Works Products, H. H. Gray; Organic Medicinal Chemicals, M. Barrowcliff and F. H. Carr; The Petroleum Industry, D. A. Sutherland; Wood and Cellulose, R. W. Sindall and W. Bacon; Rubber, Resins, Paints and Varnishes, Dr. S. Rideal; and Economic Fuel Production in Chemical Industry, Dr. H. S. Taylor. *G. Bell and Sons, Ltd.*—Notions fondamentales de chimie organique, Prof. Moureu, translated. *J. and A. Churchill.*—A Dictionary of Explosives, A. Marshall, and a new edition of Qualitative Analysis and Practical Chemistry, adapted for use in the Laboratories of Colleges and Schools, Dr. F. Clowes and J. B. Coleman. *Constable and Co., Ltd.*—A Treatise of Electro-Chemistry, edited by B. Blount; Ozone: Its Properties and Uses, Dr. E. K. Rideal; The Profession of Chemistry, R. B. Pilcher; Problems in Physical Chemistry, E. B. R. Prideaux, new edition; Fuel, Water, and Gas Analysis, J. B. C. Kershaw, new edition, illustrated. *Hodder and Stoughton.*—Chemistry from the Industrial Standpoint, P. C. L. Thorne (The New Teaching Series of Practical Text-books); A Foundation Course in Chemistry for Students of Agriculture and Technology, J. W. Dodgson and J. A. Murray. *Henry Holt and Co. (New York).*—College Textbook of Chemistry, Prof. W. A. Noyes; Laboratory Exercises in Chemistry, C. E. Dull; Manual of Classroom Exercises in Chemistry, Profs. W. A. Noyes and B. S. Hopkins, new edition. *J. B. Lippincott Co.*—The Analysis of Minerals and Ores of the Rarer Elements, Dr. W. R. Schoeller and A. R. Powell. *Crosby Lockwood and Son.*—Animal and Vegetable Oils, Fats, and Waxes: Their Manufacture, Refining, and Analysis, Dr. G. Martin; Applied Chemistry for Technical Students, Dr. C. K. Tinkler and H. Masters; Practical Leather Chemistry, A. Harvey; Industrial and Manufacturing Chemistry, Dr. G. Martin and others, Organic, new edition, illustrated. *Longmans and Co.*—In Monographs on Industrial Chemistry: Synthetic Colouring Matters: Sulphur Dyes, Prof. G. T. Morgan; Synthetic Colouring Matters: Vat Colours, Prof. Jocelyn F. Thorpe; Naphthalene, Prof. W. P. Wynne; Synthetic Colouring Matters: Azo-Dyes, Dr. Francis W. Kay; Utilisation of Atmospheric Nitrogen: Synthetical Production of Ammonia and Nitric Acid, Prof. A. W. Crossley; Cement, B. Blount; The Principles and Practice of Gas-purification, E. V. Evans; Refractories, Dr. J. W. Mellor; Ozone and Hydrogen Peroxide: Their Properties, Technical Production, and Applications, Dr. H. V. A. Briscoe; The Nickel Industry, W. G. Wagner; Cellulose-Silk, C. F. Cross; The Electric Arc in Chemical Industry, Dr. J. N. Pring; Byproduct Coking Practice, E. Bury; Organic Synthetic Reactions: Their Application to Chemical Industry, Prof. J. B. Cohen; Synthetic Colouring Matters: Triphenylmethane Dyes, Prof. R. Robinson; Synthetic Colouring Matters: Anthracene and Allied Dyestuffs, F. W. Atack; Synthetic Colouring Matters: Acridine and Xanthene Dyestuffs, Dr. J. T. Hewitt; Synthetic Colouring Matters: Azine and Oxazine Dyestuffs, Dr. J. T. Hewitt; Synthetic Drugs: Local Anæsthetics, Drs. W. H. Hurtley and M. A. Whiteley; Plantation Rubber, G. S. Whitby; Margarine and Butter Substitutes, W. Clayton; Lead and its Compounds, Dr. J. A. Smythe; and Corrosion and Decay of Metals, Prof. C. H. Desch. *Macmillan and Co., Ltd.*—Alcohol: Its Production, Properties, Chemistry, and Industrial Applications, with Chapters on Methyl Alcohol, Fusel Oil, and Spirituous Beverages, C. Simmonds, illustrated. *Methuen and Co., Ltd.*—Everyday Chemistry, W. Robinson; Chemistry for Public Health Students, G. Jones. *G. Routledge and Sons, Ltd.*—Chemical Industries (Industrial Supremacy Books). *Seeley, Service, and Co., Ltd.*—Chemistry and its Mysteries, C. R. Gibson, illustrated.

Engineering.

Edward Arnold.—Modern Roads, H. P. Boulnois. *Benn Bros., Ltd.*—Electric Switch and Controlling Gear, Dr. Garrard; The Electric Handling of Materials, H. H. Broughton, 4 vols., illustrated; The Design of Model Aeroplanes, F. J. Camm, illustrated. *Cassell and Co., Ltd.*—Electrical Engineering, H. M. Simmons, revised by A. H. Avery, in fourteen parts. *J. and A. Churchill.*—The Mechanical Principles of the Aeroplane, Dr. S. Brodetsky. *Constable and Co., Ltd.*—Hot Bulb Oil Engines and Suitable Vessels, W. Pollock, illustrated; The Internal Combustion Engine, H. E. Wimperis, new edition; Locomotive Valves and Valve Gears, J. H. Yoder and G. B. Wharen, illustrated; Handbook for the Care and Operation of Naval Machinery, Comdr. H. C. Dinger, new edition. *Hodder and Stoughton.*—Foundations of Engineering, W. H. Spikes (The New Teaching Series of Practical Text-books); Aerial Transport, G. H. Thomas; Applied Aero-Dynamics, G. P. Thompson, illustrated; Steam Engine Troubles, H. Hamkens; Model Making: Including Workshop Practice, Design, and Construction of Models, edited by R. F. Yates; Gasoline Engines: Their Operation, Use, and Care, A. H. Verrill; American Stationary Engineering, W. E. Crane; Automobile Welding with the Oxy-acetylene Flame, M. K. Dunham; Plain Answers to Direct Questions on Steam, Hot-water, Vapour, and Vacuum Heating Practice, A. G. King; Modern Machine Shop Construction Equipment, and Management, O. E. Perrigo. *Crosby Lockwood and Son.*—The Engineering Workshop Handbook, E. J. Pull; Motor-Car Catechism, J. H. Knight, new edition; Streamline Kite Balloons: Design and Stability, with Useful Tables, Aeronautical and Mechanical Formulæ, Capt. P. H. Sumner; Engineer's Year Book for 1920: Comprising Formulæ, Rules, Tables, Data, and Memoranda, forming a Compendium of the Modern Practice of Civil, Mechanical, Electrical, Marine, Gas, and Mine Engineering, H. R. Kempe and others. *Longmans and Co.*—Ships' Boats: Their Qualities, Construction, Equipment, and Launching Appliances, E. W. Blocksidge, illustrated; Efficient Boiler Management: With Notes on the Operation of Steel Re-heating Furnaces, C. F. Wade; Principles and Practice of Electrical Testing, as Applied to Apparatus, Circuits, and Machines, R. G. Allen; Telephonic Transmission, Theoretical and Applied, J. G. Hill, illustrated; Applied Aero-Dynamics, L. Bairstow, illustrated; The Design of Screw Propellers, with Special Reference to their Adaptation for Aircraft, H. C. Watts. *Methuen and Co., Ltd.*—The Engineering Draughtsman, E. Rowarth. *Sir Isaac Pitman and Sons, Ltd.*—Gas and Oil Engine Operation, J. Okill; Aeronautical Engineering, A. Klemin; and new editions of Modern Illuminants, L. Gaster and J. S. Dow; Electrical Engineers' Pocket-Book; and Elementary Aeronautics, A. P. Thurston. *G. Bourry, a revised translation from the French, with some critical notes by A. B. Searle, new edition.

THE BRITISH ASSOCIATION AT BOURNEMOUTH.

SECTION E.

GEOGRAPHY.

OPENING ADDRESS BY PROF. L. W. LYDE, M.A., PRESIDENT OF THE SECTION.

The International Rivers of Europe.

THIS subject was chosen before the publication of the Treaty of Peace, and was dictated by a wish to combine my geographical creed with the political conditions of an "Americanised" Europe. The Treaty embodies so many of the principles which I wished to emphasise that my treatment should perhaps now be rather historical than political.

My geographical faith is in Outlook; the jargon of to-day is about Leagues of Nations. This is the day of nations and nationalities, and geographers must rejoice in the fact, because civilisation depends on a blend of varied influences—each an individual element, a *genius loci*—and the triumph of nationality must curb that tendency to a drab cosmopolitanism which would crush out all such variety. But these varied influences cannot blend into a progressive civilisation unless they have all possible facilities for friendly meeting; for instance, international rivers should not be, like international finance, anti-national, but really inter-national, "between nations," common to all nations, and encouraging the friendly meeting of diverse political elements and ideas. Liberty always makes for differentiation—in nations as in individuals; and if our international intercourse becomes really "free," the desired variety is guaranteed.

That is why I should like to press the truth that Outlook is, or ought to be, the motto of geography. It is so for many of us, and it ought to be for all. But the word covers both a process and an objective. The outlook is essentially over big Mother Earth; the process is visualisation—the picturing of forms and forces, places and peoples, beyond the horizon, all possible horizons being included in the one great unit of the globe. But the geographical interaction of the man and the place cannot be dissociated—least of all in political geography—from the historical interdependence of group and group. Both alike are concerned with progress. We want to know, therefore, the whole simple truth—what the particular features and phenomena mean as world-features and world-phenomena, *not* what special meaning can be read into them, or extracted from them, by some local and interested political unit. Geography is, first of all, the visualisation of the world and the relations of the various parts of that world.

Now, the one predominant feature of the earth's surface is not land, but water. Nearly all international problems to-day have to do, explicitly or implicitly, with the ocean, *i.e.* with access to cheap water transport on the medium which covers three-quarters of the whole surface of the earth. Even the problem of Alsace-Lorraine, itself perhaps purely a land problem, conceals—especially from the Swiss point of view—a problem of access to the sea; and the problems of Poland, of Italy, of Jugo-Slavia, are obviously sea problems, or sea problems very slightly disguised.

It is a truism that the ocean attracts rivers and their trade and their riverine population. Industry, commerce, even culture, have been starved and stunted in various parts of the world by lack of easy access to the sea. Even your League of Nations idea has more than once approximated to a substantial fact—round the Mediterranean and round the Baltic, facilitated by inter-national or inter-racial rivers. The Hanseatic League was essentially based on the relation of a number of more or less navigable rivers to an inland sea, and that was why it came to include such distant "inland" members as Breslau and Cracow.

Accessibility is now more than ever before a supreme factor in all cultural and economic development, and rivers are still the chief natural intermediaries between land and sea. The first real international attempt to solve the problem of international rivers followed the victory of sea-power over the France of Napoleon the Great; the second has followed the victory of sea-power over this would-be "Napoleon" of Prussia.

Now, I submit that to many of us the mere word "river" by itself suggests, at once and primarily, a physical unity—no doubt, with some variety of relief and climate—and that on this physical unity we are prepared to sanction some social and economic, and even political, unity. But directly you add the qualifying "international," the suggestion changes; the adjective raises a picture not of local features, but of regional relations.

In recent years I have pleaded for the use of rivers as political boundaries—on the ground that they clearly separate lands without at all separating peoples except in time of war; we want to preserve the valuable variety of political and cultural units, but to draw the various units together. Our object is unity, not uniformity. The proposal has been objected to—even by some who are not at heart hostile to the idea of fostering all possible aids to the easy, honourable, friendly intercourse of peoples—on the ground that rivers shift their courses. They do, and trouble has come of this in the past, political trouble as well as economic. The Missouri was a fertile source of inter-State squabbles. But no normal person would *choose* a mud-carrier, like the Missouri, as a political boundary unless there was marked difference of racial type or nationality running approximately along the line of the river. In fact, I would suggest that the troubles along the Upper Missouri were really due to the fact that the river was *nowhere* an inter-State boundary, and therefore each State claimed the right to monopolise it in the particular section. If it had been an inter-State boundary from the first, such a claim would have been obviously absurd. And it was the iniquity of the claim to monopoly that forced the United States, as similar conditions forced the Australian Commonwealth, to take over the control of the inter-State rivers.

The principles behind the control are significant. Thus the Murrumbidgee is entirely within New South Wales, as the Goulburn is entirely within Victoria; but the Murray is an inter-State river—in a double sense, acting as the boundary between New South Wales and Victoria, and emptying through South Australia. New South Wales has entire use of the Murrumbidgee, and Victoria of the Goulburn, but the whole volume of the Murray up to normal low-water level is left to South Australia. In Europe navigation is usually far more important than irrigation. Why should not Europe exercise similar control over the navigable rivers of Europe?

For, geographically, great navigable rivers are essentially a continental feature, *i.e.* really a world feature, for all major continental features must be included in a survey of world features, even if they are minor world features; and the world can recognise no right of a political unit to regional monopoly of the commercial advantages of such a feature to the disadvantage of other political units—least of all, others in the same region. As with the irrigation, when a river is obviously and entirely within an area where identity of culture and sentiment proclaims a natural or national unit, then that unit has a claim—even if it should prove impolitic to press it—to some monopoly of the facilities afforded by that river. But when the river runs through or between two or more such natural or national units, *i.e.* is really international, one of the units has no claim to any monopoly against the other or others.

It was reasonable that expanding Prussia should get to the mouth of the Elbe, and it was certain that Holstein had been both a fief of the Holy Roman Empire and in the German Confederation of 1815, and that succession in Holstein could *not* go in the female line. It was equally certain that Schleswig had never been in either the Holy Roman Empire or the German Confederation, and that succession in Schleswig *could* go in the female line. The reasonable sequel in 1864 would have been for Prussia to purchase Holstein from Denmark, and share the facilities of the international river.

One would not expect such a view to be taken by a Prussian, but that was the actual principle laid down by France nearly one hundred years earlier. The famous Decree of November 16, 1792, asserted that:—"No nation can, without injustice, claim the right to occupy exclusively a river-channel, and to prevent the riparian States from enjoying the same advantages. Such an attitude is a relic of feudal slavery, or at any rate an odious monopoly imposed by force." This was not mere talk. It was followed in 1793 by the complete freeing of the Scheldt and the Meuse to all riparians—France herself being a riparian in each case, for the Scheldt was naturally navigable up to Valenciennes. Somewhat similar rights were extended in 1795 to all riparians on the Rhine—France herself, of course, being again a riparian; and in 1797 the freedom was extended, so far as France was concerned, to the ships of foreign nations, though Holland was able to make the privilege valueless.

The original Decree had not pressed the precise question of internationality. But if the general principle holds—that a great navigable river cannot be monopolised by a single political unit against riparians, even if they are its subjects and of alien "race," still more must it hold when the river in question is fully international, flowing through or between two or more States. Of course, the Rhine, Danube, and Vistula do both.

As a matter of fact, in Europe this principle has been generally accepted for the last century except by Holland. Prussia and Saxony agreed about the Elbe in 1815, and the agreement was extended to Austria, Hanover, and Denmark in 1821. Prussia, Hanover, and Bremen made a similar agreement about the Weser in 1823; and Spain and Portugal made similar agreements about the Tagus and the Douro in 1829 and 1835. Holland, however, has a tarnished record.

One has not an atom of sympathy with the arrogant German demand that "small nations must not be allowed to interfere with the development of great nations, "least of all with that of the greatest of nations," and that Holland, simply on the ground of her small size, should be robbed of her three estuaries in the interest of Germany. But neither has one an atom of sympathy with the Dutch habit of taking advantage of that small size to behave in a mean and unreasonable way on the assumption that no Power except Germany would use force against such a little people. I would like to illustrate the position by an analysis of the problem on a canal, for one must include straits and canals with rivers. Their inclusion may involve some difficulty, but in the most serious case the difficulty is already largely solved. I refer to the Panama Canal during the second year of the war, when British shipping was exactly half as large again as U.S.A. shipping, amounting to very nearly 42 per cent. of the whole traffic. The total result of the war, however, has been a loss of more than 5,200,000 tons of British shipping, involving a reduction of 13·5 per cent. in our carrying power at sea, while the U.S.A. tonnage has increased by nearly 6,730,000 tons, *i.e.* an increase of 382·1 per cent. in the U.S.A. sea-going tonnage (June, 1919).

The case which I propose to analyse is that of the Terneuzen Canal, and I wish to press it with all possible emphasis, because it shows a typical case of quite natural—and, therefore, almost pardonable—human selfishness, and its supporters are guilty of an extraordinary blindness to their own mercantile *advantage.*

Ghent is the second port in Belgium and the first industrial town in Flanders. In the days before the separation of the two countries it was connected with Terneuzen, *i.e.* "open-sea" navigation on the Scheldt, by a canal twenty miles long, of which rather more than half was in "Belgian" and rather less than half in "Dutch" territory, the actual sea connection being, unfortunately, in the Dutch territory.

At the time of the Franco-Prussian War the Belgians decided to enlarge the canal, but had to *waste eight years* in obtaining the consent of the Dutch to the undertaking. Even then the consent was given only on the condition that the Belgians should pay for all work done by the Dutch, give an annual grant of some 13,000*l.* for the upkeep of the new works, and grant Terneuzen reduction of rates on Belgian railways! Some twenty-five years later it became necessary again to enlarge the canal; this was begun in 1895 on condition that Belgium again paid all the cost, that the Dutch had the right to close the locks "whenever they deemed it useful to safeguard Dutch interests," and that various other concessions were granted, *e.g.* about the Antwerp-Rozendaal railway; and the complete agreement was signed in 1902. The total cost was 1,600,000*l.*, a large proportion being spent *on the canal port at Terneuzen*; but the control is entirely in the hands of the Dutch; the Belgian part of the canal is both broader and deeper than the Dutch part, and the larger Belgian boats even now cannot reach Terneuzen! That is to say, after all the cost, the concessions, the delay, etc., the trade of Ghent is still hampered and may be cut off at any moment. Of course, the stupidity of the Dutch in thus crippling their own trade is unpardonable; but what about Belgium? Even then her boats have only reached the Scheldt—a river of little use to Holland, but vital to Belgium.

The case is important, because the two nations have lived together in peace in spite of the serious "international servitude" of Belgium, and because practically everything that Holland has done has been quite legal. Dutch officials claim that "Belgium has enjoyed absolute freedom of navigation"; that "Belgium has in no way been made to feel that she had to use the waterway of a neighbour to get access to the sea"; and that "Holland has been perfectly right in asking Belgium to pay for improvements on a canal which admittedly (!) serves almost exclusively Belgian interests." To a Belgian this is mere mockery. And I submit that, if Belgium has to pay almost the entire cost, she ought to have also almost the entire control; that the traffic is very profitable, the tonnage of Terneuzen being relatively larger than that of any other Dutch town, even Rotterdam; that part of the cost has been due to the canal having formed part of the Dutch polder system; and that, under international control, the total cost would have been met out of the profits on the traffic.

Further, I submit that, although the waterway was originally not artificial at all, but a distributary of the Lys, navigation has *not* been free for Belgium. Facilities have been both denied and delayed. Denials have been rare; but the Dutch refused, in 1907, to forgo customs formalities on cargoes moving only and directly between Ghent and Antwerp, and they have refused to provide fog-signals or beacons at Terneuzen. Preposterous delays have been more or less normal. For instance, the request about the customs was made in January, 1906, and was refused in January, 1907; a request for permission to dredge a sandbank, made on November 11, was granted on the following September 17; and another made on July 9 was granted on December 2.

Even the dimensions on the Dutch part of the canal have prevented any real freedom of navigation. These dimensions were originally agreed upon by a mixed body of experts, and accepted almost verbatim by the Dutch Government in 1895. They were modified in 1902, though the 1902 Convention was not ratified; and, thus modified, the scheme of 1895 was completed in 1910. Now, under international control, it would have been completed much sooner; all unnecessary formalities due to riparian sovereignty would have been avoided; all necessary safety would have been immediately provided for, *e.g.* by dredging or fog-signals; and all improvements would have been adopted on their merits. In the absence of international control Belgium has been subject, as I have indicated, to serious "international servitude," which has involved her in heavy costs and continual annoyances. Yet Holland has, practically from first to last, acted with perfect legality. (I intentionally exclude the undoubted illegality of the closing of the Scheldt in August, 1914, the transport of excessive quantities of sand and gravel for German use during the war, and the free passage through Limburg granted to the retreating German armies.) But if the other things referred to are legal, it is high time that they were made illegal.

It has been typical, too, that when the Dutch have granted any facilities, it has been done by a specific treaty, *i.e.* done as a matter of policy, not of justice. It was from this point of view that they agreed to the Lek and the Waal being recognised as the proper mouths of the Rhine. This emphasis on policy rather than on justice has not, however, been confined to Holland, though she alone still adheres to it. In Europe, in America, in Africa, and even in Asia, there have been, first, attempts to enforce a so-called political right of sovereignty against neighbours, *e.g.* on the Mississippi by Spain, on the St. Lawrence by us, on the Amazon by Brazil, on the Zambezi by Portugal, and then special conventions somewhat on the lines of a treaty of commerce. Such treaties grant commercial facilities, and power of navigation is such a facility; but if the navigation is on a great continental feature, such as an international river, surely the particular facility should be admitted *without* any special treaty.

This claim has been specifically put forward on several occasions. For instance, by the Treaty of Paris (1763) we had the privilege granted to us of "navigation on the Mississippi to the sea," and "*to* the sea" meant "*out onto* the sea." When the river passed under the control of the United States, the conditions were altered. Spain had granted no such facility to them, and she claimed the *political* right to block the estuary against them, while Jefferson claimed that they had a *natural* right to use the whole river, *i.e.* had such a "right in equity, in reason, in humanity." The same question arose on the St. Lawrence, where we claimed the political right to block the lower river against the United States in 1824. The case is specially important because Adams at once admitted the *political* right, *i.e.* the riparian "sovereignty," but claimed—as Jefferson had done—a *natural* right to use the river itself, a right which he based on necessity and on the support of the political Powers of Europe as formulated in many conventions and agreements and commercial treaties.

There had been so many of these that it had become possible to generalise as to a common principle—really the principle of justice; and so the Treaty of Paris in 1814 and the Congress of Vienna had adopted the principle, and had passed general rules in sympathy with it—rules which have been applied to many rivers and even to canals, *e.g.* in the old Kingdom of Poland. In the particular case of the St. Lawrence the water right would not cover any right of portage; but, of course, the international boundary comes to this river from New York State below the last of the rapids.

In 1851 Brazil claimed the political right to block the mouth of the Amazon, but this was universally condemned as a gross misuse of the right of riparian sovereignty, for the mouth of the Amazon is so truly an arm of the sea that it separates two distinct faunas; and, as the Plate was declared free in 1852, Brazil could not in decency exercise her dubious "right." It was not formally given up, however, until 1867; and it lies implicity behind the recent so-called "concessions" to Bolivia.

Portuguese law raised a similar difficulty in 1883 on the Zambezi. Of course, Portugal was our oldest ally, and our relations were very friendly; but, though she neither controlled nor traded with the interior, she claimed the political right to block the estuary against us, and we admitted the *political* right so far as to consent to her imposing duties—which, in theory, might have been prohibitive of all trade.

The Zambezi is specially interesting because it was concerned with one of the first of those land-corridors about which there has been so much discussion lately—the "Caprivi finger." Everyone except our lawyer-politicians knew the real object, the certain meaning, and the probable result of our conceding that strip to Germany—though most of us pictured German troops marching eastward along it to cut the "Cape-to-Cairo" route in Rhodesia, rather than Rhodesians riding westward into Ovamboland. But theoretically the Germans made a demand for access to navigable water on an international river, and we recognised this as a reasonable demand, and granted it. Here, again, we stand historically in a position of great moral strength. Further, if we accept international land-corridors and international air-corridors, we must accept also international water-corridors, such as a navigable river or a narrow strait.

I do not want, however, to press an African example, partly because I do want to repudiate entirely the application of the Berlin Conference to any rivers outside Africa. For in 1884 Africa was essentially a virgin continent, and its inhabitants were completely ignored—in theory by all the deliberators, and in practice also by the nation which had engineered the conference. For one of Germany's essential objects was to converge on the Congo, and squeeze out Belgian interests; and eventually, to do that, she did not hesitate to employ the most unscrupulous propagandists in this country on "Congo atrocities." It was, therefore, part of her scheme to press—what was accepted by the conference—that the Congo should be open to all flags for all commercial purposes, and that *no riparian rights* should be recognised. It was equally to her interest that the International Committee of Administration agreed upon should never be set up, and it never has been; and, of course, in 1911 she used the trouble which she had provoked in Morocco to acquire 100,000 square miles of the French Congo, so that she became a territorial Power in the west as well as in the east of the Congo basin.

The whole question has two aspects—(1) the freedom of the actual navigation, and (2) the administration of the river. The former is largely a matter of equity, and so did not appeal to the Dutch or Portuguese lawyers; the latter is largely a matter of law, and has been much complicated by legal subtleties. But the two are closely connected, for the European rivers with which we are specially concerned, all have a lower course over the plain and an upper course involved in the folds and blocks of Central Europe. They are, therefore, important in the one case merely as carriers by water, and—all things considered, and in spite of superstitions to the contrary—are probably dearer as well as less flexible than the carriers by rail that cross them from west to east; thus the quantity of foodstuffs that reached Berlin—or New Orleans—by water in 1913 was quite insignificant. In the other case, however, they are of supreme importance, for their valleys focus the whole commercial movement, *e.g.* of Switzerland, both by rail and by water. This puts the people of the upper river-basin commercially at the mercy of the holders of the lower; at least a third of the Swiss imports before the war were from Germany, and a fifth of the exports went to Germany—much, in each case, under what the Swiss felt as "compulsion."

In this particular case the people of the Rhine delta were also—politically—at the mercy of the Germans. For the natural outlets of the Rhine basin, such as Rotterdam and Antwerp, had taken on naturally the international character of all great ports, while the river-towns behind them, such as Cologne and Frankfort, were nurseries of intense national feeling, most carefully and criminally fostered by the Government with the declared object of presently imposing that "nationality" upon the "internationalised" port. One way of entirely undermining a position offering such opportunities to the unscrupulous is international control, with its impartial improvement of the waterway *on its own merits.* Thus in 1913 nothing like 1 per cent. of the navigation on the Rhine was British, while more than 65 per cent. was Dutch; but the deepening of the Rhine up to Basel to admit sea-going vessels, *e.g.* from London or Newcastle, would instantly free the Swiss from their slavish dependence on *e.g.* Westphalian coal.

It is the political aspect, however, rather than the economic that I want to press for the moment. The economic aspect is useful only because it can be presented more easily in a statistical form, while the historic—though equally, if not more, illuminating—cannot be applied to recent events. We can see now that Peter the Great did not provide "a gate by which [his] people could get out to the Baltic," only one by which foreigners got into Russia; but we cannot have similar knowledge of the political value to Bohemia of the economically invaluable Elbe-Moldau. We can note, however, that it is essentially a way *out*, for the quantity of down-stream traffic (*e.g.* lignite, sugar, grain) is five times that of the up-stream traffic (*e.g.* iron, cotton, oils).

The agreements already mentioned, with regard to Elbe and Weser, Tagus and Douro, show that freedom of navigation has been granted as a reasonable courtesy for many years by nearly all civilised Powers, though even to this day Holland has persistently blocked progress by her stupid commercial policy and her unique position at the mouths of Rhine and Maas and Scheldt; and the essential principles are illustrated by the irrigation laws of Australia and the United States, where everyone now admits that the individual State cannot have any local standing, any riparian claims, as against the Commonwealth. All States, whatever their size or wealth or population, must be equal, though the natural advantages are with the upper riparians for irrigation as with the lower riparians for navigation.

The serious administrative difficulties are two—concerned respectively with the riparian sovereignty and with the different geographical conditions of different rivers or different parts of the same river; *e.g.* you can easily decrease the pace of the Rhine above Mannheim, but not without increasing the susceptibility to frost.

Historically, riparian sovereignty, in the case of Rhine and Danube, is only a relic of feudal robbery. When they first became part of the civilised world under Rome, there was no such thing as riparian sovereignty. They were public property, which had to be kept in order and improved; and for this purpose the Romans exacted dues, which were spent wholly and solely on the upkeep of the waterway. The Franks continued the same custom on the Rhine, but the feudal system brought in a horde of petty princelings—as impecunious as German princelings have normally been—who completely upset the old *régime*, converted public into private property, and exacted every kind of tax and toll. Unfortunately, because Rhine and Danube had been frontiers for Rome, they had been associated with a strictly military control, and the legacy of this favoured the feudal princelings—as it also helped to poison the whole political development along both rivers, for they got only the worst side of Roman civilisation. Now we must go back to the primitive conditions. If an international river is a world feature, then its world relation is the first consideration. In that case riparians must tolerate representatives of the whole world, or of such parts of the world as are most concerned with the particular river, on the executive for the administration of the river. In most cases, moreover, riparian sovereignty must be limited, even in the interests of the riparians themselves, for the presence of non-riparians on the executive may be, and has been on the Danube, of the greatest value in minimising friction amongst the riparians. In this respect France has played a most honourable part, generally supported by Britain, especially on the Danube, where, *e.g.* Austria tried to exclude Bavaria from the deliberations about the river, and to dominate and intimidate the representatives of the lower riparians. Indeed, it was only "the day before yesterday" that we had the gratification of reading the German decision to "exclude French and British representatives from the Danube Commission on the ground that they had hindered the ships of the more important nations from obtaining *priority* of treatment." What greater compliment could have been paid to us?

The fact only emphasises the vital point referred to above, that different parts of the same river have different conditions and may need different treatment, *i.e.* that even riparians have not all naturally equal use of the river, and that the strongest or the most favourably situated can grossly misuse their opportunities. The Dutch showed this on the Rhine in 1816, and the Austrians on the Danube in 1856. Obviously such differences are, in themselves, potential causes of serious trouble; riparians have not necessarily and naturally real equality even when the executive consists of only one representative from each riparian State. The greater opportunities of expansion, political and economic, on the lower river may favour the growth of a stronger Power; and the State with the largest share of the river or the best position on it has already an advantage over the others. For instance, the Dutch on the Maas and the Russians on the Danube have indulged in "voluntary negligence"; it was in this way that Russia blocked the mouth of the Danube, and that Holland made it impossible for the Belgians to *continue* their commercial navigation on the Meuse down through Holland to the sea, though since the discovery of coal in Limburg the Belgians have—stupidly—turned the tables on Holland to some extent. A low riparian may no more monopolise or ruin navigation on the lower course of a river than a high riparian may poison or exhaust its upper waters. The river is a unit, and its unity is essential to the fulfilling of its duties in the evolution of world commerce; and, therefore, it needs a unity of administration. This is best secured by a commission of riparians and non-riparians, and such conditions facilitate the use of a river as a political boundary.

Nearly all the important details involved in the internationalising of navigable rivers have been illustrated already in the history of Rhine and Danube, and in both cases France has been an admirable guide to Europe. On the Rhine, as I have mentioned, she abolished in 1795 most of the restrictions which had made the river practically useless even to riparians; and that she was not thinking only of her own interests was proved by her attempt—defeated by Holland—to extend the freedom of the river to all nations in 1797. Again, in the Convention of Paris (1804) France enforced unity of administration—sharing this with Germany on the ground that the river was of special concern to herself and to Germany, as she has shared the administration of the Niger with us in recent years on the same ground.

The Rhine thus received a simple, just, uniform administration, which is a model for us now. All tolls were abolished except two—one on the boat and the other on the cargo—which were to be only large enough to meet the upkeep of the waterway, and were to be used for no other purposes. These tolls could be paid in each political area with the coin of that area, but a fixed ratio was maintained between the various coinages.

Of course, in 1815 France was ousted from the bank of the river; and in the reorganisation elaborated by the Congress of Vienna von Humboldt, the Prussian representative, adroitly introduced into the regulations for the Central Commission of Riparian Representatives words which were afterwards made to mean exactly the opposite of the freedom enforced by France, and exactly the opposite of what our British diplomats at the time thought and said that they meant! Not only so, but during the sixteen long years while France remained more or less submerged, Holland was allowed to make the whole scheme ridiculous by the claim that "to the sea" did not mean "out onto the sea," and that a tidal estuary was "sea." The Regulations of Mainz gave each riparian State full sovereignty over its own part of the river, and limited the right of pilotage to the subjects of riparian States; and in 1868 the Regulations of Mannheim further whittled down the old liberal principles of France—to the disadvantage of non-riparians, although they were admitted to rights of navigation. The revised Rhine Navigation Treaty of that year was still in force in 1913, administered by the six riparian States—Holland, Prussia, Hesse, Baden, Bavaria, and Germany (as owning Alsace). Even since 1871 Prussia, as the strongest Power, has hampered the development of non-Prussian ports, using even the most childish tricks with pontoon bridges, choice of wharves, accessibility to rail, etc., against other German States.

Since 1871, too, the Rhine has illustrated another important point—namely, that the traffic on an inland waterway depends largely, perhaps vitally, on the extent to which railways are willing or forced to co-operate; and this has a present importance even from a purely international point of view. One of the results of the Franco-Prussian War was that Prussia bought up a number of private railways in the Rhine valley, and eventually used the profits of the transaction to make a secret fund for aggressive purposes. Now, if properly administered as an international waterway, the Rhine will be perfectly free except for trifling dues on boat or cargo for the expenses of upkeep; and it will compete so favourably with the Prussian railways that their rates will have to be reduced to a minimum. This will cut hard at such differential treatment as has handicapped British trade in the last twenty years, and it will leave no surplus with which the unscrupulous can juggle.

Of course, the Rhine is essentially linked with the Meuse and the Scheldt—politically, economically, historically; and the Powers have long been too lenient or too timid with Holland, possibly because her purely *legal* position appeals to lawyer politicians. The Dutch base their claims to monopolise the estuary of the Scheldt on the Treaty of Munster (1648), but have greatly strengthened their legal position in recent years. The marriage of the Dutch Queen to a German princelet was followed immediately by the intrigue that ended in Belgium definitely granting to Holland in 1892 special rights on the Scheldt in time of war, and Germany strongly supported Holland in getting these rights extended between 1905 and 1908. But the Scheldt is merely an international river; it is navigable into France, and it was only by France waiving her claims in 1839, and proposing a dual control by Belgium and Holland—like that of the Rhine by France and Germany at the beginning of last century, and that of the Niger by France and ourselves now—that Holland ever obtained the power which she has abused. When Napoleon annexed Antwerp, he declared the Scheldt free; and the Rhine Regulations, when extended to the Scheldt, were interpreted as meaning "free for all flags out onto the sea." Even so, the Dutch raised every possible difficulty, and navigation had no fair chance until the railway from Cologne to Antwerp brought in the only kind of influence which the Dutch seem to understand.

We have, therefore, full knowledge of all the essential conditions necessary to ensure the proper administration of international rivers, and shall have no kind of excuse if we are caught napping or misled by plausible and "interested" tricksters. Amongst their last tricks is "the great difficulty of policing such a river, where a German boat may be stopped by a French official." That is not more terrible than a Rumanian boat being stopped by an Austrian official; and the experience on the Danube shows that there is really no difficulty at all—for the simple reason that offenders are always dealt with, naturally and reasonably, by officials of their own nation, just as the various European Powers have the right of jurisdiction over their own subjects in the Belgian Congo. In Article 25 the effete and pharisaical Berlin Act of 1884–85 provided that its regulations for the Congo "shall remain in force in time of war." To-day we are less ambitious, and desire only to further safe, easy, honourable intercourse, in time of peace, between nations that are unequal in size and population, wealth and power, situation and relation to navigation facilities. We have seen that one small nation may ill-treat another small nation from stupidity almost as easily and as grossly as a large nation may ill-treat a small nation from tyranny. In the circumstances it seems necessary to remove from both the stupid and the tyrannical the opportunities for misusing such facilities; and the obvious way of doing this is to make international rivers international in use and in government. Commerce is already a prime factor in the evolution of human brotherhood. Progress towards that ideal may be gauged as well by the price of a banana or a piece of chocolate as by the number of sermons preached on the subject; the sea is already free, made so mainly by British perseverance in clearing it of pirates; it only remains to make navigable rivers equally free, and the opposition comes mainly from those who have talked most loudly about "the freedom of the seas." But "the freedom of the seas" does not means that war is to be removed only from that element on which land-power is weak, while the land-power may still block access to the free sea by the natural avenue—the navigable river.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—On October 10 Mr. A. J. Balfour was duly elected to the office of Chancellor of the University in succession to the late Lord Rayleigh.

DR. ROBERT J. T. BELL, of the University of Glasgow, has been appointed to the chair of pure and applied mathematics in the University of Otago.

THE National Union of Scientific Workers is holding a social evening at 52 St. Martin's Lane, W.C.2, on Thursday, October 30, at 7.30, to inaugurate a London branch of the Union. The meeting will be open to all scientific workers.

THE Lord Strathcona legacy to Yale University, which amounts to about 120,000*l.*, will, *Science* announces, be used as follows: Two professorships in the graduate school will be established, and several fellowships founded, and a memorial building, costing about 50,000*l.*, will be built.

DALHOUSIE UNIVERSITY, Halifax, Nova Scotia, celebrated the centenary of its foundation (1818) on September 11, 12, and 13. Representatives were present from a large number of universities and learned bodies. On September 11, in the Macdonald Memorial Library Hall, President A. S. MacKenzie conferred the degree of LL.D. *honoris causa* on the following gentlemen, those marked with an asterisk being *in absentia*:—David Allison, ex-President of the University of Mount Allison; R. B. Bennett, Calgary; the Right Hon. Sir Robert L. Borden, Prime Minister of Canada *; the Hon. W. J. Bowser, Victoria, B.C., ex-Premier of British Columbia *; G. S. Campbell, Halifax, chairman of the Board of Governors, Dalhousie University; C. H. Cahan, Montreal; T. Cantley, New Glasgow; Dr. M. Chisholm, Halifax; the Hon. Robert E. Harris, Chief Justice of Nova Scotia; H. P. Judson, President of the University of Chicago; the Most Rev. Neil MacNeill, Archbishop of Ontario, Toronto*; I. Pitblado, Winnipeg; the Right Rev. John Pringle. Sydney, Moderator of the General Assembly of the Presbyterian Church in Canada; H. S. Pritchett, President of the Carnegie Corporation of New York*; Prof. W. T. Raymond, University of New Brunswick, Fredericton; S. N. Robertson, Principal of the Prince of Wales College, Charlottetown, P.E.I.; J. Gould Schurman, President of the University of Cornell*; J. Seth, professor of moral philosophy in the University of Edinburgh; F. H. Sexton, Principal of the Nova Scotia Technical College, Halifax; the Rev. Prof. Simeon Spidle, Acadia University, Wolfville; J. Stewart, Halifax; the Rev. Prof. J. J. Tompkins, St. Francis Xavier College, Antigonish; and Dr. F. Woodbury, dean of the faculty of dentistry, Dalhousie University, Halifax. The celebration was a great success in many ways; it was made the occasion of a reunion of old graduates dating back to classes as remote as 1852. Besides a procession of representatives of as many of the classes as could be got together, there were a dinner, a dance, a smoking concert, a regatta, and amateur theatricals. Addresses on the future of the University were given as follows:—On arts and science, by Prof. H. L. Stewart (philosophy); on law, by Prof. MacRae, dean of the faculty of law; on medicine, by Prof. Fraser Harris (physiology), dean of the faculty of medicine; and on dentistry, by Dr. Frank Woodbury, dean of the faculty of dentistry. The urgent need of increased endowments, and, especially in the professional schools, of increased equipment as well, was urged by the speakers. There is a large increase in the number of those entering for the coming session, but the University revenues are as in pre-war days.

The second annual Streatfeild memorial lecture was delivered by Prof. G. T. Morgan at the Technical College, Finsbury, on October 2. In the course of his remarks on "Applied Chemistry in Relation to University Training," Prof. Morgan surveyed the progress of technical education in London from the pioneer college at Finsbury, through the polytechnic movement, to such recent developments as the Imperial College of Science and Technology and the Salters' Institute of Industrial Chemistry. The view which advocates the concentration of instruction and research in applied science into a single large institute, having the status of a specialised university with power to grant degrees in technology, was contrasted with that whereby the technical colleges are to be brought into closer union with the existing University of London. Prof. Morgan pointed out that fundamentally and so far as college training is concerned there is no distinction between pure and applied chemistry. The great generalisations of chemical science must, in any case, be mastered before the student can hope to become competent to enlarge the field of knowledge. Ultimately the difference between university and technical college becomes one of breadth of outlook. In extending the research section of the chemical department at Finsbury, the City and Guilds of London Institute had, during the difficult period of the war, done much to render practicable Streatfeild's ideal of a school of applied chemistry. This objective was an intimate blending of practical elementary training for beginners with specialised investigation in various branches of industrial chemistry carried out by research chemists and other post-graduate workers sent to the college by interested chemical firms. At the present time when considerations of economy are paramount, this mode of developing a technical college of university rank has the merit of involving the least outlay of capital on the part of the educational body, inasmuch as the cost is borne to a considerable extent by those benefiting from the additional facilities.

SOCIETIES AND ACADEMIES.

Sydney.

Linnean Society of New South Wales, July 30.—Mr. J. J. Fletcher, president, in the chair.—Dr. R. J. **Tillyard**: Mesozoic insects of Queensland. No. 6: Blattoidea. The paper deals with eleven specimens from the Ipswich Trias, of which nine are named, being placed in three new genera belonging to the family Mesoblattinidæ, Handl. This family occurs from the Carboniferous onwards to the Jurassic, but reaches its dominant position in the Lias. One of the Ipswich genera, Triassoblatta, n.g., is more archaic than any of the known Liassic genera; while a second, Samaroblatta, n.g., shows close affinity with Mesoblattula, Handl., from the Lias of Dobbertin. The author deals with the venation of the cockroach tegmen, and shows the main lines of its evolution from the Carboniferous onwards. The Ipswich specimens, though none of them are absolutely complete, are, on the whole, very well preserved, so that details like intercalated veins, cross-venation, etc., can be easily made out if present. Most of the tegmina are of moderate size, about 13 mm. or 14 mm. long; but there is one species of Triassoblatta that is much larger. Keys are given for distinguishing the genera and species described, and each new species is figured in the text.—Dr. R. J. **Tillyard**: Studies in Australian Neuroptera. No. 8. Revision of the family Ithonidæ, with descriptions of a new genus and two new species. The members of this family are stout-bodied, moth-like Lacewings, very distinct in their appearance, habits, and life-history from any other representatives of the order. Owing to the inadequacy of Newman's original description of *Ithone fusca*, much confusion has been caused, and two species that were not really even congeneric have been regarded as this species. The doubt as to which was Newman's species had to be cleared up by reference to the type in the British Museum. It was then found that Ithone, Newm., with one radial sector in forewing, is a monotypic genus, all the other species going either into Varnia, Walker, which McLachlan erroneously suppressed, or Heterithone, n.g. (type *Ithone fulva*, Till.). Two new species of this latter genus are described, making in all a total of six species for the family. The genus Nespra, Navás, is suppressed, being the same as Varnia, Walker. A description of the peculiar sand-plough of the female Ithonidæ is given; the insect uses it to plough up the sand when ovipositing. A note is added describing the imaginal mouth-parts, and comparing them with those of the Psychopsidæ. The full life-history of Ithone, which is very remarkable, the larva being a blind melolonthoid grub, is reserved for another paper.—Dr. A. J. **Turner**: Revision of Australian Lepidoptera. Part vi. (last instalment). In this paper fifty-nine species belonging to twenty-six genera (fam. Geometridæ, subfam. Boarmianæ) are dealt with, eighteen species and five genera being described as new.

Royal Society of New South Wales, August 6.—Prof. C. E. Fawsitt, president, in the chair.—G. J. **Burrows**: Volume changes in the process of solution.

The paper contains figures showing the change in volume which takes place when two liquids are mixed or when a solid is dissolved in a liquid. These results are discussed, and also the change in volume which results from the solution of a solid in a mixture of two liquids. A much smaller contraction is observed when a solid is dissolved in a mixture of water and alcohol than when it is dissolved in either of the liquids separately.—G. M. **Bennett** and E. E. **Turner**: Note on organo-metallic derivatives of chromium, tungsten, and iron. Organic compounds containing iron in direct union with carbon play an important *rôle* in animal and plant chemistry, and have an interesting future in connection with pharmacology. An attempt has been made to prepare such compounds, and a few preliminary experiments have been carried out also on similar compounds of chromium and tungsten.

CAPE TOWN.

Royal Society of South Africa, August 20.—Dr. J. D. F. Gilchrist, president, in the chair.—Sir Thomas **Muir**: Note on a sum of products which involves symmetrically the *n*th roots of 1.—C. v. **Bonde**: Note on some abnormalities in the Cape crawfish (*Jasus lalandii*). An account was given of some peculiarities observed among specimens procured for laboratory use in the Zoological Department of the University of Cape Town.

BOOKS RECEIVED.

A Laboratory Manual for Elementary Zoölogy. By Dr. L. H. Hyman. Pp. xvi+149. (Chicago, Ill.: The University of Chicago Press; Cambridge: University Press, 1919.) 1.50 dollars.

A Field and Laboratory Guide in Biological Nature-Study. By Prof. Elliot R. Downing. (The University of Chicago Nature-Study Series.) Pp. 120. (Chicago, Ill.: The University of Chicago Press; Cambridge: University Press, 1918.) 1 dollar.

The Hydrogenation of Oils: Catalyzers and Catalysis and the Generation of Hydrogen and Oxygen. By Carleton Ellis. Second edition, thoroughly revised and enlarged. Pp. xvii+767. (London: Constable and Co., Ltd., 1919.) 36*s*. net.

The Manufacture of Chemicals by Electrolysis. By Arthur J. Hale. (A Treatise of Electro-Chemistry.) Pp. xi+80. (London: Constable and Co., Ltd., 1919.) 6*s*. net.

Insect Pests and Plant Diseases in the Vegetable and Fruit Garden. By F. Martin Duncan. Pp. 95+xii plates. (London: Constable and Co., Ltd., 1919.) 3*s*. 6*d*. net.

The Teaching of Science in the Elementary School. By Gilbert H. Trafton. (Riverside Text-books in Education.) Pp. x+293. (New York: Houghton Mifflin Co.; London: Constable and Co., Ltd., 1919.) 6*s*. 6*d*. net.

Problems of Cosmogony and Stellar Dynamics. By J. H. Jeans. Pp. viii+293+plates v. (Cambridge: At the University Press.) 21*s*. net.

Petrology for Students. By Dr. A. Harker. Fifth edition. Pp. viii+300. (Cambridge: At the University Press.) 8*s*. 6*d*. net.

The Nature of Enzyme Action. By Prof. W. M. Bayliss. Fourth edition. Pp. viii+190. (London: Longmans and Co.) 7*s*. 6*d*. net.

Kingston-upon-Hull Before, During, and After the Great War. By T. Sheppard. Pp. 120. (London and Hull: A. Brown and Sons, Ltd.)

The Condensed Chemical Dictionary. Compiled and edited by the Editorial Staff of the Chemical Engineering Catalogue. Pp. 525. (New York: The Chemical Catalogue Co., Inc.) 5 dollars.

Annuaire de l'Observatoire Royal de Belgique, 1920. Pp. vi+353. (Bruxelles: Hayez.)

Hidden Treasure: The Story of a Chore Boy who Made the Old Farm Pay. By J. T. Simpson. Pp. 303. (Philadelphia and London: J. B. Lippincott Co.) 6*s*. net.

Applied Economic Botany Based upon Actual Agricultural and Gardening Projects. By Dr. M. T. Cook. Pp. xviii+261. (Philadelphia and London: J. B. Lippincott Co.) 7*s*. 6*d*. net.

The Amoebae Living in Man. By Prof. C. Dobell. Pp. vi+155+plates v. (London: John Bale, Sons, and Danielsson, Ltd.) 7*s*. 6*d*. net.

DIARY OF SOCIETIES.

THURSDAY, OCTOBER 16.

THE INSTITUTION OF MINING AND METALLURGY, at 5.30.—C. M. Harris: Prospecting for Gold and Other Ores in Western Australia.—F. Danvers Power: Coral Island Phosphates in the Making.

OPTICAL SOCIETY, at 7.30.—J. W. French: The Unaided Eye, II.—Chas. W. Gamble: Projection Screens.

TUESDAY, OCTOBER 21.

ZOOLOGICAL SOCIETY, at 5.30.—E. G. Boulenger: Report on Research Experiments on Methods of Rat Destruction at the Zoological Society's Gardens.—Dr. A. Smith Woodward, Prof. F. Wood Jones, Prof. J. P. Hill, Prof. A. Keith, Mr. R. I. Pocock, Prof. G. Elliot Smith, and Others: Discussion on the Zoological Position and Affinities of Tarsius.

INSTITUTION OF PETROLEUM TECHNOLOGISTS, at 5.30.—Arnold Philip: Some Laboratory Tests on Mineral Oils.

WEDNESDAY, OCTOBER 22.

INSTITUTION OF AUTOMOBILE ENGINEERS, at 8.—Thos. Clarkson: Presidential Address.

FRIDAY, OCTOBER 24.

PHYSICAL SOCIETY, at 5.—Dr. N. W. McLachlan: The Effect of Pressure and Temperature on a Meter for Measuring the Rate of Flow of a Gas.—J. H. Shaxby: A Cheap and Simple Micro-balance.—J. W. T. Walsh: The Resolution of a Curve into a Number of Exponentials.

INSTITUTION OF MECHANICAL ENGINEERS, at 6.—Dr. E. Hopkinson: Presidential Address.

FACTS AND FACTORS OF EVOLUTION.

The Causes and Course of Organic Evolution: A Study in Bioenergics. By Prof. John Muirhead Macfarlane. Pp. ix+875. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1918.) Price 17s. net.

THIS book is the outcome of a lifetime of biological reflection and investigation, and will be read with much interest. The author, who left Edinburgh for Philadelphia many years ago, was early disciplined in zoology, as well as botany, but it is to the latter that he has especially devoted himself as professor in the University of Pennsylvania. His treatise is erudite and careful, very instructive, even apart from its theories; it expresses the convictions of a patient and independent thinker; it states a number of piquant conclusions more or less peculiar to the author; and it is carefully written. It covers a very wide range—the origin of organisms upon the earth, the phylogeny of plants and animals, the evolution of morals and man, the ethical factor in organic evolution, the rôle of religion in the ascent of man, the competitive and the co-operative systems among animals and in mankind, the human environment as it has been and is, and the evolution yet to come. We must restrict our attention to a few of the salient features.

(1) Prof. Macfarlane notes that "energy, continuity, and evolution," which may be said to constitute "the triune basis of existence," form the keynote of his book. But all that is distinctive is the prominence given to "energy." The author recognises a series of forms of energy, which he calls thermic, lumic, tonic, chemic, molic or gravic, electric, biotic, cognitic, and cogitic. Biotic energy is associated with protoplasm in general, cognitic with chromatin, and cogitic with neuratin or Nissl substance. The terms "cognitic" and "cogitic" are far from happy, and it is of dubious utility to apply the physical concept of energy to certain aspects of vital activities which remain undescribed when a physical and chemical formulation has been given of the others. If it could be definitely stated—as it cannot—that the particles which ultra-microscopic examination shows in movement in a living nerve-cell are associated with a particular kind of energy, distinct from and yet in a line with such recognised energies as heat and electricity, then there would be an objective basis for a form of positive vitalism, similar to that held by some modern biologists, such as Prof. Marcus Hartog and the late Prof. Richard Assheton; but more evidence of the reality of "biotic energy" is required than Prof. Macfarlane adduces—more evidence than the usually admitted inability to give an adequate description of the most characteristic features of the activities of living creatures in physico-chemical terms. The living organism is a riddle imperfectly read, but our confidence in Prof. Macfarlane's contribution is not increased when we find two or three more particular forms of energy piled on the top of biotic.

(2) The author has discovered, he thinks, overlooked factor in organic evolution, which he calls proenvironment—"the resultant response of an organism to the sum-total of all the environal agents that act on it or on any part of it, and which causes the organism to proenviron a course or pathway that is temporarily *satisfying* to it, and that can alone be taken in virtue of the action of the several environal agents, and the reaction to each of these by appropriate organismal molecules." More briefly, Prof. Macfarlane defines the "law of proenvironment" as "the correlated resultant response by any body to the summated correlation of stimulatory action, that leads to a temporarily *satisfied* state." We rub our eyes; the so-called law of proenvironment takes us back to Herbert Spencer (with his emphasis on equilibrium and "effective response") and farther. Surely it is a commonplace that the lines taken by development and activity alike are resultants of environmental stimuli acting on living organisation which is internally determined by the inheritance and by previous experiences so that its responses are on the whole adaptive. We confess that we see very little in Prof. Macfarlane's discovery, and we doubt whether the capacity of giving a more or less satisfying unified response to a variety of external stimuli is a factor of evolution at all, except in the sense that every organism is a factor in its own evolution. It is a fundamental fact of life. The "five organic factors that are form-producing," the co-operative action of which is "pentamorphogeny," are Heredity, Environment, Proenvironment, Selection, and Reproduction. But there would have been heredity, environment, proenvironment, and reproduction though there were no evolution, and what would Darwin say to leaving Variability out of the Pentarchy?

(3) The author contends vigorously that "the main and dominant lines of animal evolution have all originated in fresh water or on land, and that only side lines have assumed a marine life, though these have often branched out profusely into species, and even have given off again groups that have in rare cases returned to a fresh-water or a land life." This is a good-going heresy, and the author supports it with learning and ingenuity. It is directly counter to the conclusion of most authorities, who hold that the probabilities are in favour of a marine origin of most of the phyla. Prof. Macfarlane makes out such a strong case that we feel how uncertain these speculative conclusions are. In our ignorance of the actual beginning of most of the phyla it is difficult to prove the erroneousness of the view that the buds were in fresh water, though the blossoms may have been in salt. We submit, however, a few considerations:

(*a*) At this distance of time appeals to present-day numbers of fresh-water and marine species in any particular phylum cannot be of much value in reference to origins, but there is some utility in thinking of the numbers of types in the two habitats, and of cases where the enormous majority of the types in a phylum are in the one or the other. Now, if we begin with the lowest phyla of Metazoa, the Sponges and Cœlentera, we find in both cases the vast majority of types in the sea and a very small minority in fresh water. The most natural—though not inevitable—inference is that the present-day habitat of the vast majority is the original habitat. The Echinoderms represent a well-defined phylum, all the living representatives of which are marine. The types at the base of the Chordate phylum—namely, Enteropneusts, Tunicates, and Lancelets—are all marine, which is again significant. Many similar cases might be given, but Prof. Macfarlane advances counter cases, and actual demonstration is out of the question.

(*b*) If we take a number of notable advances, such as paired unjointed limbs or parapodia, such as body-segments or metameres, such as genuine pre-oral appendages, such as the annulate or the chordate type of nervous system, such as true gill-clefts, such as a dorsal axis, and ask where they began, the evidence from present-day forms and from palæontology is on the whole in favour of the answer: In the sea. But Prof. Macfarlane brings forward counter instances, and no doubt the fresh waters have been a very educative school of life.

(*c*) Types with direct life-histories are very generally, though not always, less primitive than related types with larval stages, and the tendency of fresh-water animals to have little in the way of larval stages (telescoping these, according to our theory) is very striking except along a few lines, such as that of aquatic insects, which are no doubt primarily terrestrial. And it is not difficult to see why it should be so.

(*d*) For most of the types of fresh-water animals it is possible to give a plausible pedigree, starting from marine or terrestrial forms.

(*e*) It is a significant fact, emphasised by Quinton, that the blood of land animals, such as mammals, is in the proportion of sodium, potassium, and calcium ions almost identical with sea-water. It is difficult to interpret this except as a hint of pedigree.

(4) It is impossible to do justice in a few lines to Prof. Macfarlane's long discussion of the phylogeny of animals. He regards Rotifers—in spite of the specialisation of most of them—as "the foundational group" of the simpler Metazoa, and he has the hardihood to place a ciliated Infusorian and a Rotifer side by side, for "the lines of stereogenesis in the Rotifera remain fundamentally as in ciliate Infusoria." We do not profess to know much about stereogenesis, but the juxtaposition of a Rotifer not only with an Infusorian, but also with a larval Entomostracan and a larval Gastropod strains our morphological faith. It must be a foundational creature indeed which is like three things so different. The author traces the main line of ascent from the Rotifers through Turbellarians, Nemerteans, Cyclostomes, Cæcilians, to Marsupials and higher Mammals. The difficulties involved in side-tracking Tunicates and Lancelets and in dragging Cyclostomes and Cæcilians on to the direct line of ascent seem to us to be insurmountable. But this is largely a matter of opinion. It seems to be truer of phylogeny than of statistics that if you pick your data you can prove anything you like. There are, naturally enough, some loose ends in Prof. Macfarlane's arguments. These are of two kinds—matters of fact, as when he says that the eggs of Cyclostomata undergo holoblastic segmentation, which is not true of Myxinoids; and matters of interpretation, as when he says of the Cæcilians: "the active gliding habits and slippery skin, also, scarcely serve to set up the needed irritable stimuli that would start paired limbs as a response-result." This surely verges on the poetical.

(5) A useful chapter on "higher" animals expounds the not unfamiliar idea that along different lines and at different structural levels animals rise to approximately equal complexity of behaviour. Thus octopus, spider, ant, crow, and elephant are types that rise high along different lines of structural advance. This is sound enough, though it is time that Sir Ray Lankester's distinction between the "little brain" and the "big brain" types of cleverness was recognised in all such comparisons, but what seems to us quite in the air is Prof. Macfarlane's theory that the "energising stimuli" of a complexified environment excite the biotic system of the body and the cogitic cells of the brain to new adjustments and adaptive changes, "all of which are more or less shared by and influence the generative cells, which in turn affect the succeeding organisms hereditarily." In other words, without any submission of evidence, we are asked to return to the credulity of Lamarckism. The author says: "To repeat once more our fundamental position: flows of energy, often and steadily repeated from sense-collecting centres, start stereo-energetic stimulation-acts, that inevitably affect the brain-cells, and these by expenditure of cogitic energy give rise to proenvironal responses that constantly tend to place the organism for the time being in 'satisfied' relations to its environment." In so saying he seems to us to be stating with unnecessary technicality the fact that living creatures adjust themselves within limits to their surroundings; but when he suggests that the elephant's trunk evolved by the transmission of the results of individual "proenvironal reponses," we feel bound to say "napoo."

(6) In regard to the Ascent of Man, the author lays emphasis (as Anthony, Wood Jones, and others have done) on the evolutionary importance of the emancipation of the hand which "stimulated the brain to increased flows of energy and so increased complexity and growth." "In all such advance by environal stimulation-action and brain reaction, followed by proenvironal outreach-

ing and succeeding response, the great law of proenvironment is constantly at work." Again, we have the same fallacious hysteron proteron. Surely the emancipation of the hand was the outcome of variations of structure and habit which are left unexplained (not that *we* can explain them); surely the cerebral initiative that put the free hand to manifold tests and found for it a thousand uses was and is a cause, not a consequence; moreover, the hereditary entailment of individual gains is a hypothesis, not a proven fact. We wish to make clear that when Prof. Macfarlane speaks of "the capacity of an organism for perceiving and then positively growing or moving toward an environment that is most satisfying for it," he is not defining any new "law of proenvironment," but referring to the fundamental fact that the organism is a self-preservative agent. In so far as other evolutionists have forgotten this and made the organism a passive pawn in a game, or a portmanteau of potentialities which require only liberating stimuli, Prof. Macfarlane's thesis is of great service. He has hold of the open secret that the organism shares in its own evolution.

(7) Our admiration is commanded by the two chapters in which the author gives an appreciation of the two great ways—competitive and co-operative—in which organisms answer back to the difficulties and limitations that beset them, though we do not think he realises what Darwin clearly expressed, that a co-operative reaction to a crisis is as much part of the struggle for existence as a competitive one. We wish that we had space to refer to the concluding chapters on human evolution, which are marked by a splendid earnestness and a truly evolutionistic hope. We can only refer to the cope-stone of Prof. Macfarlane's hierarchy of substance. Just as biotic energy is associated with protoplasm, cognitic energy with chromatin, cogitic energy with neuratin, so there is "spiritic energy"—a still more condensed mode—which "has so functioned as to energise the more aspiring and lofty souls of humanity to widest outreachings, toward the most profound questions of the world and the universe." "The phenomena, the experiences of human life in the past millennia especially, powerfully suggest to the writer that built up on, energised by, linked into complex relations by, a combined bio-cognito-cogitic union is a still more complex substance than the protoplasmatin, chromatin, or neuratin, probably resident in some part of the gray frontal matter of the brain, and which hypothetically we may call the *spiritin*." No man understands his brother's philosophy, and we do not know what Prof. Macfarlane is getting at by his quaint and uninviting system of substances and energies. There may be some, however, to whom it makes the riddle of the organism—body-mind and mind-body—clearer; and we are sure of this, that there are facts enough in the volume to reward even the learned, and that the whole work is marked by resoluteness and sincerity.

AMERICAN UNIVERSITIES.

(1) *The America of To-day. Being Lectures delivered at the Local Lectures Summer Meeting of the University of Cambridge,* 1918. Edited by Dr. Gaillard Lapsley. Pp. xxv+254. (Cambridge: At the University Press, 1919.) Price 12*s.* net.

(2) *The Voyage of a Vice-Chancellor.* Pp. ix+139. (Cambridge: At the University Press, 1919.) Price 6*s.* net.

(1) THIS volume of lectures delivered at Cambridge in the summer of 1918 contains only two chapters of direct technical interest to the readers of NATURE—namely, that of Prof. J. W. Cunliffe, on "American Universities: their Beginnings and Development," and that by Dr. G. E. MacLean on "State Universities, School Systems, and Colleges in the United States of America." The first of these gives a very interesting account of the English origins of American universities, of the effect of the different environments in bringing about a gradual departure from the English model, the injection of German influence, and the subsequent growth along more independent lines. The similar process of development is traced by Dr. MacLean with respect to the State-supported institutions, which have no direct counterpart in Great Britain. A very clear account is given of the various ways in which State and federal subsidy is provided for these institutions, and there is a brief discussion of the type of administrative organisation which has grown up. Both Prof. Cunliffe and Dr. MacLean rightly emphasise the ideals of universal education which have led to such a large expenditure of public money upon the school system as a whole. The result is, perhaps, that the reader unfamiliar with the situation would get too rosy a picture of the state of affairs. Not that there is any loss of faith in the ideals, but that, as Dr. MacLean points out, there is a strong feeling that great changes of method are necessary, and, indeed, such changes are constantly under discussion and under trial. Though they have no direct bearing on the subject of education, chaps. iii. and iv., by Lord Eustace Percy, on "State Municipal Government" and "Social Legislation," read in conjunction with those on education, will give a fairer idea of the tremendous problems presented by education in America and of the political and social difficulties involved in their solution.

(2) Such an important journey as that of the British University Mission in the autumn of 1918 to Canada and the United States will doubtless be the subject of formal and formidable reports both in England and America, but it is well to have also such an intimate and clever personal record of daily happenings as Dr. Shipley has given us in this volume. Though the account, in diary form, is very brief, one gains a clear impression of the differing characteristics of the various institutions and regions which were visited. As one reads of the unbroken series of banquets and

luncheons to which the commission was ruthlessly exposed, the number of speeches which they were forced to make, and the other at least equal number to which they were compelled to listen, one is impressed by the fact that this academic group "did their bit" in a very real sense. One also wonders whether the present demand for a reduction in the hours of labour could not be directed towards a change in the customs of after-dinner speaking, resulting in a great conservation of the nervous energy of the world. It is to be hoped that the journey which is here so gracefully described is but the first of many, perhaps less formal but more leisurely, which will be undertaken by academic and scientific men of both countries. It would be a pity if the greater intimacy and understanding, which war conditions have undoubtedly brought about between the men of science of England and America, should for any cause be allowed to lapse. C. E. M.

OUR BOOKSHELF.

The Statesman's Year-book. Statistical and Historical Annual of the States of the World for the Year 1919. Edited by Sir John Scott Keltie and Dr. M. Epstein. Fifty-sixth Annual Publication. Revised after Official Returns. Pp. lii+1476. (London: Macmillan and Co., Ltd., 1919.) Price 18*s*. net.

ONE turns to the new volume of this ever-welcome annual with considerable interest in view of the present fluid condition of international affairs. The coloured map shows the condition of Europe in June of this year, the accession to political sovereignty of Iceland, Poland, and Czecho-Slovakia is recognised by their treatment in new and separate sections, and the introductory pages contain the League of Nations Covenant, a summary of the peace terms to Germany, and a continuation of the diary of the war. The Iceland section summarises the consequences of the Act of Union of November, 1918, which makes the connection between Denmark and Iceland, in other than certain temporary arrangements, entirely due to the fact that both States have the same King. Although it has not been possible to include statistics regarding the dismembered Austro-Hungarian Empire, various estimates have been included—*e.g.* the new Austrian Republic has a population of some ten millions, of whom 90 per cent. are Germans; the probable population of Yugo-Slavia is twelve to thirteen millions. There are brief summaries of the results already achieved by British administrators in Mesopotamia, and of the newly independent kingdom of Hejas.

The Boys' Own Book of Great Inventions. By Floyd L. Darrow. Pp. ix+385. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1918.) Price 12*s*. 6*d*. net.

THIS book contains a popular and interesting account of the more important inventions of the last hundred years. One chapter is devoted to the gyroscope; six to telegraphy and telephony, with and without wires; two to aviation; and one each to the submarine; the steam engine; petrol, oil, and gas engines; the use of machinery in agriculture; the development of electricity; the evolution of artificial illumination; fire and high temperatures; some notable achievements in chemistry; the story of iron and steel; and Galileo and the telescope. The treatment is unusual. The author in most cases first appeals to general interest by describing practical achievement. He then gives an account of the theory, and concludes with a few experiments which the boy may perform for himself.

The style is good, the information is accurate, and the explanations are generally clear. The experiments are to the point, but, appearing as they do detached from the descriptions of the apparatus and process, they appear to be scrappy and unsatisfactory. Many of them are quite unnecessary in the case of a boy who is doing science at school, and to a boy who is not they would not all prove helpful. We prefer description and explanation, even where that involves experiment, to be more closely associated.

The value of some of the half-tone blocks is much reduced by printing two or three on a page, which renders them indistinct.

Apart from these minor defects, the book is first-rate, and will form an excellent gift for a boy who is interested in scientific achievement.

E. C.

Interpolation Tables or Multiplication Tables of Decimal Fractions. Giving the Products to the Nearest Unit of All Numbers from 1 *to* 100 *by* 0·01 *to* 0·99 *and from* 1 *to* 1000 *by* 0·001 *to* 0·999. By Dr. Henry B. Hedrick. Pp. ix+139. (Washington: Carnegie Institution of Washington, 1918.)

THE simplest description of these tables is to say that they give such results as $0·302 \times 441 = 133$ with the certainty (barring errors in the tables) that the third digit in the product is correct. Taking out such a product from the tables is an easy operation, requiring very little time; probably, with practice, the use of the book would be as expeditious as that of an ordinary slide-rule, and the results more trustworthy.

Various other ways of using the tables are explained in the introduction. The editor also gives interpolation formulæ, and worked applications to astronomy, etc., in which these tables are used.

This publication appeals to a large body of computers and scientific workers, and affords another instance of the wise enterprise of the directors of the Carnegie Institution. They have already earned the gratitude of arithmeticians by their tables of primes and factors, and they are doing a public service by thus undertaking the cost of printing works at which no ordinary publisher would look for a moment.

The printing and arrangement of the tables seem to be all that could be desired.

The Doubly Refracting Structure of Silica Glass.

I have recently observed that "silica glass" possesses a remarkable crystalline or quasi-crystalline structure when examined in the polariscope.

The double refraction is extremely weak, the retardation being probably of the order of 1/1000th of a wave. The structure cannot be advantageously examined with a polarising microscope as used by geologists, for the large number of lenses between the Nicols show enough double refraction to spoil the contrast between the dark and light parts. It is advisable to use a Nicol, and not a glass reflector, as polariser, and to dispense with lenses between the Nicols. A magnifier of 2 in. focus is placed above the analyser. An extremely bright light is necessary; I have used sunlight reflected straight into the apparatus, thus obtaining an intrinsic brightness comparable with that of the sun's disc. (No doubt an arc with a suitable condenser would do equally well.) The Nicols are to be accurately crossed so that the sun is invisible.

If a circular plate of fused silica of "ordinary" quality with polished faces is examined in this arrangement, it shows a striking mosaic of dark and bright parts without regular arrangement. The size of this structure is of the order of half a millimetre. It is seen superposed on the ordinary "dark cross" due to strain, which extends across the whole disc, 6 cm. in diameter.

A rectangular plate of the same class of material showed the dark parts elongated into bands set in a definite direction, and suggestive of a flow structure.

A circular disc of optical quality silica showed a spiral structure.

I have examined a large number of specimens of sheet- and bottle-glass without meeting with any trace of such a structure, which is evidently something quite peculiar to silica glass. It may be suggested tentatively that silica glass consists of a mass of "liquid crystals" comparable with those described by Lehmann in the case of certain organic substances.

It is intended to obtain photographs of these structures, and to study the effect of heat treatment on the silica until it becomes visibly devitrified.

A Search for Fine Wool.

Mr. Lydekker in his monograph on "Wild Oxen, Sheep, and Goats," published in 1898, stated that the ancestral stock of sheep is not only extinct, "but totally unknown." But in a book on sheep published in 1912 Lydekker admitted that the mouflon and urial had probably contributed to the making of domestic breeds. As a matter of fact, it has been proved beyond doubt (1) that the first domesticated sheep in Europe (*i.e.* the sheep introduced by the Alpine race about 7000 B.C.) were derived from a urial (*Ovis vignei*) not unlike the one now inhabiting the Kapet-Dagh, and (2) that nearly pure descendants of the ancient Neolithic breed still survive on the small uninhabited island of Soay (Sheep Island) near St. Kilda. Further, it is now realised that rams of at least three varieties of *Ovis ammon* have long been used for maintaining the size and vigour of fat-rumped and other breeds of Central Asia. More important still, it has recently been ascertained that the wool forming the inner coat of several of the wild sheep of Asia is longer than in the Soay, and decidedly finer than and quite as white as superfine Australian merino, usually said to be the finest and whitest wool in the world. Crosses between Soay and Southdown sheep yield excellent mutton, and beautiful wool remarkable alike for its strength and quality.

It is hence possible that, with the help of the urial and other wild types, new fine-woolled, vigorous varieties of the merino might be introduced. In the meantime, I am anxious to examine the wool of crosses which include wild species amongst their recent ancestors. Sir Joseph Banks, president of the Royal Society when the attempt was made to establish the merino breed in England, was a keeper of sheep, and was "well informed on all points relating to the production and uses of wool." Some of the readers of Nature who, like Banks, are interested in sheep may be in a position to help in the new search for the Golden Fleece.

Radiation Temperatures.

In a letter to Nature of October 9 (p. 113) Mr. Mallock points out the uncertainties attaching to records of "temperatures in the sun," due to the influence of the nature of the thermometer bulb on the readings. Similar uncertainties attach to readings of instruments exposed to a clear sky at night, and with even greater force, for there are two main radiation factors here, one of them being the cold ground—such thermometers being generally placed only four inches above the soil—and radiation to the ground is dependent to a very large extent on the nature and condition of the soil, or of the vegetation growing on it. It would appear that the so-called minimum earth radiation temperatures have very little value as meteorological data. Both these and readings of "temperatures in the sun" are affected by a source of error other than that noticed by Mr. Mallock, namely, the size of the thermometer bulb. With very large bulbs this may not obtain, but with bulbs of ordinary dimensions, say from 1·2 to 0·2 c.c., the difference caused by size is very noticeable, and is a curvilinear function of that size; with still smaller bulbs the function becomes rectilinear, the apparent radiation effect varying inversely with the linear dimensions of the bulb. Within the limits of bulb-size above mentioned, the differences observed may be 5 to 10 per cent. of the total radiation effect; and this, with readings "in the sun," might represent differences of 3° to 6° F. These figures apply to mercury thermometers; I have no observations yet with alcohol thermometers.

Differences of radiation temperatures due to the size of the object have an important bearing on subjects other than meteorological records. Thus, it will be impossible to cool a very small object by radiation to a temperature appreciably below that of the surrounding medium; hence the damage done to the pistils and stamens of flowers by frost cannot be due to radiation, but must be the result of the coldness of the air about them; therefore, methods of protection from frost dependent on preventing radiation by interposing a smoke cloud, or smudge, between the tree and the sky, will be ineffective, unless, indeed, the smoke cloud is sufficiently extensive to cover a large tract of country, and thus ensure a material reduction in the loss of heat from the ground by radiation, and a consequent reduction in the cooling of the air above it. Local and restricted smudging will not prevent the inflow of colder air from the surrounding land where radiation is active.

In England and on the Continent most of the recent suggestions for frost-fighting have been erroneously based on smoke production; but in Canada and the United States, although the reason of the inefficiency of smoke production does not seem to have been realised, the steps actually adopted for frost-fighting have taken the right direction, aiming at orchard heating—that is, actual heating by artificial means the air and the trees in the plantation. It is true that smudging is still used, but with a very different object, the smudge fires being lighted at dawn to prevent the sun's rays from heating too rapidly the frozen blossoms. It appears that the damage usually done by frost is not due to the freezing of the contents of the cells and the disruption of the cell-walls, but to the freezing of the intercellular liquid, the formation of ice here resulting in the abstraction of water from the cells; on thawing, this water is re-absorbed, but only very gradually; and, if the heating be too rapid, much evaporation occurs before the re-absorption is complete, and the cells remain permanently depleted of part of their water. The dehydrating action of freezing water in this case is analogous to that observed by the present writer in the case of clay and other highly hydrated substances, when the liquid in which they are suspended is frozen. But in those cases no re-absorption of the water occurs on thawing.

Spencer Pickering.

Time Relations in a Dream.

The following account of a dream which I had last night, and of which I took some notes, may be of interest. The dream commenced by my, as I thought, hearing a drop fall on the laboratory floor; after a time there was another drop. I then realised that mercury was dropping on the floor from a small split in some rubber tubing in a gas-analysis apparatus. As I became more wakeful and seemed to realise that I must get up to deal with the leak, the drops fell more rapidly until they were coming quite fast at the moment when I definitely awoke. I then realised that the dropping of mercury which I heard in my dream was in reality the ticking of the clock in my room.

The point which interested me, and may, I think, interest you, is that of the time relations of the dream. I went over my memory afterwards with a stop watch—and, of course, it is only one's memory of a dream that one ever has to go upon—with the following results:—

As I dreamed it, the interval between the first two drops seemed to be of the order of five seconds, and the drops seemed to quicken until they were at an estimated rate of about one drop per second.

Now the actual rate of ticking of the clock was one tick every quarter of a second. It is, of course, evident that one's judgment of time in a dream is quite erroneous in the sense that the occurrences as they take place in the dream seem to extend over a much longer time than the actual time of the dream.

On the assumption that each consecutive drop in my dream corresponded with one consecutive tick, it would appear that at the commencement of the dream the time interval between two consecutive ticks was exaggerated about twenty-fold in the dream, and that as I got more nearly awake the degree of exaggeration became reduced to something like four-fold. At a guess, I heard about thirty drops, in which case the dream would have lasted seven to eight seconds.

There is another possible interpretation, namely, that when I was most soundly asleep only one tick out of twenty came through to my consciousness, and that as I became more wakeful the number increased until one tick in four came through. On the latter theory the dream would have lasted considerably longer than on the former.

Whatever the interpretation, however, it occurred to me that the time records might be of interest, as a dream is rarely so simple or of such a kind as to admit of even the vague degree of measurement which I obtained.

Physiological Laboratory, Cambridge, October 14.

International Relations in Science.

A circular letter has been addressed, within these last few days, to "Members of the Academies of the Allied Nations and of the United States" by their brethren of the learned societies of the neutral countries. It is an appeal for toleration, even for generosity, an earnest and eloquent protest against a policy which would seek to exclude the present generation of German scholars and men of science from all our scientific and scholarly intercourse.

I cannot say that I have always been on the side of tolerance and reconciliation; but already we have had some little time to think, and this all but cosmopolitan appeal is bound, as it seems to me, to become a factor in the case. It is signed by very many friendly and honoured names; we cannot shut our ears to it, we cannot resolve upon isolation, lest it be isolation indeed.

This is not a matter to be decided for us by the votes of others, but by each man for himself—by all who claim liberty of action and freedom of thought. I am convinced that very many men feel, as I feel, that whatsoever overtures our German-speaking colleagues may make to us on matters scientific should be freely reciprocated. Need we ask what a man has thought or said, or even what he has done, in these last sad years? If he come in the universal name of science let that suffice; let it be granted that he means, now and henceforth, to follow the paths of learning and to walk in the way of peace.

St. Andrews. D'Arcy W. Thompson.

INTERNATIONAL ORGANISATION IN SCIENCE.

An appeal addressed "to the members of the Academies of the Allied Nations and of the United States of America" and signed by a number of scientific and literary men in neutral countries has been circulated and has already given rise to comments in the Press. It deals mainly with the formation, by the Allied academics, of new international scientific associations which neutral countries are now invited to join. Stripped of its rhetorical clothing, the document is an appeal to let bygones be bygones and to allow science to become again "the great conciliator and benefactor of mankind."

There will be much sympathy with the arguments used, the regrets expressed, and the hopes foreshadowed by our neutral friends, but they have left untouched, and to a great extent misunderstood, the principal considerations which have driven the allied academies to the policy they have adopted. It is only that part of our scientific activity which involves a regular personal and intimate relationship between men of different nationalities that is affected by the action of these academies. The question, therefore, simply resolves itself into this. Is it possible that an international scientific meeting in which the belligerent countries sit side by side can, at the present moment, lead to any satisfactory results, or tend towards that reconciliation which the neutral countries very naturally and legitimately hope for? There can be but few who will answer that question in the affirmative, and it is doubtful whether those few would include anyone who has had experience of international meetings before the war. The questions discussed at these meetings frequently touch national interests or national ambitions, be it only a discussion whether units adopted in one country shall be universally accepted. It often requires tactful leadership and a conciliatory disposition on the part of everyone present to steer an international meeting to a successful issue.

The matter is, to a great extent, decided for us by Article 282 of the Treaty of Peace which Germany has ratified. According to that article, "treaties, conventions, and agreements of an economic and technical character" not included in a specified list cease to be operative. That this article was intended to cover conventions on scientific matters appears from the list of exceptions, in which the Metric Convention and the Agricultural Institute at Rome are included.

In view of the strong feelings of resentment which still exist between the belligerent nations, feelings shared by the great majority of their members, the alternatives possible to the allied academies were either to discontinue international unions or to proceed as they have done. The former course, not perhaps very harmful in some branches of science, would have been fatal in others, and in coming to a decision they have had to give the foremost consideration to the interests of science. It is intelligible that, both in the review of the past and in the outlook of the future, neutral opinion should differ from ours; but we may be confident that the academies of the nations to which the signatories of the appeal belong will, in considering the invitations which are to be sent to them, be guided in their response by the same interest for the future of scientific progress which lies at the heart of the allied academies.

EVOLUTION OF OSTRICH PLUMES.

PROF. J. E. DUERDEN has published (Bulletin No. 7, 1918, Department of Agriculture, Union of South Africa, pp. 39, 12 figs.) a fourth report on his breeding experiments with ostriches at the Grootfontein School of Agriculture. His work is full of interest, both theoretically and practically. Birds brought from Nigeria have 33–39 first-row feathers on each wing, with an arithmetical mean of 36·54. If these imported birds represent a pure line, the likelihood is that the numerical variations are fluctuating somatic modifications, and that no amount of selection will increase the average number of plumes beyond that given. If the imported birds represent a mixed population of several pure lines, only appearing pure as a whole because of their small differences, it should be possible to obtain higher averages by always selecting as breeders the birds giving the highest number of plumes.

It turns out that Cape birds have the same number of plumes as the wild Nigerian birds, and it appears, therefore, that during the fifty years of ostrich farming in South Africa no advance whatever has been made on the number of plumes originally present on the wild bird. For farmers have always bred for quality; quantity has never been taken into account. As regards the number of plumes, ostrich-breeding has been carried on altogether indiscriminately, and no advance has been made.

Among the Cape birds in the Grootfontein flock there have been two cases of 42 plumes to the first row. One of these met with a fatal accident; the other bred true. The 42-plumed bird might be regarded as a novel mutation, but there is a more plausible view. Recent studies on the ostrich afford strong evidence that the wings of its ancestors were much better covered with feathers than is the case to-day. There has been retrogression, and it is still continuing. The 42-plumed wing is a survival of an ancestral condition. Very interesting facts are communicated in regard to the retrogressive or degenerative processes which are still going on in the ostrich's wing. The retrogression proceeds in one part of the wing quite independently of the other parts. Thus, apart from the plumes altogether, the third finger shows retrogression. It is almost buried in the flesh, and the claw which some books describe has never been found on the hundreds of birds coming under Prof. Duerden's observation. But a study of the plumes lends no countenance to the common view that degeneration takes place by slow, continuous stages. There may be the full presence of particular plumes in one individual, and their total absence in others; but there is not a gradual passage from full expression to the vanishing-point. The degeneracy of an organ may stop at any stage according to the number of constituent factors which happen to be lost. We are apt to think of the degeneracy as a somatic affair, whereas it is germinal.

As to the possibilities of the 42-plumed survival, no chicks have yet been produced from the 42-plumed cock mated with a hen with the same number of plumes, for no hen has been forthcoming. But a score or so of chicks have been reared from the 42-plumed cock crossed with different 36-plumed hens, and these showed an interesting series of numbers from 37 to 43. It seems probable, therefore, that if the 42-plumed cock had been mated with a 42-plumed hen there would have been a full 42-plumed progeny. If similar 42-plumed survivals occur, it should be possible for farmers to increase by as much as 25 per cent. the crop of feathers from the same number of birds, or, a more desirable outcome, to procure the same quantity of plumes from three-quarters of their present number of birds. Prof. Duerden is to be congratulated on reaching conclusions at once of high theoretical interest and great practical utility.

EDUCATION IN INDIA.[1]

THIS is the second quinquennial review compiled by Mr. Sharp, Educational Commissioner with the Government of India. Shortage of paper and other conditions bred of a period of war have compelled him to curtail his report and, not without advantage, to diminish his statistics. What remains is full of interest and significance, especially, of course, to those who have some first-hand knowledge of Indian education. There is the inevitable, and in some respects useful, comparison with the educational statistics of various European countries and Japan. Of this it is necessary to repeat that the comparison is obviously unfair, even in the case of Japan. British India is a continent rather than a country, and is far more varied in culture and civilisation than Europe or Japan. It is the great towns, such as Calcutta or Bombay, that should be compared with European countries, since there alone are conditions sensibly similar to those of Western nations.

We should have welcomed, too, a fuller account of the attempts to impart instruction in the local languages. So long as British rule exists it will be as necessary for Indians to learn English as for educated Englishmen to learn French and German. But English as a medium of instruction is open to obvious objection. We continue to hear complaints of superficial thought, parrot learning of cram text-books, absence of originality, and so forth. Surely this is largely due to making lads, many of whom are not gifted linguists, learn difficult subjects, such as science and mathematics, in a language in which they cannot think. Were it not that many Indians have attained to a surprising proficiency in English, the system would have been condemned long ago. In the chapter on Oriental teaching Mr. Sharp confines his remarks to education in the Indian classics, and has little or nothing to say of the attempts now being made to gain for the modern languages of India the same facilities that English universities are now supplying for European living speeches, their philology, phonology, and literature.

From the point of view of education in India, war and the economies it involved came at an unfortunate moment, since it was necessary to suspend a great part of the reforms projected in Lord Hardinge's resolution of 1913. Even in that circumstance, however, we may ultimately find comfort, since what India chiefly needs is not official encouragement and the vicarious liberality of Government so much as public appreciation of what good and solid education is and by what means it can be supplied to the people at large. One of the most important steps in this direction (less neglected than official reports seem to show) is to make the greater Indian languages fit vehicles for supplying instruction to immature minds. In many Indian provinces non-official committees and societies have carefully compiled vocabularies of scientific terms. Some of these seem pedantic and clumsy enough to those who study Indian languages merely with a view to the enjoyment of literature or the understanding of local life and character. But we must not forget that our own scientific nomenclature is chiefly borrowed from dead, inflected languages, and presents difficulties which, to an Indian mind, would not occur in the use of similar phrases borrowed from Sanskrit in the case of Hindu languages or from Arabic for Mohammedan learners of science.

On the whole, in spite of war and other lets and hindrances, some permanent, some, we hope, temporary, Mr. Sharp's admirably arranged and very valuable report tells us a tale of substantial progress. *E pur si muove!* Public expenditure on education has increased by one-half in the five years under review. There is a steady improvement in the number of boys and girls under instruction. Teachers are better paid, though it is probable that much of their increased salaries has been swallowed up by rising prices. The huge, too huge, examining universities are gradually being supplemented by smaller residential and teaching colleges. This change implies some recognition, on the part of Government and parents alike, of the fact that education comprises a moulding of character and will as well as the training of memory, intelligence, and interest.

It is perhaps a little surprising that Government reports on education do not deal with the significant results of school and university teaching as these appear in vernacular literature and journalism. Most of us in Europe have heard of Rabindranath Tagore and one or two other contemporary Indian authors. There are others, locally held in equal, or almost equal, esteem. A system of education which produces really fine literature, much of it entailing solid research and thought in history, in philosophy, and, to a growing extent, in science, is probably more full of hope and promise than can well be shown in an official summary of the educational doings of some 200 millions of human beings of extraordinarily various degrees of social, religious, and scientific progress. This, of course, will be sufficiently apparent to any careful and disinterested reader of Mr. Sharp's admirable report.

[1] "Seventh Quinquennial Review of the Progress of Education in India." By H. Sharp. (Bureau of Education, India.) Price 5s. 6d. net.

NOTES.

The Board of Agriculture and Fisheries has taken a step long overdue, and now the one competent entomologist on its permanent staff can look forward to assistance in doing the work which twenty competent entomologists might, perhaps, be expected to perform. An entomological laboratory has been established and placed at Rothamsted, where a chief entomologist and two research assistants are to devote their whole time to investigation. The further proposal to appoint twelve advisory entomologists for the twelve agricultural divisions of England is one the advantages of which are doubted in a leading article in the *Times* of October 10. It would be better, our contemporary thinks, "were the research staff at Rothamsted to be increased, and arrangements made for the investigators to visit, now Cornwall, now Northumberland, wherever a local problem became urgent, returning to their headquarters to pool their experience and their results." Research is needed, very much needed, and probably nowhere else in England could greater facilities for investigations of the kind required be found than those at Rothamsted. But if the practical value of entomological research is to be brought home to the farmer, the fruit grower, or the breeder of stock, he must have his eyes opened for him and be given instruction on the spot; it can never be attained simply by the distribution of pamphlets or journals, no matter how well prepared or how valuable the advice they may give. The divisional entomologists should do something more than give advice when called upon; they might make periodical inspections, and have a look out for incipient stages in the diseases of crops in their divisions, as well as for critical stages, so that means could be taken in time to prevent the spread of the disease. It should also be their duty, rather than directly that of the farmer, to keep in touch with what was going on at headquarters, and to become acquainted with all the latest discoveries brought about by research. Even in research they themselves need not be idle, if they have been properly trained, and are qualified, as they should be, to carry it on.

The annual exhibition of the Royal Photographic Society is again held at 35 Russell Square, as, owing to the requirements of the Government, none of the larger galleries are available. But the scientific section suffers nothing on this account, as the society in its own house has greater facilities for displaying the exhibits. This section fully maintains its reputation. There are forty-three colour transparencies on autochrome plates out of a total of forty-six, but this kind of work is now so well established and so perfect that the interest has passed to the subject rather than to the process. Photomicrography is well represented by entomological and botanical series. A photomicrograph that stands alone must have something very remarkable indeed about it to justify its exhibition. The radiographs of surgical and medical interest are as numerous and valuable as ever, and the application of Röntgen rays to the detection of hidden defects in metal castings and in aeroplane parts is strikingly and beautifully illustrated. Concerning novelties in scientific methods and apparatus, the splendid exhibit of grainless and filmless photography by the Messrs. Rheinberg richly deserves the medal awarded to it. It includes scales on glass for apparently every conceivable purpose, from micrometer scales to scales 30 cm. long. Messrs. Adam Hilger show a spectrograph on an improved Schumann plate which records lines from wave-lengths 21 to 67, and photographs that illustrate the use of the interferometer for testing camera-lenses. The exhibition closes at the end of November.

The subject of the declining birth-rate was raised at the Church Congress on October 15 in two papers. The Bishop of Birmingham held that restriction of births was due in most cases to prudential motives and to a sense of responsibility, and noted as a curious fact that statistics showed that doctors and clergy, who used to be very prolific, now had smaller families on the average than other people. The nation wants more children, but wants them of the best quality. There must be cases where some kind of control should be exercised, and that must be before conception is known to have taken place. Dr. Amand Routh directed attention to parental syphilis and alcoholism as causes of ante-natal and neo-natal disease and death. He condemned the circulation of so-called "prophylactic packets" as likely to increase rather than to diminish venereal disease. He stated that in the six months ended March 31 last deaths in England and Wales exceeded births by 126,445—for the first time in our statistical history. Dr. Stevenson, Superintendent of Statistics, attributed this to a decline in fertility. Dr. Letitia Fairfield stated that venereal diseases had not only spread during the war, but had rapidly increased since the armistice, and urged an addition to the number of clinics. The Archbishop of Canterbury considered that the use of prophylactics would be perilous as smoothing the way towards vice, but approved the efforts of the National Committee for the Prevention of Venereal Diseases.

It is with sincere pleasure that we learn that M. Emmanuel de Margerie has been appointed Director of the new Geological Survey of Alsace and Lorraine. M. de Margerie brings to his official duties the knowledge gained by years of cultured conference with geologists throughout the world, and we are indebted to his wide reading and his personal acquaintance with the face of the earth for the French edition of Suess's "Antlitz der Erde." This, far from being a mere translation, is the form in which the book will live as a monument to Austrian powers of collation and construction and to French lucidity of exposition. M. de Margerie's published work has been geographical as well as geological, and it is pleasant to picture him as looking out from the heights of the Vosges on river-profiles once more associated with France. Many questions of economic geology, and therefore of national welfare, will come before him in the recovered provinces. While his sympathetic spirit will find no barrier in the Rhine, his vindication of the attitude of the Entente Powers, addressed during the war to Prof. Heim of Zürich, proves him to be the right man for the task of reconstruction on the frontier.

Mr. Francis Jeffrey Bell, who has just retired from the Natural History Museum under the age-limit, entered the service of the trustees on August 12, 1878, when the Zoological Department was still at Bloomsbury and Prof. Owen the superintendent. He took an active part in the removal of the collections to South Kensington in 1882–83, and concerned himself with various divisions of the marine invertebrata, giving especial care to the exhibition of selected types. Mr. Bell is emeritus professor of comparative anatomy in King's College, London, and he served for many years as one of the secretaries of the Royal Microscopical Society, the Journal of which he also edited. In 1898 he acted as general secretary of the International Congress of Zoology, and for many years was a constant attendant at the council of the Marine Biological Association. Mr. Bell is part editor of the Museum report on the collections of the

Southern Cross, and he has seen all six volumes of the *Discovery* Antarctic report through the press.

WE learn from *Science* that Mr. John D. Rockefeller has given to the General Education Board, founded by him in 1902, twenty million dollars, the income of which is to be currently used and the entire principal to be distributed within fifty years for the improvement of medical education in the United States. The working capital previous to this accretion amounted to between 35,000,000 and 40,000,000 dollars. Since the present sum is to be devoted exclusively to medical education, whereas the board's previous resources, under the terms of the charter granted to it by Congress, have been devoted to "promoting education within the United States, without distinction of race, creed, or sex," the activities of the organisation with respect to medical teaching will be greatly increased.

ACCORDING to the *Morning Post*, the Norwegian traveller, Dr. O. Olsen, proposes to conduct a small anthropological and botanical expedition to Siberia next spring. Dr. Olsen has had previous experience in Siberia when in 1914 he studied the Soyot tribes in southern Transbaikalia, near the Kitoisk Mountains. His present project is to go to the Yenisei valley north of Krasnoyarsk, and to push thence into the less known regions immediately to the east, with the object of studying several little-known tribes. These include the Dolgans, a Yakut tribe living between the Yenisei and the Khatanga; certain races of Samoyedes; and certain tribes of Tungus. The expedition also proposes to bring back with it, about January, 1921, seeds of Siberian conifers suitable for planting in Norway.

WE have received a copy of the "Annuaire de l'observatoire royal de Belgique" for 1920, edited by M. G. Lecointe. We are glad to note that the publication of this useful little annual was continued throughout the years of the German occupation of Belgium. The observatory at Uccle was held by the Germans, but its scientific work continued. There was no interruption in its publications, and even research did not completely cease. Needless to say, the Belgian staff was responsible for this continuous activity, M. Stroobant replacing for the time M. Lecointe, who was with the Belgian Army.

THE assistant secretary of the British Association, Mr. O. J. R. Howarth, has been charged with the collection of materials for a history of the association. The records available in the office, especially those referring to the foundation of the association, are far from exhaustive, and the loan of any letters or other documents bearing upon the history of the association will be gratefully welcomed by Mr. Howarth at the office of the association, Burlington House, W.1, and they will be duly returned after use.

THE Secretary of the Department of Scientific and Industrial Research informs us that the following research associations have been formed in accordance with the Government scheme for the encouragement of industrial research:—British Rubber and Tyre Manufacturers' Research Association (c/o Messrs. W. B. Peat and Co., 11 Ironmonger Lane, E.C.2) and the Linen Industry Research Association (secretary, Miss M. K. E. Allen, 3 Bedford Street, Belfast).

THE council of the Chemical Society has arranged for the delivery of three lectures during the coming session dealing with the work accomplished by chemists during the war. The first of these will be delivered at Burlington House on December 18 at 8 p.m. by Prof. James Walker, who will lecture on "War Experiences in the Manufacture of Nitric Acid and the Recovery of Nitrous Fumes."

THE council of the Ray Society has appointed Dr. W. T. Calman, of the Zoological Department, British Museum (Natural History), to be secretary in succession to the late Mr. John Hopkinson.

THE annual report for 1918 on the Forest Administration of Nigeria shows the number of forest reserves to be gradually increasing. Their total area now amounts approximately to 1462 square miles in the Southern Provinces and to 3965 square miles in the Northern Provinces. Plantations continue to be made, in spite of the greatly depleted European staff and the disorganisation caused by the influenza epidemic. Apart from mahogany and *Albizzia lebbek*, the species that have proved most successful are *Cassia siamea*, *Dalbergia sissoo*, *Grevillia robusta*, and *Melaleuca leucodendron*, all of them exotics. In fact, it is very probable that, as experienced in South Africa, the planting difficulty in the Northern Provinces will be solved only by the introduction of suitable exotics. Hence these operations must, for some years to come, be of an experimental nature.

A NUMBER of papers dealing with marine biological and fishery subjects have recently been published. The Danish series, "Meddelelser fra Kommissionen for Havundersogelser," contains articles on purely fishery, hydrographic, and biological investigations. A very useful account of the North Atlantic halibut fishery, including work on the biology of the species, as well as on its exploitation by fishing vessels, is given by P. Jespersen in Bd. v. (No. 5) of the Fishery Series, and a very interesting paper by A. C. Johansen in the same series deals with the biometrics of the spring-spawning herrings that form the bulk of the fish caught during the great spring and summer fisheries. There is also an account of fish-marking experiments carried out on the Faröese fishing grounds. This is local in its scope, but it is interesting to see, from the results, to what an extent this region must have been exploited by British trawlers in the years immediately preceding the war.

IN Report No. 4 of the Industrial Fatigue Research Board Mr. Major Greenwood discusses "The Incidence of Industrial Accidents upon Individuals, with Special Reference to Multiple Accidents." As a result of an elaborate mathematical analysis of a large mass of statistical data, Mr. Greenwood comes to the conclusion that the distribution of accidents among the employees at a factory is by no means a matter of chance, but that certain individuals are much more liable to accidents than others. This susceptibility to accidents is not due to the workers being quicker at their job than their fellows, nor do they differ from them appreciably in general health. It seems to be a matter of personality, and not determined by any obvious extrinsic factor. As Mr. Greenwood points out, the weeding-out of these specially susceptible individuals would lower the average accident-rate of a factory considerably, and it might, in certain instances, have a more important effect than this. In some industries, such as certain of the explosive-supply trades, an accident may lead to frightful disaster, and it might be well worth while to track down these unsafe people by a study of the ambulance-room records and get them transferred to a less risky industry.

THE limitation of human settlement in South Africa through deficient water-supply has moved Prof. E. H. L. Schwarz to undertake a journey to Ovamboland, a little-known district north-west of the Kalahari region, which seems threatened by the desiccation that has overtaken the country to the south. In a paper entitled "The Kalahari Lake Scheme" (*S. African Mining and Engineering Journal*—the complete reference is not given on the separate copy sent us), Prof. Schwarz proposes to save Ovamboland and its native population by damming the Cunene River at the cataracts and diverting the water that now flows into the Atlantic back into a depression known as the Etosha Pan. Hence irrigation could be arranged northwards and eastwards. A "Makarikari Lake" is also proposed as a development of the Soa Pan, west of Bulawayo, and from this irrigation might be possible in the eastern Kalahari down the channels of streams flowing to the Orange River. The scheme is already exciting discussion in the States of the Union.

IN a recently published memoir of the Carnegie Institution of Washington (No. 285), Prof. T. H. Morgan gives an account of his experiments relating to the secondary sexual characters of poultry, and discusses at some length the genetic and operative evidence with regard to secondary sexual characters in general. In some breeds of poultry, notably Sebright bantams, the cocks are feathered like the hens, lacking the long, silky hackles of the neck and saddle, and the curved sickle feathers in the tail that distinguish the cocks of normal breeds. Prof. Morgan demonstrates by crossing experiments with game bantams—a breed with the normal sexual differences of feathering in the cock—that the hen-feathered condition is dominant. His figures suggest that two factors are concerned, but the experiments are not sufficiently extensive to render this certain. Castration experiments were performed on the Sebright cocks and some of their hen-feathered progeny, and the interesting fact was disclosed that removal of the testes results in the male assuming a type of plumage characteristic of the cocks of normal breeds. The fact is of great interest in connection with the recent work of Goodale, who showed that removal of the ovary from the hen leads to the assumption of the male plumage. A further point of interest lay in the demonstration of luteal cells in the testes of hen-feathered cocks, similar to those which are known to occur in the ovary of normal hens. Cells of this type are stated to be absent from the testes of normal cocks. The greater part of the memoir is taken up with a discussion of secondary sexual characters in animals generally, in relation both to Darwin's hypothesis of sexual selection, and to the many other views which have been put forward at various times since. A brief review is also given of the heredity of the colour of the plumage in domestic fowls. The memoir contains an ample and useful bibliography, and is well illustrated with coloured and other plates.

THE economic value of the forests of New Zealand is discussed by Mr. D. E. Hutchins in the Transactions of the Royal Scottish Arboricultural Society (vol. xxxiii., part 2, July, 1919). The forests are of great value, and admittedly the best soft-wood forests in the southern hemisphere. In quality New Zealand timbers come before those of Europe and Australia and after those of North America. The valuable kauri-pine (*Agathis australis*) is the largest timber-producing tree in the world, owing to its massive bole having little or no taper. At one time there were about three million acres of kauri forest in New Zealand, now reduced to about half a million, in the extreme north. The next most valuable timber is supplied by another conifer, Totara (*Podocarpus totara*); it is very durable and of a fine colour. This tree is generally distributed through the North and South Islands. A third conifer, Rimu (*Dacrydium cupressinum*), also abundant throughout the islands, is the common house-building timber, a deep red, strong, hard, and heavy wood. White pine (*Podocarpus dacrydioides*), one of the tallest trees in the colony (the writer records one of 210 ft.), has white, easily worked timber suitable for inside work. Honeysuckle (*Knightia excelsa*), a tall, handsome tree with beautifully variegated wood, has never been exported. There is a large class of so-called secondary timbers in New Zealand forests which have never been utilised. The writer deplores the destruction of forests without any attempt to discriminate between land best suited for farming and land best suited for forestry. In 1886 the forest area of New Zealand was estimated at 21,000,000 acres, which by 1909 had become reduced to about 17,000,000 acres. The forests even in their present reduced and neglected condition are worth more than all the known mineral wealth of New Zealand, and they still offer more employment than any other industry. Compared with sheep-farming, the New Zealand forest, if worked as are forests in Europe, would afford about ten times the employment.

IN the *Indian Forester* for July last, Mr. H. H. Haines gives an elaborate description, with figures, of the various shrubs belonging to the genus Carissa, the bark and leaves of which are an important source of tannin. Thirteen species have been described by various authors, but these are reduced by Mr. Haines to five distinct species with several varieties.

MR. ALEX. L. HOWARD wrote some time ago in the *Timber Trades Journal* a series of short articles giving a popular description of the most important woods that are imported into London from India, with notes upon their properties and uses in this country. These articles are now issued by Messrs. W. Rider and Son in pamphlet form, entitled "The Timbers of India" (pp. 16, quarto, price 2*s.* 6*d.*).

IN the description which appeared in NATURE of October 9 of the aurora of October 1, and the simultaneous magnetic storm, several observations were recorded, but unfortunately the time reckoning is not the same throughout. The observations described in the first and last paragraphs were received from the Meteorological Office, and the times mentioned in them were all referred to the civil day, which runs from midnight to midnight, whereas in the other paragraphs describing observations at Bristol and in the Isle of Man the astronomical "day" seems to have been used. When the change of time reckoning to which astronomers have agreed comes into force, the risk of similar accidents will be obviated.

SIR ROBERT HADFIELD has just issued copies of a Foreword which he prepared on the occasion of the Prime Minister's recent visit to Messrs. Hadfield's works at Sheffield. Sir Robert has some timely remarks on the labour situation in the country and the extreme necessity for joint intelligent effort on the part of capital and labour, without which understanding the burden of debt arising from the war cannot be wiped out. During the present year many hundreds of valuable working hours have been lost as the result of trade disputes; but it is really hard to see what can be done without increased enlightenment of the working classes, whose destinies may be said largely to rest with themselves. Sir Robert pleads for the revision of the existing patent laws in this country, so that all classes, without distinction, may benefit from the fruit of their discoveries.

Some space is devoted to the importance of inventions and research in connection with war munitions, and it is interesting to note that Sir Robert's firm is now in a position to manufacture a heavy calibre naval shell which, for range and piercing power, will far outstrip anything previously accomplished. Invention should be stimulated and every effort made to discover fresh inventors, and, once they are discovered, to encourage them to give their ideas to the world so that everyone may benefit from them.

CONSIDERABLE interest is attached to the description in *Engineering* for October 10 of the geared turbines supplied by the De Laval Steam Turbine Co. to the Swedish destroyers *Wrangel* and *Wachtmeister*. The high- and low-pressure turbines occupy separate casings, and drive pinions engaging on opposite sides of the main gear wheel. The high-pressure turbine casing accommodates a cruising element, and the low-pressure turbine an astern turbine. The wheels of both high- and low-pressure turbines are designed to make 3600 revs. per min. at full power, and the maximum peripheral speed is 180 metres per second. The cruising element consists of one velocity-compounded wheel, followed by a simple impulse wheel. The main turbine has four wheels. The astern turbine has one velocity-compounded wheel with two rows of blading, followed by a simple impulse wheel. The aggregate shaft horse-power at full power is 11,000, with the propellers running at 450; the astern shaft horse-power is 4400, with propellers running at 250. With steam 97 per cent. dry, the turbines were guaranteed to consume not more than 5·2 kg. of steam per shaft horse-power hour at full load. Double helical gear wheels are used for speed reduction, and the pinions are rigidly mounted. The pitch line speed at full power is 35 metres per second. Michel thrust-blocks have been fitted, and their remarkable qualities confirmed by the tests.

OUR ASTRONOMICAL COLUMN.

NOVÆ.—Yet another nova has been found on the Harvard plates, this time by Miss Woods (Harvard Bulletin 693). Position for 1875: R.A. 18h. 24m. 6·2s., S. declination 29° 28·9′. Its former magnitude was 14, but it rose temporarily to 11 in 1901. On April 24, 1919, it rose to 7, and has now sunk again to 12, its image appearing nebulous. The magnitudes are photographic.

Pubs. Ast. Soc. Pac., August, 1919, contains a paper by Dr. Shapley on a nova of another kind that was discovered by Prof. Wolf two years ago, and independently by Prof. Barnard in the present year. Its place for 1917·0 is R.A. 17h. 35m. 13·45s., S. declination 11° 53′ 57·6″; its photographic magnitude is 11 (Harvard scale); spectral type, FO; radial velocity large and positive. All plates exposed before 1909 fail to show it; all since 1910 show it. Three interpretations are suggested:—(1) That it is really just beginning its stellar career, in which case it is of unique interest; (2) that it is a long-period or irregular variable, somewhat like η Argûs; and (3) that it has just emerged from behind an obscuring nebula. To test this last suggestion, Dr. Shapley took a long exposure with the 60-in. reflector and studied the distribution of faint stars. The results, given in the paper, while not inconsistent with the hypothesis, give no decisive evidence in its favour; there is no distinct line of demarcation of stellar density, as in some of Prof. Barnard's dark nebular regions. However, a much smaller cloud than these would suffice in this case.

Mr. Joy has made an estimate of the star's distance by the Adams spectroscopic method, finding 500 parsecs. A Harvard plate of 1909 July 9 shows it of magnitude 14·4; 1910 March 21, 11·3. Since 1915 it has been 11.

Both Mr. C. P. Olivier (*Ast. Journ.*, No. 757) and Messrs. Van Maanen and Sanford (Pubs. Ast. Soc. Pac., August, 1919) publish preliminary values of the parallax of Nova Aquilæ 1918. Their values (absolute parallax) are 0·060″ and 0·009″. The latter, which implies a distance of 362 light-years, is close to the values found for Nova Persei, both by direct measures and by the expanding nebular illumination. All the observers contemplate further measures when the brightness of the nova has sunk nearly to that of the comparison stars.

THE SUN-SPOT CURVE.—Mr. Seth B. Nicholson gives an interesting curve of sun-spot activity in Pubs. Ast. Soc. Pac., August, 1919. It is constructed simply from the number of spots, regardless of area. Mr. Nicholson places the late maximum in September, 1917, and the curve since then shows a notable decline. The previous maximum is placed in May, 1905, and is both flatter and lower than the recent one. The minimum is shown in June, 1913. There are also curves of the mean latitude of spots, which show that the fall in latitude since the last minimum has been much steeper than in the preceding cycle.

Mr. Nicholson directs attention once more to the resemblance of the spot-activity curve with the light-curve of Cepheid variables. The sun's surface is certainly not pulsating, as those of the Cepheids are believed to be; if the resemblance of curve means anything, it suggests that there may still be remnants of pulsation in the sun's interior.

SOLAR RADIATION.—Mr. C. G. Abbot (Proc. Nat. Acad. Sci., U.S.A., September, 1919) gives an account of the simultaneous measures of solar radiation made in 1918 at Mount Wilson and Calama, Chile. The results give still stronger support to the hypothesis that the short-period variations in the radiation are in the sun itself than did those at Mount Wilson and Algeria in 1911–12. Mr. Abbot states that the Calama results are telegraphed to Argentina, and successful predictions of temperature are based upon them. He suggests additional radiation stations at various cloudless regions, which he anticipates would be of great utility in weather prediction.

NEW SOURCES OF ALUMINIUM IN NORWAY.

DURING the war neutral as well as belligerent countries had to search within their own borders for those raw materials which formerly they were content to import; new occurrences of well-known ores have been discovered, and new methods devised for winning important products from rocks which hitherto have possessed no commercial value. Norway was particularly hard hit by the curtailment of international trade, and, amongst other problems, that of finding a home source of aluminium presented itself, and seems to have received a promising solution.

The metal aluminium can be obtained by electrolytic means from its oxide, and nearly all the suggested methods of manufacture depend upon this as a final stage, the main difficulty being the preparation of a sufficiently pure oxide, free from iron and silica. The ore commonly used is bauxite, after a rather costly preliminary purification by the Baeyer process. At the outbreak of war the Central Powers utilised their available bauxite, including the small deposits of poor quality in Germany; but the necessity of finding a more widespread source was felt, and a process was discovered and successfully put into operation by Dr. Buchner, of Heidelberg, for winning the metal from kaolin and kaolin-rich clays. Clay is extracted with sulphuric acid, and, after removal of the iron, the alumina is precipitated from the solution with ammonia, four tons of a clay with an alumina content of 30 per cent. yielding one ton of the oxide. This process seems to have a considerable future before it, and plans are laid for its introduction on a large scale into Sweden.

There is no bauxite in Norway, and it was first proposed to work the clays after the Buchner and other suggested methods. This, however, has for the most part proved impracticable owing to the unfavourable character of the clays, which are relatively unweathered glacial deposits, not only poor in alumina, 16–20 per cent., but with part of it bound in alkali felspar, and therefore unavailable. In 1917 Prof. V. M. Goldschmidt, of the Mineralogical Institute, Kristiania, conceived the idea of using labrador-stone as a source of aluminium.[1] Labrador-stone is a white rock extensively developed in south-western Norway, and especially in the inner Sognefjord district, where it builds the huge laccolitic mountain masses so familiar to tourists, by whom it is commonly mistaken for marble. The main constituent of this rock is a plagioclase felspar of the labrador group, the more felspathic varieties containing only a very small amount of iron-bearing pyroxenes, and with an alumina content of 30 per cent. Prof. Goldschmidt has found that the felspar is surprisingly soluble in dilute acids, so that it can be dissolved out, leaving a residue of insoluble ferro-magnesian minerals and silica. The calcium and sodium oxides of the felspar, 13 per cent. and 5 per cent. in amount respectively, go into solution with the alumina, and, using sulphuric acid, there is thus a considerable loss in the form of a useless by-product. This method is rejected for the manufacture of alumina, although it is used in the preparation of sufficient quantities of aluminium sulphate to satisfy Norwegian needs. By using nitric acid as a solvent, not only is a waste of acid avoided, but the precipitation with ammonia can be dispensed with—a valuable consideration in Norway, where ammonia cannot be obtained cheaply in quantity.

The main features of the process, which has been worked out by Prof. H. Goldschmidt, are as follows:—The labrador-stone is extracted with dilute nitric acid, the 30 per cent. acid, first raw product of the electrical air-industry, serving for this purpose. The silica and greater proportion of the iron minerals remain insoluble, aluminium, calcium, and sodium going into solution together with a little iron. After removal of this iron the solution is evaporated down and the residue heated to a certain temperature at which the aluminium salt alone is decomposed, the nitric acid driven off being collected as a valuable concentrate. By washing with water the nitrates of calcium and sodium are removed, to be recovered and used in agriculture, the alumina remaining.

This process seems to be full of promise for Norway—a country with such abundant water-power, a flourishing nitric acid industry, and an unlimited quantity of a raw material which few other countries possess; and hopes are entertained that a product will be obtained which will not only suffice for local needs, but also win a footing in the world's rapidly expanding aluminium market. L. Hawkes.

[1] "Om Aluminiumfremstilling av Norske Raastoffer." By V. M. Goldschmidt. Særtryk av Tidsskrift. for Kemi, No. 2, 1919.

HYDRO-ELECTRIC DEVELOPMENT WORKS.[1]

An extremely able and informative paper has recently been contributed to the Institution of Electrical Engineers by Mr. J. W. Meares, chief engineer of the Hydroelectric Service of India, dealing with the general principles of the development and storage of water for electrical purposes—a subject which is of the greatest interest at the present time from an industrial and economic point of view. Mr. Meares's paper is a general survey of the various problems connected with the inception of hydro-electric installations; it outlines the conditions essential to the satisfactory development of any scheme of water-power, for it must, of course, be borne in mind that it is quite possible for a country to have considerable water resources, say, in the form of rivers, which are incapable of economical development. The paper treats of all the preliminary considerations relating to the gathering of supplies, flow and storage, the lay-out and efficiency of hydro-electric plant, and the principles underlying the design of headworks, canals, and delivery mains.

Supplies of water at different heads entail distinct methods of treatment. The heads may be broadly grouped as high, medium, and low, in which, without too rigidly defining the boundary lines, high heads are taken at from 300 ft. or 400 ft. to a possible 5000 ft., low heads from 3 ft. as a minimum to, say, 80 ft. or 100 ft., with medium heads between these limits. A high head is associated with small volumetric flow, and a low head with a large flow; the former is adapted to jet-impulse wheels of the Pelton type, and the latter to pressure, or reaction, turbines.

In areas dependent on the collection of rainfall for supplies, the amount of fall and the run-off are important considerations. The following empirical table devised by Mr. G. T. Barlow, formerly Chief Engineer of the United Provinces, India, gives a working hypothesis for preliminary calculations which, while perhaps inapplicable to many parts of Europe or America, affords a clear indication of the nature of the variations to be met with in a particular locality:—

	Percentage run-off				
	A	B	C	D	E
Light falls, say under $1\frac{1}{2}''$ in 24 hours	1	3	5	10	15
Medium falls, say from $1\frac{1}{2}''$ to $3''$ in 24 hours	10	15	20	25	33
Heavy falls, say above $3''$ ...	20	33	40	55	70

A is flat, cultivated and black cotton soil catchment.
B is flat, partly cultivated and stiff soils.
C is average catchment.
D is hills and plains, with little cultivation.
E is very hilly, steep, and rocky, with very little cultivation.

The paper also contains a table giving the over-all commercial efficiency of hydro-electric plant as follows:—

For 500 kilowatts	74 per cent.
,, 1000 ,, ...	76 ,, ,,
,, 1500 ,, ...	78 ,, ,,
,, 2000 ,, ...	80 ,, ,,
,, 3000 ,, and over ...	82 ,, ,,

As a rough approximation, the capacity of plant in kilowatts may be obtained by dividing by 15 the product of the quantity of water in cubic feet per

[1] "The General Principles of the Development and Storage of Water for Electrical Purposes." By J. W. Meares.

second into the head in feet; the b.h.p. of the turbine will be given by one-eleventh of the same product.

The ground covered by the paper is too extensive to admit of adequate notice in the space at disposal. From the foregoing extracts the paper will be seen to be replete with useful information.

BRYSSON CUNNINGHAM.

THE BRITISH ASSOCIATION AT BOURNEMOUTH.

SECTION F.

ECONOMIC SCIENCE AND STATISTICS.

OPENING ADDRESS (ABRIDGED) BY SIR HUGH BELL, BART., D.L., J.P., PRESIDENT OF THE SECTION.

THE cessation of hostilities did not carry with it the cessation of expenditure. The figures given each week in the *Economist* show the daily disbursements of the kingdom to have amounted to 6,500,000*l.* for the twenty-one weeks from November 16 to April 12. Our expenditure from August 24 to November 9 amounted to 585,500,000*l.* From November 23 to July 8 we expended 564,000,000*l.*, a reduction of only 21,500,000*l.*, or about 250,000*l.* a day. The debt with which the war burdened us continued to augment long after the cause of it had ceased to operate. We are still vastly exceeding our income. Even if we take into account the interest on the war debt, which amounts to about 1,000,000*l.* a day, it is clear that the various obligations undertaken by the Government during the war continue to impose on us a huge expenditure which is largely in excess of our revenue.

New claims are made on the national purse and are accepted with the same apparent light-heartedness and disregard of consequences which mark so many previous acts of those responsible for our expenditure both during the war and before it.

The call made on the men and women of the nation for services differing from those to which they had been accustomed involves great changes in the conditions of those affected. Some compensation for these sudden changes was, no doubt, inevitable. The disorganisation of the whole industrial machine made it difficult, if not impossible, to turn these different classes adrift into a world in the chaotic condition into which the war had thrown it. But it does not follow that this compensation should have been given in a way actually to encourage unemployment. There are only too many indications of a general tendency to extravagant expenditure which must be checked before the course of our economic existence can return to normal lines. To enable us to do this we must consider what has happened to the world economically since August, 1914.

The first and perhaps most striking change to be noticed is that in these five years an immense quantity of wealth has been destroyed.

There must be many hundred thousand acres of cultivated land, with the apparatus required for its cultivation, which has been reduced to a state of complete desolation. It is difficult to see how it can be brought again into use at an early date. The mere clearing away of the wire entanglements must be a costly operation. Great quantities of shell abandoned by the Germans in their hasty retreat still cumbered the ground they had occupied. These must be carefully removed—not a very simple operation, and one which must be carried out under skilled direction.

Can anyone doubt the huge destruction of wealth which has occurred? But it is really worse than it appears, for the very process of destruction was even more costly than the damage which was done. Millions of tons of steel in the form of guns and their projectiles—millions of lives had gone to produce this untoward result. For fifty months all the energies of the most active and energetic people on the globe had been turned from beneficial enterprise to work of which the result was the annihilation of vast masses of wealth.

When all these things are considered it is not surprising to find our estimate of the cost of the war reaches a total the mind cannot grasp. When you begin to speak of pounds by thousands of millions, the difference between twenty-five and forty is scarcely noticeable. But be the sum larger or smaller, the all-important fact to be borne in mind is that the wealth which it represents has passed out of being.

So much confusion exists on this subject that it is worth while dwelling on it for a moment. Some contend that there has been a mere change of wealth from one ownership to another. Into whose possession, may we ask, has passed the wealth which used to exist in the towns and villages and cultivated land of the battle area? It is true that the steel which went to effect this destruction has been paid for, but from what source has that payment come? Let us think what might have happened but for the war. The steel might have made rails and been laid on a railway to bring the produce of Central Africa to lands ready to pay for it and desiring to consume it for useful purposes. For all time there would have arisen in the process an income which would have gone to support in comfort those receiving it, and its surplus after this had been effected would have served to add yet more miles of railway and to bring yet more tons of useful produce. All this energy has been dissipated in the manner indicated, and all that remains is the obligation of the "State" for all time to pay interest on a debt which has been created.

There is, as it seems to me, but one way to escape from the situation we have created. No measure of confiscation, however disguised, will remove the burden under which we lie. It may be decided to alter the incidence of the burden from one set of shoulders to another. Any proposal of the kind must have very careful and earnest consideration.

If a really sound and equitable scheme of taxation could be devised, each taxable unit would contribute to the common fund raised for the purpose of the Government an amount which would be arrived at after due allowance was made for his services to the community and his ability to pay. A bachelor, with no claim on him but to support himself without State aid, who had done nothing to provide for a citizen to take his place in the fullness of time, might be called upon to pay more than a man under obligation to maintain a family, and supply, by his children, the means of carrying on the torch of progress.

One of the chief objections of graduation seems to be the danger of gradually increasing the steepness of the scale until the higher incomes would be taxed out of existence and the revenue they produced disappear. This would, no doubt, bring its own remedy. The State needs a certain annual revenue to provide the services demanded by the community. If the result of taking much the greater part of incomes over a certain amount ends by extinguishing these, the State will cease to derive the revenue on which it counts. It must then either reduce the tax on them until a point is reached at which they will continue to exist, or it must increase the tax on all or some of the other incomes. Unless it means to rush headlong into bankruptcy, it must find the point of equilibrium at which its scheme of graduated taxation continues to produce the revenue required, not in any one year, but in all future years. Such a scheme, could it be discovered, would meet entirely that very important desideratum of a tax, namely, that it should be based on ability to pay.

Two other points must be kept in view. A tax must be equitable in its incidence and reasonably continuous in its imposition. Given these three conditions, the economic burden of the impost will quickly fall on the right shoulders. We may dismiss the argument which asks for a levy on capital, and defends it against the accusation of being confiscatory on the ground that it is no more confiscatory than any other means of raising money by the State. No juggling with the balance-sheets of the nations of the world will get rid of the fact that many thousands of millions of wealth slowly accumulated in the generations which lived before August, 1914, have been dissipated.

[After a brief examination of the changes in the amount of the National Debt for the past century and its gradual reduction since 1814, the address proceeds:—]

In the last five years all this has been changed. From August, 1914, to March, 1915, 450,000,000*l*. were added. The next year added more than 1,000,000,000*l*. By March, 1917, it stood at 3,906,000,000*l*., and now it has nearly doubled, and is more than ten times what it was at the outbreak of the war.

It is true we have something to set against this vast sum. We have acted as the financial agents of our Allies. The sums we have found for them amount to close on 2,000,000,000*l*. On the other hand, we have ourselves contracted debts abroad to the extent of well on to 1,500,000,000*l*. On balance, therefore, we have interest to receive on about 400,000,000*l*. to 500,000,000*l*. But to enable the inhabitants of this country to find money for our Government, we have sold fully as large an amount of our holdings in foreign securities. It may be contended that we are little worse off. I fear on closer examination this view will not be found good.

Let us admit that our Allies will find no difficulty in paying the 100,000,000*l*. a year or thereabouts due for the interest on their debt to us. We must recognise that this will make a serious draft on their resources. Very different were the securities held by individuals in this country with which they parted to take up each successive issue of Government Bonds at the urgent insistence of successive Chancellors of the Exchequer. The securities sold were usually first-class industrial or public utility issues. What have we got now? A charge on a heavily burdened country of which, it may be, many thousand acres have passed out of cultivation for years to come.

Put at the highest, not many of our millions of pounds will find their own interest. All the balance must come out of the product of the other and real industries of the debtor country, and to this branch of the subject we must now turn.

At the present moment it is of more vital importance than ever that we should come to a clear and unprejudiced understanding on this subject. To judge by appearances, the vaguest opinions exist as to the capacity of the community to meet the various claims which are preferred for a share of the wealth from which alone these claims can be satisfied. Many people seem to think that no demand is too exorbitant. We are asked to provide houses by the hundred thousand, undeterred by the consideration that they will cost two-, three-, or even four-fold the amount at which they could have been built before the war. They are, moreover, to afford accommodation of a much better character than was thought sufficient a very short time ago. Houses built so recently as twenty years ago are no longer good enough for the social reformers of to-day. It is forgotten that something like 80,000 houses are needed each year to accommodate the growth of the population. There are to-day something more than eight million inhabited houses in Great Britain. Not more than half of these are above fifty years old. During the war housebuilding had almost ceased, but before 1914 the building of houses had been checked by two causes. The various Acts of Parliament dealing with matters affecting the building of houses had so enhanced their cost that there was the greatest uncertainty whether houses could be built to return a reasonable interest on their cost.

But the second cause was of as great, or possibly even greater, significance. The trade unions connected with the building trades had gradually succeeded in imposing conditions which had added enormously to the cost of building. It would not be difficult to show why this had been possible, but it would take us too far to follow this line of thought. The fact will not be denied by anyone conversant with the circumstances. The result of all this is a serious shortage of houses, and this it is proposed to make up by grants from the public purse. If this were the only demand of the kind we might face it with more equanimity than is in fact the case. But when we look elsewhere we see other claims comparable in their effects on the public purse, but differing in kind.

The railway enterprise in this country may serve as typical of what is meant. Prior to the war the railways were carrying on their duties in a manner which enabled the country to get through its business in a profitable and, on the whole, fairly satisfactory way. They earned sufficient revenue to pay a fair return to the shareholders. It is true the prospect was not reassuring. The railway management was meeting the usual contradictory claims preferred against almost every industry. It was asserted that they were rendering services which were not nearly so great as were demanded by their customers, and they were charging for them rates which were regarded as quite out of proportion to the value of the services. On the other hand, they were paying wages which the recipients thought entirely inadequate, for much longer hours of service than their workmen were disposed to give. Negotiations between the parties had obtained certain concessions as to hours of work, and also as to rates of pay; but these were not accepted as sufficient, and Parliament was called upon to intervene, with the result that statutory hours were imposed.

The very essential difference between hours of work or rates of pay resulting from convention between the parties interested and the same imposed by statute is often overlooked. The convention can be varied to meet the varying circumstances. The statute provides a hard-and-fast rule, from which it is impossible to depart without incurring penalties.

When the railway companies pointed out the serious effect which these statutory obligations imposed on them had on their revenue-earning capacity, and sought power to increase the rates, their customers were up in arms. The very men who, in Parliament and elsewhere, were applauding the decision to give relief to the railway servants, resolutely refused to pay the extra cost thus incurred. With difficulty was Parliament induced to give the companies leave to add to their charges something towards meeting this cost. The companies found still greater difficulty in obtaining a settlement with their customers as to the amount which should be so added. The question was still awaiting a final settlement at the outbreak of war.

[The position of the railways is examined; the small yield to the shareholders is set out; the need of the expenditure of fresh capital to enable the companies to cope with the growing traffic is stated; and the address proceeds :—]

There has been a persistent demand by labour throughout the country for better pay, and an equally persistent demand for more leisure. To these demands no objection can be taken. On the contrary, rightly understood, they must meet with approval by all who desire to see the country, as a whole, happy and prosperous. But we must consider how they can be satisfied.

The only source from which satisfaction can be derived is the sum-total of the product of the industry of the country, and indeed of the world, in the period under consideration. It must be noted that in many cases the product may not be realised within that period, as, for example, when a manufacturer holds large stocks of goods which he has not yet marketed, but on which much the greater part of the cost has been paid. It must also be noted that a very considerable part of the industry of the country does not add to the total product which is the subject of division, but is, in fact, a charge on that product. The whole burden is borne by those engaged in providing commodities or services necessary for the members. We touch at this point a very difficult problem, the proper solution of which may possibly show us how all our economic troubles may be ended. I can do no more than state it as briefly as may be.

There can be no question that a very great part of human activities is spent, and the resulting product used, in providing things which cannot be called necessaries of existence. The simplest food, clothing, and shelter may be said to cover all that comes under this head. But life that gives us nothing but the indispensable minimum of these essentials would be so dull and monotonous as to be scarcely worth the exertion needed to procure them. We must have more than these if we are to get enjoyment as well as mere life. How much more can we claim—perhaps we might say, extort—from our environment? And how shall this extra tribute be shared among us?

If we made a complete analysis of the division of the product of industry we should be astonished to find how large is the amount which remains after the essential demands have been satisfied. If we sought to classify our expenditure we might come to some such division as this :—

On essential needs.

On things making for the irreproachable amenities of life.

On luxuries which add to and aid our reasonable enjoyment.

On those which subserve mere pleasures.

On extravagant expenditure for which no justification can be offered.

It is difficult to draw any clear line between the heads of this very rough division. Each class passes imperceptibly into the next. Fortunately for our present purpose, we do not require to do this. It is enough that we should admit that not all activities are well directed, and that we consume a great many things we could do without. No class is exempt from this blame, if blame it be. Each is disposed to look askance at what is called the extravagance of some other. When people talk of waste, they often mean expenditure on things for which they themselves do not care. But the question is: How can we check this extravagance and provide more fully for the more essential needs of the whole people?

If rich men did not drive motor-cars or drink costly wines, would the people who produce these luxuries be better off? Or if, instead of making these things, they made articles needed for the mass of the people, could these buy the result if they had no more means than they now possess? Do we not come back at the end to the proposition that men can have more only if they have more to offer in exchange?

It may be contended that men have obtained more or less completely what they wanted most urgently. They wanted shorter hours. In many trades they have got them, and might have had them in more had they gone about it in the right way. They were not sufficiently desirous of having better houses, and they failed to procure what their well-wishers desired for them.

A relatively small part of the population does unquestionably get a very large share of the total income produced by the whole community. Can we do anything by which this share may be reduced without bringing about greater evils than those we seek to overcome? The history of the sumptuary laws does not encourage much hope that attempts to prevent expenditure in particular directions will have much success. My own studies had brought me, many years ago, to the conclusion that in every industry examined there is no way of giving to those engaged shares greatly differing from what has been afforded in the past. The margins on which manufacture in general is conducted are too small to make it possible to give the larger contributors to the ultimate result any considerable addition to what they have been accustomed to receive. This impression was confirmed by the elaborate general survey of the industry of the kingdom carried out by the Census of Production of 1907.

No doubt labour (which is much the most important item of cost) has obtained a gradually increasing payment, though not necessarily any larger proportionate share. A steady improvement in the methods in which the labour of men is applied has resulted in enabling a larger product to be obtained. Each new implement, each fresh application of energy of various kinds, as, for example, steam and electricity, has meant that the individual man produced more in his day's work, and he got, in fact, a larger return for what he did. But at the same time the capital engaged was increased, and consequently the proportion of the product to be allotted to rewarding capital also increased. It is neither possible nor desirable to attempt to alter this state of things.

The whole question has been treated in a very masterly way by Prof. Bowley in a book published some months ago, entitled "The Division of the Product of Industry." Mr. Herbert G. Williams's pamphlet, entitled "The Nation's Income," also deals with the same subject with much care and skill. In it he makes a critical examination of Sir Leo Chiozza Money's book entitled "Riches and Poverty."

The conclusion reached in these publications is practically the same. It may be stated, in the cautious words with which Mr. Bowley ends his book :—

"This analysis has failed in part of its purpose if it has not shown that the problem of securing the wages, which people rather optimistically believe to be immediately and permanently possible, is to a great extent independent of the question of national and individual ownership unless it is seriously believed that production would increase greatly if the State were sole employer. The wealth of the country, however divided, was insufficient before the war for a general high standard; there is nothing as yet to show that it will be greater in the future. Hence the most important task—more important immediately than the improvement of the division of the product—incumbent on employers and workmen alike, is to increase the national product, and that without sacrificing leisure and the amenities of life."

I shall have failed in my object if I have left my hearers under the impression that I am wedded to or pleading for any particular division of the wealth of the country. We hear much talk about abstractions called "capital" and "labour." The terms are convenient enough if we do not let ourselves be deluded with the idea that they mean more than the sum of those who own the capital or supply the labour. Labour itself is a somewhat ambiguous term. Until comparatively recently the members of the "labouring classes" so called thought it was synonymous with the man who laboured with his hands. The Labour Party itself has been fain to enlarge its definition so as to include all those who "labour by hand or brain." Not one of us is independent of capital. The most poverty-stricken member of the community relies as implicitly on it as the richest among us. To talk of the "abolition of capital" is to use a form of words which is absolutely meaningless. What most people who use them really mean is one or other of two things, sometimes both at the same time—either that the capital is in the wrong hands and that it should not be held in the way or to the amount which is at present the case, or that the division of the joint product of capital and industry is defective and should be altered.

I see great difficulty in saying no man's fortune shall exceed some given sum, and even in saying no man shall bequeath to his survivors more than some very moderate amount. In either case I should fear endangering that building up of capital which, however it may be divided, is essential to our national progress.

When we come to the division of the joint product of industry and capital other considerations become apparent. The question at once arises whether any other division would have been possible in the past, or could be accomplished in the future, without great changes in the way in which the product arises. Reference has already been made to my own examination of this matter, which leaves me in no doubt that any considerable increase of the part of labour would have left the share of capital so small as to have stifled enterprise.

This does not mean that large fortunes may not have been made by those whose skill and industry and enterprise enabled them to seize the advantages presented to them.

Those who cry out against capital overlook the fact that in modern industries no man can be set to work except by means of a capital sum first found for the purpose. In the industries I know best something above 200*l*. is needed to put a man to work. The population of this country increases at the rate of about 1 per cent. per annum. This means that for every 1000 men to whom employment is being given, about ten youths are ready to be set to work each year, and something above 2000*l*. must be found year by year to give them employment.

One further point must be made. Men see some great enterprise (and the railways will serve very well as an example), and look upon it as a capitalist organisation. But when the circumstances are examined it is found that it consists of a multitude of small holdings, and comparatively few of large amount. In the North-Eastern Railway something like 60,000 shareholders hold the 83,000,000*l*. of capital of various denominations—say, on the average, some 1400*l*. each. Consider the widespread distress which would be caused if the income from the sum were to cease.

I have made a similar calculation for a large colliery undertaking in which I am interested, with the following result. The capital in shares and debentures is about 1,300,000*l*. There are a little more than 1800 shareholders. We employ 5500 men. Each shareholder therefore provides employment for about three men, and holds on the average 725*l*. Before long we shall require further capital. We see our way to enlarge our operations and so to provide employment near to their homes for the fifty to sixty youths who, each year, grow to manhood, and need productive employment if they are not to become burdens on the community. We hope our 1800 shareholders will have laid by enough to provide the 12,000*l*. a year which is necessary for this purpose. We are assuming they or someone will provide it, for we are using our resources (reserves and depreciation funds) in this way, and shortly it will be incumbent on us to fund this obligation and add it to our capital.

We are thus brought to the last subject which I desire to consider with you—the widespread tendency towards what is somewhat vaguely called Nationalisation. It may be questioned whether any large number of people have very clear ideas what is meant by the term.

Let us assume for the present purpose that it signifies that the State shall become the owner of any enterprise which is nationalised—as it owns the business of the Post Office, the Telegraphs, and the Telephones. Let us ask what advantage will be gained by the assumption of ownership. A centralised management, even of so simple a business as that of collecting and distributing letters and parcels, has not been an unqualified success. Where the business is more complicated, as in the other examples, the success has been even less conspicuous. What reason have we to hope, then, in such intricate matters as the railways or the mines, better results will follow?

The incentive of individual gain will have disappeared, and with it the readiness to accept such risks as those to which reference has already been made. We may easily find that the developments needed to find employment for our young people are not forthcoming, for without such risks being run no growth of employment will take place. Unless I am much mistaken, a great temptation will be put before politicians to make concessions to the huge army of voters who will be in the direct employment of the Government.

The experience of these five years has failed to teach the lesson that you cannot touch one branch of labour without affecting all others. An advance of wages given to one section will inevitably be demanded by all others. The result will be prejudicial to the whole community. As regards international trade, we may find ourselves shut out of foreign markets because our wages are made artificially high, just as we should be excluded if, for example, the shipowners could compel us to pay inordinate freights on some indispensable raw material like cotton.

A cure will speedily come, but it may come after great suffering has been inflicted on the whole community. Parliament can easily impose on the employer, whether a private individual or the State, the payment of a certain wage if a man is employed, but one thing it cannot do, and that is compel the employment of the man at a wage which the price of the article he produces will not suffice to pay. The man will remain unemployed. That is the drastic remedy which economic law imposes. We may escape it by making up from some other source the deficiency if we insist on having the article and refuse to pay the cost. But this remedy is applicable only to some small part of our total product. When we come to such industries as those now talked of it is impossible. We must make the industry self-contained.

But it may be said that those most concerned are not striving alone, or even chiefly, for higher wages, but desire to participate in the management and to bear their part in deciding the questions of policy which up to now have been in the hands of the employers. To this no fundamental objection can be raised. The more completely the men engaged in any enterprise understand it, the better it will probably be for the whole. But large questions of policy require knowledge and appreciation of circumstances which can with difficulty be acquired by persons whose life is necessarily passed in quite other surroundings. That the fullest information should be given to the persons in question cannot be denied. The claim to deal with matters of management lying quite beyond their competence cannot be conceded. The final impulse comes from one mind which cannot divest itself of its responsibility or exercise it under such conditions as those suggested would impose.

A universal unrest pervades the world. This had indeed already become apparent before 1914. The war has exacerbated the symptoms which were already sufficiently menacing. Remedies by legislation had been applied here and elsewhere without success. In the nineteenth century the political emancipation of the inhabitants of this country was gradually effected. By the end of it freedom had been practically won. The great changes which occurred in the political condition of the country as it was before 1832 and as it became by the end of the century had been brought about with relatively little trouble. It is not surprising that this should have led to the conclusion that economic changes could be effected with equal ease. Perhaps the confusion which we continually observe between a "law" imposed by the will of a legislature and a "law of Nature," so called, is responsible for this conclusion.

Having gained political freedom comparatively easily, people seem to have thought economic freedom could be got with equal facility. We have had numerous instances of this on which it is unnecessary to dwell. Concessions have been made by which, apparently, life was made much easier for certain people. But the fund out of which these concessions were to come has not been increased. Many of them, though not so intended, had the effect of positively lessening that total. In a perfect world it ought not to have had this effect, but, human nature being what it is, it was easy to foresee the result. It could have been foretold that a minimum wage established by law would sooner or later reduce the output of the man paid by piece. It had that effect on the coal-miners at a very early date after its enactment.

The demand for higher wages without a corresponding increased output was causing anxiety before the outbreak of war. The inordinate expenditure which the war brought with it seemed to justify the contention of the workmen that the claims they had put forward could easily have been met in the past, and must be conceded when things became normal again. It was forgotten that all thought of economic production had ceased. We were living, not on the earnings of the year, but on credit raised on our expectations of the future. In the past this course was also pursued, but (as has already been pointed out) in very different circumstances, for the capital thus created was calculated to yield an adequate return to the persons interested.

None of the remedies proposed touches the difficulty. We must obtain a larger product if we are to have more to divide. Restrictions in output, whether produced by the act of the Legislature, the will of the worker, or (let us add) the hindrance of a tariff, will fail to effect this. None of the short cuts now proposed will lead us to our goal. Can we convince those most deeply interested of the truth of this? The task is not an easy one, for promises without end are made to accomplish what is desired without pursuing the patient and laborious course which alone can lead to a happy solution. For my part, I rely on the common sense of my fellow-countrymen. The speedy abolition of all artificial prices by which we shall get to know the real cost of what we buy will be a great help. We may hope that on this will follow an earnest desire on the part of all to do their best for the commonweal—convinced that on this intelligent altruism we are best serving our own ends. A better division of industry would ensue. The net result would be a happy and contented nation, in which the efforts of each would be more guided by the common welfare than by the selfish desire for the advantage of the individual.

None of these things can be accomplished by Acts of Parliament. Statutory prices and statutory hours offer no solution—rather increase the evil than lessen it. There is no royal road by which we can travel to a solution. We must, by patience and mutual forbearance, seek to alter the present hostile attitude. We may frankly accept Prof. Cannan's opinion that "the economic organisation of the nineteenth and early twentieth centuries will not endure for ever, but will be gradually replaced by something else more suitable for its own day and generation."[1]

Let all parties in the State bend themselves to this change, in which, again to quote Prof. Cannan, "free associations of free men able to go out and come in as each pleased would voluntarily give service for service, irrespective of domicile and nationality." This is a change which we may agree with him in thinking more "desirable than any restoration of the feudal system basing economic organisation on the territory of the lord, even if the personal lord of the Middle Ages is replaced by a Parliament elected by universal suffrage and proportional representation."[2]

FORTHCOMING BOOKS OF SCIENCE.

SINCE the appearance of the article on "Forthcoming Books of Science" in NATURE of October 16, some further lists of books likely to appear in the near future have reached us. *The Cambridge University Press* is to publish "The Transmutation of Bacteria," Dr. S. Gurney-Dixon, and "Notes on Magnetism," C. G. Lamb. *Messrs. C. Griffin and Co., Ltd.*, announce "The Flow and Measurement of Air and Gas," A. B. Eason; "The Practical Design of Plate Girder Bridges," H. Bird, illustrated; "Marine Diesel Engines: Maintenance and Running," J. Lamb, illustrated; "Laboratory Aids in Practical Mechanics," G. S. Bowling; "Airman's International Dictionary, English–French–Italian–German," Lieut. M. M. Dander; "A Treatise on Surveying and Levelling," S. Threlfall, illustrated; "Modern Mine Valuation," D. Penman, illustrated; "Peat Reference Book," F. T. Gissing; "Coke-Oven and By-Products Works Chemistry," T. B. Smith, illustrated; "Coal Economy: The Reduction of National Coal Consumption by 50 Million Tons a Year," W. H. Casmey; "Analytical Chemistry as a Profession for Women," Emily A. L. Forster; "Text-book of Inorganic Chemistry,"

[1] "Coal Nationalisation," p. 25. [2] *Ibid.*

vol. ix., Cobalt, Nickel, and the Elements of the Platinum Group, Dr. J. Newton Friend, and Iron, Dr. J. Newton Friend and J. Bentley; and new editions of "A Treatise on Petroleum," Sir Boverton Redwood, Bart., in 4 vols.; "Electrical Practice in Collieries," Prof. D. Burns; "The Problem of Flight: A Text-book of Aerial Engineering," H. Chatley; "The Mineralogy of the Rarer Metals," E. Cahen and W. O. Wootton; "Elementary Agricultural Chemistry," H. Ingle; "Dairy Chemistry," H. D. Richmond; "Paper Technology," R. W. Sindall; "Modern Road Construction," F. Wood; "The Physico-Chemical Properties of Steel," Dr. C. A. Edwards; "General Foundry Practice," A. McWilliam and P. Longmuir; "A Medical Handbook." Dr. R. S. Aitchison; "Introduction to the Study of Midwifery," by Dr. A. Donald, illustrated; "A Manual of Elementary Seamanship," D. Wilson-Barker; and "Elementary Coal-Mining," G. L. Kerr. The new list of the *J. B. Lippincott Co.* includes "The Harvey Lectures, Delivered under the Auspices of the Harvey Society of New York, 1917–1919"; "Training of a Pharmacist," D. C. O'Connor, illustrated; "Airplane Photography," Major H. E. Ives, illustrated; "Training for the Electric Railway Business," C. B. Fairchild, illustrated; and "Applied Economic Botany," Prof. M. T. Cook, illustrated. They have also a number of volumes in preparation for appearance in the series of "Monographs on Experimental Biology and General Physiology." *Mr. John Murray* promises "Science and Life: Aberdeen Addresses," Prof. F. Soddy; "Springtime and Other Essays," Sir Francis Darwin; "The Life of Sir William White, K.C.B., F.R.S.," F. Manning, illustrated; "The Shibboleths of Tuberculosis," Dr. M. Paterson; "Theodore Roosevelt's Letters to his Children," edited by J. B. Bishop; "Wild Life in Canada," Capt. A. Buchanan, illustrated; "Homing with the Birds," Gene Stratton-Porter; "Strategic Camouflage: The Probing of a German Secret," S. A. Solomon, illustrated; and a new and enlarged edition of "Microscopy: The Construction, Theory, and Use of the Microscope," E. J. Spitta, illustrated. We notice that Dr. E. A. Wallis Budge's long-expected new book is to be entitled "By Nile and Tigris: A Narrative of Journeys in Egypt and Mesopotamia on Behalf of the British Museum between the Years 1886–1913." It will be in two volumes and illustrated.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BRISTOL.—A new chair of physical chemistry has been established in the University on the endowment of Lord Leverhulme. Capt. J. W. McBain, lecturer in physical chemistry in the University since its foundation, has been appointed to the chair.

OXFORD.—We understand that Prof. S. H. Vines is retiring from the Sherardian professorship of botany in the University at the end of the current year.

SHEFFIELD.—On Friday, October 17, the Prime Minister received an honorary degree at the University, and took the opportunity of speaking on the place which the university, especially the modern university, can fill in the general field of education. He spoke with great cordiality on the function in the educational world of the modern universities, illustrating particularly by the influence which the University of Wales has exercised throughout the entire Principality. He congratulated Sheffield on the progress that it had made, and paid a warm tribute of appreciation to the work of Mr. H. A. L. Fisher, both as Vice-Chancellor of the University and as President of the Board of Education. In particular he spoke of the work done by the applied science department during the whole history of the University, and especially in relation to the supply of munitions for the British Army. "The contribution of Sheffield," the Prime Minister said, "was not merely a contribution drawn from the ranks of its students and its staff on the fighting side. It made a real contribution on the side of the provision of materials—an essential part of the winning of the war." At the same time he pointed out that the work of a modern university was not by any means comprised in the service which it rendered to material needs or to local industries, important as these were; it should be, in addition, the intellectual centre of the whole district in which it was situated. "It leads," he said, "the population which surrounds it to a higher culture; that is the great task of all these young universities; and I am glad to know that Sheffield is thoroughly realising the importance of this aspect of its work, as well as the more and immediately practical part of the enterprise."

THE Salters' Institute of Industrial Chemistry has awarded grants in aid to thirty young persons occupied in chemical factories in or near London to assist them in improving their knowledge of chemistry.

THE estate left by the late Gen. Horace W. Carpentier is valued, says *Science*, at 721,200*l*. The principal beneficiaries are Columbia University and Barnard College, each of which receives 284,000*l*., and the University of California receives 20,000*l*. From the same source we learn that by the will of the late Mr. Charles W. Lenney, of New York, 10,000*l*. is left to Boston University.

THE Rev. S. Graham Brade-Birks has been appointed lecturer in zoology at the South-Eastern Agricultural College, Wye. Mr. Brade-Birks is an honours graduate of the Victoria University of Manchester, and since his ordination in 1914 has spent much of his leisure researching with his wife (Dr. Brade-Birks) on the English millipedes and centipedes. Last session (1918–19) he acted as demonstrator in the zoological laboratories at the University of Manchester.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 22.—M. Léon Guignard in the chair.—The president announced the death of Gustaf Retzius, correspondant for the section of anatomy and zoology.—N. E. **Nörlund**: The polynomials of Bernoulli.—L. B. **Robinson**: A symmetrical system of polynomials.—J. **Chazy**: Solutions of the problem of three bodies where the three bodies form an isosceles triangle.—G. **Sagnac**: The æther and absolute mechanics of waves.—L. **Bruninghaus**: The conditions of production of fluorescence.—J. **Guyot** and L. J. **Simon**: The action of hydrates, oxides, and carbonates of the alkaline earths on dimethyl sulphate. Quicklime and caustic baryta are almost without action upon methyl sulphate; baryta-water and lime-water give barium and calcium methyl sulphates in theoretical quantities. Crystallised barium hydrate or slaked lime with methyl sulphate gives methyl ether and the sulphate of the metal.—M. **Delpech**: Flameless powders. An account of experiments on the effect of adding charcoal, vaseline, and other substances to propellant explosive from the point of view of producing a flameless explosion at the gun. Vaseline and heavy petroleum oil proved to be the most effective, provided that suitable additions to the weight of the charge were made to make up for the addition of the non-explosive material.—M. **Bourgeat**: The discovery of coal-bearing schists on the borders of the Serre.—E. **Chaput**: Remarks on the origins and classification of Desmoceras.—F. **Morvillez**: The leaf-conductor apparatus in the Hamamelidaceæ and neighbouring forms.—J. **Dufrénoy**: Experimental bacterial tumours in pines. This disease is due to a coccus, and is transmissible from tree to tree. The tumour is caused by a deposit of resin at the infected part.—G. **Bazile**: New methods for the destruction of Acridians. The experiments were carried out in Algeria on columns of *Schistocerca tatarica*. Of the methods tried, the use of flame-projectors proved to be the best.—P. **Godin**: Difference of progression of the index of growth in the male and female sexes.

SYDNEY.

Royal Society of New South Wales, September 3.—Prof. C. E. Fawsitt, president, in the chair.—J. H. **Maiden**: Two new Western Australian species of Eucalyptus. The two species have hitherto been wrongly included in *Eucalyptus Oldfieldii* One is a mallee that was originally collected by the Elder Exploring Expedition in 1891 both in South Australia and in Western Australia. It is now recorded from the Murchison River. It attains a height of about 20 ft., and has a singular, striate bark. The other species grows in damp, sandy land between the Darling Range, south of Perth, and the sea. It is a white gum, and has for many years been confused with the wandoo.—E. **Cheel**: Three new species of Leptospermum. One of the species from North Queensland, collected by Dr. E. Mjoberg during the Swedish Scientific Expedition to the Commonwealth in 1913, has been named *Leptospermum Mjobergi* in honour of the discoverer. The other two species are found chiefly along the south coast of this State, and include a species which somewhat resembles some of our native Epacris. This has been named *Leptospermum epacridioideum*, and the other *L. odoratum* on account of the fragrant oil contained in the leaves.

BOOKS RECEIVED.

Stereochemistry. By Prof. A. W. Stewart. Second edition. Pp. xvi+277. (London: Longmans and Co.) 12*s*. 6*d*. net.

Immunity in Health: The Function of the Tonsils and other Subepithelial Lymphatic Glands in the Bodily Economy. By Prof. K. H. Digby. Pp. viii+130. (London: Henry Frowde and Hodder and Stoughton.) 8*s*. 6*d*. net.

EDUCATION AND LIFE.

Education for the Needs of Life: A Text-book in the Principles of Education. By Dr. I. E. Miller. (Home and School Series.) Pp. vii+353. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1919.) Price 7s. net.

BOOKS on education may be roughly divided into two classes—those to be read and those to be avoided. There need be no hesitation in placing Dr. Miller's work in the former class. It is designed chiefly as a text-book, but may be studied with profit by those who have long passed student days. It is a fresh and attractive re-statement of the educational problem and its suggested solution. Education is conceived of as an integral phase of the life process; its task is to ascertain the child's vital needs and satisfactions, and to prepare him for their discharge or enjoyment, as the case may be. The starting-point is the biological adjustment to an environment. But adjustment is not mere passive moulding; it includes also dynamic response by the child. Nor does environment consist solely of the physical and material world; it embraces also mental, moral, social, æsthetic, and religious factors. The general treatment of the biological presuppositions occupies the first chapter, in the course of which it appears that the several elements involved are the aim of education, the child, the curriculum, methods, and the teacher. These, therefore, are the titles of the other five chapters.

Dr. Miller is a trained and sane psychologist, and his chapter on the child is an admirable epitome of our present knowledge of the stages of development up to adolescence, with hints for guidance in their treatment. Education must be functional; it must follow the child; it must wait upon development; it must catch the seasons of opportunity. The curriculum and the method must alike be organic to the pupil's capacities and requirements, and the teacher must by character and training be a person who can adapt himself to the varying situations which continually confront him. No mere structural or mechanical view satisfies the conditions of the problem, for any education deserving of the name must be subjective, not simply superposed. While the author would probably hesitate to subscribe to Rousseau's doctrine that the child should learn no lesson of which he does not see the present need, yet his theory seems to suggest that the appeal must always be through the consciousness of a felt want. He does, indeed, distinctly recognise the remote end—the needs of life; but as "two points determine a straight line," the present needs of the child and the destination in life are sufficient, he thinks, for the teacher's guidance and the pupil's well-being. But surely education is, like human progress in general, not a straight line. The analogy is rather that of zigzagging in a mountain ascent, or tacking on a voyage, where the goal is reached by humouring the gale, availing of the currents, and, above all, avoiding the shoals. Or, like the billiard player, the teacher may have to effect a cannon through a series of carefully calculated reactions along numerous lines, and with ultimate dual or multiple aim.

The volume bears evidence all through of the influence of Profs. Dewey, James, and other American writers, but Dr. Miller is by no means a slavish copyist. Among points of special merit are the treatment of imagination, the fundamental conception of the curriculum in its relation to life, and the plea for generous æsthetic culture based on psychological no less than on practical considerations. Dr. Miller writes out of the fullness of knowledge, first-hand acquaintance with the problems he discusses, and a belief in the efficacy of education which is an indispensable qualification of all workers in the field. But one would welcome a modification of expressions like "to gushingly remark" (p. 29), "to continually reconstruct" (p. 242), "run way beyond" (p. 292), and the like.

MATHEMATICAL TEXT-BOOKS.

(1) *Introductory Mathematical Analysis.* By Dr. W. Paul Webber and Prof. Louis Clark Plant. Pp. xiii+304. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1919.) Price 9s. 6d. net.

(2) *Descriptive Geometry.* By H. W. Miller. Revised in 1917 by the Department of General Engineering Drawing. Fourth edition. Pp. v+176. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1918.) Price 7s. net.

(3) *Premiers Eléments d'une Théorie du Quadrilatère Complet.* By A. Oppermann. Pp. 76+1 plate. (Paris: Gauthier-Villars et Cie, 1919.) Price 4 fr.

(1) THIS book contains the elements of algebra, trigonometry, analytical geometry, and infinitesimal calculus; it is apparently intended for first-year students at a university. The reviewer does not feel able to recommend the book; the reason for his opinions will be gathered from the following notes, which may be of use to the authors in the event of their having to prepare another edition:—

P. 122. It is tacitly assumed that complex numbers obey the ordinary laws of algebra; the assumption is pointed out in a footnote on p. 240.

P. 199. The proofs of the formulæ for the derivates of irrational and imaginary powers appear to assume what they profess to prove. Incidentally, imaginary powers do not seem to be defined anywhere in the book.

P. 236. The exponential series is defined as the limit of $(1+x/n)^n$, and is denoted by e^x; on p. 237 it is taken for granted that e^x, so defined, obeys the laws of indices.

P. 241. The proof of Euler's exponential expressions for the sine and cosine is new to the reviewer, but he fails to see why the variable must be expressed in radians rather than in any other unit of angular measure. The fact that the authors tell us on three occasions (pp. 108, 147, 243) that angles must be given in radians scarcely seems an adequate reason.

We are told twice (pp. 22 and 29) that feet and inches are denoted by the symbols $'$ and $''$, but it is apparently considered superfluous to define a degree (until p. 106, though degrees are used on p. 41) or to give the details of sexagesimal measure, and the student is referred to the tables for the values of the trigonometrical functions of $30°$, $45°$, and $60°$.

P. 63. A definition of "variable" is given, but no definition of "constant."

P. 91, ex. 10. To solve $\sin(x-25°)=0{\cdot}6$ by using the addition theorem is a method which seems unnecessarily cumbrous.

P. 91, ex. 11. The equation $\operatorname{arc}\tan x = \operatorname{arc}\sec x - 45°$ seems to lead to a cubic equation. Methods for solving cubics are not given until p. 144.

P. 182. The student should not be asked to prove that, in the hyperbola, $F'P-FP=2a$, without being told that the equation is true for one branch only.

P. 269. In a book which does not define even hyperbolic functions, it is going rather far to ask the student to find the length of $y=\sin x$ from $x=0$ to $x=\pi$.

Chap. xvii. The notations $\int f(x)$ and $\int f(x)dx$ seem to be used indifferently. The object of the former notation is not apparent. The notation "cot" used hitherto is here replaced by "ctn" without explanation.

Misprints and other minor errors have been noted at p. 35, ex. 17; p. 50, ex. 17; p. 69, l. 9; p. 106, l. 7 up; p. 116, ex. 9; p. 120, l. 2 up; p. 123, l. 2 up; p. 136, l. 21; p. 173, ex. 12; p. 180, ex. 6; p. 232, ll. 3, 4; p. 243, ll. 5, 7, and 8; p. 253, ex. 22; p. 263, l. 1; p. 271, ex. 2; p. 274, exs. 14, 21; p. 275, ex. 25; and p. 277, ex. 15.

(2) This work, which was first published in 1911, has now been revised by the author, with the assistance of six of his colleagues. It forms an admirable introduction to the subject for the student, and deserves very high commendation. The mode of presentation has been carefully thought out, with the result that the style is clear and lucid, and any student of ordinary intelligence should be able to get from the book a sound knowledge of the subject without the aid of a teacher.

The first chapter contains a synopsis of the notations used in the book; then follow four chapters on the representations of points and lines by elevation and plan, and of planes by their traces; next there are four chapters on curved surfaces—mainly cones, cylinders, and spheres—a useful chapter on shadows, and a brief account of perspective. These chapters contain numerous practical problems, each worked out in full with enunciation, discussion, analysis, and construction. The book concludes with a collection of eight long papers of problems and a good index. The diagrams are clear and well-proportioned, though a few of them would have been improved by being made rather larger.

The reviewer would like to make a few minor suggestions for the improvement of future editions. In the first place, the student may be a little puzzled at finding that the "profile-plane" plays a subordinate part compared with the other two co-ordinate planes (*e.g.* it is not mentioned in § 19 on the "alphabet" of a point), and the explanation of this would be useful. Also, the terms "profile ground-line" (§ 13) for a line which is not horizontal, and "vertical of a plane" (§ 42) for a line which is not vertical, seem somewhat misleading.

Two omissions must be mentioned. The first is that no use is made of the method of changing the co-ordinate planes—a method which gives an elegant solution of such a problem as finding the true length of a line, by taking a new vertical plane parallel to the plan of the line. The second omission is of rather more importance to the student; he would find the subject much more interesting and concrete if some work (possibly in the form of examples) on solids with plane faces were included. The reviewer well remembers how fascinated he used to be by drawing cubes and pyramids in fantastic positions, particularly if a section of the solid had also to be drawn.

The book would have been enhanced in value to the student of crystallography if some account of isometric projection had been given, and the reviewer would have been glad to see some developments of the theory of perspective—*e.g.* the theorem that plane figures in perspective remain in perspective when rotated about their axis of collineation; but possibly the author considers that such additions would have unduly increased the size of the book.

(3) In this, an interesting and suggestive work, the author (an engineer) discusses the theory of the quadrilateral after the manner in which various modern geometers have discussed the triangle. The treatment is quite elementary, and the object of the author is not to give a complete discussion of the subject, but to encourage and facilitate research. The book, "publié au moment où la France vient de reconquérir les provinces qui lui ont été arrachées en 1871," is dedicated to the memory of Joseph Pruvost, professor of mathematics at Strasbourg until the annexation; it contains a useful bibliography—a feature hitherto somewhat rare in mathematical works published in France.

MINERAL RESOURCES OF GEORGIA.

Mineral Resources of Georgia and Caucasia: Manganese Industry of Georgia. By D. Ghambashidze. Pp. 182. (London: George Allen and Unwin, Ltd.; New York: The Macmillan Co., 1919.) Price 8s. 6d. net.

THIS little book is interesting as being the outcome of the reorganisation of national boundaries after the war and as evidence of the political and economic independence of the new Republic of Georgia; this was an independent kingdom until it was forcibly annexed by Russia in 1801, and only recommenced its autonomous existence in 1917. The object of the work now published by Mr. Ghambashidze is to make British readers acquainted with the industrial importance of Georgia and Caucasia so far as the mineral wealth of this region is concerned. The author gives a long list of the various mineral substances of economic value known to occur therein, although relatively few have been worked on an industrial scale.

The oilfields of Caucasia have long been known, the principal field, that of Baku, having been for many years one of the world's great producers, with an annual (pre-war) output of about 7 million tons of petroleum. Next in importance comes that of Grozny, with a production of 1–1½ million tons, and there are also several smaller ones, the output from which is at present negligible; even the Maikop field, the first borings in which aroused so much excitement, has sunk to a quite unimportant factor in the general production. Of the other non-metallic minerals, bitumen is at present the most important, though the sulphur deposits in the province of Erivan, 30 miles from a railway line, may prove to be of value in the near future.

Of the metallic minerals, a few deposits of iron-ore are known, but none apparently of great importance. There are several known deposits of blende and galena, but only one, a mine at Sadon, is being worked at present; it is in the hands of a Russo-Belgian company, the Société Minière et Chimique Alagir. Copper is abundant and has been worked in many parts of Georgia and Caucasia. The best known of all is the Kedabek mine at Mis-Dag, which was an important producer up to about 1912, when the deposits began to show signs of exhaustion, so that the present output is barely 100 tons of copper per annum, whereas it was at one time up to 1750 tons. Altogether there were in 1914 some twenty-eight copper mines at work, fourteen of which had their own smelters; the total production of copper in 1914 was 8259 tons. The most important of the metalliferous minerals is manganese ore. In addition to a number of deposits in various parts of Georgia, which are not being worked at present, and are briefly referred to, the well-known deposits in the province of Kutais, which cover an area of 400 square miles and are estimated to contain 200 million tons of available ore, are described in some detail. The exports of this ore from Georgia had reached more than a million tons in 1913, but then fell off rapidly owing to the war. There appears to be no reason why this industry should not again recover its previous importance. The book contains a valuable amount of statistical information carefully tabulated, showing the mineral production of the districts treated of, and should be of use to all engaged in the mineral industry of the Near East.

H. L.

OUR BOOKSHELF.

A Simple and Rapid Method of Tide Prediction. (Including Diurnal Time and Height Inequalities.) By Sgt. M. E. J. Gheury. Pp. 53. (London: J. D. Potter, 1919.) Price 5s.

IN this little book the author explains the method which he developed for predicting the time and height of high and low water at Richborough, on the River Stour (Kent). From observations of these variables, extending over a fortnight only (in the first instance), it proved possible to deduce satisfactory predictions with but little trouble. The method has a rational basis, which is described in a preliminary account of the tide-producing forces and their variations. The work involved is partly graphical and partly tabular, but no harmonic analyses are required. The aim is to replace the unsatisfactory method by which a set of corrections is applied to the high- and low-water data for the nearest standard port, which at some stations may be as much as 200 miles away. In the present case the nearest standard port was only 20 miles away (Dover), but even in this instance Mr. Gheury's method, applied to deduce times of high water, gave better results than did the application of a correction to the elaborately derived Dover data. Richborough, being situated several miles up a narrow and sinuous tidal stream opening in a bay, presents some rather complex tidal features, including well-marked diurnal height and time inequalities; the success of the method, which can readily be applied to other similar or simpler stations, is therefore the more significant. The book is marred by some irritating misprints and grammatical errors, but the explanations are, on the whole, correct and lucid.

Fermat's Last Theorem: Three Proofs by Elementary Algebra. By M. Cashmore. Revised edition. Pp. 55. (London: G. Bell and Sons, Ltd., 1918.) Price 2s. 6d. net.

IT is unfortunate that F. P. Wolfkehl's legacy of a prize for settling the vexed question of "Fermat's Last Theorem" should have stimulated such a large erroneous mathematical literature. Most of the publications pretending to prove the theorem are deplorable for at least three reasons: first, because many of their authors have had insufficient mathematical training to enable them to decide whether a supposed proof is sound or not; secondly, because of the expense incurred by the authors in printing invalid proofs; and thirdly, because useless publications increase the burden of librarians and scholars. We are far from wishing to discourage genuine attempts to reproduce Fermat's line of thought. In view of the state of mathematical knowledge 250 years ago, Fermat's proof, assuming it to be correct—a point on which expert opinions differ—is as likely to be discovered by a clever schoolboy of seventeen as by a more highly trained mathematician.

Mr. Cashmore, in the tract before us, presents three distinct "proofs," all erroneous. In I. (p. 14) he states that when

$$ax^2+by^2=w^n, \text{ then } w=au^2+bv^2,$$

the letters denoting ordinary integers. A numerical example is enough to show that this is erroneous; thus

$$2^2+5\cdot1^2=3^2, \quad 11\cdot2^2+9^2=5^3;$$

but there are no integral solutions of

$$x^2+5y^2=3, \quad 11x^2+y^2=5.$$

The first of several fallacies in II. occurs on p. 26, and in III. (p. 43) Mr. Cashmore states that when $(p^n-q^n)y^{n-1}$ is divisible by pq, then y is divisible by pq, it being assumed that p and q are integers with no common factor It is seen that this deduction is erroneous by taking

$$p=9, q=4, y=6, n=3.$$

W. E. H. B.

Secrets of Animal Life. By Prof. J. Arthur Thomson. Pp. viii+324. (London: Andrew Melrose, Ltd., 1919.) Price 7s. 6d. net.

This is a collection of forty essays, contributed during recent years by Prof. Thomson to the *New Statesman*, and now collected in a handy and attractive volume. In his own clear and charming style the author seeks "to interest thoughtful readers in the multitudinous problems of animal life," and he wisely enforces the lesson that, in many cases, the solutions of these problems are "secrets" still. Such familiar subjects as the habits of rooks and cuckoos or the "Fall of the Year" are mixed with review-summaries of noteworthy recent zoological literature of general interest such as Watson and Lashley's observations on the "homing" of terns, Emery's researches on the habits of Amazon ants, or Petersen's surveys of the Zostera-beds off the coasts of Denmark. The problems of inheritance and evolution are prominent, as might be expected, and from such papers as "With Darwin Forwards" and "The Mendelian Clue," the "thoughtful reader" may gain a clear introductory view of the fields of biological inquiry, as well as guidance in the way of deeper study. Prof. Thomson never misleads those for whom he writes by implying that after reading him they have no more to learn; his treatment of "The Problem of Cave Blindness," for example, affords a needed corrective to widespread dogmatism on a subject that has appealed to popular imagination since the early days of evolutionary biology.

G. H. C.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.]*

International Relations in Science.

I do not agree with the proposals made by Prof. D'Arcy Thompson in Nature of October 23. I think that the less our academies and societies move in this matter the better. For my own part I objected altogether to the proposal made during the war to strike off our records the names of distinguished men of enemy nationality who had been elected "foreign members" before the war. They had not been admitted to any power or rights in consequence of that election, and it was, in my judgment, futile and petty to endeavour to obliterate the record of the honour which had been justly accorded to them.

As to making overtures to, and the reception of overtures from, the academies of those hostile nationalities with which peace is not yet ratified, it seems to me that our own societies and academies should at present neither offer nor accept any such overtures. They are mere formalities and demonstrations without any real significance or value, and must be, and are often designed to be, misleading. On the other hand, I think every individual should act according to his own feeling and judgment, and not according to mass sentiment, in regard to entering into friendly relations with German men of science. At present I personally could not accept such relations. I wish to reserve all action in the matter until my memory of many things has faded. But I will never wittingly treat even those whom I most dislike with less than justice tempered by generosity.

E. Ray Lankester.

The Response of Plants to Wireless Stimulation.

A growing plant bends towards light; this is true, not only of the main stem, but also of its branches and attached leaves and leaflets. This movement in response is described as the tropic effect of light. Growth itself is modified by the action of light: two different effects depending on the intensity are produced; strong stimulus of light causes a diminution of rate of growth, but very feeble stimulus induces an acceleration of growth. The tropic effect is very strong in the ultra-violet region of the spectrum with its extremely short wave-length of light; but the effect declines practically to zero as we move towards the less refrangible rays, the yellow and the red, with their comparatively long wave-length. As we proceed further in the infra-red region we come across the vast range of electric radiation, the wave-lengths of which vary from the shortest wave I have been able to produce (0·6 cm.) to others which may be miles in length. There thus arises the very interesting question whether plants perceive and respond to the long æther-waves, including those employed in signalling through space.

At first sight this would appear to be very unlikely, for the most effective rays are in the ultra-violet region with wave-length as short as 20×10^{-6} cm.; but with electric waves used in wireless signalling we have to deal with waves 50,000,000 times as long. The perceptive power of our retina is confined within the very narrow range of a single octave, the wave-lengths of which lie between 70×10^{-6} cm. and 35×10^{-6} cm. It is difficult to imagine that plants could perceive radiations so widely separated from each other as the visible light and the invisible electric waves.

But the subject assumes a different aspect when we take into consideration the total effect of radiation on the plant. Light induces two different effects which may broadly be distinguished as external and internal. The former is visible as movement; the latter finds no outward manifestation, but consists of an "up" or assimilatory chemical change with concomitant increase of potential energy. Of the two reactions, then, one is dynamic, attended by dissimilatory "down" change; the other is potential, associated with the opposite "up" change. In reality, the two effects take place simultaneously; but one of them becomes predominant under definite conditions.

The modifying condition is the *quality* of light. With reference to this I quote the following from Pfeffer:—"So far as is at present known, the action of different rays of the spectrum gives similar curves in regard to heliotropic and phototactic movements, to protoplasmic streaming and movements of the chloroplastids, as well as the photonastic movements produced by growth or by changes of turgor. On the other hand, it is the less refrangible rays which are most active in photosynthesis."[1] The dynamic and potential manifestations are thus seen to be complementary to each other, the rays which induce photosynthesis being relatively ineffective for tropic reaction, and *vice versa*.

Returning to the action of electric waves, since they exert no photosynthetic action they might conceivably induce the complementary tropic effect. These considerations led me to the investigation of the subject fourteen years ago, and my results showed that very short electric waves induce a retardation of rate of growth; they also produce responsive movements of the leaf of Mimosa when the plant is in a highly sensitive condition.[2] The energy of the short electric waves is very feeble, and undergoes great diminution at a distance; hence the necessity for employment of a specimen of plant in a highly sensitive condition.

I resumed my investigations on the subject at the beginning of this year. I wished to find out whether plants in general perceived and responded to long æther-waves reaching them from a distance. The perception of the wireless stimulation was to be tested, not merely by the responsive movement of sensitive plants, but also by diverse modes of response given by all kinds of plants.

The Wireless System.

For sending wireless signals I had to improvise the following arrangement, more powerful means not being available. The secondary terminals of a moderate-sized Ruhmkorff's coil were connected with two cylinders of brass, each 20 cm. in length; the sparking took place between two small spheres of steel attached to the cylinders. One of the two cylinders was earthed and the other connected with the aerial 10 metres in height. The receiving aerial was also 10 metres in height, and its lower terminal led to the laboratory, and connected by means of a thin wire with the experimental plant growing in a pot; this latter was put in electric connection with the earth (Fig. 1). The distance between the transmitting and receiving aerial was about 200 metres, the maximum length permitted by the grounds of the institute.

I may state here that with the arrangement described above I obtained very definite mechanical and electric response to wireless impulse. For the former I employed the plant Mimosa; the latter effect was detected in all plants, sensitive and ordinary. Limitation of space will allow only a detailed description of the responsive modification of growth.[3]

[1] Pfeffer, "Physiology of Plants," vol. ii., p. 104.
[2] Bose, "Plant Response," p. 618. (1905.)
[3] A detailed account of the response of plants to wireless stimulation will be found in the Transactions of the Bose Institute, vol. ii., to be published in November, 1919.

Effect of Wireless Stimulation on Growth.

For the detection of variation of growth it was necessary to devise the extremely sensitive balanced crescograph. In this apparatus a compensating movement is given to the plant-holder by which the plant subsides exactly at the same rate as its growth-elongation, so that the tip of the plant remains at the same point. This perfect balance is attained by a variable regulator. The compound magnifying

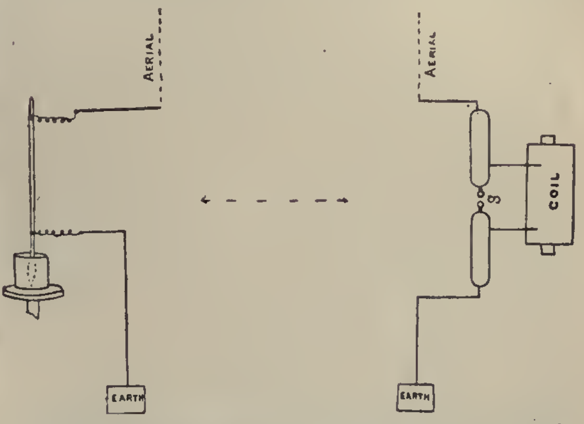

Fig. 1.—Diagrammatic representation of the method of wireless stimulation. On the right is seen the generating apparatus. The tip of the growing plant is connected with the receiving aerial, and the lower part or the flower-pot is earthed.

lever attached to the plant records the movement of growth. Under exact balance the record is horizontal. Any induced acceleration of growth would upset the balance, with a resulting down record; induced retardation, on the other hand, would cause an upset in the opposite direction and an up curve. The results given below show that growing plants not only perceive, but also respond to the stimulus of electric waves. These effects were found in all

Fig. 2.—Automatic records obtained with the balanced crescograph showing the effects of wireless stimulation on growth. (*a*) Feeble stimulus inducing acceleration; (*b*) strong stimulus inducing retardation of rate of growth; (*c*) series of growth responses by variation of growth due to uniform moderate stimulation. Up-curve represents retardation of growth and down-curve acceleration (seedling of wheat).

growing plants. The following records were obtained with the seedlings of wheat.

Effect of Feeble Stimulus.—Experiment 1: I first studied the effect of feeble stimulus. This was secured by decreasing the energy of sparks of the radiator. The response was an acceleration of rate of growth as seen in Fig. 2, (*a*). This is analogous to the accelerating effect of light stimulation of subminimal intensity.

Effect of Strong Stimulus.—Experiment 2: The maximum energy radiated by my transmitter, as stated before, was only moderate. In spite of this, its effect on plants was exhibited in a very striking manner. The balance was immediately upset, indicating a retardation of the rate of growth. The latent period, *i.e.* the interval between the incident wave and the response, was only a few seconds (Fig. 2, (*b*)). The record given in the figure was obtained with the moderate magnification of 2000 times only; but with my crescograph the magnification can easily be raised ten million times, and the perception of plant to the space-signalling can be exalted in the same proportion.

Under an intensity of stimulus slightly above the subminimal, the response exhibits retardation of growth followed by quick recovery, as seen in the series of records given in Fig. 2, (*c*). The perceptive range of the plant is inconceivably greater than ours; it not only perceives, but also responds to the different rays of the vast æthereal spectrum. J. C. BOSE.

Calcutta, August 16.

A New British Enchytræid Worm.

IN a collection of worms brought from Lapworth by Mr. Hillman on August 11, I found one which is new to this country, and of great interest on account of its unusual character and relationships. In 1877 Vejdovsky described his *Pachydrilus sphagnetorum.* Eleven years later Michaelsen added to it a variety named *glandulosus.* In course of time the name Pachydrilus was changed to Marionina, and the two worms above-named were placed as distinct species under this genus, forming a section by themselves on account of their aberrance. They both had the girdle thrown forward, the spermathecæ were free in the cœlom, the septal glands were more numerous than in the type, and there were other peculiarities. In Michaelsen's "Oligochæta," published in 1900, they appear as *Marionina sphagnetorum*, Vejd., and *M. glandulosa*, Mich.

In 1913 I described a new British Enchytræid (*Chamaedrilus chlorophilus*, Friend), which could not be fitted into any then known genus. Its relationships were discussed and its affinities with the two aberrant Marioninas pointed out. On finding *M. glandulosa,* I was for a time in doubt about its true name, as it so closely resembled Chamædrilus. Careful study, however, shows that the three worms are very nearly related, and must be referred to one and the same genus. In Marionina the blood is slightly coloured, in Chamædrilus it is quite colourless. In the former the spermathecæ are free, whereas in Chamædrilus they are attached to the intestine. In all other respects they agree. The forward position of the girdle, the shape and number of the setæ, absence of salivary glands, form of spermathecæ, size of cœlomic corpuscles and chloragogen cells, enlarged number of septal glands, incised brain, and other important characters, all point to one genus.

They are exceedingly slender worms, and Vejdovsky has pointed out a peculiarity in *M. sphagnetorum* which is of special interest. Like certain waterworms, it can multiply by subdivision. We have here, very clearly, a genus which links the Enchytræids with some of the other families of worms. Details cannot be discussed now, but it is evident that we shall for the present have to regard the genus Chamædrilus as consisting in this country of three species, viz. *Chamaedrilus sphagnetorum,* Vejd., *C. glandulosus*, Mich., and *C. chlorophilus*, Friend. The generic characters are roughly as follows:—

CHAMÆDRILUS.—Girdle advanced to segment 10, 9, or 8; nephridia begin in 8/9 or 9/10; spermathecæ with posterior outgrowth, either free or attached to the intestine; cœlomic corpuscles and chloragogen cells large; blood colourless or but slightly tinged with yellow or red; the dorsal vessel originating behind the girdle and possessing no anterior commissures (apparently). Salivary gland absent, brain deeply incised. Related to Stercutus and Bryodrilus.

HILDERIC FRIEND.

"Cathay," Solihull, September 24.

A Photoelectric Theory of Colour Vision.

IN view of the recent letters from Prof. Joly and Sir Oliver Lodge under the above heading, I may be allowed to point out that such a theory of colour vision was advanced by me in a lecture delivered before the Röntgen Society on January 7 last, and published in the Journal of the society for April. After referring to Prof. Joly's views as to the nature of the change taking place in the formation of the latent image and in radio-therapy, I said: "In my opinion, it is unnecessary to assume that a photochemical change is the cause of the visual sensation. It appears to me sufficient to suppose that photoelectric action takes place in the rods or cones, so that we have a separation of electrons resulting in electrification of the nerve-cells which set up the nervous impulse to the sensorium." A number of familiar facts were adduced in support of this view, and it was mentioned that the peaked curve which shows the relation between the sensitiveness of the eye for light of different wavelengths bears a very close resemblance to the curve which shows the variation of photoelectric activity with wave-length. H. STANLEY ALLEN.

Luminous Worms.

AROUND Nottingham forty-five years ago it was a common practice among anglers to search the meadows by aid of a lantern for "dew-worms and cockspurs," as they were locally known. After collection they were placed in damp moss in a dark shed for a few days until they were "scoured"; this brought them into condition, and rendered them more attractive as bait and fresher and redder in colour. After this treatment worms were phosphorescent for about one-fourth of the entire length of the body, while the light was most noticeable in the ventral region. H. E. ALDRIDGE.

40 Great Queen Street, Dartford.

RECONSTRUCTION.

IT has been a reproach, not without foundation, frequently cast at the British Empire that there has been hitherto a lack of reasonable and sufficient organisation. The circumstances arising out of a state of war have led necessarily to the institution of a number of new Departments which have been called into existence hastily and without adequate consideration. Some of these will, of course, disappear, and others will remain to be reconstituted. In view of these facts the Government did wisely in July, 1917, in appointing a Committee with the purpose of considering the changes which would become necessary after the war, and the report of one of its Sub-Committees, that on the Machinery of Government, under the chairmanship of Lord Haldane, is now before us. This Sub-Committee was appointed "to inquire into the responsibilities of various Departments of the Central Executive Government and to advise in what manner the exercise and distribution by the Government of its functions should be improved." It is obvious that here is a field of inquiry which is necessarily very extensive and very complicated, and the report fills eighty octavo pages. We have already (April 3) dealt with some aspects of the report, but the subject is so important that no excuse is necessary for considering others now. One of the most striking declarations by the Sub-Committee is to be found very early in the report in reference to the formulation of policy, for the conclusion is reached that "the duty of investigation and thought, as preliminary to action, might with great advantage be more definitely recognised." In elaborating its remarks on the importance of distinguishing the business of inquiry and research from that of administration, it refers especially to the desirability of giving special attention to the methods of recruiting the *personnel* to be employed in the Departments charged with the duty of inquiry, research, and reflection before policy is defined and put into operation.

This is one of the questions concerning which there is room for criticism of the methods generally pursued in the past. Attention has been repeatedly directed to the neglect of physical and natural science in the qualifications demanded of every member of the higher branches of the Civil Service in this country. The effect of this neglect has been that it frequently happens that when a new Department is to be called into existence the men appointed to take charge of the work are deficient in knowledge of the facts, principles, and methods which should be employed in carrying out their duties, inasmuch as it is still the custom generally to select for these appointments Civil Servants whose good general characters as active and intelligent men are their only qualification. In a few cases, far too infrequent, appointments of this kind have been offered to men outside the Civil Service with special qualifications for the work contemplated. Such a post as that of the Government Chemist has necessarily been filled by an eminent outsider, and the Board of Agriculture has in several cases selected for posts in that Department men who have an established reputation in connection with problems relating to agricultural practice.

The remarks of the Sub-Committee on the necessity for collaboration among Departments so that all information collected by any one Department may be accessible to all the rest whenever it is required without waste of energy or time in re-collection are very appropriate, and it may be hoped will be acted upon.

To the readers of Nature probably the contents of chap. iv. of the report, concerning research and information, will be found most interesting, and among the subjects dealt with in some detail is the work of the Medical Research Committee and of the Department of Scientific and Industrial Research. Both of these cover a wide field. The work of the former may be roughly divided into the study of questions connected with the National Health Insurance Acts on one hand, and general medical research on the other. Here, as in other directions, applications of science are subject to constant modification arising out of the discovery of new facts or principles. By way of illustration reference may be made to researches on food which are now being carried on. The discoveries which in very recent times have been made as to the existence in certain foodstuffs of the remarkable substances known as *vitamines* and their non-existence in others must lead to a modification of our views concerning the whole question of dietary and health. The exact nature of the vitamines is at present unknown, whether they consist of definite chemical, but hitherto unrecognised, substances, or whether they consist of mixtures of products of degradation of proteins. All that can be said is that the amount present in any case is minute. It is therefore not sufficient to determine roughly the composition of a given foodstuff and the proportion of fat, starch, or protein it may contain. Another line of work arises from the study of the question of the preservation of food by cold storage. It is now well known that the temperatures requisite in one case are not suitable in others; thus the cold required for meat and fish is not required for fruit, and even different kinds of fruit, such as plums and pears, cannot be shipped safely in the same chamber where slight differences of temperature may be found between the centre of the room and the walls.

The Department of Scientific and Industrial Research, the third annual report of which was noticed in Nature of October 17, 1918, comes in for a good deal of discussion in the report before us. It will be remembered that this is a Department for which the Lord President of the Council (then Lord Crewe) was responsible, and was created with funds at its disposal for instituting (1) specific researches, (2) scientific research in connection with industry, and (3) the award of studentships or fellowships to assist in research. The sum of 1,000,000*l.* was granted for use in applying over an agreed period a special stimulus to industry. This fund is applied in making grants to approved trade associations for research to supplement the resources of the associations. Some difficulties have occurred in determining to whom the results of research undertaken by the respective associations belong, and it seems doubtful whether procedure through the agency of trade associations is likely in the long run to prove the best avenue to progress in the way of applying discovery to industry. At any rate, the claims of the individual researcher will have to be considered and provided for in each case.

Funds are also provided by an annual vote for the general purposes of the Department, and from this source assistance is given to other bodies and other questions which may have only an indirect relation to particular industries or trades. The Fuel Research Board affords an example of the kind of work which may be undertaken with the aid of Government funds, and is now in active operation in connection with the South Metropolitan Gasworks. The inquiry is too costly and altogether beyond the means of such agencies as a British Association Committee or the private persons by whom the research was initiated.

But with regard to special scientific studies undertaken by individuals help is still urgently wanted, and the question arises whether such help can always be obtained from the Department so long as one of the conditions of a grant is that details of the research contemplated must be communicated to so large a number of persons as form an advisory council or board. Aids to research must be given in other ways. There seems to be some difference of opinion whether this would be best accomplished by increasing substantially the present grant of 4000*l.* per annum to the Royal Society, or by augmenting the annual grant to universities and other teaching institutions where teachers and students may co-operate in the work. The scientific worker is often shy of exposing his ideas in their early crude form to external criticism, and tentative preliminary inquiry should be provided for before the researcher is called on to expose the whole of his plan.

The whole scheme foreshadowed in this report shows and acknowledges in more than one passage the need for men. It has often been claimed for the Oxford classical system of education that it does select and equip with the necessary knowledge the young Englishmen whose destiny it is to become administrators. The Oxford of the future will doubtless furnish at least some of them with science and scientific ideas. But in the meantime there exists throughout the universities of the country a body of some hundreds of able men of science in the form of professors and lecturers to which recourse might, one would suppose, be had when occasion arises.

The report discusses at some length the momentous question as to the employment of women in the Civil Service. All the world has now profited by the experience derived from the war, and much prejudice on this subject has been cleared away. But while many women have distinguished themselves by patriotic fervour, physical energy, and administrative ability, the education of women has in general been more defective than that of men, and it will be necessary to wait for another generation before the question can be determined on satisfactory grounds whether sex will not always stand in the way of substituting women for men in many of the professions and callings necessary to the world.

Since the issue of the report—viz. on February 12, 1919—a lecture has been given to the Royal Society of Arts by Sir Frank Heath, Chief Secretary of the Department of Scientific and Industrial Research, on the work of that Department. The lecture is lucid and interesting, and shows that some definite results have already been attained. Lord Crewe, who was in the chair, remarked that this was "the only country in which a Government Department of Research existed." Such a statement can be accepted only with some reservations. Research stations in connection with agriculture have been instituted and supported by the State in many European countries during the last half century, and the United States Department of Agriculture at Washington maintains a scientific staff and issues a very valuable illustrated annual report. Moreover, the assistance given to the universities from national funds has always been in European countries far more liberal than has ever been the case in the United Kingdom, even at the present day, when the Government grants have been so considerably augmented.

THE FAUNA OF THE INLÉ LAKE.[1]

THE Inlé Lake, lying at a height of 3000 ft. in the great limestone zone of the Shan plateau, is of peculiar bionomical interest, since, although it belongs to the Salween river-basin, it has become sequestered, or at least obstructed in its biological commerce, by the behaviour both of its principal feeders and of its only effluent, which in considerable parts of their course flow deep underground. Another point of interest in a biological view is that it appears to be a relic of a former lake, or system of lakes, of great depth and extent. Two other remarkable features of the Inlé Lake are the extraordinary limpidity of its waters, through which its animal population can be watched as in an aquarium, and its girdle of floating marshland. This curious terraqueous fringe is capable of exuberant cultivation: the local genius cuts from it an island plot, tows it off where he lists, there turns it upside down and anchors it with stakes, then dredges and adds more clotted vegetable ooze to its surface, until it becomes solid enough for tillage, and perhaps firm enough to carry a sty for his pig, or a hut for himself. Such an islander, as he turns from spearing and trapping fish to tend with incessant care the homely market-garden trade, or strictly meditate the vocal pig, might well avouch the philosophy of Thales.

In this fine report, which includes twenty-eight first-class plates, and more than 200 large pages close packed with information both descriptive and ratiocinative, the fauna of the lake (exclusive of the plankton) is fully disclosed. Dr. Annandale, the editor, contributes an introduction mainly physiographical, a summary comprehensively biological, compendious treatises on the fishes and the aquatic mollusca, and minor papers on the sponges, hydrozoa, polyzoa, and amphibia. Among other contributions may be mentioned that by Mr. S. W. Kemp on the Decapod Crustacea, that by Mr. C. A. Paiva on the Aquatic Hymenoptera, and those by Mr. Baini Prashad on the Marsupium and Glochidium of

[1] Records of the Indian Museum, vol. xiv. (Calcutta, 1918).

Physunio, and on the anatomy of a Chironomid larva of the genus Polypedilum.

The most peculiar elements of the fauna are the fishes and mollusca. Of fishes there have been found thirty-one species, representing seventeen genera and seven families; among the many new forms is an extraordinary eel-like creature which Dr. Annandale regards as a type of a distinct family of Apodes. Common features of the fishes are a large eye and small development of tactile appendages—features thought perhaps to be directly correlated with the remarkable transparency of the water. Of aquatic mollusca thirty-seven species are mentioned—a large proportion being new—representing twelve genera and eight families; they are said to display extraordinary variability, and their evolutional plasticity is discussed with much learning and an equal wealth of illustration.

Altogether, this investigation of the fauna of the Inlé Lake is a refined piece of work, reflecting high credit on the new zoological survey of India and its versatile director. Moreover, although the report shows an intelligent appreciation of the economic perspective, as is seen in the full and critical description of the fisheries of the lake and all their apparatus, it is free from any taint of that meretricious stuff which so commonly in ponderous administrative circles of the British Empire lives and spreads aloft under the pseudonym of science.

NOTES.

THE first number of NATURE appeared on November 4, 1869, so that the jubilee of the journal will be attained next week. In celebration of this event the issue of November 6 will be devoted to articles upon scientific progress and developments of the past fifty years, contributed by eminent workers in different fields. Through the active co-operation of these authorities it has been possible to secure a comprehensive collection of articles of great interest, which we believe will be accepted as a worthy epitome of outstanding advances in the half-century during which NATURE has been published.

A MEETING of the International Electrotechnical Commission was held in London on October 20 and the three following days, under the presidency of M. Maurice Leblanc. Representatives of twenty nations were present, and the reports of the various committees were considered. Signor Semenza stated that national agreement had been obtained in Italy on the subject of symbols, both in those used in textbooks and in those used in engineering drawings. He pointed out the many advantages that would ensue if international agreement could be obtained. The British list of symbols, which is finished and will shortly be published, is very similar to the Italian list, and complete agreement could be easily obtained. Nearly all the committees on nomenclature have published lists of definitions, etc., and the next step to take is to compare them all closely and then to issue a standard list. The committee on the rating of electrical machinery has been very busy, and has held many meetings. This subject, however, proves to be very difficult, as trade considerations have to be taken into account. The commission has definitely taken up the question of preparing a specification for aluminium on the same lines that it adopted for specifying pure copper. The copper specification was most useful, and has been adopted by every country in the world. A special committee was appointed to consider the question of screw-lamp caps and holders. This country is almost the only one which retains bayonet-holders for electric lamps, although many electrical engineers think that the screw-lamp caps are the best. Sir Richard Glazebrook presided at the banquet, and the Right Hon. A. J. Balfour made a thoughtful speech on standardisation which was much appreciated by all the engineers present. He pointed out that if it did not entirely prevent waste, it at least diminished it.

AT the annual statutory meeting of the Royal Society of Edinburgh, held on October 27, the following office-bearers and members of council were elected:—*President:* Prof. F. O. Bower. *Vice-Presidents:* Prof. G. A. Gibson, Dr. R. Kidston, Prof. D. Noël Paton, Prof. A. Robinson, Sir George A. Berry, and Prof. W. Peddie. *General Secretary:* Dr. C. G. Knott. *Secretaries to Ordinary Meetings:* Prof. E. T. Whittaker and Dr. J. H. Ashworth. *Treasurer:* Dr. J. Currie. *Curator of Library and Museum:* Dr. A. Crichton Mitchell. *Councillors:* Prof. P. T. Herring, Prof. T. J. Jehu, Dr. A. Lauder, the Hon. Lord Guthrie, Prof. R. A. Sampson, Prof. J. Lorrain Smith, Dr. W. A. Tait, Surg.-Gen. W. B. Bannerman, Mr. H. M. Cadell, Prof. A. R. Cushny, Sir J. A. Ewing, and Mr. G. J. Lidstone.

MR. BRUCE FREDERIC CUMMINGS, who died on October 22, will probably be known to a wider public as "W. N. P. Barbellion," author of "The Journal of a Disappointed Man," noticed by us on July 10 last, but his few scientific papers will ensure for him a no less enduring, if a more limited, reputation. Born at Barnstaple in August, 1889, in spite of meagre circumstances and increasing ill-health he taught himself zoology to such good purpose as to gain an assistantship in the entomological department of the British Museum, which he entered in January, 1912. He had previously contributed notes on local natural history to the *Zoologist*, and had been offered in the Marine Biological Laboratory at Plymouth a post which the illness of his father prevented him from taking up. In his "Journal" he affected scorn for the entomological work to which he was set, but his studies of lice soon gave rise to important papers published by the Zoological Society and in the *Annals of Natural History*. Another paper of much interest was on a scent-organ in the caddis-fly, *Sericostoma personatum*. Failing health caused him to resign his appointment in July, 1917. Mr. Cummings might never "have revolutionised systematic zoology," but he gave something more than the promise of distinguished work.

IN a Memorandum by the Chancellor of the Exchequer on the future Exchequer balance-sheet (Cd. 376) an attempt is made to arrive at very tentative revised estimates of the national revenue and expenditure in a "normal" year. The estimated normal yearly expenditure is 808,000,000*l.*, and includes the following items:—Education, 45,900,000*l.*; upkeep of museums and galleries, 600,000*l.*; and scientific investigation and research, 400,000*l.* The year 1919–20 will not be a normal year, but as regards the above items of expenditure the only difference in the estimate is that the education is down for 41,000,000*l.* instead of 45,900,000*l.*

DR. K. E. LAMAN, leader of the Congo mission of the Swedish Missionary Union, has lately returned to Stockholm with a large collection of ethnographical material drawn from the Bakongo, Bateke, and Bakuta people, as well as from five races of Ngunu.

This will be distributed between the ethnographic department of the Swedish Riksmuseum, the Ethnographic Museum of Gothenburg, and the Missionary Union's museum. Dr. Laman has made six visits to the Congo since 1890, and has paid particular attention to the language. His collection includes gramophone records of native songs.

THE Swedish Academy of Science has reported favourably on a request by Prof. J. G. Andersson (formerly Director of the Swedish Geological Survey) for a Government grant of 90,000 kronor towards scientific researches and collections in China, where Dr. Andersson is now Geological Adviser to the Chinese Government. It is hoped that the Swedish Riksmuseum will thus receive rich collections in palæontology, prehistory, and zoology, but, to comply with conditions laid down by Profs. Andersson and Wiman, the fossil vertebrates will go to Upsala.

ON October 21 the Manchester Chemical Club (president, Mr. R. H. Clayton) was incorporated with the Manchester Literary and Philosophical Society. A new chemical section of the society has been formed, and Sir William J. Pope, professor of chemistry in the University of Cambridge, delivered an address on "The Photography of Coloured Objects" to a large audience at the opening meeting on October 24.

A COURSE of twelve Swiney lectures on "Geology and Mineral Resources of the British Possessions in Africa" will be given in the lecture-theatre of the Imperial College of Science and Technology (Royal College of Science, Old Building), Exhibition Road, S.W.7, by Dr. J. D. Falconer, on Mondays, Wednesdays, and Fridays, at 5.30, beginning on Monday, November 10. There will be no charge for admission.

A JOINT meeting of the Royal Society and the Royal Astronomical Society will be held at the Royal Society on Thursday, November 6, at 4.30 p.m., for the discussion of observations made during the total solar eclipse of May 29 last. Sir Frank Dyson will open the discussion, and will be followed by Prof. Eddington and other members of the eclipse expedition.

THE Aristotelian Society will open its forty-first session on November 3. The president, Prof. James Ward, will deliver the inaugural address on the subject "In the Beginning . . ." The congress which the society arranges annually will be held next year at Oxford in September, and the French Philosophical Society will take part.

THE opening meeting of the new session of the Institution of Electrical Engineers will be held at the Institution of Civil Engineers, Great George Street, Westminster, S.W.1, on Thursday, November 13, at 6 p.m., when the president, Mr. Roger T. Smith, will deliver his inaugural address.

THE one hundred and first session of the Institution of Civil Engineers will be opened on Tuesday, November 4, at 5.30 p.m., when Sir John Purser Griffith, president, will deliver an address, and will present awards made by the council for papers dealt with during the past session.

SIR HENRY ALEXANDER MIERS, Vice-Chancellor of the University of Manchester, has been appointed by an Order of Council dated October 16 to be a member of the Advisory Council to the Committee of the Privy Council for Scientific and Industrial Research.

THE first meeting of the session of the Royal Geographical Society will be held at 8.30 p.m. on Monday, November 3, at the Æolian Hall, New Bond Street, when Major Kenneth Mason will read a paper on Central Kurdistan.

MESSRS. HODGSON AND CO., 115 Chancery Lane, W.C.2, are to sell by auction on Thursday, November 13, and Friday, November 14, the library of the late Sir William Crookes. A catalogue is obtainable from the auctioneers upon application.

AN interesting series of fragments of prehistoric pottery was found early in the year in Eastern Macedonia near Drama and the plain of Philippi. The chief importance of the discovery lies in the relation with both the north and the south which is seen in the types of pottery found. Pottery similar to the so-called Dimini ware of Thessaly, and not hitherto found in Macedonia, occurred in large quantities. Fragments of a white-on-black ware of a date later than the Dimini ware and common in Thessaly were also found. A few fragments of this latter ware were found in Macedonia in 1916 near Salonica. Some remarkable fragments showed a combination of the white-on-black painted technique with incised white-filled patterns, thus showing that the two types of technique were contemporaneous. The wares of a northern type consisted for the most part of simple pottery decorated with large spiral or semi-spiral designs. Similar wares are common in the Upper Maritsa Valley near Philippopolis and generally in the Danubian area, and are essentially northern in type. A number of clay figurines of men, women, and domestic animals were also found. The human figures are for the most part steatopygous. The importance of these discoveries for the prehistoric study of Macedonia cannot be overestimated. The series will be published in the forthcoming Annual of the British School at Athens.

THE October issue of *British Birds* contains an extremely interesting account of the nesting habits of the sparrowhawk. The author, Mr. J. H. Owen, gives a vivid description of the bathing habits of this bird and of its playful feints at capturing prey. At one time a hen he had under observation stooped at a rabbit two or three times, yet made no serious attempt to seize it; at another it trifled in the same way with a brood of partridges. But perhaps the most important of Mr. Owen's notes are those concerning the efforts of the bird to protect her eggs from the sun, which she did at the cost of great distress to herself. The nestlings suffered no less from this cause; at times, indeed, they were on the verge of collapse. Some very beautiful illustrations add greatly to the value of these notes.

THE first number of the *Radio Review*, a monthly magazine devoted to scientific radio-telegraphy and radio-telephony, has been published. It contains short instalments of papers by André Blondel and Dr. Eccles on the functions applicable to directive aerials and on the internal action of a triode valve. In Blondel's paper the definitions are not very explicit, and so it is not easy to follow his reasoning. Dr. Eccles's paper is simpler, but in order to follow it the reader must have a knowledge of Child's and Langmuir's papers in the *Physical Review*. In a brief introduction the editor, Prof. Howe, states the policy and aims of the review. The remaining part of this issue consists of abstracts and reviews of books. Apparently the aim of the journal is to do for radio-telegraphy what the *Philosophical Magazine* does for physics. The amount of matter in the first number strikes us as rather meagre.

THE Institution of Electrical Engineers has issued an amended edition of its Wiring Rules. These rules have been universally adopted in this country, and they are annually amended so as to keep them abreast of the latest practice. The amendments this year are almost of revolutionary importance. As we foreshadowed some months ago, the electricians have now abandoned measuring the size of wires in terms of the standard wire gauge (S.W.G.). They have dropped gauges altogether. Instead of speaking of a No. 20 wire, they speak of a 0·036 wire—that is, one having a diameter of 0·036 of an inch. Similarly, instead of writing 3/20 for a cable consisting of three strands of No. 20 wire, they write 3/0·036″. Formerly they had a choice of fifty-seven cables for use in electric wiring, but now there are only twenty-four sizes. Careful consideration has shown that this number is sufficient. Naturally this will be a great boon to the cable manufacturers. The British Engineering Standards Association (the B.E.S.A.) is to be congratulated on having initiated this important reform.

For more than forty years the Institution of Civil Engineers has printed in its Proceedings short abstracts of papers on engineering subjects which have appeared in periodicals and in the Transactions of scientific and technical societies. The institution now proposes to issue them separately in quarterly numbers, the first of which appears this month. Although its length is affected by the difficulty of obtaining periodicals from abroad, the first number gives ninety-nine abstracts, which cover seventy pages. Subject- and name-indexes are provided, and it is much to be desired that these should be made more useful by co-ordination in annual or two-yearly indexes. The abstracts are grouped under two heads:—Materials, Measurements, etc., and Engineering Practice. As the latter term is interpreted generously, there is some overlapping with abstracts issued by other bodies, and some system of interchange of abstracts will have to be evolved to prevent several abstracts of the same paper being written.

At University College, London, on October 21, a public lecture was given by Prof. J. A. Fleming entitled "Speaking Across the Atlantic by Wireless Telephony." Prof. Fleming opened by giving a general review of the physical facts leading up to ordinary telephony, and the application of Fourier's theorem to wave-forms, with their consequent resolution into harmonics, and the distortion produced in ordinary speech, due to the different velocities and damping of the various harmonics. Since the electromagnetic waves employed in wireless telegraphy have a velocity which is independent of the wave-length, and a falling-off of intensity with distance which is the same for all frequencies, there is no distortion of the sound in wireless telephony similar to that which occurs in long-distance telephony of the ordinary kind. Speech transmitted by wireless is particularly clear and distinct. The three typical modes of producing electromagnetic waves were explained and illustrated by lantern-slides—the high-frequency alternator, the Poulsen arc, and the three-electrode thermionic valve used as generator. Prof. Fleming explained the mode of action of the Fleming valve as a rectifier, and the development of the three-electrode valve from this. The Marconi Co. now uses seven such valves in cascade for amplifying in receiving the feeble trans-Atlantic speech, since the amplification increases geometrically with the number of valves used. By a series of trials the Marconi Co. has demonstrated the possibility of speech over 1800 miles across the Atlantic, and, moreover, the trials were carried out at an unfavourable time of day, 10 a.m. to 1 p.m. The audience was large and appreciative, one of the larger lecture-theatres of the college being required. A course of six lectures on "Thermionic Valves" is to follow on succeeding Wednesdays at 5 p.m.

Messrs. Chapman and Hall, Ltd., announce:—"Aeronautical Engines," Major A. G. Clark; "Theory and Practice of Aeroplane Design," S. T. G. Andrews and S. F. Benson; "Geometry for Architects and Builders," J. E. Paynter; "Mathematics for Engineers," W. N. Rose, vol. ii.; and "Metric System for Engineers," C. B. Clapham. *Mr. W. Heinemann* is to publish this autumn Sir Ernest Shackleton's new book. It will be entitled "South: The Story of Shackleton's Last Expedition, 1914–1917." *Messrs. G. Routledge and Sons, Ltd.*, promise "Bakery Machinery," A. W. Mathys; "The Utilisation of Natural Powers," E. L. Burne; "Engineering Instruments and Meters," E. A. Griffiths; "Direct-current Dynamos and Motors," Prof. W. B. Griffith; and "Manufacture and Installation of Electric Cables," C. J. Beaver (in the Industrial Supremacy Books Series). In their Efficiency Books they will publish "Bibliography of Industrial Efficiency and Factory Management," H. G. T. Cannons, and a new edition of "Lectures on Industrial Psychology," B. Muscio. *Messrs. H. Sotheran and Co.* will shortly issue an Illustrated Library edition of their "Bibliotheca Chemico-Mathematica." It will contain many full-page plates, reproductions of title-pages, textual passages from rare or historically important works, and an analytical subject-index.

The special catalogues of Messrs. H. Sotheran and Co. (140 Strand, W.C.2) are models of what catalogues of second-hand books should be, for they furnish in an interesting manner much out-of-the-way information respecting many of the volumes offered for sale, and are carefully classified. Messrs. Sotheran's latest catalogue (No. 773, 2*s*. 6*d*. net) deals with rare books on exact and applied science, and includes the library of the late Prof. Henrici and a portion of that of Prof. G. Govi, of the University of Naples. Its 3336 items are classified under the headings: General and Collected Works; Mathematics; Astronomy and Geodesy; Dialling and Horology; Physics; The Microscope and Microscopy; Meteorology and Physical Geography; Chemistry; Crystallography; Chemical Technology, including Photography; Mining and Metallurgy; Engineering; Seamanship, Airmanship, and Naval Architecture; and sets of Learned Societies' Publications and other scientific journals. The catalogue will be very useful for reference.

OUR ASTRONOMICAL COLUMN.

Large Meteors.—On October 21, at 8h. 35m. G.M.T., a meteor brighter than Jupiter was observed by Mrs. Wilson at Totteridge, by Mr. C. P. Adamson at Wimborne, and by Mr. H. G. Baker at Wangford. It was directed from a radiant near α Cephei, and moved slowly at an average height in the atmosphere. On October 22 at 7h. 42m. G.M.T. a bright meteor was seen from Bristol, Stowmarket, Wimborne, and Plumstead, S.E. It had a very long horizontal flight of about three hundred and thirty-five miles at a velocity of thirty-three miles per second, and passed from over a point twenty miles north-east of York to thirty miles south-west of St. Valery, France. Its height was about seventy-four miles, and its radiant at $156^\circ+39^\circ$. It is very suggestive that the radiant point of meteors from the comet of 1739, as computed by Prof. A. S. Herschel, was at $157^\circ+39^\circ$ for October 22; meteor speed = 39 miles per second. The comet passed about 7,500,000 miles outside the earth's orbit.

COMET 1919*b* (BRORSEN-METCALF).—Messrs. Braae and Fischer-Petersen have redetermined the orbit of this comet from observations on August 21 and September 7 and 27. They first assumed the period as seventy-two years, and found that on this assumption there were residuals of $+1{\cdot}61'$, $-1{\cdot}47'$ in longitude (great circle) and latitude in the middle observation. They then left the period to be determined by the observations, and obtained the following orbit (*Ast. Nach.*, No. 5015):—

$$T = 1919 \text{ Oct. } 17{\cdot}156 \text{ G.M.T.} \qquad \log q = 9{\cdot}68695$$
$$\left.\begin{array}{l}\omega = 129^\circ\ 53{\cdot}10' \\ \Omega = 310^\circ\ 28\ 56' \\ i = 18^\circ\ 53{\cdot}02'\end{array}\right\} 1919{\cdot}0 \qquad \begin{array}{l}\log e = 9{\cdot}98229 \\ \text{Period} = 42{\cdot}465 \text{ years}\end{array}$$

The residuals are now $-0{\cdot}21'$, $-0{\cdot}12'$, and, as it appears that a further reduction of the period would make them smaller, it is concluded that the comet has made two revolutions since 1847. The observations in that year were not very numerous, and the periods then deduced were liable to much uncertainty.

If the 36-year period is right, the comet belongs to the family of Uranus, not to that of Neptune as formerly supposed.

It is now more than ever desirable that the comet should be observed for as long a period as possible. The following ephemeris, for Greenwich midnight, has been corrected approximately for the change in the orbit:—

THE NEW LABORATORIES AT ROTHAMSTED.

ON Monday, October 20, the new laboratories at Rothamsted were opened by Sir Arthur Griffith-Boscawen, Parliamentary Secretary of the Board of Agriculture and Fisheries, in the unavoidable absence of the Right Hon. Lord Lee of Fareham, President of the Board of Agriculture, who had intended to be present himself. There was a distinguished gathering of men and women interested in the practice of agriculture and in the sciences underlying it, which included Sir Horace Plunkett, the Hon. Rupert and Lady Gwendolen Guinness, Sir David Prain, Sir Francis Watts, Mr. Otto Beit, Prof. V. H. Blackman, Dr. M. O. Forster, Prof. MacBride, Sir Robert and Lady Robertson, Mr. Arthur Sutton, Mr. M. R. Pryor, Dr. M. C. Rayner, Dr. T. A. Henry, Dr. J. A. Voelcker, and others.

The chair was taken by Prof. H. E. Armstrong, vice-chairman of the Lawes Agricultural Committee, who said that Rothamsted had long been known throughout the world as the chief centre of scientific inquiry into the problems of agricultural practice. It was now the Mecca of agricultural pilgrims. Its sphere had been further widened by the recent action of the Board of Agriculture in establishing there an institute for the study of plant pathology, where entomological and mycological investigations could be carried on. The demands of modern scientific workers were very considerable, but no pains had been spared to make the equipment and laboratories as efficient as possible. The total cost of these improvements had been 26,000*l.*; of this sum no less than 10,000*l.* was collected in public subscriptions from farmers and their friends. The Board of Agriculture gave generous assistance, and granted an equal sum—10,000*l.*—from its Development Fund. The remaining 6000*l.* had been given by private donors and obtained in other ways. Fortunately, the work was completed before the recent rise in prices, and at a conservative estimate could not be done now for less than 60,000*l*.

Sir Arthur Griffith-Boscawen said that for many years agriculture had been neglected by the State, but its national importance was discovered during the war, and he knew it was the intention of the Government, and of the Prime Minister in particular, that agriculture should not be neglected in the future as it had been in the past. It was possible that some of the methods proposed might lead to controversy, but he was sure that on one point there would be complete agreement, and that was the necessity of adequate provision for research in agricultural science. It was a fortunate, and perhaps significant, coincidence that the opening of the new Rothamsted laboratories was almost simultaneous with the Prime Minister's speech, which might announce an important agricultural policy. Sir Arthur expressed his faith in the system of demonstration farms, at which farmers could see new methods in operation. But behind and above all such farms must be the research stations, where facts and principles could be ascertained in a truly scientific manner and with truly scientific precision. The Board of Agriculture realised that reduced expenditure on agricultural research would be false economy; it was essential that agricultural production should be increased and that the best possible advice should be available for the farmer. The Board of Agriculture was conscious of the splendid work that was being done at Rothamsted, and he wished every success to that admirable institution.

The Hon. Rupert Guinness, in thanking Sir Arthur Griffith-Boscawen for having, at only an hour's notice, taken Lord Lee's place, emphasised the need for increased facilities for investigations in agricultural science as one of the surest means of progress, and expressed his satisfaction with the work done at Rothamsted.

Sir Horace Plunkett, in seconding the vote of thanks, referred to the simplicity of language in which the results of the Rothamsted inquiries were expressed, thereby making them intelligible to the ordinary farmer.

The door of the building was then opened by Sir Arthur Griffith-Boscawen, and the company proceeded to the inspection of the various laboratories and of the interesting series of exhibits which had been arranged by the staff.

THE BRITISH ASSOCIATION AT BOURNEMOUTH.

SECTION G.

ENGINEERING.

OPENING ADDRESS BY PROF. J. E. PETAVEL, D.Sc., F.R.S., PRESIDENT OF THE SECTION.

DURING the last five years every resource of the Empire, moral, intellectual, and material, has been concentrated on one great task, now successfully achieved; and the present period marks the end of a gigantic military struggle and the beginning of a new social era

I.—*Engineering and Science during the War.*

To summarise adequately the part played by engineering in the war would constitute a task far beyond the power of the writer or the scope of the present address. Now, as in the past, the fate of nations in war or peace is primarily determined by moral, intellectual, and physical attributes; but, under modern conditions, these forces can find efficient application only through the agency of science and engineering.

A large army depends for its subsistence and equipment on the combined effort of every branch of human activity; and every productive industry, when organised on a large scale, is in turn dependent upon the engineer.

Before the end of the war this country had become transformed into one vast factory, every department of which required the services of trained engineers. Every member of this section has contributed his own share to the task, and our programme includes papers giving detailed accounts of several branches of the work.

It is fitting, therefore, that I should restrict myself to a mere outline of some of the more outstanding facts.

The urgent necessity for an output of munitions vastly in excess of any previous production made centralisation and standardisation essential, and involved a complete revolution in workshop practice. The Ministry of Munitions was responsible for the formation of the required organisations and guided the transformation of industrial conditions, and, when the dilution of skilled labour became inevitable, the technical engineer designed the machinery and devised the methods which made efficient work possible.

Credit is due to the unions for the concessions made; greater credit to the women for their enthusiastic response to the call and the steady output they maintained.

Munitions.—The Ministry of Munitions was created in May, 1915, its early efforts being concentrated on the production of guns and shells. A year later the Ministry was in a position to meet the ever-increasing demands of the Army, and by 1918 a large reserve of munitions had been established, the expenditure being limited only by difficulties of transport at the Front. The maximum expenditure of ammunition was reached one day in October in that year, when 900,000 shells, weighing 40,000 tons, were fired. The total number of guns manufactured during the war was 20,000, and more than 200,000 machine-guns had been delivered by November, 1918.

The Ministry of Munitions took charge also of the production of aircraft, which were ultimately turned out at the rate of 4000 per month; later, the provision of motor transport was in addition placed under its control. Finally, our production of "poison gas," for which this Ministry was responsible, rose during the last few months of war to several thousand tons a month, sufficient to make the Germans rue the day on which they had introduced this weapon into warfare.

Among the inventions which have had an influence on military operations I will mention only three as typical of three distinct classes:—

Tanks were first used in 1916, and the results produced were greatly enhanced by the surprise created, and consequent moral effect, but the idea of an armoured chariot is as old as organised warfare. The problem of constructing a vehicle which could travel across the trackless and shell-pitted district which extended between the two armies remained to be solved. In the light of the experience gained with various types of tractors it was, however, clearly not insoluble, and credit is due to the man who had the courage to hazard a novel and important experiment. The resulting tank was the product of careful design and experiment, and the outcome of the co-operation of several engineers with special knowledge. Sound-ranging introduced the complex methods and delicate instruments of physical research into the trenches, and, against all precedents, proved them to be trustworthy and practical under the most adverse conditions. The Stokes gun, on the other hand, superseded all other trench-mortars by simplicity of design of manufacture and convenience in handling; 20,000 of these guns were used during the war.

Transport.—On August 4, 1914, the Government assumed control of the railway systems in this country, but the working and management were left in the hands of the railway officials, and to them is due the smooth working of the lines during a long period of exceptional difficulty. British engineers, civil or military, have been responsible for the transport through France, and during the last two years of the war large numbers of engines were sent across the Channel and miles of track were taken up in England and relaid in France. Road transport was organised on an unprecedented scale, and 100,000 new vehicles were delivered. A network of narrow-gauge railways was carried right up to the trenches, and numerous new roads, railway lines, and bridges constructed. Railway construction formed an important factor in connection with the advances in Mesopotamia and Palestine; in the latter case the entire water-supply had for a long period to be drawn from the Egyptian base through a specially laid pipe-line.

In France and elsewhere the armies were primarily dependent upon sea transport for their food and equipment. This service, organised by the Navy, culminated in the unique effort which brought American troops at the rate of 300,000 per month, and thus overbore the balance which for four years had been oscillating between defeat and victory.

Among the notable new departures the cross-Channel train ferry and the portable steel bridges, principally of the Inglis type, should be specially mentioned.

Navy.—At the outbreak of war the Navy was ill-prepared with regard to anti-submarine defence and mining. The influence of the submarine on naval warfare had been under-estimated, and mines were regarded as a somewhat discreditable means of destruction; but during 1915 the depth-charge and the paravane were developed by the Naval Experimental Department at Portsmouth, and later thousands of these were brought into use. In principle the depth-charge consists of a canister containing a large charge of explosive and a pistol actuated by a hydrostatic valve. The merit of the invention resides in the simplicity, safety, and trustworthiness of the mechanism. In designing the paravane the body was borrowed from a torpedo, and wings, rudder, and elevator from an aeroplane. The secret of the device lies in the stabilising mechanism, which enables it to keep its position when the ship is running at high speeds. The paravane enabled most ships to pass unscathed through a minefield, and in a slightly modified form it served to seek out and destroy submarines under the water.

Sound-location proved to be one of the most valuable inventions developed by the Board of Invention and Research. By its means the position of a submarine explosion off the coast of Belgium could be found within a few hundred yards by observers on the English coast; passing ships or submarines could also be identified and located. Sound-locators were also used on board anti-submarine craft, but at the time of the armistice were for this purpose being superseded by other methods.

Mine construction, laying, and sweeping formed the object of many successive improvements. Mines of special construction, which cannot be swept by ordinary means and explode without actual contact, were used in large numbers in 1918, and were particularly effective against submarines. Various new types of oscillating mines were also developed.

Many of the newer fighting units of the Navy were designed for speeds far in excess of anything that had been previously contemplated; the attainment of the required horse-power was rendered possible by improvements in boiler construction, by the development of oil-firing, and by the invention of the geared turbine. At the present time the horse-power of some of the fastest destroyers equals that of any pre-war Dreadnoughts.

Numbers of strange craft were designed for special purposes. The monitor was used as a floating fortress, and ships without funnels or masts formed cruising aerodromes. The torpedo-net was known to be ineffective as well as inconvenient, but some years elapsed before ships were rendered immune from torpedo attacks by a wide outer sheath of resilient construction. Some protection was first given to minesweepers by fitting the vessels with a false prow; the newer minesweepers were rendered nearly unsinkable by the provision of numerous bulkheads. The submarine was developed with regard to size, range, and speed. The latest, and perhaps the strangest, craft was the submarine fitted with a heavy calibre gun which could be fired when all but the muzzle was submerged.

Aircraft.—The rapid progress and expansion of aeronautical science and construction are perhaps the most remarkable achievements of engineering during the war.

In 1909 Blériot flew the Channel. In 1910 Cody won the British Michelin Cup by a flight of 185 miles. The Royal Flying Corps was formed in 1912, and it was decided that the equipment should consist of seventy-two aeroplanes and two airships. The number of aeroplanes available in 1914 was less than 200; the number ultimately required proved to be more than 3000 a month. The aeroplanes which were sent out with the Expeditionary Force in 1914 had a maximum speed of some 80 miles an hour, a rate of climb at ground-level of 300 ft. or 400 ft. a minute; they were equipped with engines of 60 h.p. to 100 h.p. In 1918 the fast machine had a maximum speed of 140 miles an hour, a rate of climb at ground-level of 2000 ft. a minute; single-seaters were fitted with engines of 200 h.p to 300 h.p., and the largest machines were equipped with a power plant developing more than 1300 h.p. The maximum height attainable had increased from 5000 ft. to 25,000 ft.

The Atlantic flight has given the measure of the success achieved in the design of long-range bombing machines. Two types were evolved: the fast day bomber, capable of carrying a useful load of about 3000 lb. at a speed of 130 miles an hour, and the night bomber with a larger load and slower speed. The largest aeroplane manufactured in numbers was the Handley Page V/1500, with a weight of 11 tons and a power plant of 1300 h.p. Three days before the armistice two of these machines stood fully equipped waiting for the order to start for Berlin. The largest bombs in use weighed more than a ton, and during the war 8000 tons of explosives were dropped on the enemy. The experience which they had gained in the construction of the high-powered engines required for airship work proved to be a valuable asset for the Germans. Initially also their rate of production, both of aeroplanes and engines, was far superior to ours, and, faced with the menace of otherwise being for a period deprived of machines, we were bound to continue the use of a certain standardised types longer than was desirable.

The labour difficulty was overcome by the introduction of a large proportion of female labour, which proved to be very suitable for aeroplane manufacture, and especially for wing construction. The bulk production of aero-engines presented grave difficulties. Every part had to be made to close limits so as to be interchangeable, and it was necessary to maintain the highest quality with the minimum amount of skilled labour. For a period the supply of magnetos was both inadequate and unsatisfactory. The Germans had acquired practically a monopoly in this direction, and it became essential for us to build up a new industry on the results of careful research and experiment. The fact that in these circumstances a total of 8,000,000 h.p. was produced during the last twelve months of the war represents one of the greatest achievements of engineering organisation.

Synchronised gun-firing through the propeller was first brought into use by the enemy, and the success of the Fokker was due, not to superior design, but to this characteristic armament and to the relatively high engine power. On the other hand, throughout the war the only stable machines were British. For observation work, night flying, and flight in fog and cloud the advantages of a stable machine are obvious. Instability, inasmuch as it favours rapid and unexpected manœuvres, was for a time regarded as an advantage in aerial fighting, but later experience proved that a well-designed aeroplane could be made stable and yet remain quick and light on the controls.

Seaworthiness, no less than airworthiness, is required of the seaplane, and this implies a machine of considerable size and weight. Most of the best seaplanes in use in 1918 had a total weight of four or five tons each, a speed of nearly 100 miles, and engines of about 700 h.p.

The machines used by the special aeroplane-ships were principally small fast scouts, but one type was of sufficient size to carry an 18-in. torpedo. In 1918 seventy aeroplanes were carried by the Fleet as part of the regular equipment.

Airships proved to be of great importance in connection with naval work. The smaller non-rigids were used for patrol duty along the coast and convoy service, and by their means a submarine could be detected and attacked while still at a considerable distance below the surface. The success achieved was extensive, and ships convoyed by airships were practically immune from submarine attack. The larger non-rigids served as scouts in naval operations.

The SSZ had a speed of 50 miles and a gross lift of about two tons; the North Sea type a lift of 11 tons and a speed of 60 miles.

Compared with the achievements in other directions the record of British work in connection with the development of rigid airships is not entirely satisfactory. In this field, where consistent policy and firmness of purpose were essential, the Admiralty vacillated strangely. The *May-fly*, constructed at Barrow in 1910, was admittedly an experiment, and although an accident ended her career after the first few mooring tests, she had already served her purpose in providing the experience and data necessary for a more perfect construction. Nothing further was done, however, until after the war had started.

In Germany, on the other hand, painstaking plodding had built up success on the ruins of a dozen failures.

Improvements in the rate of climb of aeroplanes and the invention of the incendiary bullet brought an end to the effectiveness of the Zeppelin as a bomber, but as a scout in long-range naval operations its influence remained considerable, and the recent successful journey of R 34 indicates the possibilities of the rigid airship in times of peace. The useful load increases rapidly with size, and a ship 15 per cent. larger than R 34 in linear dimensions could have carried 100 people to America.

What is popularly known as an invention, or an idea of revolutionary importance emanating from one person, has played relatively little part in the recent development of aeronautics. Success has been due to systematic investigation and the combined effort of many scientific workers, trained designers, and practical constructors. With some exceptions the same holds true in the case of engine construction. Inventions there have been (8000 are duly recorded in the files of the Air Inventions Committee), but equipment and armament and accessories appear to have offered most scope for brilliant new departures.

Several inventions notably influenced the course of the war. The successful manufacture of incendiary bullets put an end to the Zeppelin raids, tracer bullets increased the accuracy of aim, and synchronising gear made it possible to fire through the propeller at the rate of nearly 1000 rounds per minute. A satisfactory self-sealing petrol tank was manufactured after many unsuccessful attempts, and greatly diminished the risk of fire. Much ingenuity was displayed in connection with bomb-sighting and navigational instruments. Wireless telephone and directional wireless were introduced. A trustworthy turn-indicator and improved compass made accurate navigation through clouds possible. Armoured aeroplanes were constructed; special machines were also designed for carrying 37-mm. quick-firing guns for use at the Front and against submarines; these guns fired a 1½-lb. high-explosive shell.

The increased efficiency of the anti-aircraft artillery and the high rate of climb of the defending machines put a check on daylight aeroplane raids, while at night and in mist both searchlights and guns could be trained on the enemy, even if invisible, by means of sound-directors. A screen of kite-balloons supporting nets formed part of the night defences of London, and justified its existence by the moral effect produced on the enemy pilots.

The use of airships near the fighting zone or within reach of enemy aeroplanes was impossible owing to the inflammable nature of the gas they contained, and, in spite of all precautions, the loss in kite-balloons was serious. The proposal to replace the hydrogen by helium came from a member of the Board of Invention and Research, and in 1915 experiments were started with a view to the ultimate production of several million cubic feet per month. The boldness of the idea is best emphasised by the fact that at that time it took weeks to obtain the few cubic inches of gas required for the preliminary permeability tests. Progress was accelerated when America came into the war, and at the time of the armistice a supply of 350,000 cubic ft. per week was ensured.

The above outline of engineering activities during the war is both incomplete and imperfect. It may, however, serve to emphasise and illustrate the two features which characterised the period and made victory possible.

The first is: Large production, obtained by organisation, standardisation, and co-operation.

The second is: Rapid progress resulting from the stimulus to research and invention and the immediate application of the results obtained.

The required organisation did not arise as a natural development of the pre-war industrial activity: it was called into being by dire necessity and applied with grim determination. Before the war the British nation was anti-militarist, non-scientific, and strongly individualistic. To achieve victory the nation accepted universal conscription, and submitted to the mixture of Socialism and tyranny which necessity dictated. Under extreme pressure scientific knowledge, technical skill, industrial ability, military and naval experience welded into a homogeneous and efficient organisation.

It is easy to disparage the effort or to point to defects, large or small, which tarnish the record, but the fact remains that, whereas in 1914 we were inferior to the enemy in every military asset except moral courage, in 1918 victory came as the result of mastery in practically all the thousand factors on which modern warfare depends.

The organisation involved the direct control of food, every essential raw material, shipping, and transport; further, under the cloak of various euphemisms, it involved the indirect control of all available capital and labour. The capitalist was granted the privilege of receiving and paying the interest on the money required. High wages and the Military Conscription Act ensured an adequate supply of labour in the factories. And these things came to pass, not by the tyrannical order of an all-powerful Government, but by the force of a great idea working within the nation.

II.—*Industrial and Economic Reconstruction.*

The peace declaration is the opening of a new act in the world's greatest drama, and the events of the next few years will decide the fate of many generations. The future is always the logical sequence of the past; it is the present which gives direction to the forces which are acting in virtue of the ideals which are operative. The world is emerging from a furnace, and the rigid constitution of civilisation, for a moment plastic, will harden in the mould we form. It is, therefore, the duty of each one of us to attempt to understand the transformation which is going on, and influence it in the right direction.

The principal feature of the day is the insistent craving for better and easier conditions of life; in popular language, this is quite inaccurately expressed by a demand for higher wages and less work. The two aims are far from identical; in fact, a little consideration will show that in some respects they are contradictory.

The total remuneration received by a nation is measured by its production, and this law cannot be altered or affected by legislation or revolution. On the other hand, the share received by a class or an individual is capable of adjustment within certain limits. Thus any class may increase its remuneration either by increasing the total production or by decreasing the remuneration received by the other classes. The capitalist who corners wheat, and the miner who corners coal, are examples of the latter method. No such limitations exist, however, with regard to the face-value of the wages paid; by Act of Parliament all wages might be increased arbitrarily twentyfold, but as a result the cost of living would rise to a similar ratio.

Incalculable harm has been done by ignorance and wilful misrepresentation. During a generation the working classes have been told, and have firmly believed, that they receive but a tithe of the value of their work, and that the bulk goes to swell the fortune of the capitalistic class. The actual facts so far as engineering is concerned will be found in the address of my predecessor in this chair. On an average in pre-war days the share of the capitalist was one-ninth that of the workman. The actual position with regard to coal is now known to all. For each ton raised 19*s.* 5½*d.* goes for labour, and a total of 2*s.* is paid as royalties, owners' profits, and owners' compensation. It is obvious that the 13*s.* rise in the miner's wages cannot be paid out of profits and royalties amounting to a total of 2*s.*, but the miner, who has been brought up to believe in the fabulous profits of the wicked duke, is quite ready to strike against the owners, the Government, and the laws of arithmetic.

These facts, though clearly established, are not easily credited by the working man; he may have received a penny for what he considers is the manufacture of an article, and sees it selling for a shilling in a shop. He forgets that the price must include, not only his wage, but that of the men in the mine, the smelting works, and the rolling mill, who provided the material in the shape required, the wages of the men who built the factory in which he works and made the machine he uses, the wages of transport workers, packers, shop assistants, advertising agents, printer, papermakers, etc., and that, finally, some minute fraction of a farthing might with justice be allotted to the engineer who designed the machine or invented the process. The general position, though similar, cannot, unfortunately, be followed so closely; the limitations, however, are clear. The income of the United Kingdom per head of the population was before the war about 50*l.* If, therefore, the State were run on completely communistic lines, and if under these conditions there were no reduction either in the working hours or the output, our wages would average a sovereign a week each, and we could buy our goods at pre-war prices.[1]

The above considerations indicate that a real improvement in material welfare is necessarily associated with increased production. The needs of mankind are many, its desires are unlimited, and for this reason general over-production need never arise. Many circumstances may, however, lead to uneven balance, and, unfortunately, when this occurs, the producers of the commodity which is in excess are penalised, and those responsible for a deficiency are rewarded. The instability is fostered and increased by speculation, and, although it forms the most powerful check on national prosperity, no serious effort has yet been made to apply a remedy.

I am inclined to think that two of the most important problems of our time relate to economic balance and increased production. The solution in the former case is dependent on the statesman, the economist, and the business man, in the latter on the combined efforts of various branches of applied science, and more especially on engineering.

At one time production was directly dependent on muscular effort; it is now mainly influenced by equipment, organisation, and skill. Increased production does not necessarily imply harder work or longer hours; it can be secured by improvements in method and machinery, but only with the willing co-operation of all concerned.

Before the war the Americans were far ahead of us in stardardisation and specialised machinery. The American clock and the Ford car are two well-known examples. During the war we adopted and developed these methods. As a result, although the cost of all materials increased considerably, although the wages more than doubled and the profits were more than adequate, the cost was in many cases reduced. Thus the eighteen-pounder shell fell from 22*s.* to 12*s.*, the Lewis gun from 165*l.* to 62*l.* The importance of standardisation has been fully realised by the manufacturers of this country, and as a result we may hope to see a general reduction in cost.

The economic value of an individual depends exclusively on the nature, quality, and quantity of

[1] This statement is optimistic in so far as it does not take account of war losses.

his output, and his remuneration should correspond with his economic value. The rule is simple, its application would solve most of the problems which vex the present generation, but no scheme has yet been evolved to make its application possible.

There can be no doubt that in this respect our present system is a complete failure. It has been built up casually in the course of the industrial warfare of the last twenty years, and each side, regardless of consequences, has entrenched itself in any position won. The result is a system nearly perfect from the point of view of offence and defence, well arranged for mutual destruction, but, like the trenches in France, unsuitable for use in time of peace.

The minimum wage is beneficial in so far as it prevents sweating, but in two other respects its consequences are most unfortunate. Under the operation of this rule the man whose value is a fraction below the minimum is unemployed and economically unemployable. Further, the minimum wage becomes the standard wage, and the better men are inadequately paid. Both causes lead to decreased production. The weaker or less skilful men drift into enforced idleness, and become a charge to the community under the heading of charity, poor-law, or some newly invented euphemism The better men, finding extra effort uncompensated, drop to an ever-decreasing minimum. Small output is in most cases the result of inadequate incentive rather than active restriction. Promotion by seniority is an example of a similar cause, producing similar effects in other classes of the community.

Among the professional and business classes the remuneration is proportional to the skill and to the effort; a barrister, an engineer, or a merchant has neither minimum wage nor fixed maximum output, and, the vagaries of chance excepted, generally speaking gets what he is worth. At the two extremes stand riches and starvation, and the economic world can offer no stronger motive forces than the allurements of the one, the fear of the other. There is no absolute reason why the working man should not be offered the same incentives to hard work and progress, but up to the present most efforts have tended in the opposite direction. Any form of payment by result is viewed with indifference or distrust by the unions, and past experience with piece-work explains that attitude. There has been a disposition for employers to make large individual earnings an excuse for cutting rates. Errors in rate-fixing may easily arise, and in certain cases special investigation might be necessary, but the advantages of high individual production are so great to both employer and employed that in all cases of doubt the higher rate should be maintained. In this connection the method of time-study first developed by Taylor in America and the various systems of payment by results which have been successfully applied deserve careful consideration.

Another important but difficult subject is the distinction drawn between skilled and unskilled labour. The experience gained during the war has proved that many operations scheduled as skilled work could be effectively performed by women who had received only a few weeks' special instruction. The oft-repeated demand for equal opportunity for all becomes a senseless parrot cry if it does not imply that an individual has the right to undertake better-remunerated work if qualified to do so. It is a misconception which leads the skilled worker to believe that such a concession would reduce his earnings. Just as it is clear that if labourers and skilled men were grouped together at a uniform wage, that wage would necessarily be lower than the present minimum for skilled work, so also the separation of tasks which require but a nominal period of training would increase the rate of remuneration available for the really skilled man.

I have directed attention to some of the difficulties which must be solved if the country is to emerge from the present crisis prosperous or even solvent. There is little doubt that an elucidation is possible, but it can only be evolved by the honest and intelligent collaboration of all parties concerned, a task rendered difficult or impossible by mutual distrust and class hatred. Class differences there are, and always will be; they exist as the result of breeding, education, and environment, but they do not extend to the fundamental characteristics of humanity. Many dukes and many miners are lazy; most capitalists and most trade unionists are greedy; all men, with a few exceptions, are selfish. The war has shown that lazy, greedy, and selfish men will die, or even work, for their country in a great exigency, but there is a limit to, and a reaction after, any profound emotional stimulus, and the present unrest and dissatisfaction are but normal symptoms. A satisfactory economic system can be based only on natural human impulses, and of these the most fundamental is self-preservation, or, more generally, self-interest. Increased production is at the present moment the most pressing national need, but it will become effective only when for every man increased production becomes the talisman by which *his* paper-wages can be turned to gold.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

London.—A massive bronze medal has been received from the University of Paris in commemoration of the manifold services rendered during the war by the universities of the Allied nations and "in token of a friendship henceforth indestructible." It bears in relief on the obverse the figure of "Scientia Instrumentum Justitiæ—Libro—Ense—MCMXIV–MCMXVIII," and on the reverse the old courtyard of the Sorbonne, with the inscription "Fidelissimæ Sorori Universitas Parisiensis dicavit."

The thanks of the Senate have been accorded to the Worshipful Company of Drapers for renewing for a further period of two years their pre-war grant of 500*l.* a year to the biometric laboratory of the Department of Applied Statistics and Eugenics at University College; and to the London County Council for a grant of 6000*l.* for the erection of temporary buildings for the Department of Engineering at King's College.

The following doctorates have been conferred:—*D.Sc. in Chemistry:* Mr. E. K. Rideal, an internal student of University College, for a thesis entitled "The Synthesis and Thermocatalytic Combustion of Ammonia." *D.Sc. in Botany:* Mr. H. Wormald, an external student, for a thesis entitled "Researches into the Biology, Morphology, and Mode of Parasitism of the Species of Monilia Occurring on Fruit Trees," and other papers.

A course of advanced lectures on (*a*) "The Energy Balance of the Human Body," (*b*) "Electrical Signs of Emotive Phenomena," is being given by Prof. A. D. Waller, professor of physiology in the University, at 5 p.m. on Wednesdays, November 5, 12, 19, and 26, and December 3, in the physiological laboratory of the University, South Kensington, S.W.7. The lectures are addressed to advanced students of the University and to others interested in the subject. Admission is free, without ticket.

OXFORD.—The entry of freshmen at the beginning of the present term is probably the largest on record. Nearly all the colleges have admitted members far in excess of their usual numbers, and very great difficulty has been met with in finding accommodation for undergraduates both within the colleges and in the town outside. In some cases quarters have been provided by the erection of Army huts. The science laboratories are overcrowded with students.

Prof. Vines has resigned the chair of botany as from December 31, 1919. Candidates for the professorship are requested to send in their applications to the Registrar of the University by November 22 next. Applications for the chair of geometry, vacated by the death of Prof. Esson, should be sent in to the Registrar by the same date. Particulars of these two professorships may be seen in the *Oxford University Gazette* of October 22.

Mr. R. S. Troup, Assistant Inspector-General of Forests, India, has been elected professor of forestry.

A Treasury grant of 15,000*l.* has been received for the University under the condition of an inquiry into the financial resources of the University and colleges.

Counsel's opinion has been taken on the question of the powers of the University in the matter of the admission of women to matriculation and degrees. Counsel advise that the University has the power, proceeding by statute, to provide for this object; but they also recommend application to Parliament for an expressly enabling Act. A decree will therefore be proposed on November 4 requesting the burgesses of the University to take steps with the view of securing the requisite legislative sanction.

MAJOR G. THORP has been appointed chief instructor in electricity at the School of Military Engineering, Chatham.

MAJOR RUPERT STANLEY has been appointed principal of the Belfast Municipal Technical Institute, and director of technical instruction for Belfast, in succession to the late Mr. F. C. Forth.

MR. E. DE BARRY BARNETT has been appointed to the post of lecturer in organic chemistry, and Mr. R. H. Humphry to that of lecturer in physics, at the Sir John Cass Technical Institute, Jewry Street, Aldgate.

DR. W. M. McDOUGALL, Wilde reader in mental philosophy in the University of Oxford, has been appointed to the chair of psychology in Harvard University, in succession to the late Dr. Hugo Münsterberg.

MR. B. MOUAT JONES, assistant professor of chemistry in the Imperial College of Science and Technology, has been elected to the chair of chemistry in the University College of Wales, Aberystwyth, in succession to Prof. Alex. Findlay.

THE council of the Institution of Naval Architects has awarded the Cammell Laird scholarship in naval architecture (150*l.* per annum for three years) to Mr. H. J. R. Biles, of the Fairfield Shipbuilding and Engineering Co., Ltd.; and the Parsons scholarship in marine engineering (150*l.* per annum for three years) to Mr. W. G. Simmonds, of Chatham Dockyard.

THE President of the Board of Education has appointed a Departmental Committee to inquire into the working of the existing arrangements (*a*) for the award by local education authorities of scholarships tenable at secondary schools or institutions of higher education other than universities or institutions for the training of teachers; (*b*) for the provision of free places in secondary schools under the Regulations of the Board of Education; and to make recommendations with the view of improving such arrangements, and thereby rendering facilities for higher education more generally accessible and advantageous to all classes of the population, regard being had (*inter alia*) to the migration of pupils from one school or area to another. The members of the Committee are:—Lt.-Comdr. E. Hilton Young, M.P. (chairman), Mr. E. K. Chambers, Mr. R. F. Cholmeley, Sir Mark Collet, Bart., Miss E. R. Conway, Miss Philippa Fawcett, Mr. F. W. Goldstone, Mr. H. J. Hallam, Mr. R. T. Jones, Mr. J. Murray, M.P., Major the Hon. W. G. A. Ormsby-Gore, M.P., Mr. C. J. Phillips, Mr. T. J. Rees, Mr. R. Richardson, M.P., Miss B. M. Sparks, and Mr. H. E. Mann (secretary). All communications should be addressed to Mr. Mann at the office of the Board of Education, Victoria and Albert Museum, South Kensington, S.W.7.

EARLY this year an account was given in these columns (January 23, p. 418) of a conference of representatives of scientific and educational associations interested in both the production and the distribution of knowledge, held to consider proposals for the publication of a monthly journal which should present in popular form the most recent results of research in all the chief subjects of knowledge. This conference appointed a committee to frame a scheme, and the report of the committee was presented and adopted at the adjourned meeting of the conference held on October 24. The meeting approved the title *Discovery* for the new journal, consent having been given to the use of this title by Sir Richard Gregory and by Messrs. Macmillan and Co., Ltd., the publishers of his book so named. Mr. John Murray will publish the journal, and Capt. A. S. Russell, recently of the R.G.A., now of the University, Sheffield, and reader-elect in chemistry at Christ Church, Oxford, will be editor. The first number will be issued on January 15, 1920, at the price of sixpence. It is understood that the journal will at first contain about twenty-four pages of matter, and will undertake in the course of the year to represent in interesting form, though it will make no attempt to describe in full, the progress of knowledge in all its chief branches. Canon Temple has been appointed by the trustees to be the first chairman of the managing committee, of which Dr. Armitage-Smith is the treasurer and Prof. R. S. Conway, of Manchester, the hon. secretary.

IT will be recalled that in July–August last a joint committee of the Empire Cotton-growing Committee of the Board of Trade and of the British Cotton Industry Research Association offered five botanical research studentships to graduates and others recommended as likely to prove successful research workers, for the prosecution of research bearing upon any of the numerous technical problems affecting the cotton industry. The studentships were of the value of 150*l.* per annum (or in certain circumstances 200*l.* per annum), and in the first instance were available for one year. Considerable freedom was allowed in the choice of the line of research, the joint committee recognising that the economic results hoped for can be obtained only by increasing the volume of purely scientific inquiry now being conducted into the physiology and genetics of plants. We are now officially informed that, although advertisement was given to the scheme and the heads of the botanical departments of the universities were approached in the matter, the response on the part of graduates has been disappointing. The committee hopes that it will be possible to offer similar studentships next year, and desires to give the scheme early publicity in order that senior students may be able to consider the offer when planning their post-graduate work. For the present the studentships are limited to men, though with the development of the scheme it is hoped that it will cover fields open to research workers of both sexes. The studentships appear to offer considerable attractions to young economic botanists, but the joint committee will no doubt consult the heads of the botanical schools as to the probable cause of the poor response to its first offer, with the object of mitigating any drawbacks which may have become apparent in the scheme. We venture to suggest also the desirability of indicating a selection of typical problems with which the cotton industry is confronted.

SOCIETIES AND ACADEMIES.

Manchester.

Literary and Philosophical Society, October 21.—Mr. William Thomson, vice-president, in the chair.—Prof. W. L. **Bragg**: Sound-ranging. A sound spreads from the point where it originates as a spherical cone moving with constant velocity. If it is intercepted by three or more stations the positions of which are accurately known, and if the time-intervals elapsing between its arrival at the stations are measured, a simple construction gives the position of the sources of the sound. Soon after the commencement of hostilities it became clear that the struggle was going to take the form of trench warfare. This gave rise to the idea of locating the enemy guns by sound in the way described. The French made experiments with sound-ranging in October, 1914, and showed that it was feasible, and the British Army was encouraged by their success to send an experimental sound-ranging section to the Front. This section started operations in October, 1915, taking up its position opposite Wytschaete. The first results obtained were poor, but they improved with experience and better apparatus. The original section became a training school for officers and men, and sufficient sections were formed to cover the whole of our Front. Each section had six microphones spaced along a base opposite the German front line. The microphones were connected to a chronographic instrument at a central headquarters, and when the sound reached each microphone it sent an electric signal recorded by the instrument. In front of the base there were two observation posts so placed that the sound reached them a few seconds before it reached the microphones, which gave time for an observer at the post to press a key which started the recording apparatus at headquarters. By studying the record the time-intervals could be measured and the position of the gun plotted on the map and telephoned to the artillery. There were between thirty and forty sections along the Front. They could locate batteries between 10,000 and 15,000 yards away with a mean error of about fifty yards. Each section sent in about one thousand results in the year.

Paris.

Academy of Sciences, September 29.—M. Léon Guignard in the chair.—A. **Rateau**: Speech given at the James Watt centenary dinner, September 17, 1919, at Birmingham.—MM. **Blondel** and **Touly**: New arrangements of universal potentiometer amplifiers.—**Albert, Prince of Monaco**: Stray mines in the North Atlantic. In December, 1918, the author gave a chart showing the probable course of floating mines in the North Atlantic, with the view of minimising the danger to navigation. Since then thirty-three mines have been located, the positions of which are shown on an accompanying map. The conclusions of the first note are confirmed.—J. **Wolff**: Series of holomorphic functions.—M. **Foch**: The period of water-mains furnished with an air-cushion.—M. **Grard**: Thermal treatment of aluminium alloys. The alloys studied contained 3·5–4 per cent. of copper, about 0·5 per cent. of magnesium, and from 0·5–1 per cent. of manganese, and were of the duralumin type. The treatment giving the alloy the maximum malleability was found to be heating to 450° C., with a cooling velocity of 100° C. per hour. Heating to 475° C., followed by immersion in water at 20° C., gave the highest elastic limit and breaking strain.—A. **Riccò**: Heliographic latitudes of the solar protuberances (1880–1918). The observations are summarised both in tabular and graphical form, the general conclusions being more clearly shown by the latter.—C. **Benedicks**: The thermo-electricity of liquid mercury demonstrated by means of the galvanometer. In an earlier paper the author has shown that thermo-electric currents of the first species can be proved in a column of liquid mercury asymmetrically heated. These results have been called in question, and confirmation by a different method is now given.—M. **Delpech**: The flashes produced by the fire of artillery, and a general method for the extinction of these flashes. For small-bore cannon (47 mm.) a simple lubrication of the projectile with vaseline suffices to prevent the flash; for larger bores the addition of vaseline to the powder serves the same end.—P. **Thiéry**: Some new observations on the *klippes* of the Alais Plain.—Mlle. M. **Goldsmith**: The behaviour of *Convoluta roscoffensis* in presence of the rhythm of the tides.—F. **Ladreyt**: Physiological dedifferentiation and cellular reinvigoration in intestinal epithelium.

Calcutta.

Asiatic Society of Bengal, September 3.—**Hashmat Rai** and H. B. **Dunnicliff**: The purification of Indian sesame ("til") oil. The following conclusions were arrived at:—(1) Of all the filtering materials used, bone charcoal and French chalk are the best decolorising agents; all of them are ineffective as deodorisers. (2) Exposure to sunlight alone gives progressive improvement in colour, but the odour still persists. (3) Treatment with air alone improves the colour, but the odour is not removed. (4) Exposure to both air and sunlight combined has a very marked effect on the colour. The odour, though not absent, is not unpleasant. (5) Sulphuric acid reduces the colour very slightly, but the odour practically disappears. (6) Caustic soda acts both as a very good decolorising and a deodorising agent. (7) In all the bleached samples the colour more or less comes back on standing for a long period. (8) On heating all the deodorised samples the odour becomes perceptible. On cooling, however, it disappears.—**Hashmat Rai**: Note on nitrogen. A new method of preparation. Nitrogen gas may be readily prepared by passing an electric current through an ammonium chloride solution with platinum foil electrodes, the anode and the cathode chambers being separated by a porous diaphragm. Air is excluded from the electrolytic cell and the connecting tubes. The anodic gas is practically pure nitrogen, containing less than 0·2 per cent. of oxygen. It should, however, be collected over caustic soda solution so as to absorb any chlorine gas that may possibly be mixed with it. This affords a ready method for the preparation of a continuous supply of pure nitrogen.—N. N. **Chatterjee**: The rationalisation of algebraic equations. An earlier paper on the subject by the author was referred to in a paper by Prof. Mahendra Nath De, "The Rationalisation of Algebraic Equations" (J.A.S.B., July, 1908), in which objection was taken that the method does not always lead to an equation of the lowest degree. The present paper aims at meeting this objection by employing the method of indeterminate coefficients, which, although applied to various other problems, has not, it is believed, been previously applied to the particular class of problems in hand.—E. G. **Barter**: Radiation pressure. This paper is a criticism of Sir Joseph Larmor's method of deducing the pressure of radiant energy, and directs attention to certain obscure points in the train of arguments used by him.

DIARY OF SOCIETIES.

MONDAY, NOVEMBER 3.

SOCIETY OF ENGINEERS (at Geological Society), at 5.30.—W. Brown: Sewer Ventilation and Health.

ARISTOTELIAN SOCIETY (at 22 Albemarle Street, W.1), at 8.—Prof. J. Ward (President's Inaugural Address): In the Beginning . . .

SOCIETY OF CHEMICAL INDUSTRY (at Chemical Society), at 8.—C. A. Mitchell: Black Lead Pencils and their Pigments in Writing.—Capt. E. T. Sterne: Shawiningan Chemical Industries.

ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 8.30.—Major K. Mason: Central Kurdistan.

TUESDAY, NOVEMBER 4.

ROYAL HORTICULTURAL SOCIETY (at London Scottish Drill Hall), at 3.—J. Snell: The Ormskirk Potato Trials.

ZOOLOGICAL SOCIETY OF LONDON, at 5.30.—E. Heron Allen: Exhibition of Skiagraphs of Vermiculina from examples grown in a Hypertonic Tank.—Dr. G. Marshall: The Species of Balaninus occurring in Borneo (Coleoptera, Curculionidæ).—Miss J. B. Proctor: The Variation in the Number of Dorsal Scale-rows in our British Snakes.—G. A. Boulenger. Some New Fishes from near the West Coast of Lake Tanganyika.—The Hon. Paul Methuen: Description of a New Snake from the Transvaal together with a New Diagnosis and Key of the Genus Xenocalmus, and of some Batrachia from Madagascar.

MINERALOGICAL SOCIETY (Anniversary Meeting, at Geological Society), at 5.30.—Dr. W. R. Schoeller and A. R. Powell: Villamaninite, a New Mineral.—A. Russell: The Occurrence of Phenasite and Scheelite at Wheal Cock, St. Just, Cornwall.—L. J. Spencer: New Crystal-forms on Pyrites, Calcite, and Epidote.—Dr. G. F. H. Smith: A Curious Crystal from the Binnenthal.

INSTITUTION OF CIVIL ENGINEERS, at 5.30.—Sir John Purser Griffith: Presidential Address.

RÖNTGEN SOCIETY (at the Medical Society of London), at 8.15.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.30.—J. W. Simpson: Presidential Address.

WEDNESDAY, NOVEMBER 5.

GEOLOGICAL SOCIETY OF LONDON, at 5.30.—H. H. Thomas: Some Features in the Topography and Geological History of Palestine, Illustrated by Aeroplane Photographs taken during the War.

INSTITUTION OF AUTOMOBILE ENGINEERS (at Royal Society of Arts), at 8.—Dr. L. Aitchison: Valve Failures and Valve Steels in Internal Combustion Engines.

SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS (at Chemical Society), at 8.—G. R. Thompson: Egyptian Bricks.—A. R. Powell and Dr. W. R. Schoeller: The Analysis of Brazilian Zirconium Ore.—Ethel M. Taylor: The Halogen Absorption of Turpentine.

ENTOMOLOGICAL SOCIETY OF LONDON, at 8.—*Probable Papers*: Dr. T. A. Chapman: (1) Contributions to the Life-history of *Lycaena euphemus*, Hb.; (2) Notes on *Lycaena arcon*, F.—Dr. G. D. H. Carpenter: Notes on Species of Pseudacræa from Uganda.

THURSDAY, NOVEMBER 6.

ROYAL SOCIETY (jointly with the ROYAL ASTRONOMICAL SOCIETY), at 4.30.—Sir Frank Dyson, Prof Eddington, and Others: Discussion on the Results of the Observations obtained at the Total Solar Eclipse on May 29, 1919.

LINNEAN SOCIETY, at 5.

ROYAL COLLEGE OF PHYSICIANS, at 5.—Dr. A. P. Beddard: Some Remarks on Chronic Arthritis (Bradshaw Lecture).

CHEMICAL SOCIETY, at 8.

FRIDAY, NOVEMBER 7.

ROYAL ASTRONOMICAL SOCIETY (Geophysical Committee), at 5.—Col. Sir S. G. Burrard, Prof. A. E. H. Love, and Others: Discussion on Isostasy.

TECHNICAL INSPECTION ASSOCIATION (at Royal Society of Arts), at 7.30.—Prof. Baly: The Spectroscope in the Science of To-day.

NATURE

1869–1919.

JUBILEE ISSUE.

THURSDAY, NOVEMBER 6, 1919.

VALEDICTORY MEMORIES.

By Sir Norman Lockyer, K.C.B., F.R.S.

It has been suggested to me that some reminiscences relating to the circumstances which led to the establishment of Nature would be of interest, and I am glad to be able to contribute them to this jubilee issue. It is a great satisfaction to me again to have the opportunity of expressing my best thanks to the many friends whose knowledge has always been placed freely at my disposal, and to know that the vitality of the journal is now as strong as ever it was.

At the time when Nature first made its appearance, just fifty years ago, scientific progress was commanding increased attention from the public mind, and British workers were experiencing the need for an organ devoted to their common activities and interests. In 1858 a fortnightly column of scientific notes was started in the *Saturday Review*, and two years later Huxley became the chief editor of the *Natural History Review*, with the intention of providing a quarterly which would deal with scientific matters systematically and thoroughly. He ceased to contribute to that magazine, however, in 1863, and became associated with the *Reader*, a weekly journal of which I was the science editor.

My first literary work arose from observations of a transit of the shadow of Titan across Saturn's disc. I sent an account of these observations to the *London Review*, and it appeared in the issue of May 10, 1862. This communication brought me two letters—one from Mr. W. R. Dawes, who was at that time recognised as one of the keenest astronomical observers in England, and the other from Mr. W. Little asking me to send astronomical notes from time to time to the *London Review*, together with an article each month on the "face of the sky."

I was then living at Wimbledon, and was honorary secretary of the Wimbledon Village Club, on the committee of which were Thomas Hughes, J. M. Ludlow, and George Pollock. It was this connection that led to my appointment as science editor of the *Reader*, when it was established with Hughes and Ludlow among the proprietors. My astronomical work thus led me into literature, and the subject with which I was particularly concerned—astronomy—was also the product of my Wimbledon environment.

When the *Reader* ceased publication the idea occurred to me of starting a general scientific journal of a more comprehensive scope than the *Natural History Review*, which, like other specialised scientific periodicals, had failed for want of circulation. On discussing the matter with my friends, I found that they were favourable to the idea; and one of them, Mr. Alexander Macmillan, greatly encouraged me to develop it. It was in consequence of his sympathy and enthusiastic assistance that the journal was started. He was unwavering in his support of the belief that British science would be advanced by a periodical devoted to its interests—a point on which I had always laid stress as the result of experience up to that time. It was the hope that a more favourable condition for the advancement of science might be thereby secured that led Mr. Alexander Macmillan to enter warmly into the establishment of Nature in 1869. He enlisted the interest of Sir Joseph Hooker and other of his scientific friends, and before the journal had started I was assured of the support of Huxley, Tyndall, and practically all the other leading workers in science of the time.

It may be of interest to reprint here the following circular which was issued broadcast to bring the aims and intentions of the journal before scientific readers and others:—

The object which it is proposed to attain by this periodical may be broadly stated as follows. It is intended:

First, to place before the general public the grand results of Scientific Work and Scientific Discovery, and to urge the claims of Science to a more general recognition in Education and in Daily Life: and

Secondly, to aid Scientific men themselves, by giving early information of all advances made in any branch of Natural Knowledge throughout the world, and by affording them an opportunity of discussing the various Scientific questions which arise from time to time.

To accomplish this twofold object, the following plan is followed as closely as possible.

Those portions of the paper more especially devoted to the discussion of matters interesting to the public at large contain:

I. Articles written by men eminent in Science on subjects connected with the various points of contact of Natural Knowledge with practical affairs, the public health, and material progress; and on the advancement of Science, and its educational and civilising functions.

II. Full accounts, illustrated when necessary, of Scientific Discoveries of general interest.

III. Records of all efforts made for the encouragement of Natural Knowledge in our Colleges and Schools, and notices of aids to Science-teaching.

IV. Full Reviews of Scientific Works, especially directed to the exact Scientific ground gone over, and the contributions to knowledge, whether in the shape of new facts, maps, illustrations, tables, and the like, which they may contain.

In those portions of NATURE more especially interesting to Scientific men are given:

V. Abstracts of important papers communicated to British, American, and Continental Scientific societies and periodicals.

VI. Reports of the meetings of Scientific bodies at home and abroad.

In addition to the above, there are columns devoted to Correspondence.

From the first I was helped by the free kindness of most of the men of science in the country, by their permitting me to appeal to them for assistance and advice, and my election into the Royal Astronomical Society, and afterwards into the Royal Society, in 1869, brought me into closer correspondence and contact with many of the active workers in scientific fields. I am very grateful for what they did, and for what men of science are still ready to do to ensure that NATURE shall represent scientific claims justly and scientific fact and thought in correct proportion. While this common interest in the journal exists among men of science, not only in the United Kingdom, but also in Europe and America, there will be no falling off from the high standard maintained in its pages from the commencement of its existence.

PROGRESS AND PROMISE.

IN the career of a journal, as in the life of a man, stages are met from which it is appropriate to take a glance backward at the road traversed and to contemplate the outlook of the future. Such an epoch has been reached in the history of NATURE, the first number of which was published fifty years ago—on November 4, 1869. The circumstances which led to the establishment of this journal are described briefly by Sir Norman Lockyer in the preceding article. Men of science had felt the need for an organ devoted to their interests in common, and several attempts had been made to meet it, but unsuccessfully. It required the rare combination of scientific authority, untiring energy, wise judgment, and business aptitude to construct a platform on which investigators of the many and diverse fields of natural knowledge could put their trust, and from which descriptions of their work would command attention.

How fully these attributes are possessed by the founder of this journal, and how consistently they have been made manifest in its pages, is shown by numerous appreciative messages received from scientific societies and distinguished workers. Thanks to the sound and comprehensive programme laid down by Sir Norman Lockyer at the beginning, and followed ever since, NATURE now occupies a high place in scientific life. It would be disingenuous to pretend that we are not proud of the testimonies which have been sent by many leading representatives of progressive knowledge as to services rendered by the journal in various ways. Among those who have expressed their congratulations upon the attainment of the jubilee are readers who have never missed a number since the first issue, while others of a new generation equally acknowledge the stimulus they derive from a wide view in these days of minute specialisation.

The intellectual background is different now from what it was in 1869, and the outlook, as well as the conceptions, of science has changed. Specialised work is necessary to acquire new knowledge, but for the great generalisations which provide an impulse to wide inquiry attention must be given to results achieved in the whole sphere of related investigations. It is the particular function of NATURE to present this comprehensive view, and to bring to a focus upon its pages the living picture of scientific advance as a whole, so that workers in separate fields may see the growth of the grand edifice of natural knowledge, and the place their own contributions take in it.

At one time—as, for example, in the early days of the Royal Society—it was possible for every member of a general scientific society to take an intelligent interest in every paper presented. Since then, however, science has passed from the stage of a simple organism to that of a body made up of parts with highly differentiated functions. Numerous specialised scientific societies have been formed, as may be seen by the list published in this issue of those established since 1869, and many periodicals similarly devoted to distinct branches of pure and applied science have come into existence. The common factor is interest in the advancement of knowledge; and a society or a journal concerned with this as a whole can best assist the aim in general by providing the segregated groups of investigators with intelligible accounts of activities in other fields, which may or may not be on the borders of their own.

The remarkable collection of articles published in this issue represents the highest type of contributions of this kind. Each article is by an eminent authority upon the subject with which it deals, and each can be comprehended by everyone who has had a scientific training. It is scarcely too much to say that no such authoritative epitome of fifty years of scientific progress, as viewed by pioneers in particular fields, has ever been brought together in any one periodical. Contributions of such high distinction are rendered possible largely because the writers know that in these pages they are addressing themselves to fellow-workers throughout the world, as well as to other readers having an intelligent interest in the march of scientific knowledge.

Four of the writers—Sir Archibald Geikie, Sir E. Ray Lankester, Prof. Bonney, and Canon Wilson—were contributors to the earliest issues of this journal; and every reader will be grateful for the enlightening descriptions of stepping-stones of scientific progress which we are now privileged to publish. Nature could not have maintained its original standard for so long but for the active support which these and many other leading men of science have been ready to give it since its foundation. This is as true of the new generation as it was when the journal was founded; and the value of the association is most highly appreciated. While Nature is honoured by the active co-operation of the men of genius who are traversing the royal roads of science, its functions will extend, and its influence increase, with the expansion of knowledge. With this assurance, and the encouragement which the past has given, we look with confidence and strength at the prospect of the future.

SCIENTIFIC WORTHIES.

XLI.—Sir Norman Lockyer, K.C.B., F.R.S.

The simple title Nature, embracing all in a single word, was most appropriately chosen by Sir Norman Lockyer when, exactly fifty years ago, he founded this weekly journal, which is devoted to all the sciences, and has had so successful a career. The first article in the journal reproduced profound aphorisms of Goethe on the intimate relations of man with Nature, of which he is a part. The poet-philosopher set forth in striking language, which was rendered into English by Huxley, the innate feebleness of man before the immutable forces and the great mysteries which everywhere surround him, and at the same time the incessant human desire, never completely satisfied, of comprehending and penetrating them. The contribution is a stimulating preface to a scientific periodical; it well exhibits the high character of the journal at the outset, and the spirit in which it has always been conducted.

Indeed, Nature is, of all scientific journals, the most comprehensive in the world; it includes articles of the highest scientific standard, as well as those of a more popular kind; it has open columns for the discussion of current subjects, and it provides summaries of most of the papers presented to the chief academies and learned societies; it gives the latest events of the scientific world, news about men of science, and accounts of the most recent discoveries in scientific fields. It has rendered inestimable services to the cause of science in general.

Since the first issue the journal has maintained the form and character which we see to-day. A comparison of a number issued in the year 1869 with one of 1919 shows the same general arrangement, the same sequence of subject-matter; moreover, the pages and the style of type are nearly identical in appearance. The founder, who in 1869 was only thirty-three years of age, has proved himself a publicist and an organiser of the first rank. During its existence the journal has ably recorded the magnificent discoveries which have distinguished the last fifty years in every branch of science; it has had to deal with subjects beyond one's dreams; and it has been the better able to present them to the public because the founder has himself been one of the foremost builders of this noble edifice.

Sir Norman Lockyer is distinguished not only by his eminent public work, but also as one of the greatest men of science of our time. In the three years which preceded the foundation of this journal he made discoveries relating to the sun which will permanently preserve his memory among men. He was one of the pioneers of astrophysics, the new branch of astronomy which is now of such importance. For fifty years, with untiring activity, he has carried on a multitude of researches in the three observatories established by him and in the physical laboratories associated with them; and, like a true philosopher, he has presented a general synthesis of celestial phenomena. The title "Nature" might be justly given to the record of his personal achievements, to which the remarks which follow are particularly devoted.

Sir Norman Lockyer is not the product of a university; he may be termed a self-made man of science. He was at first employed in a Government Department, where he remained for more than ten years; but he was irresistibly drawn towards science, and especially to astronomy, the wonder of which exercises a powerful attraction. All his leisure and all his personal resources were devoted to scientific pursuits. Spectrum analysis had come into being, and its application to celestial bodies opened up the widest horizons. Sir Norman Lockyer attached a small spectroscope to a modest equatorial telescope of 6-in. aperture, which constituted his private observatory, and he studied the light emanating from the solar spots. The first results were summarised in a note presented to the Royal Society in 1866, where the author discussed the bearing of his observations on the two rival theories which were then to the front as to the nature of sun-spots. He foresaw the possible daily observation of the red flames, or prominences, which up to that time had only been observed on the outer edges of the sun during total eclipses. He conceived the idea that the spectroscope might be able to reveal them at ordinary times under the same conditions as those which caused the appearance of bright lines in the new star in Corona Borealis. This star had appeared a few months previously, and, as observed by Huggins, had presented a stellar nucleus surrounded by a relatively feeble nebulosity; but in the spectroscope the light of the nucleus was spread out in a continuous spectrum and thereby enfeebled, while the atmosphere showed the bright lines of hydrogen with great brilliance.

This idea was really a flash of genius, because it contained the germ, or the principle, of the method which, for fifty years, has revealed to us at all hours of the day the gaseous atmosphere of the sun. The first application of the method to the sun's edge, however, gave no result; the spectroscope employed was not sufficiently powerful. Two years later the observations in India of the total eclipse of the sun of August, 1868, gave valuable information—the solar prominences were gaseous, and showed the red and green lines of hydrogen with very great intensity.

On October 20, 1868, Sir Norman Lockyer, at last provided with a powerful spectroscope, for which he had waited two years, discovered, at Hampstead, a prominence on the sun's edge, and made a drawing of it two days later. The discovery was communicated to the Royal Society on October 20 and to the Academy of Sciences at Paris on October 26. By a striking coincidence, at the same meeting of the Academy, a letter sent from India by the French astronomer Janssen announced the same result. During the eclipse Janssen had recognised in the spectroscope the nature of the prominences, and was able to see them again on the following day with the same instrument. Janssen continued to observe them daily during three weeks, and found that they were composed principally of hydrogen, and were subject to remarkable variations of form which were often very rapid. The astronomer Faye then pointed out that the first idea of the method was certainly due to Lockyer, but that the first application had been realised by Janssen, and since then the two names have been justly united in connection with the discovery.

During the weeks and months which followed, Sir Norman, with praiseworthy activity, continued the study of the sun by the new method without intermission, and he successively recognised several new facts of the first importance, namely:—

1. The prominences emanate from a gaseous layer of the same composition, which envelops the entire sun, and reaches a height of 8–10 secs. of arc. This layer is of a rose colour, like that of the prominences themselves, and Sir Norman Lockyer gave it the name of the *chromosphere*; it had already been glimpsed in preceding eclipses, but its existence was not generally acknowledged.

2. The yellow radiation of the prominences, which had been attributed to sodium by the eclipse observers, proclaimed in reality the existence of a new gas, to which Sir Norman gave the name of *helium*. It was the first recognition of the famous gas which was afterwards obtained from terrestrial sources by Ramsay in 1898; it is emitted by radio-active bodies, and now can be used for the inflation of dirigibles.

3. The green line of hydrogen becomes broader in passing from the summit to the base of a prominence. From a series of experiments on hydrogen at low pressures, carried on in the chemical laboratory of his friend, Frankland, Sir Norman concluded that this widening is simply due

to an increase of pressure. Spectrum analysis disclosed not only the chemical composition of the prominences, but also to a certain extent their physical state.

4. The lines of the prominences are often displaced and distorted. This phenomenon was correctly attributed to the movements of the vapour in the direction of the observer; it was the first real verification of the velocity displacements which have since become of such great importance in astronomy.

This first series of investigations is set forth in some detail, because it represents magnificent work; it is an example for all, and has its place marked out in the history of science, especially as it was carried out with simple means. The greatest discoveries, as one knows, have not been made in the largest laboratories, and the capacity of the man is always of more consequence in research than that of his instruments. In his investigations Sir Norman Lockyer has shown a power, an acuteness of mind, and a creative imagination which are truly exceptional. These are the qualities of men who, like him, have overcome all difficulties placed in their way in order to pursue fixed ideas and follow vocations which they have fully resolved to adopt.

In the succeeding years Sir Norman organised several eclipse expeditions under Government auspices; all the important solar eclipses since 1868 have been observed by him or by his assistants, with programmes laid down by the Solar Physics Committee, of which he was a member. At the same time, he undertook extensive work which may be summarised in the words: "Comparative study of terrestrial spectra and the spectrum of the sun, extended afterwards to stars, nebulæ, and comets. Special and general consequences drawn from them." After fifty years of continuous labour the work has certainly been advanced, but it is not yet completed. It was carried on at first in his own observatory, then from 1879 in the establishment at South Kensington which the Government had created for the development of the new methods and placed under his direction.

The astrophysical observatory at South Kensington was a model of its kind; it consisted of two parts, quite distinct but closely related, namely, an observatory properly so called and a physical laboratory. The astrophysicist must pass constantly from one to the other, and, in fact, the number of publications issued from South Kensington has been nearly the same in the two sections. It has been said that an astrophysical observatory is merely a physical laboratory oriented towards astronomy, the astronomical instruments being in reality nothing more than physical apparatus of large dimensions; and it is therefore necessary to attach to them men who have been trained by the study of physics and capable of immediately applying to the celestial bodies the most recent discoveries made in the laboratory.

In this connection Sir Norman has trained at South Kensington several investigators, including Prof. Fowler, Dr. Lockyer, and Messrs. Shackleton, Baxandall, and Butler, at once physicists and astronomers, and well known by their publications. Prof. Fowler, now president of the Royal Astronomical Society, is already distinguished; we owe to him important discoveries and some fine series of precise measurements.

In 1912 the land occupied by the observatory at South Kensington was required for the extension of the Science Museum, and the observatory, with all its instruments, was transferred to Cambridge. Sir Norman, having passed the age-limit, was obliged to retire from the directorship, but, feeling that his work was not yet accomplished, and still vigorous in body and mind, he forthwith set up another observatory—the Hill Observatory—with the aid of several friends of science. The site chosen, at Sidmouth, is very favourable for astronomical observations, and as the first buildings were erected very quickly and provided immediately with some fine instruments, the researches commenced at South Kensington, especially those on stellar spectra, have been continued with but little interruption. It is hoped to establish there an astrophysical observatory comparable with the American observatories and worthy of the United Kingdom.

The new facts gathered together in the course of these fifty years are extremely numerous; they are set forth with the inferences drawn from them in 200 memoirs, and it is impossible to give any detailed analysis of them here. Fortunately, the author, who has an affection for great generalisations, has always sought to connect the facts in a few leading ideas which are for him "working hypotheses," and he has expounded each hypothesis in a special book. The volume on "The Chemistry of the Sun" (1887) deals with the differences of spectrum emitted by different parts of the sun, and explains them by the dissociation hypothesis, according to which the molecules and atoms are grouped in different ways or are split up into simpler elements. In his book on "The Meteoritic Hypothesis" (1890) the author explains all the celestial bodies by collisions of meteorites; it is a simple and fertile idea, which has been adopted by several astronomers. The last volume, entitled "Inorganic Evolution" (1900), develops the final methods and ideas of the author, and presents a general classification of all the stars. It is only necessary to add one remark: Sir Norman is one of those who publish the observed facts immediately, and also the interpretations which present themselves at once to his mind. This method inevitably involves imperfect detail, or over-sanguine conclusions, which have been freely criticised. Pruning and revision have become necessary, and this work has recently been taken in hand by the author himself. The main body of facts and ideas remains unaffected, and is always worthy of being retained.

It will suffice to mention here very briefly on one part some of the more important results on the sun and the effects of its radiation, and, on the other, the great classification of the stars.

Sir Norman was the first to recognise the presence in the solar spectrum of lines due to a band spectrum, attributed at first to cyanogen, and now assigned to nitrogen alone. He observed the widening of the dark lines in the spectra of sun-spots, a phenomenon which has since been so brilliantly explained by Prof. Hale, of the Mount Wilson Observatory.

With the simple arrangement of the objective prism, he was the first to photograph in an eclipse the spectrum of bright lines given by the reversing layer, situated at the base of the chromosphere, thus obtaining a verification of the general accordance of these bright lines with the ordinary dark lines, and confirming the simple explanation of the dark lines given by Kirchhoff.

He discovered in the fluctuations of the solar prominences a period of 3·8 years, which is superposed on the great eleven-yearly period, and he showed later, in collaboration with Dr. Lockyer, that this same period of 3·8 years reveals itself in variations of pressure of the terrestrial atmosphere. This last result has a practical importance because it renders possible the forecasting of the variations of the monsoons in the Indian Ocean. In addition, the schematic chart of the law of the winds in the southern hemisphere, drawn up in this case by Dr. Lockyer, has been verified by all later observations; it has been reannounced in 1919 by Prof. Hildebrandson, one of the founders of meteorology, in a note on the general movements of the atmosphere presented to the Paris Academy of Sciences.

One of the questions which have most occupied Sir Norman is that of the variation of laboratory spectra with the energy of the excitation. He has from the first distinguished the long and short lines in the same spectrum, and the employment of a very powerful induction spark has given him new lines which he has called "enhanced lines." The three types of lines—long, short, and enhanced—correspond with increasing temperature, and constitute valuable tests which serve to differentiate the stars. Sir Norman has observed the presence of these lines in the spectra of stars, and at the same time the different behaviour of the lines of hydrogen, of helium, and of the metals, which has led to a new classification of the stars. The labour involved in this investigation was considerable, because it became necessary to photograph stellar spectra under the unfavourable conditions of London and with a high dispersion. Its success was secured by the use of an objective prism of large angle and by great patience.

At the same time, the great American astronomer Pickering, with much more powerful means, had entered upon the observation and classification of stellar spectra over the entire sky, and was content to use a small dispersion which enabled him to reach the fainter stars. But as the study of enhanced lines demanded a high dispersion, Sir Norman confined himself to the stars visible to the naked eye.

The classification adopted differs essentially from all previous classifications, which had considered only the actual temperatures of the stars and supposed a continuous cooling. Sir Norman went much further, and in the year 1888 established a distinction between the stars in which the temperature was rising, and those in which the temperature was diminishing. Beginning with a primitive nebula, the body which forms by condensation will at first become hotter, then attain a stationary temperature, and will finally cool. Its natural evolution, expressed by temperature as a function of time, ought to comprise an ascending branch, a steady state corresponding with the maximum, and a descending branch. In the ascending phase the lines of hydrogen are narrow and the chromosphere is of low density; at the time of maximum the enhanced lines predominate and the maximum intensity of the spectrum is far in the ultra-violet; in the later phase the lines of hydrogen are broad and diffuse, and the chromosphere is of greater density. It is certain that one thus penetrates more deeply into the nature of things. Further, Sir Norman does not explain the variable number of metallic lines by a different distribution of the chemical elements in the stellar atmosphere. When the star is very hot the metallic lines are wanting, and he has attributed this to a dissociation of the elements analogous to that of radioactive bodies. On this view the heavier elements are split up into lighter and even into new and simpler elements which he has called "protoelements." The evolution of the stars is accompanied by a simultaneous evolution of the simple elements of Nature.

The great chemist, Ramsay, who was a pioneer in many directions, gave the greatest attention to these new ideas and to the numerous observations which appeared to support them. The classification of the stars in accordance with the foregoing tests has been fully confirmed by optical measurements of their absolute temperatures.

To sum up, in his latest researches, as well as in the first, Sir Norman Lockyer has exhibited an aptitude for experiment, a creative faculty, a penetration, and a breadth of view which are truly remarkable; and the results obtained on the sole basis of experiment are of the first importance. He is one of the great men of science of England and one of the greatest astronomers of all time. Finally, let us hope that, bearing the weight of years in comfort, he may continue his services to science and his association with this journal, and witness for himself the increasing success of his ideas and his methods.

H. Deslandres.

(Vice-President of the Academy of Sciences of Paris, Director of the Astrophysical Observatory of Meudon.)

RETROSPECT AND PROSPECT.

By Sir Archibald Geikie, O.M., K.C.B., F.R.S.

FIFTY years have passed since the publication of the first number of Nature on November 4, 1869. To start successfully a weekly journal entirely devoted to chronicling the onward march of science was an experiment that could not but involve some financial risk, and certainly required no small editorial ability. To maintain such a journal for half a century on a high level of excellence, and to gain for it a place admittedly of importance in the periodical literature of our time, is a feat of which Editor and publishers have good reason to be proud. The weekly contributions of this journal to current scientific literature now amount altogether to more than a hundred volumes, which contain a contemporary record of the progress made by every department of natural knowledge, often contributed by the men to whom the progress was due. It may be appropriate, as we take note of this achievement, to cast an eye back upon the condition of science among us fifty years ago, to survey our present position, and to look forward into the vista that is opening out for the future.

In taking such a retrospect one of the most conspicuous and satisfactory features to attract attention is the remarkable increase and steady growth of fresh centres of higher education all over Britain, where not only is the time-honoured literary side cherished, but ample room and full equipment are found for the theoretical and practical teaching of science. These centres, beginning perhaps as modest colleges, have attracted a constantly increasing number of students, and each of them has become a nursery in which the men of science of the future are being bred. A convincing proof of their vitality is furnished by their successful claim for recognition as universities. They have already added half a dozen new universities to our educational strength, and this year one of the youngest yet most important of them, the Imperial College of Science and Technology, is now in turn demanding the status and powers of a university. There has never been a time in our history when the opportunities for obtaining a thorough scientific training have been thrown open so widely and attractively, and when advantage has been taken of them in so large a measure.

That one of the great duties of a nation is to promote the cultivation of science by appropriating funds not only in aid of education in theory and practice, but also in support of research and experiment, never began to be realised until within living memory. British science has attained its greatness without State aid. There are, indeed, a few directions in which public money has been disbursed for scientific objects, such, for instance, as Greenwich Observatory, the British Museum, and the various geographical expeditions and geological surveys. But not until the middle of last century did it dawn upon the attention of the Ministry of the day, awakened possibly by the portents of the coming Great Exhibition of 1851, that men of science are not as a rule wealthy, that they must often be involved in considerable expense in carrying on their researches, that they cannot always look to the universities, colleges, or learned societies for financial support, and therefore that it might be of public advantage to come to their help from the public purse. Accordingly, in November, 1849, Lord John Russell, then Prime Minister, sent a confidential communication on the subject to the president of the Royal Society (Earl of Rosse), who remitted to a committee to report how a financial grant, if made by Government, could best be employed.

After deliberate Governmental consideration for the space of nearly a year it was decided at the beginning of 1851 to make an annual grant of one thousand pounds to be administered by the Royal

Society, chiefly in aid of private individual scientific investigation. At the end of four years the Treasury declined to continue the grant of this sum (trifling as it was, compared with the revenue of the country), on the ground that the fund from which it was taken would no longer admit of "an annual grant to the Royal Society." The council replied with spirit that it was not a grant to the Royal Society, but "a contribution on the part of the nation towards the promotion of science generally in the United Kingdom," the council being only trustees for the due administration of the fund. The grant was then placed on the Parliamentary Estimates, and the 1000*l*. continued to be paid annually for nearly twenty years. In 1877 the vote was increased to 4000*l*., but the council had still some difficulty in preventing the grant from being regarded as one to the Royal Society, which was in no way benefited by it, but, on the contrary, had an onerous and difficult task in looking after its proper administration. In 1894 application was made for an increase in the amount of the grant, but without success.

Meanwhile the German Government, looking keenly to the future and thoroughly impressed with the importance of stimulating the cultivation of science, was spending large sums to equip laboratories and otherwise further education in science, and to stimulate discovery and invention. The example of that country was often cited here, and contrasted with the unsympathetic attitude and stingy support of our authorities, much to the surprise and annoyance of the permanent officials of the Treasury, who rather seemed to think that their grants to science were remarkably liberal. I remember an occasion when I had to go to the Treasury about a matter connected with the Geological Survey. The official on whom I called was one of the heads of the Department, with whom I had long been on terms of friendly intimacy. He began the interview by saying that he would be glad to hear me, but begged that the example of Germany might not be mentioned.

Happily these times of indifference belong to the past. Twenty years ago an appeal was made to Government for the creation of a National Physical Laboratory for the purpose of standardising and verifying instruments, testing materials, and for the determination of physical constants. After some effort and with the persistent support of Lord Rayleigh, the appeal was eventually successful. The institution began on a modest scale with a staff of only twenty-six, no more than two departments, and a small grant annually voted by Parliament. But under the able supervision of Sir Richard Glazebrook it rapidly increased the scope of its work, the extent of its buildings, and the size of its staff, until the burden of responsibility for its administration was becoming too heavy for the Royal Society. In April of last year it was transferred to the newly established Department of Scientific and Industrial Research, the number of its departments of investigation having now grown to seven, and that of the staff to more than 600. In this enlarged sphere of public utility it will no doubt achieve still greater success, while at the same time research in all directions and its practical applications will be greatly quickened. The day of parsimony in regard to the prosecution of scientific inquiry and its applications is now gone beyond the power of any Government to revive.

Obviously it is not zeal for the advance of pure science that has led to the augmented general interest in research. The appreciation of the practical value of many discoveries in relation to the daily life of mankind has naturally been the main stimulus. The philosophers might have experimented until doomsday upon æther and its undulations without awaking more than a languid interest in their work, or receiving any pecuniary help in their expenses; but when they showed that by means of these undulations messages could be flashed across the ocean without any wires, the public imagination was at once excited, and millions of money were ready for investment in any company that would undertake to fit up the necessary apparatus for sending such messages. In like manner, there might have been but a feeble appreciation of the phenomena of radioactivity, but when it was shown that by means of Röntgen rays the surgeon could see the bones inside a human body and detect there the existence and exact place of any bullet or other dense substance, a wide interest in the discovery was awakened, and little difficulty was found in supplying every hospital with the requisite apparatus.

The War has brought the economic value of science before the world on a colossal scale of demonstration. While scientific inventions have enormously augmented the offensive powers of the belligerents, it is pleasing to know that the applications of science have not been all on the destructive side, but that at the same time the greatest stimulus in the history of mankind has been given to medicine and surgery, and that each of these great divisions of the healing art has made notable advances and gained fresh powers for dealing with diseases and wounds.

Exactly ten years had elapsed after the publication of Darwin's "Origin of Species" when the first number of NATURE was issued. The doctrine of Evolution had long been before the world. Laplace had introduced it into the history of the solar system; Lamarck, after Buffon, had proposed an ingenious ætiology in the history of organised life upon the earth; while towards the middle of last century came the cruder efforts of the author of the "Vestiges of the Natural History of Creation," which so perturbed the minds of his generation. But it was not until after the appearance of Darwin's book, and in consequence of that book, that Evolution came slowly to be regarded as the great law of the whole cosmos. If we consider broadly the relation of the community to scientific progress during the last fifty years, its most outstanding feature will probably be recognised in the general acceptance of this great generalisation.

The views of Darwin made their way with

more speed on the Continent than in his own country. Probably not many survivors are left to recall the astonishment and indignation with which some of the older geologists of the day read his two chapters "On the Imperfection of the Geological Record" and "On the Geological Succession of Organic Beings." To the younger men, on the other hand, these chapters were a luminous revelation. I shall never forget their influence on myself. They gave me a new key to unlock the history recorded in the rocky crust of the globe. They linked together Stratigraphy and Palæontology in the most masterly way, making each of them explanatory of the other, and confirming the doctrine of Evolution more clearly than ever.

The bearing of the "Origin of Species" on social questions was more promptly recognised abroad than at home. Thus, in the first number of Nature, it was stated that when the Austrian Reichsrath, after the disastrous war with Prussia, assembled in December, 1866, to deliberate on the best means of re-consolidating the prostrate empire, a distinguished member of the Upper Chamber, Prof. Rokitansky, began a great speech with this sentence: "The question we have first to consider is, 'Is Charles Darwin right or no?'" Such phrases as "the struggle for existence" and "the survival of the fittest" have not only become household words, but they have been brought into the domain of social relations and of the physical improvement of mankind. Foremost among those who have insisted on the vital importance of these subjects to human society was Darwin's cousin, Sir Francis Galton, to whose writings and persistent advocacy the new study of Eugenics owes its existence.

In one important branch of research Britain has always taken a foremost place. Geographical exploration, where it can be undertaken by the Navy, has long been a favourite task with our Admiralty. The earlier expeditions were mainly intended for geographical discovery. Those of the last fifty years have been in increasing measure devoted to scientific observations in magnetism, meteorology, oceanography, and natural history. A new type of equipment has thus arisen, in which each vessel becomes a kind of floating workshop of laboratories, microscope rooms, photographic chambers, and all the other requirements of physical and biological science. It was the naturalists who asked for State assistance in the exploration of the ocean, its temperature, currents, depths, and living things. In 1868 they succeeded in obtaining from the Admiralty the services of the *Lightning*, and two years later of the *Porcupine*. These tentative missions brought to light so much fresh information and raised so many new problems that, in response to a loud appeal from the scientific world, the *Challenger* was prepared on a more complete and elaborated scale, fitted with every kind of appliance, and furnished with a company of skilled investigators, under the leading of a distinguished naturalist. For the first time in the history of exploration the globe was circumnavigated during four years (1872–76), not for the discovery of new lands, but for an investigation of the oceans from their surface waters to their utmost depths. Splendid in its conception and admirable in its achievement, this great expedition laid a solid foundation for the new department of science which has now been named Oceanography. And the fifty quarto volumes in which its labours and results are recorded form a noble monument of successful research.

Since that time the problems of the Antarctic regions have been attacked by several expeditions. The two brave adventures of Capt. Scott and his associates in 1901 and 1910, amply supported by the Admiralty, were meant not merely for the increase of geographical knowledge, but were fitted out with all the needful appliances for observations of the magnetism, meteorology, geology, and zoology of the area around the South Pole. They have added much to our knowledge of Nature in that region of the globe.

If, now, we cast our eyes towards the future, the prospect for British science is eminently encouraging. The opportunities for research and experiment were never before so ample, the co-operation of the State never so cordial, the ranks of the investigators never so full, and the joy and enthusiasm for investigation never more ardent. For years to come this prosperity ought to continue and increase. But unquestionably in the distance a cloud may be discerned, which has long been in sight, but is now much nearer. Our present great source of power is coal, but at a not very remote date our coal-fields will be exhausted. If before that time some other source is not discovered, our position as a great manufacturing country will be seriously affected. Hopes have been raised on the possibility of finding large supplies of mineral oil in our islands. It is well known that in one or two places oil has long been coming to the surface in small quantities. It is possible that these indications may point to larger supplies below. But we are still so ignorant of the distribution of the oil within the earth that no confident prognostications are warranted. Much misunderstanding still exists on this subject. There can be now no doubt that the oil found so abundantly in some regions has no connection with coal-fields or with any deposits of organic origin, but comes from a depth probably below all the stratified part of the terrestrial crust. The most probable explanation of its origin is that it results from the decomposition of carbides forming part of the original constitution of the globe. These carbides, or compounds of carbon with some metal, such as iron, are decomposable by water and then give rise to the production of hydrocarbons, such as mineral oil and marsh gas. If water descending from the surface through the upper crust should reach those deeper-seated compounds, this decomposition would take place, and the pressure of the generated gas might force the oil up the fissured crust to the surface. Only where it makes its appearance do we know for certain that there must be some oil below, but whether in quantity sufficient even to repay the cost of boring for it cannot be predicted.

But before our coal supplies are worked out, and whether or not we discover subterranean supplies of oil, we may surely hope that some of the sources of power which are now unused will be harnessed to the service of man. To the waterfalls, tides, and winds, which have long been considered, Sir Charles Parsons in 1904 suggested another possible source of power in the internal heat of the globe, and in his recent presidential address to the British Association he has returned to the subject. His proposal is to sink a bore-hole 12 miles deep, which would cost five million pounds and require about eighty-five years for its completion. With the use of a fresh source of power and an extended development of electricity, we should doubtless be able to hold our own in the competition of the nations.

It may be allowed to me to end this article on a more personal note. To the foresight, energy, and constant attention bestowed on NATURE by its founder, Sir Norman Lockyer, the world of science has been indebted during half a century for the possession of a journal which with persistent force has sustained the cause of science in this country, has been an invaluable medium for recording the progress of research and discovery, and has played a most useful part as a medium for the discussion of questions of general interest and for public intercommunication between the cultivators of science, to whom it has become indispensable. I contributed to its first number, and have often sent communications since then, and now I am proud to be asked to write a preface to this jubilee issue and to wish continued life and prosperity to my old and valued friend, the founder of the journal.

THE FOUNDATION OF BIOLOGICAL SCIENCES.

By Sir E. Ray Lankester, K.C.B., F.R.S.

When the first number of NATURE was published in November, 1869, the word "biology" had not the currency now given to it. The word had been adopted by Whewell, and was used by Treviranus and philosophical writers of the early half of last century. What is now called hypnotism was termed "electro-biology," but the extent of the great field of exploration signified by "biology" was little understood. The great event in the history of biological science occurred ten years before the appearance of the first issue of NATURE, namely, in 1859, when Darwin published his book "On the Origin of Species by Means of Natural Selection or the Preservation of Favoured Races in the Struggle for Life."

The new conception of organic phenomena brought about by Darwin's work took deep root in the ten years from 1859 to 1869, and the main lines of study necessitated by it had been boldly laid by the pioneers, chief of whom were Huxley and Hooker. One main line of work set going, and ever since continued, was the production of further evidence of the kind brought forward by Darwin and Wallace. The period was one of intense activity and movement. The Darwinian theory spread in every direction, and new evidence in its favour was accumulated by naturalists, collectors, and explorers. By a remarkable coincidence, the year 1859 was marked not alone by the publication of the "Origin of Species," but—owing to the work of Joseph Prestwich and a small group of English geologists—it is definitely distinguished as the date when the occurrence of flint implements in the gravels of the Somme was recognised as proving (as had been maintained since 1847 by M. Boucher de Perthes and denied by the French *savants*) the existence of man as a contemporary of the mammoth and the woolly rhinoceros.

When this journal started its career we had already Darwin's additional volume on the "Variation of Animals and Plants under Domestication," which was followed in 1871 by the "Descent of Man." Practically the whole scientific world (and much of the thinking world outside it) had been convinced of the truth of the doctrine of organic evolution and also of the vast antiquity of man. The evolution of man from animal ancestry, with all its consequences as to the development of the human mind, became an inevitable inference.

Elementary Biology.

By the year 1869 the triumph of the Darwinian theory was assured. In that year Huxley began his course of lectures and laboratory work on elementary biology. The class numbered about a hundred, and Huxley's three assistants were (Sir) Michael Foster, Rutherford (then professor at King's College, London, afterwards professor at Edinburgh), and myself. This course of lectures to teachers, which was given also in the following year, largely emphasised the unity of animals and plants, and it aroused great enthusiasm. Each lecture by Huxley was followed by demonstrations by his assistants in the laboratory, which lasted all day. This became the model for the courses in biology in all English-speaking countries, and formed the basis of the examinations in the University of London.

Huxley by no means sought to put forward zoology at the expense of physiology and botany. In the new laboratories at South Kensington the first course of botany dealing with the vegetable kingdom as a whole, and not, as heretofore, merely with flowering plants, was given at Huxley's invitation by Thiselton-Dyer. It included the very complete study of lower as well as higher plants. This and the publication of the translation of Sach's "Text-book of Botany," in which Dyer was chiefly concerned, were the starting points of the rapid and remarkable development in botany in the English-speaking universities, which has continued very actively ever since. Profs. Vines and Marshall Ward and others who became leaders in botany were pupils of Dyer at that time.

About the same date, and as part of the same general movement, the development of "physiology" began, so far as this country is concerned. This name has been curiously, by sheer chance, assigned to a study which would more properly be called "organology." Originally physiology meant the study of Nature, but it has been whittled down until now it means essentially the activities of organisms. Burdon Sanderson, together with Michael Foster and Rutherford, were especially active in the introduction of the laboratory study of physiology in connection with physical measuring apparatus, such as the kymograph and other devices already in use in German and French universities. This has resulted during these fifty years in great progress in both the teaching and the understanding of physiology in every university in Great Britain and America.

In 1868 our greatest teacher of physiology in London—Prof. Sharpey, of University College—used to exhibit the mode of record by means of a kymograph by fitting a piece of paper round his tall hat and slowly rotating it on the lecture-table! There was no physiological laboratory in the place at that time.

Methods of Research.

Another great development connected with the new outburst of biology was the improvement both of the microscope itself and of methods of microscopical research. In 1870 all biological workers and teachers became convinced that the long tube and immensely complicated brass-work of English microscopes were superfluous, and that the smaller microscopes of the Continent were better suited to ordinary work. Moreover, the high powers made by Hartnack, of Paris, especially the No. 10 immersion, were found to be more suitable for work upon living and biological material generally than the equivalent powers of English makers. In Vienna in 1869 I worked with Stricker in his laboratory, and learnt from him the method of embedding in waxy materials for the purpose of section-cutting, of which he was the actual inventor. I also studied the methods which he had devised for the investigation of living protoplasm—the outwandering of white corpuscles in inflammation, movements of the large connective tissue-cells of the cornea, etc.

In 1870, owing to the connection thus established, Dr. Emmanuel Klein came to London as assistant to Burdon Sanderson, and was afterwards, by his appointment at Bartholomew's Hospital, the chief teacher of Continental methods of staining, section-cutting, and refined histology, which at once took firm root in English schools of medicine. Previous to this it was not realised in England that it was easy to watch the movements of the white corpuscles of the blood and other living cells of the animal body.

Also previous to 1870 a few individuals, such as Lockhart Clark, had in this country used the method of carmine staining for the study of such tissues as the spinal cord. But the method of hardening in various fluids, passing the sections from absolute alcohol to chloroform and ultimately to Canada balsam or Damma varnish, and so rendering them transparent, was practically unknown. But since 1870 the methods of staining and section-cutting have enormously developed in this country. English workers are especially responsible for the development of the microtome and the methods of producing long ribbons of consecutive sections, which has had an immense effect on the study of the microscopic structure of all organisms.

Embryology.

Obviously, a line of research the importance of which was greatly accentuated by the Darwinian point of view was embryology. The discovery in 1866, by Kowalevsky, of the identity in the early stages of cell arrangement in embryos of the Ascidians and Amphioxus gave an enormous impulse to the study of embryology, and raised the hope that secrets of organic relationship in plants and animals might be revealed in other cases. Indeed, Kowalevsky's great discovery may be considered to rank in biology with that of his fellow-countryman Mendeléeff in chemistry. For he showed that the study of cell development could be carried further, and laid the foundation of cellular embryology, which culminated in what is called the ascertainment of "cell-lineage." That remarkably accurate pursuit had its inception in a paper by Whitman published in the *Quarterly Journal of Microscopical Science* in 1878, and has been largely continued by Conklin and others in America.

The actual study of embryology took a new departure in this country under the influence of Frank Balfour, who published papers on the development of the Elasmobranchs, and established the origin of the notochord and the cœlomic cavity in Vertebrates as identical with that shown in Amphioxus and Ascidians by Kowalevsky. My own part in this embryological work was chiefly in regard to the Mollusca, but general conceptions were, I think, facilitated by the introduction by me of the terms "archenteron," "blastopore" (orifice of invagination by which the two-cell-layered sac, called by Haeckel the gastrula, is formed), "stomodæum," and "proctodæum" (the in-pushing of the outer layer relating respectively to the mouth and anus). The German terms "Vorderdarm" and "Hinterdarm," referring merely to the anterior and posterior ends of the alimentary canal, were not identical with my terms, which apply only to portions of ectodermal origin. The doctrine that the cœlom throughout the animal kingdom is actually or implicitly an out-growth or a series of out-growths of the archenteron was maintained by me in opposition to the views of Haeckel and Gegenbaur and others, and was finally established by the observations of Sedgwick on Peripatus. It was further proved by me that the vascular system was an organic unit entirely independent of the cœlom, and my conception of "phlebœdesis" made an end of the German misinterpretations of the body-cavities of Arthropods and Molluscs. The abundant cumulative study of embryology during these years has led to most important conceptions with regard to the relationship of various animals—*e.g.* the origin of vertebrate limbs. Present conclusions are really based on inquiries into embryological beginnings, and the whole interpretation of morphology in its embryological aspect is still in progress.

The Cell.

The study of the structure of the cell itself, and of the processes of cell division, shortly after 1869 made a very great advance. Chromosomes and their importance, and the whole subject of mitosis, became a part of our fundamental knowledge. This very naturally, in view of the importance of heredity with regard to the whole theory of organic evolution, led to the minute study of the structural facts connected with the egg- and sperm-cells, as well as fertilisation and the earliest divisions of the fertilised egg-cell to form the embryo. This study, beginning about the commencement of the period under consideration, is still actively proceeding. Whilst it seems that in the chromosome we have got very much closer to an understanding of the actual visible features relating to the phenomena of heredity, yet there are important facts in course of discovery.

Oceanic Research.

Another line which also suddenly came into activity and has been a prominent feature since 1869 is deep-sea exploration, which began with the voyage of the *Challenger*. When the first number of NATURE was published, this was having its initiation under Dr. W. B. Carpenter and Prof. Wyville Thompson, who, led by the discoveries made by those who laid the first deep-sea cables, had conceived the notion of exploring great depths of the ocean by means of the dredge. They obtained the brief loan of a warship from the Government for the purpose of their explorations. This led to the three years' voyage of the specially fitted ship *Challenger* and its staff of scientific experts, and the publication afterwards of a magnificent series of reports. This example of the *Challenger* has been followed by every country, and valuable explorations of the ocean—oceanographical research as it is called—has become an established branch of scientific inquiry.

A complement of the pursuit of oceanography by means of ships and apparatus for deep-sea dredging has been the establishment of zoological laboratories in specially suitable localities on the seashore. The one organised on an international basis by Dr. Anton Dohrn was the first to become widely known and useful, although the French naturalists had some years before this founded marine laboratories—Coste at Concarneau and Lacaze-Duthiers at Roscoff. Now they are established everywhere.

Palaeontology.

Beginning with our starting point, and more especially connected with the founders of the Darwinian theory, there has been an immensely important and productive activity in palæontology. A large part of Huxley's scientific work consists of the thirty or more valuable memoirs on the remains of extinct fishes and reptiles published by him as naturalist of the Geological Survey. By his palæontological studies he was led to views as to the genealogical history and connection of the birds and reptiles, and also as to the special development of certain mammalian forms, such as the horse. Also at this period there developed in America an enormous activity in palæontological discovery. Up to 1869 we knew some few of the extinct animals of America through the work of Leidy. Marsh and Cope then burst upon the scene with most astonishing and valuable accounts of extinct dinosaurs, birds, and mammals. These have been followed ever since by a stream of important discoveries in which Henry Fairfield Osborn is now the leader. The stimulus of this work for the Darwinian theory and its vast importance in relation to that theory are obvious.

Pathology.

A study which has greatly developed, and has had an effect on Darwinism and been re-acted upon in turn by Darwinism, is that of the whole field of pathology. Before 1869 the germ theory and the importance of bacteria in disease had begun through Pasteur's work to be appreciated. Since then knowledge has accumulated, and the work of Lister has fundamentally altered views as to the effective nature of asepsis in the treatment of wounds. The outcome of this is an immensely increased study and knowledge of bacteria and other parasitic organisms, and also of the means of resistance to their attack.

Special importance attaches to the recognition by Metchnikoff of the function of the colourless corpuscles as scavengers in the blood and tissues—his doctrine of phagocytosis and the *rôle* of phagocytes in immunity. Perhaps most strikingly significant is his explanation of inflammation, which is now seen in the light of the Darwinian theory to be a life-preserving property of the higher organisms in which, by local arrest or slackening of the circulation, the access of phagocytes to injured and diseased tissues is facilitated.

General Retrospect.

All these developments will be found recorded in successive volumes of NATURE, in reviews of books, correspondence, and articles. In this way greater perfection of record and comprehensiveness of treatment have been attained than in any other scientific journal.

Whilst all these studies were going on, the more direct observations by the Darwinian method have been accumulating enormously. Classification and general views on morphology have been affected accordingly. Various serious attempts have been made to improve upon or to add to Darwinian theory, perhaps to its detriment. One example of this is Romanes's notion of physiological selection. Another is the attention given to the experiments and conclusions as to hybrid breeding of the Abbé Mendel. Mendel's conclusions differ but little from those contained in Darwin's own work, as was pointed out in a letter to NATURE for August 14 last, p. 463. No doubt the breeding experiments which are now carried out in the name of Mendel might equally well be performed in the name of Darwin. The importance of this work was little assisted by those interested in Mendelism, when in the early days they called it a "new science."

Within the limits of a short survey it is impossible to measure the heights of more than a few peaks of biological science, or to describe the boundaries of even a few fields of work. Others will deal with particular branches of biology, including psychology, which will be developed in the near future as the basis of anthropology, and should be to education what physiology is to medicine. Physiology itself has yet to come under the full influence of the Darwinian doctrine —"the preservation of favoured races in the struggle for life." As yet there has been no investigation of the *development* and survival of functions. It is necessary to study their evolution from simpler types and to analyse by experiment the progressive series of chemical activities involved in digestion, secretion, excretion, and so on. At present physiology is as incomplete as morphology would be if no forms below terrestrial vertebrates had been studied.

In concluding this sketch I desire to bear testimony to the valuable services in the promotion of scientific progress which NATURE has rendered throughout its existence. In the hundred and three volumes which have been published since 1869 the names of all the most active workers in the realm of natural knowledge will be found in their pages, not only in papers and books recorded and epitomised, but also as the authors of articles, letters, and other contributions. Every man of science knows the useful function performed by NATURE, and appreciates its essential importance to the vitality of the scientific organism. I am particularly glad that my friend, Sir Norman Lockyer, has lived to see the completion of the fiftieth year of the journal established by him. The high and secure position which NATURE occupies is due to the sympathetic, impartial, and honourable editorial traditions gained for it by him and still maintained. As a personal friend I cherish the recollection of association with the founder of the journal throughout the long period of its existence, and with all other scientific workers I tender him grateful congratulations for what he has done through it to stimulate the increase and application of knowledge.

SCIENCE AND THE CHURCH.

By the VEN. JAMES M. WILSON, D.D., CANON AND VICE-DEAN OF WORCESTER.

THE Editor of NATURE reminds me that in its first year of publication I was one of its contributors, and he asks me to write something for its jubilee issue. He goes on, further, to assign me a subject—"The General Attitude of the Church and the Religious Laity towards Science now compared with what it was fifty years ago"—and he limits me to "about a thousand words." It is a sufficiently large subject for, say, ten or twenty thousand, and yet I am going to double that subject by adding the words "and that of the scientific world towards the Church." I think there has been an equal change in both, and I take the latter half first.

About fifty years ago I was more at home in the scientific than in the clerical world. I was a fair mathematician; an enthusiastic, though ill-equipped, teacher of science; an observer in astronomy; on the council of the Royal Astronomical Society; and associated with Huxley and Tyndall in a small British Association Committee on teaching science in schools. They were among my friends. I had also many friends among the rank and file of men of science. Such are my credentials to speak of the attitude at that time of men of the scientific world to the Church.

That world, impressed and dazzled as it was by the vast extension of the sphere of the natural —that is, of what was sure to recur in like physical circumstances—felt, speaking generally, that "the Church," which insisted on the supernatural, was *ipso facto* an upholder of error and superstition, an enemy to truth. They were out to sweep the Christian faith away. It might hold out, they thought, for a few decades in obscure circles, but its time had come. They were as cocksure and contemptuous of believers in the supernatural as were the Germans of the English in 1914. I am speaking generally, and chiefly of the smaller fry and hangers-on. But some of the leaders occasionally showed the same tone.

The attitude of men like Huxley, Adams, Stokes, H. J. S. Smith, Asa Gray, Salmon, Maxwell, and others was very different. They never wavered in their sense of the duty of setting truth first, and of the value of knowledge. They saw and welcomed the setting far back the traditional boundary between the natural and the supernatural. But they stopped there. They felt the presence of the unknown, and humbly suspended their judgment, conscious of limitations. Tyndall and his admiring school seemed to feel no such limitations. I remember talking with him at his house on the Bel Alp one glorious evening. He gave some two or three of us a brilliant monologue on his doorstep. But that universe of stars and snow-peaks was to him a magnificent field of exercise of atomic forces. Further knowledge, he doubted not, would establish the fact that we also, with our mental faculties, were only items in the same field, products of the same forces.

Such was the impression given of their beliefs by the dominant and aggressive school of men of science of that time—that freedom in spiritual life, and therefore responsibility, were illusions, though goodness was no illusion.

Insensibly a change has occurred which is not easy to define. Perhaps it may be described broadly as the discovery by that scientific world that the sphere of religion is not inherently anti-rational; that faith, like knowledge, rests ultimately on experience; that science has its sphere in the world of matter leading up to forces of unknown origin and nature; and that faith has its sphere in a world of personality leading up to a similarly unknown goal of personality: that their methods are not inconsistent; and that their goals may be identical.

There is a pregnant saying of Augustin: "Interrogate thyself, O man, and make of thyself a step to the things which are above thee." Science has of late begun to do this. Previously it had turned its face to things which are below us. Faith has ever turned its eyes to that which is above us, dim though it is, proofs of the existence of which it finds in its own mental and spiritual faculties—in the sphere of the good, the beautiful, and the true. Through that experience faith is led up to the conviction of a Personal origin of Nature, with whom it is possible for us to be in some communion.

Miss Jane E. Harrison, in her recent "Conway Memorial Lecture on Rationalism and Religious Reaction" (Watts and Co.), has laid us all under a debt by her characteristic frankness on this subject. "If you will pardon," she says, "a personal reminiscence, I should like to acknowledge my debt as a rationalist to a reviewer. Mr. Clutton-Brock, in reviewing a review of mine—I do not think he has read my book—noted, truly enough, that I always implied that religion was obsolete, and only to be examined as a curious survival of man's past. 'And,' he ended, 'it is hardly scientific to lecture on the corpse of religion when all the while religion is alive and laughing at you'! It is a staggering experience to learn anything from a reviewer. That sentence made me reel for a moment. When I recovered I determined that religion anyhow should not go on laughing at me any longer. So I turned to the study of modern developments, and I confess the result has in some ways surprised me."

This is an illuminating statement.

There has been also, during the last fifty years, a corresponding change in the attitude of religious faith towards science. The following points strike me as the most obvious.

First, the clergy and the educated laity have lost their fear that the predictions of the science of fifty years ago would be verified, and that we should find ourselves in a world of determinism and materialism.

Secondly, the younger generation of both clergy and laity take it as a matter of course that science has helped faith to extricate itself from many crude mythological forms in which its exponents in pre-scientific days expressed their beliefs. Science has shattered some of our idols, and we are grateful, and shall be more grateful as the years pass.

Thirdly, all Christians value highly the enormous extension of knowledge of the works of God due to scientific labour and genius. Moreover, not a few would like to say emphatically that the disinterested search after truth, which is the very soul of science, is in itself a worship of the God of truth. It is faith. It is a religion. It is a consecration.

Lastly, the ordered reason and method which have won such conquests in the physical world, and revealed fresh sources of power, have helped religious thinkers to see an inexhaustible source of spiritual power in that conception of the divine indwelling life which leads, not to the quietism and the static passivity of Pantheism, or to a selfish individualism, but to ever-hopeful and ever-fruitful activities for the common good of men.

May we not in conclusion say that the human and spiritual energies which in the past have created religion and science have now begun to see that they can work as independent allies, urged by a common motive, which one of the two would describe as the elevation of humanity in the scale of being, and the other would call seeking the kingdom of God?

THE EXPANSION OF GEOLOGY.

By Prof. T. G. Bonney, F.R.S.

IN the fifty years since this journal began, the progress in geology has kept pace with that of the other natural sciences. In regard to them, in an article contributed to the first volume, I wrote of what had been done and what yet required to be done for their study in Cambridge, where I was then resident, and whither I have since returned. The changes may almost be called a transformation. The museums and laboratories, though the supply is not yet quite equal to the demand, far surpass what we desired in those early days, and the class-list of the Natural Sciences Tripos, instead of containing about a dozen names, had risen before the war to fully 130. The same is true of the other older universities, while more than as many, non-existent fifty years ago, are now busily engaged in educating natural science students.

But to refer to geology only. In 1869 even the geography of considerable regions on the earth's surface was unknown. There were large areas in Africa, away from the coasts, where only here and there had a traveller passed. Hundreds of square miles about the North and South Poles were blanks upon the maps. With the exception of Western Europe, North America east of the Rocky Mountains, some portions of Asia, and a little of Australia, geological knowledge was very limited. Now careful surveys have been made far beyond the original boundaries, and it is not too much to say that a general idea has been obtained of the geology of the earth as a whole, for, in addition to exploration of its surface, deep-sea sounding has revealed the nature of the deposits now forming on the ocean floor.

The advances in stratigraphical knowledge have told on every branch of geology, but especially on palæontology. Much valuable work had no doubt been done by 1869 on the Corals, the Echinoderms, the Crustaceans, the Brachiopods, the Molluscs, and the Vertebrates, but great discoveries have been made, particularly in regard to the last. The work on them, begun by Cuvier and carried on by Owen, has now been extended to most parts of the globe. Even so near as Belgium, the buried ravines of Bernissart have yielded up whole skeletons of the Iguanodon; the more central parts of North America show that, when the Rocky Mountains had partly begun to rise, reptiles, stranger in form and vaster in bulk than the founders of palæontology had imagined, haunted their swamps, and lakes, and rivers. Cope and Marsh, fifty years ago, were only beginning their work. Such giant reptiles as Brontosaurus; Atlantosaurus; Diplodocus, with its inordinately long neck and tail; Stegosaurus, with its strangely serrate back; and Triceratops, with its horned and armoured head, have all been reconstructed. Some century and a half ago a forerunner of the sea-serpent had been discovered at Maestricht, but the list of Mosasauroid reptiles has been much augmented from the inhabitants of the inland seas of late Cretaceous age near the Rocky Mountains of the present day. Dentigerous birds, and the Archæopteryx, half-bird, half-reptile, have been discovered, and some of the earliest Tertiary mammals, again more especially in Central North America, are no less weird in shape than the above-mentioned reptiles.

Since the publication of the "Origin of Species," which antedated that of NATURE by ten years, scientific palæontology may almost be said to have been born. Missing links in the chain of living creatures have been found, gaps in knowledge have been filled in, difficulties which raised opposition from not a few good naturalists have been removed; evolution has passed from the stage of hypothesis to that of theory, and extended from natural history to other branches of science and into yet wider fields. The pedigree of not a few forms of life has been constructed, so that "zoning" by fossils has greatly aided the stratigrapher, and the zoologist finds it possible in many cases to retrace the steps of that pedigree until, in this tree of life, the twigs are followed down into the branches, and the branches to the primary stems, though, notwithstanding recent discoveries in regard to the fauna of early Cambrian times, not a few pages have disappeared from the history of life, especially in its opening chapter. Discovery is now proceeding with quickened pace in the history of plant life, so that when NATURE celebrates its centenary the zoology and botany of the world will undoubtedly be understood far more completely than they are at the present day.

In 1869 petrology was at a low ebb. Macculloch and De la Beche had done what was possible without the microscope, but the great majority of field-workers remained well contented if they could recognise the commoner igneous rocks and vaguely identify the metamorphic. Clifton Sorby, by applying the microscope to petrological study, had pointed out, nearly twenty years before 1869, the way to success, but had attracted very few followers, so that even our official surveyors did more to retard than to advance this branch of geology, while in regard to metamorphism the wildest ideas were not seldom proclaimed. Light gradually dawned, misconception after misconception was dispelled, until in 1883 Prof. Lapworth made the great forward step in this branch of the subject by discovering the "Secret of the Highlands." Petrology now claims dozens of students, busily engaged in clearing up the difficulties and solving the puzzles of this or that region, and the study of rocks has become as truly scientific as that of palæontology.

The value of geology for economic purposes has been increasingly recognised during the last fifty years, though for no small part of that time the so-called "practical man" was accustomed to make light of it. By the middle of last century the importance of some knowledge of stratigraphy was beginning to be generally realised in regard to coal-mining; yet cases sometimes occurred such as making boreholes in search of that material in hopeless places, or carrying a shaft down into the Wenlock Limestone in the hope of striking a valuable seam, which, as the result of an unconformity, had never been deposited. Much information, however, has been obtained about underground stratigraphy by some of these borings for minerals or for water, even when they proved fruitless in themselves. Shafts also for coal and for metals have been carried to much greater depths than formerly, one or two even going down to as much as 5000 ft. below the surface. But the late war repeatedly proved the practical value of a good knowledge of geology, in the cutting of deep trenches, in driving tunnels, mines, and counter-mines, and in constructing underground shell-proof shelters, so that we may now reasonably hope that our military and political authorities will recognise the importance of geology as a subject of education.

This increase of knowledge is not without its attendant drawbacks. The microscopic study of rocks and minerals, the minute observance of the variations in closely allied species, the distinction of geological areas, tend to foster specialism. In the present age the emergence of men like Darwin, Hooker, and Huxley, men with far-reaching views and wide outlook, who make great forward steps, has become increasingly difficult, while the literature of all the subjects, though it aids, also lays a heavy burden on the student. Much time has often to be spent in searching through many volumes, for fear of overlooking some fact which may have an important bearing on a special investigation; in short, there is sometimes a great danger in being unable to "see the wood for the trees." But we may hope that these obstacles will in due time be overcome, and details be regarded in their right relation to principles.

THE NEW BIRTH OF MEDICINE.[1]

By Sir T. Clifford Allbutt, K.C.B., F.R.S.

WITHIN the period of fifty years during which NATURE has been published, medicine has undergone a revolution. It has become enlarged from an art of observation and empiricism to an applied science founded upon research; from a craft of tradition and sagacity to an applied science of analysis and law; from a descriptive code of surface phenomena to the discovery of deeper affinities; from a set of rules and axioms of quality to measurements of quantity. When I turn back to the medical text-books of my pupilage, to the wise and scholarly Watson or the respectable Alison, and contrast them with the text-books of to-day, I marvel that a change so vast, so profound, so revolutionary, should have come about in one lifetime! Many a generation had to pass before Harvey's researches established animal mechanics; many again before the half-lights on animal heat of Willis, Mayow, and Boyle were brought to quantitative verifications.

In medicine, observation cannot carry very far—not so far, let us say, as in astronomy; while skill and sagacity, if they do not die with the individual, keep in the axioms and exercises of the school but a transitory life. No observation of a thunderstorm could unravel its affinities to the action of a loadstone on a scrap of iron; no observation on diet could reveal the relation of food protein, by way of the amino-acids, to the tissues; no observation bestowed on scurvy or beri-beri could detect the occult and elusive but all-potent influence of the vitamines; no observation of secretory and muscular action could reveal the play of surface-tension in muscular contraction, or its relations to lactic acid and oxygen. By what sagacity could the shrewdest observer, let us say of heart disease, perceive the likeness of the formations of a soap bubble, or a raindrop, to the contraction of a muscle-fibre in terms of its length; or that muscular contraction is not so much a chemical as a physical system with a negative temperature coefficient? Again, the relation of sexual hormones to the development of men and women, and to the phases of their respective organs of reproduction, is an issue of the academic laboratory. The prodigious harvest medicine has reaped in the recent operations of war was derived from the original researches of a chemist into the occult causes and laws of fermentation by microbes, and from a field apparently so alien as of the silkworm disease.

One of the main lessons of our history has been that, in neglect of research into truths below the surface, medicine, for lack of a deeper anchorage, has always sunk back into empiricism and routine.

Research is the salt of the most practical training; it cannot begin too soon; it is the light of the wisdom of the man, of the mind of the boy, of the heart of the child. Education has lingered on Hellenistic and scholastic ways, on the systems of abstract notions unvexed by verification, so long that the hard-shell practical man is still occupied by the notions of antiquated theory and the phrases of a dead or moribund nosology. The

[1] Abstracted from an address by the author to the Scientific Meeting of the British Medical Association in April, 1919.

majority of medical men have to work upon the store of scientific ideas and facts with which they set out in practice; onwards they may gain in adaptiveness and technical facility, but can dig little deeper into the strata of knowledge; but for the modern academic spirit this would spell, as in our history it has spelled, stagnation.

Physics and Medicine.

Let us glance, however hastily, towards some of the fields in which new knowledge has been gained. In the venerable study of anatomy in its static aspects the student has long been taught the value of precision; but the recent tide of anatomical study towards its dynamic aspects, as by the work of Sherrington and Head, is bringing in new currents, not of theory only, but also of practice. Of other casements opening upon new visions of medicine that from the chambers of physics is perhaps the most arresting, at any rate at present. How fascinating, in their application to pathology, are the principles of osmosis with its curious reversals, of surface action and adsorption, of electrolytic differentials and electric methods of taking quantitative measurements, of mechanical pressures in the circulation of body fluids and, in the heart, as measured and graphically delineated by Hales, Ludwig, Gaskell, and Mackenzie, of the behaviour of fluid veins, and of the relative diameters, normal or variable, of the cardiac chambers and their main outlets. I need not do more than allude to the recent work on the CO_2 tension in the pulmonary alveoli, and to its immediately practical bearing on so-called acidosis, on the treatment of persons gassed in military or civil operations, and so forth.

By physics again we are shown, especially in plants, how in life the less complex molecules, working not only in planes below those in which the higher functions are developed, but also upwards by pacific penetration, moderate where they do not command. How instantly such researches as these must govern the practice of medicine we perceive, for example, in the gum-saline treatment of surgical shock. It would seem indeed that some of the most mysterious phases of immunity and anaphylaxis, of phagocytosis, as also of narcotism, may depend, at any rate in great part, on surface action; and that the behaviour of lipoids released from disintegrating proteins may lower surface energy, as in the retention of water in renal dropsy; or again in a different field may determine the touch or the permeability of synaptic neurons. These, and such physical laws, as they are revealed to us, teach that the multiplication and co-ordination of surfaces, let alone their chemistry, are operations which do not arise in mere mixtures of the same ingredients. So far it seems as if all biological reactions were determined by physico-chemical laws—that is, by molecular structure. The laws of selective absorption, as revealed in incandescent vapours, might throw some light upon those of biology; for in both fields we have to study vibration of molecular systems in unison, harmony, or discord.

When we rise from physics into systems of biological activity two conceptions especially strike us as new and marvellous; namely, those of the colloids and the cell. But throughout these systems we shall find the physical phases, if no longer constructively dominant, yet still active and effectual. We cannot even guess at the links of these chains where physics recedes and biochemistry takes the lead. The mere size of the molecules now concerned alters their relation to the spaces in or about which they move; not only so, but in organic compounds a mere change of position of a radical profoundly alters the properties of the compound and leads to manifold changes of function.

Often, moreover, these changes, as in the cases of immunity and susceptibility, do not vary gradually, but by leaps and bounds, as flames respond to musical scales of vibration. Thus great diversities, contrasts, and strange conjunctions of morbid phenomena do not necessarily signify great divergence of nature in the morbific agents; so that again we cannot get very far by grouping phenomena by direct observation. Processes outwardly disparate may be alike at the core. A small and latent change of chemical constitution may turn a benignant into a virulent substance, and conversely; as we may see in such substances as cacodylic acid and the cyanides, or as saliva, serpent's poison, and trypsin; and so forth. On a small deviation in a secretion we may be destroyed by those of our own household.

How far are hormones a particular category, how far universals? Do they differ in nature from other secretions, enzymes, antisubstances, and so on? Do they by their interactions, compensations, and inhibitions cover the ground of concerted chemical action in kind, as the nervous system does in time; or are they few and peculiar to certain limited needs? Whether inhibitory or stimulatory may often depend rather upon the term of the series to which the hormone is applied than to a difference in quality. Merely to glance at such questions as these reveals to us how vast is the realm of knowledge yet unconquered, nay undiscovered—

> . . . mazes intricate,
> Eccentric, intervolved, yet regular
> Then most when most irregular they seem.

A very interesting transition from physics to chemical biology is found in the phenomena of catalysis. By some elusive property certain inorganic substances—spongy platinum, for example, or manganese dioxide—themselves unaltered, exercise an accelerating influence upon chemical change; properties which are utilised to-day on an enormous scale in industrial processes. Now by our increasing knowledge of biochemistry we perceive that the function of which the inorganic catalyst is a simple case is manifested also in more complex orders by certain enzymes, or colloidal catalysts, upon which depends in great part the sweep of our health and of our diseases. In these enzymes which accelerate metabolism we may admire again, as in the simpler catalysts, the exquisite economy of energy in vital processes; how small the energy transactions may be, and these often reversible, which may compass great ends. A striking example of such economy is now being demonstrated to us in the calculated balances of voluntary muscular activity. The minute quantities of vitamine suggest that they, too, are catalysts, and function without much waste.

Diet and Nutrition.

During the last half-century the subject of dietetics has been strictly analysed on quantitative lines, and its energies calculated in caloric and other units. Yet even herein our attainment is far from complete. About this well-worn, almost hackneyed subject a breeze of new and far-reaching ideas is gathering. Our balances, as in the children's milk, and in the analysis of the diseases of deficiency, are eluded by imponderables, by the infinitely little; our quantities are set at naught. For health and disease the new vitamines to which I have alluded, like some other hormonic and enzymic imponderables, are as potent as they are intangible. Hormones work in infinitesimal ranks; and I believe no antibody has as yet been isolated. Once more we find that Nature laughs at our formal categories, at our several compartments of protein as such, of carbohydrates as such; a straitlaced reckoning. No one class of foods, it appears, will build or burn without another; carbohydrate metabolism leans on that of protein, the protein on carbohydrates, and all these on the fats, in mutual function; each of these is engaged in the totality of the chemical changes. For instance, deficient carbohydrate means deficient oxygenation of fats, and imperfect protein distribution.

Nor is this all; some of our great ancestors, likewise having penetrating ideas of the infinitely little, supposed that the sources of nutrition must contain a supply to each and every living tissue of its own form of minute identical elements; be they of bone, of muscle, of blood, of "nerve," and so forth, each being proper to its particular tissue, to which it attaches itself (Homœomerism). This crude notion, it is true, made no great way; still until lately we have all of us supposed some, if a more general, congruity of form between the nutritive elements and the qualities of their various destinations. But the study of the reduction of foods to amino-acids, and issues of like researches, are telling us to-day that there is no necessity even for the food proteins to be of similar constitution to the tissues which they subserve. To the almost magical part played by certain elements, such as calcium, as stabilisers, or of the alkali-metals as labilisers of equilibrium I need but allude. The bearings of these dietetic researches upon practice, for example in the treatment of diabetes, are too obvious for reiteration.

If we turn now to the cell, as described to us by Virchow, we realise that our knowledge of this tiny microcosm is as yet only beginning. The infinity of extension is not strange to us, for some of it we can see; but the infinity of the universe of the little, which far escapes even our microscopes, does not so strike the imagination. Still, even of this inward universe and its intense activities, as by present research they emerge into the field of the mathematical physicist, of the spectroscopist, of the radiologist, of the physical chemist, we are beginning to conceive something. The microcosm is no longer Man, but the cell of which he is built. To our wonder we see that, even within such tiny spheres, some of them filtrable, are multiple systems moving in relative independence of each other. The cell membrane is formed chiefly perhaps by the physical processes we have considered. Yet puzzling and intricate as these reactions are, they are all-important to the physician; as, for instance, in the relations of the glomerular epithelium to sugars; its unerring discrimination between substances, even isomeric, in the blood, as between glucose and lactose; or again in the constant and subtle opposition of the normal intestinal epithelium to the entrance of poisonous elements, or foreign proteins, into the vessels and tissues.

For the Future?

This rapid glance over a small part of the field of the medical sciences may serve to reinforce the lesson of their profound and instant bearing upon practice, and the need for linking up the laboratory with the wards. Only by disinterested research on the large patient and prophetic lines of the pure sciences can progress be made. The isolated academic worker, as well as the practitioner, loses by this isolation; he loses the spontaneous outcrops of problems and crucial instances which so often spring up in practice, but fail to show themselves in the laboratory. So complete and mischievous, however, has been the barrier between research and the industry of medicine that a reaction from "laboratorism" to symptomatology has set in, because there are no intermediary workers—no engineers—between the knowledge getters and the knowledge dealers. Thus we have laboratory investigators completely out of touch with practice, and practitioners faithless of theoretical principles—just "Philistines."

As the engineer is something of a mathematician, something of a physicist, so the professor of medicine must be something of a physicist, something of a biochemist. Through these middlemen the man of science and the practitioner should mutually feed each other. In every adequate clinical school, then, there must be a *professoriate*; whole time—or nearly whole time—professors, each with his technical laboratory, biochemical and pathological, who with their assistant staffs shall be engaged continually in irrigating our profession from the springs of the pure sciences.

DEVELOPMENTS OF PHYSIOLOGY.

By Sir Edward Sharpey Schafer, F.R.S.

MOST of the fundamental facts of physiology had been discovered before 1869, but nearly all the progress in the nineteenth century up to that time was made in France and Germany; and those who wished to learn the subject properly had perforce to seek instruction abroad—a condition of affairs which is fortunately in great measure now reversed. During the sixties of last century physiology had ceased to exist as an active science in this country. There were no laboratories, and no systematic investigations of a physiological character were carried on. The men who professed the subject in our medical schools were physicians or surgeons who were switched on to it as it came to their turn, and imparted to their hearers such knowledge as they might have acquired from books, but were themselves ignorant of the methods and aims of the science they were appointed to teach.

There was, however, one notable exception in William Sharpey, who was called from Edinburgh to fill the newly-constituted chair of general anatomy and physiology in University College, London, in 1836, and retained it until 1874. Sharpey, although a great teacher, was not really a physiologist. His training was wholly that of an anatomist, and his teaching was largely anatomical. Of the physiology he taught very little was acquired as the result of personal investigations, and his knowledge of the methods employed in modern physiology was nil. But he had clear ideas regarding the principles of the science, and an extraordinary facility for imparting his ideas and for interesting his hearers in them, so that when the opportunity came for learning the methods they were in an advantageous position to pursue the subject.

It was a pupil of Sharpey—Michael Foster—who founded the famous school of physiology at Cambridge, and it was through Sharpey's influence that Burdon Sanderson was induced to give up the practice of medicine in order to install the practical teaching of physiology in London. These were the pioneers, and their influence gradually spread, so that before very long England succeeded in again taking a foremost place in a science which may be said to have had its birth in our country, for before the immortal discovery of Harvey no true physiology was possible.

The development of the science during the last fifty years has occurred partly along the old lines, which have been thrust forward far in advance of the position they occupied half a century ago, partly on new lines which were at that time not only untraced, but even unthought of. The immense progress on the old lines of investigation is evident whatever be the branch of the science to which we may turn our attention. This progress is actively correlated with the parallel development of the sciences upon which physiology is based—physics and chemistry. More than all, perhaps, has physical chemistry—a branch of science which, if already born fifty years ago, had at any rate not been baptised—enabled the physiologist to see—if still very dimly—into the processes which make up life itself further than could ever have been dreamed of in those distant days.

To give an account of the progress which has been made on the old lines of investigation would occupy a large volume; the shortest description would take many pages. Fifty years ago nothing was known of the constitution of the proteins or of the manner in which they are built up into the tissues. The mode of action of the heart and the factors which regulate circulation and respiration were still obscure. The localisation of functions in the brain had not been discovered. The important changes which cells undergo in the performance of their functions and in multiplication were unknown. The relation of the sympathetic to the rest of the nervous system was in no way understood. But perhaps the most striking fact which has come out as the result of modern investigation is the dominant action of the central nervous system upon all physiological processes. Not that this is entirely new; it was undoubtedly indicated before the period with which we are dealing. But the paths and manner of its action have been so thoroughly studied, and the accumulation of evidence regarding it has become so great, that one may fairly look upon this as the most important development of physiology along the lines it was pursuing some fifty years since. That this advance has been assisted by the remarkable conception of the structure of the nervous system, which we owe in the first instance to an anatomist—Golgi—is willingly conceded, for it must be admitted that our understanding of the mode of action of the nervous system has become vastly simplified thereby.

The new lines on which the science has undergone development within the period with which we are dealing relate to the influence of chemical agencies in regulating the functions of the body. New lines, do I say? Nothing under the sun is ever entirely new. From the earliest times with which history deals, and doubtless even in prehistoric days, it was known that the functions of the body are affected by chemical agencies. For have not drugs, many of them of a potent, not to say poisonous, nature, been administered from time immemorial? Was it not known that the chemical condition of the circulating fluid influences the functions of some organs; that an excess of CO_2 in the blood affects respiration, an excess of sugar the kidneys; whilst any alteration in its constitution or reaction is liable to have a deleterious action on the body, and may produce fatal effects? For all that, fifty years ago no one suspected that the body itself produces drugs destined to influence its own functions, that certain organs pass chemical substances (chemical messengers, as they have appropriately been termed) into the blood to affect distant parts, and that many functions of the organism are regulated by these chemical agents and self-formed drugs, sometimes in conjunction with the nervous system, sometimes to the exclusion of its action.

The discovery of these internally formed drugs has led to the development of a new branch of physiology to which the term "endocrinology," or physiology of the internally secreting glands, has been applied. Fifty years ago the pituitary body, the thyroid gland, and the suprarenal capsules were mere names. Little was known of their structure, nothing of their functions. The account which we are now able to give of these organs reads like a fairy-tale. That one of the smallest should by its secretion be able to influence the growth and stature of the body, rendering this man a giant, that man a dwarf; that another should produce a material without which the nervous system is not in a condition to perform its functions; that yet others should elaborate materials which when discharged into the blood exercise a profound influence upon the activity of totally distinct and distant organs of the body, are secrets of Nature which were unrevealed fifty years ago, although now amongst the commonplaces of physiological instruction.

The individuals who have been responsible for these advances—whether on the old or on the new lines—are too numerous even to be mentioned here; those who most deserve such mention would indeed be the last to desire it. But History will carve their names on the monument they have joined in erecting, and Science, no less mindful of her votaries than Religion of hers, will not fail to reward their services with the grateful encomium: Εὖ, δοῦλε ἀγαθὲ καὶ πιστέ.

THE MODERN SCIENCE OF PSYCHOLOGY.

THE progress made by psychology since 1869 may be justly described as unparalleled. In that year the subject had no laboratories, and it was regarded as a matter of philosophical study. To-day a psychological laboratory exists in nearly every important university, and psychology has become recognised as the youngest recruit to the natural sciences—the natural science of mental processes.

The modern science of psychology, while admitting the great value of the older purely introspective psychology of the philosophers (represented in this country by the writings of Ward and Stout), realises its dangers and its inadequacy, and seeks to remove it from all metaphysical implications and to study mental processes under known variable conditions. From experimental psychology, thus established, have arisen the sub-sciences of (i) physiological psychology, in which the relation of mental to nervous processes is investigated, (ii) animal psychology, which studies the relation of animal to human mentality and behaviour, and (iii) individual and racial psychology, which determines the mental differences between different individuals and races of mankind.

There have also developed various "applied" psychological sub-sciences—*e.g.* (iv) educational psychology, the results of research in which are now taught to teachers in their period of training; (v) social psychology, which includes the psychology of religion and other social institutions and characteristics; (vi) abnormal psychology, which forms a subject of examination for the post-graduate diploma in psychological medicine now established in the Universities of Cambridge, Edinburgh, Manchester, and elsewhere; (vii) industrial psychology, which is concerned in discovering the best conditions for the highest mental efficiency of the workers, in connection with which applications for the services of psychologically trained investigators are now coming from pioneer industrial and commercial firms; (viii) the psychology of æsthetics, in which laboratory investigations of importance for art have been published in this country and elsewhere. Particularly in America, but also in Germany, many special journals have arisen devoted respectively to the psychology of education, abnormal psychology, individual psychology, animal psychology, industrial psychology, the psychology of evidence, etc. In this country we have the British Psychological Society, consisting of about 500 members, and publishing the *British Journal of Psychology*.

Fechner, who worked at Göttingen, and Wundt, of Leipzig, who in the 'seventies established the first psychological laboratory, may be reckoned the fathers of experimental psychology. Fechner was the first to formulate the psychophysical methods, a thorough grounding in which is indispensable for the avoidance of the many pitfalls of psychological experiment. To Wundt or to his pupils (especially Külpe) flocked students from other parts of Europe, and notably from America, who sought to be trained in the principles of the science. But in Italy, Austria, and Russia experimental psychology has attracted few workers. In Switzerland it has followed the

French guidance of Ribot and Janet, who laid the foundations of our modern conceptions of the disorders of memory and personality, and of Binet, who was among the first systematically to study individual mental differences and to devise tests of mental ability.

In the United States, under the influence of Stanley Hall and Titchener, and in Scandinavia, the German tradition was at first faithfully upheld. Most American, like most German, psychologists had their earlier training in philosophy, and the work published generally followed along German lines, consisting often in "maiden" papers written by candidates for the doctorate of philosophy. In this country, especially through the influence of Rivers, who went to Cambridge in the early 'nineties at the invitation of Michael Foster as lecturer in the physiology of the sense-organs, experimental psychology has developed on rather different lines. It has seldom received more than lukewarm support from philosophy, and it has been taken up by maturer workers, fewer in number, who in several instances came to it from physiology and medicine. Thus, Rivers and MacDougall began their psychological work on vision, and Myers on hearing, while later Spearman, who had graduated under Wundt, specialised in the correlation of mental abilities. In this country scientific psychology has never suffered, as in America, from the dangers of excessive popularity. Here stress came to be laid on one or other of the aspects of comparative psychology, rather than on the pure experimental psychology of the German laboratory. For it was quickly recognised that the mental differences found under different experimental conditions in any given individual are generally less in degree and less in significance than those observed under the same conditions in different individuals. True, both in England and in Germany there have been important investigations carried out upon the effects of alcohol and other drugs on the mental processes of a given individual. But even here, as also in the striking researches of Ebbinghaus and G. E. Müller on memory, the special interest has been found to lie in the study of the behaviour of different individuals. The Cambridge Anthropological Expedition to the Torres Straits, under the leadership of Haddon, which included in its *personnel* three psychologists, and the later rapid growth of the applied sciences of educational, industrial, and medical psychology, have likewise helped to stimulate the study of comparative psychology in this country.

But in Germany and in America there have also been signs of a breaking away from the initial, less fruitful (though fundamental) themes of research. Stern's work on individual psychology, following the pioneer investigations of Francis Galton in this country, and the work on animal behaviour by Jennings, Thorndike, and Yerkes in America, based on the foundations laid here by Romanes and by Lloyd Morgan, are examples in point.

The insufficiency of the older introspective psychology, whether studied in the laboratory or outside it, has since been growing more and more obvious. Watson and others have vainly sought to establish a psychology expressed merely in terms of behaviour, Loeb and Pawlow in terms of purely mechanical or physiological processes. Head and his collaborators have shown the impossibility of analysing and tracing the evolution of sensory and higher processes save by studying the effects of lesions in the peripheral nerves and the central nervous system. Freud and his foremost pupils and critics have indicated the enormous importance of the study of the emotional, instinctive, and sub-conscious processes which are inaccessible to introspective examination. Whether or not we accept Freud's views in their entirety, his work has given an enormous impetus to psychology by laying stress on the conflicts arising from rival incompatible mental (especially emotional) processes, and by indicating the different principles which Nature and the physician may employ to combat such conflicts. The published experiences of MacCurdy and others of the American Army, and of Brown, Hart, MacDougall, Myers, Pear, Rivers, Rows, and other psychologists engaged in the treatment of functional nervous and mental disorders in the British Army during the recent war, have also shown how much can be done by the early application of appropriate psycho-therapeutic methods to the cure of such disorders.

The war has likewise emphasised, both in this country and especially in America, the great value of psychological tests in the selection of candidates for the work to which they are best fitted. The importance of psychological experiment is now becoming recognised not only in regard to vocational guidance, but also in regard to industrial fatigue, the effects of different lengths and distributions of periods of work and rest, etc.

There was a time now past when in the popular view psychological research was supposed to be limited to reaction time experiments, or was confused with "psychical research" into spiritualistic phenomena. It is true that the enormous amount of labour spent in Germany on reaction time experiments promises at length useful results in the study of emotional complexes and of vocational selection. And only by the narrow-minded can psychical research be excluded from psychological science provided that it be conducted by workers systematically trained in experimental methods and freed from personal bias and prejudice. But the most promising future developments of psychology may be looked for along quite other lines, which have been already briefly indicated in the foregoing account of its present position, more especially in the study of the effects of nervous lesions and of mental and nervous disorders, and in the examination and recognition of individual mental differences.

PREVENTIVE MEDICINE SINCE 1869.

By Dr. C. J. Martin, F.R.S.

Preventive medicine is concerned with the application of knowledge to the prevention of disease. To this end all the sciences have been laid under tribute, but physiology, pathology, bacteriology, and epidemiology to the greatest extent, as these have the more immediate bearing.

The rapid progress of preventive medicine during the last half-century is due primarily to the increase of physiological and pathological knowledge, and pre-eminently to the completer understanding of the process of infection which has been acquired during this period. So long as defective development and disease were regarded as wholly constitutional or inherent in the individual, the only prospect of improvement lay in the weeding out of the unfit by the ruthless process of natural selection. A greater hopefulness has, however, arisen as the part played by prejudicial environmental conditions, such as improper feeding and housing, undue fatigue, the abuse of alcohol, and, above all, the invasion of pathogenic agents, was realised.

By the end of the 'sixties the necessity of supposing a *contagium vivum* as the cause of many diseases was fairly generally recognised. Pasteur's researches on fermentation and putrefaction had led him to the opinion that infectious diseases might be interpreted as the result of particular fermentations due to specific microbes, and it was the ambition of his life to substantiate this conception. Lister had launched his antiseptic methods on the basis of Pasteur's work, and these were already beginning to revolutionise surgical practice. Villemin had just demonstrated that tuberculous diseases, hitherto regarded as "constitutional," were due to a common infective agent capable of multiplying indefinitely in the bodies of animals and of being handed on from one animal to another by inoculation. Hitherto, however, although various microscopic organisms had been found to be associated with disease, and indications had been obtained of their ætiological significance, not one of them had been isolated. The causal relationships claimed were thus unproven and much of their life-history unknown.

The first isolation and propagation in pure culture of a pathogenic organism took place in 1876, and was accomplished by Koch in the case of a bacillus derived from cases of splenic fever or anthrax. Inoculations of cultures made *in vitro* into animals reproduced the disease. Progress in bacteriological discovery remained slow until in 1880 more appropriate methods for the isolation of bacteria were derived by Koch. Then followed a period of extraordinary fertility. Within fifteen years the causal agents of cholera, typhoid fever, diphtheria, tuberculosis, various types of suppurative processes, gas gangrene and erysipelas, glanders, gonorrhœa, pneumonia, food poisoning, meningitis, Malta fever, leprosy, and plague, as well as of a larger number of diseases of animals, were discovered.

The discovery of pathogenic agents of another kind soon followed. The association of relapsing fever with the presence of a minute motile spiral organism in the blood was observed by Obermeier in 1873. Later, a number of diseases of man and animals were found to be caused by various spirochætes, most important among them being relapsing fevers, syphilis, yaws, and infective jaundice.

In 1881 Laveran described the parasite of quartan malaria. This observation was followed by the discovery of more than a hundred microparasites belonging to the protozoa which are responsible for diseases in higher animals. The most important human diseases due to protozoan parasites are the three types of malaria, sleeping sickness, and kala azar.

Another class of pathogenic agents which is already known to be responsible for upwards of thirty separate diseases of man and animals remains to be mentioned. These viruses are either on the margin of visibility or invisible with the microscope. They are so small as to pass through biscuit porcelain. The causal agents of infantile paralysis, yellow fever, *molluscum contagiosum,* dengue fever, the three-day fever of the Mediterranean, and typhus fever belong to this category, as well as those of many important animal diseases, as rinderpest, horse sickness, and foot-and-mouth disease, and there are a number of indications that the infective agents of the common exanthemata—measles, scarlet fever, smallpox—are at some period of their life-history so small as to be included amongst the "filter-passers."

Since 1880 the ætiological factor of most human maladies has been brought to light. A correct ætiology is fundamentally necessary, but for preventive measures mere identification of the cause of a disease is not sufficient. The life-history of the parasite within and without its host, and particularly the channels and method of entrance and exit, must be known if a successful attack is to be made upon it. Indeed, some of the most striking triumphs of preventive medicine have been gained in the case of diseases in which the virus had not been seen or isolated (such as hydrophobia, yellow fever, and trench fever), but in which, nevertheless, many properties of the virus and the method whereby it effected entrance and exit had been revealed by experiment.

In the first half of the period under review researches were more particularly directed to the discovery and isolation of the causative factors of disease; the latter half, for the reasons outlined above, has been characterised by the amount of knowledge gained regarding the details of the life-history of various parasitic agencies, the maintenance of the infection in the absence of obvious cases of the malady, and the transmission of the infective agent from one individual to another.

If the infective agent is present in a superficial lesion, as in smallpox, syphilis, diphtheria, or pneumonia, or passes out with the excreta, as in cholera and typhoid fever, more or less direct transmission can occur, but in the case of a parasite situated only in the blood or internal organs it was for long a mystery how the disease was transmitted. The secret was revealed by the discoveries of Manson, Smith, and Bruce on filariasis, red-water fever, and Nagana, showing that in these diseases mosquitoes, ticks, and tsetse-flies respectively acted as transmitters. These observations were soon followed by those of Ross on the transmission by mosquitoes of malaria, and afterwards it was shown by the American Commission that yellow fever also was transmitted by a particular species of mosquito.

Relapsing fever, sleeping sickness, and bubonic plague were also found to be spread by the agency of insects; ticks or lice in the first case, a tsetse-fly in the second, and fleas in the last, and the most recent addition to the list is trench fever, which has been proved to be louse-borne.

The dependence of these maladies for their dissemination upon particular species of insects has afforded a long-looked-for explanation of their distribution—*e.g.* sleeping sickness, yellow fever, and dengue—and the very extensive investigations into the life-history of the parasites and their insect hosts has enabled the sanitarian to choose the stage in the cycle most convenient for attack. He could strike at the enemy whilst it was resident in either host or indirectly by preventing the insect from biting the patient and other individuals until in course of time the infection died out. By netting-in patients suffering from yellow fever so that mosquitoes could not attack them, and at the same time insisting on the removal of all small collections of water in the neighbourhood of habitations in which these insects were wont to lay their eggs, Gorgas rid the city of Havana of yellow fever. By a campaign on similar lines against malaria-bearing species of mosquitoes, the Isthmus of Panama was converted into a health resort. Equally satisfactory results have followed elsewhere when it has been possible to institute equally thorough measures.

Before leaving the subject of infection, I must not omit to mention that biological discoveries regarding the life-history of the parasitic worms —*e.g.* the hookworms and Bilharzia—have shown how diseases caused by this class of parasites could be successfully controlled.

It has not often been found possible to eliminate the cause of a disease. In some cases knowledge has not been sufficiently complete. In others its application has been too difficult, and it has been found impracticable sufficiently to control the lives of the population. In many such cases, however, preventive medicine has another arrow in her quiver. This is aimed at reducing the susceptibility of a population to a particular infection by protective inoculation. The earliest effort of preventive medicine along these lines was that of inoculation against smallpox practised in Asia for some centuries and introduced into England in 1721 by Lady Mary Montagu. Cutaneous inoculation of smallpox usually produces a local and comparatively mild illness, but the method suffers from the disadvantage that it propagates the virus of the disease. Jenner's vaccination with cow-pox—a modified virus—obviated this disadvantage.

With the discovery of the microbial origin of disease, Pasteur saw that the principle of Jennerian vaccination might be further exploited, and in 1881 successfully employed attenuated cultures of the microbes of splenic fever and chicken cholera to protect flocks and poultry against the depredations of these diseases.

In the case of man, the possible danger from the employment of living cultures of the germs of fatal diseases led to researches to determine whether the injection of the microbes which had been killed by heat or chemical agents also induced some measure of protection against a subsequent inoculation with living virulent organisms. By experiments on animals this was found to be the case, and the use of such bacterial "vaccines" was employed by Haffkine to protect man against cholera and plague. Shortly afterwards Wright and Semple elaborated a similar method of protective inoculation against typhoid fever. Anti-typhoid inoculation has been extensively used. The experience in the British and American Armies during the last fifteen years has been that a material reduction in the incidence of the disease has occurred amongst inoculated troops.

The greatest triumph of preventive medicine during the late war was the comparative rarity of typhoid fever amongst our troops. This was the case not only in France, but also in military operations in other areas, where the conditions were such that satisfactory hygienic measures could not be carried out. No other explanation of this freedom from enteric is forthcoming other than the periodic prophylactic inoculations to which our armies were subjected.

So far I have dealt exclusively with infection by living pathogenic agents. I make no apology for so doing, for the great developments in preventive medicine throughout the world which are characteristic of this period have been due to the impetus given by the conceptions of Pasteur and the methods of Koch.

At the same time, knowledge in all departments of physiology and pathology has steadily, though less dramatically, progressed. The increased understanding of animal nutrition must, owing to its important bearing upon the maintenance of the health of the peoples, be briefly referred to.

Before the period under review Pettenkofer and Voit had been able to strike a balance-sheet of the net in-goings and output of matter by the animal body. Within the last fifty years the applicability of the principle of conservation of energy to animals has been established by Rubner. The energy-value of the important foodstuffs has been ascertained, and the requirements of the human body under various conditions of age, climate, and occupation have been determined.

This knowledge has been inadequately exploited because everyone prefers to be a law unto himself in the matter of food intake. It has served as a basis for the rationing of armies and for the construction of institutional dietaries. During recent years, however, it has become increasingly apparent that man cannot live on protein, fat, and carbohydrate alone, but that a diet must contain in addition small quantities of what, until they can be isolated and identified, have been designated "accessory food factors." The best example of these is the for long recognised antiscorbutic substance in fresh vegetables and fruits. The existence of at least three accessory food substances has been since established. For all of these the animal is dependent directly or indirectly upon the vegetable kingdom. An insufficient supply of any one of these leads to trouble. If one of them is inadequate, scurvy results; deficiency of another leads to the disease beriberi; and if deprived of the third an animal fails to grow. There appears also to be no doubt that rickets in children is due to a similar cause.

This knowledge has for long been utilised to prevent scurvy. Where it has been intelligently applied it has eliminated beri-beri from coolie-camps, the population of jails, and industrial communities of the Far East, and if it is utilised in the efforts to feed the famished population of the unfortunate countries of Eastern Europe it will be the means of saving thousands of young lives during the ensuing winter.

Science has also been successfully applied in recent years to the diminution of the dangers incident upon certain industrial occupations, such as mining, caisson working, and deep-sea diving. During the last ten years, too, the influence of industrial fatigue, alcohol, improper atmospheric conditions in workshops, etc., upon the health and efficiency of the worker has been seriously studied. In these inquiries America has shown the greatest energy, but in Britain the subject is beginning to receive the attention its importance demands.

It is impossible to assess the effect of preventive medicine and improved hygienic surroundings upon the health and happiness of mankind; but the influence upon longevity can, in the case of civilised communities, be determined. During the last fifty years upwards of ten years have been added to the mean expectation of life of a child born in Britain or in the United States of America. An increase of 25 per cent. in so short a time is cause for congratulation, but, on the other hand, the fact that a million young men were found unfit for active service indicates that all is not well with Britain.

We are still far from the possession of sufficient knowledge to regulate satisfactorily our environment or to avoid all noxious influences, but owing to lack of power, money, or sometimes sense, we apply far less than we possess.

THE ANTIQUITY OF MAN.

BY DR. A. SMITH WOODWARD, F.R.S.

AT the beginning of the Tertiary period, when mammals began to spread widely over the world, they were all very small and so uniform in character that it is scarcely possible to classify them into groups or orders. They all had a comparatively small brain of a simple kind, and as in course of time they became gradually subdivided into the groups with which we are now familiar, the brain increased both in size and effectiveness, while many of the animals themselves grew larger. In the middle and towards the end of the earliest Tertiary (Eocene) epoch some of the low-brained hoofed mammals attained their greatest size and then became extinct. Next in the Oligocene another group with somewhat improved brain grew even larger just before extermination.

In the following Miocene epoch several groups that had by that time acquired a still more efficient brain, such as rhinoceroses, horses, certain carnivores, and primitive elephants, attained a comparatively large size and soon reached their maximum in the Pliocene. About the middle and towards the end of the Miocene epoch true apes, with a higher development of brain than any mammal up to that time had acquired, also began to grow to as large a size as most of the apes of the present day. It may therefore be predicted that the earliest remains of the largest members of the ape-series, with a truly overgrown brain—the great ground-apes which were the immediate forerunners of man—will not be found in rocks of older date than the Pliocene, and probably not in any but the latest of this epoch. For other reasons Sir William Boyd Dawkins came to the same conclusion so long ago as 1880, and as discoveries progress it becomes increasingly clear that true man, of the family Hominidæ, cannot be earlier than late Pliocene or the dawn of the Pleistocene.

So few fragments of apes and man have hitherto been met with that it is difficult to decide upon the region of the world that may be most hopefully searched. If, however, conclusions may be drawn merely from teeth, the most promising field at present seems to be south-central Asia. By the discovery of such teeth, Dr. Pilgrim has shown that a varied assemblage of apes lived in the forests of northern India in the Miocene epoch. At that time the Himalayan Mountains did not exist, and the late Joseph Barrell ingeniously suggested that it may have been during the uplift of this mountain range at the end of the Miocene and beginning of the Pliocene that primitive man originated. As the land rose, the temperature would be lowered, and some of the apes which had hitherto lived in the warm forest would be trapped to the north of the raised area. As comparatively dry plains would there take the place of forests, and as the apes could no longer migrate southwards, those that survived must have become adapted for living on the ground, and acquired carnivorous instead of frugivorous habits. By continued development of the brain and increase in bodily size, such ground-apes would tend to become man.

Unfortunately, we are still ignorant of fossils to test this hypothesis. We know from fragments of jaws, isolated teeth, and one limb bone that generalised apes as large as chimpanzees existed in Europe so far north as the latitude of Darmstadt until the end of Miocene times, but the only giant ground-ape, which many have claimed to be an ancestral man, was found by Dubois in Java in deposits of much later age which may even be Pleistocene. *Pithecanthropus erectus*, as the Javan species is named, is still known only by a cranial roof, two molar teeth, and a diseased thigh-bone, which bear many resemblances to the corresponding parts of the existing gibbon, and are tantalising in their imperfection.

It is, however, curious that almost the only traces of true man hitherto found with distinctively ape-like characteristics are from Western Europe. The imperfect skull and mandible of *Eoanthropus dawsoni* discovered by the late Charles Dawson at Piltdown, Sussex, represents a man with the lowest of all known human brains, and with an ape-like jaw in which typically human molar teeth are accompanied by large canines as completely interlocking as in any ape. The massive lower jaw of *Homo heidelbergensis* from Mauer, near Heidelberg, still retains much reminiscence of an ape in its retreating chin. The fine skeleton of Neanderthal or Mousterian man described by Prof. Marcellin Boule from La-Chapelle-aux-Saints, France, combines more ape-like features in a single individual than are known in any existing man. The Piltdown and Heidelberg fossils are shown by associated mammalian remains to date back at least to the beginning of the Pleistocene, perhaps even to the end of the Pliocene epoch. Neanderthal man is later, and is very soon followed by typical modern man.

As to the actual age of these various remains in years or centuries there has been much discussion, but it must be confessed that on present evidence only vague guesses are possible. It is true that Penck and Brückner have made some plausible suggestions as to the length of Pleistocene time based on their studies of the glaciation of the Alps. Baron de Geer has also been able to date more precisely the retreat of the Pleistocene ice-sheet in Scandinavia by counting the annual layers in the mud which its flood-waters left behind. It is impossible, however, with our present knowledge, to correlate the isolated patches of Piltdown gravel, Mauer sands, or cavern deposits with the surface phenomena of distant areas; and it is doubtful whether this difficulty will ever be overcome.

Our knowledge of the ancestry of man has, indeed, progressed much during recent years, but unfortunately it is necessary to depend on accidental discoveries. Systematic exploration seems to meet with little or no result. Mrs. Selenka made great and prolonged excavations in Java in the river-deposits whence Pithecanthropus was obtained, without any success. The great sandpit at Mauer has been continuously worked and most carefully watched since the famous jaw was discovered, but without recovering any further traces of man. I have worked hard in the Piltdown gravel, but for the last three seasons I have not found a fragment of either bone or tooth. The research needs much patience, but we may hope that as interest in the subject is more widely spread a larger proportion of the accidental finds relating to it will escape destruction.

THE PRESENT POSITION OF THE MUTATION THEORY.

By Prof. Hugo de Vries.

DARWIN assumed that species originate by the gradual accumulation of infinitesimal, ordinarily invisible variations on account of their utility in the struggle for life. The difficulties inherent in this conception have led to the theory of mutation, which supposes that the production of species and varieties proceeds by small but distinct steps, each step corresponding to one or more unit-characters. It is only after their appearance that the environment can decide about their utility.

The new theory reduced the time necessary for the evolution of organic life on earth to the limits deduced by Lord Kelvin and others from physical and astronomical data. It explained the appearance of the numerous useless qualities of animals and plants, and eliminated the objection that the first almost imperceptible changes could scarcely have any beneficial significance for their bearers. It developed the doctrine of two essential types of variability, which are now called fluctuating variability and mutability. The first of these describes the small but always present differences among individuals of the same stock, whereas the second is the way in which varieties are known to arise in horticulture and arboriculture.

Since the publication of my book on the mutation theory (1901–3) numerous instances of mutation have been observed by different investigators among animals as well as among plants. Half a dozen species of Œnothera, some types of Primula, the walnut, the sunflower, Narcissus, Antirrhinum, Ligustrum, and many other instances might be cited. Among insects Morgan and his pupils have described more than a hundred mutations from the fruit-fly, Drosophila. Other cases have been studied by Tower for Leptinotarsa, etc.

The production of new races of agricultural crops by means of continual selection constituted for Darwin one of his strongest arguments. He showed conclusively that new species and varieties are produced in Nature in the same way as agricultural novelties. But at that time the practical method was far from being clearly understood. The work of Hjalmar Nilsson and Hays has since shown that selection may be conducted according to the principle of the mutation theory, only one choice being necessary to start the whole new variety.

It is now generally conceded by mutationists that the initial change takes place in the production of the sexual cells before fecundation. From this conception it follows that the chance of two similarly mutated cells to meet one another in this process must be very small, whereas ordinarily the mutated cells will combine with normal ones. This must produce half-mutants, and these may, in ordinary cases at least, split off the full mutants after the same rules which Mendel discovered for his hybrids. Sometimes the half-mutants will be distinct from their ancestors, as in *Oenothera Lamarckiana rubrinervis* and *erythrina*, and, therefore, will easily be discovered. In other instances external differences may be absent, and only the unexpected production of a new type in about 20–25 per cent. or more of the individuals will betray the internal change. This explains the mass-mutations discovered by Bartlett. Such an indirect way of producing mutations by means of two successive steps seems to be very common in Nature, and will probably afterwards prove to be the general rule.

Willis has made an elaborate statistical study of the appearance of endemic species, which he considers to be the youngest of their region. He finds that utility of the new characters cannot have had any part in their production, since it cannot be shown to have any influence either on their first local extension or on their subsequent spreading over larger regions. Wide spreading is mainly the result of age, the oldest species having, as a rule, the largest areas. Moreover, in comparing the diagnoses of endemic species with the differences among the mutated forms of such a group as the evening primroses one finds a close parallelism, showing that our experimental mutations are quite analogous to the species-producing steps of Nature.

Objections against the mutation theory have been made by different investigators. Some systematists and palæontologists still adhere to the old view either wholly or only for special cases. Biologists rarely attack the theory in a direct way, but mainly discuss the question whether the observed mutations are really the representatives of the species producing changes in Nature, as is claimed. They assume that the splittings seen in our experiments are due to hybridism, and that every mutating species is a hybrid between supposed ancestors which possessed the mutative characters as specific marks. This idea can scarcely aid in simplifying the question, since it puts the origin of the characters involved on to unknown parents. Sterile varieties cannot produce hybrids, and therefore cannot originate in this way. This fact seems sufficient to disprove the hypothesis. In the case of the evening primroses this view has led to fantastic diagnoses of hypothetical ancestors, but even these fail to explain the facts observed in our cultures. Morgan's hypothesis of crossing over, which goes far to explain the splitting phenomena of the fruit-fly, fails in its application to the evening primroses, since here half-mutants are the rule. These must evidently be produced without the aid of that process. Moreover, the heterogamous mutants have dominant characters which are handed down by the egg-cells, and not by the pollen, instances of which are given by the mutations called *lata, scintillans, cana, liquida,* and others of *Oenothera Lamarckiana*. Evidently these can never be explained by the assumption of a hybrid condition of the parent species.

Thus we see that the broad arguments for the mutation theory are continually increasing in number, whereas the criticisms are more and more directed against special cases. They are concerned with the possibility of experimental proof and with the fitness of our material for further studies, but are not expected to invalidate the theory as such.

THE PROGRESS OF MENDELISM.

By Prof. W. Bateson, F.R.S.

FROM the discoveries to which the Mendelian clue immediately led, many lines of research and speculation are diverging. These enterprises have still aims in common, a fact which we recognise by including all under the one name, genetics; for, though various in their methods, all relate to the physiology of breeding, a department of science the growth of which is a feature of the period surveyed on this occasion.

Stocktaking at the present moment is, however, not easy. Much of the new work is in an incipient stage, and that which is the most attractive of all—namely, Morgan's effort to establish a close connection between cytological appearances and the results of experimental breeding—promising though it is, must be tried by tests on a scale far wider than experience of Drosophila provides before we are able to assess its value with confidence. Whether the theory that the factors are arranged in the chromosomes, like beads on a thread, stand or fall, it has already served the purpose of a good theory. It has fired the minds of many workers, and has directed their inquiries with manifest success. Its weakness lies first in the narrowness of the field studied, but besides this it is not yet wholly free from the objection that the subordinate and incidental hypotheses are not altogether independent of each other.

Various as are the methods of attack, the objects before us are sufficiently clear. Among them the most important is a determination of the moment or moments at which segregation may occur. To the solution of this problem most of the investigations contribute. On one hand, we have the large body of facts consistent with Morgan's view that synapsis is the critical moment. Were our outlook confined to animals, we should scarcely hesitate to accept that hypothesis as satisfying the conditions, but the plants give no such clear answer. Not only is an obvious somatic segregation leading to genetic diversity of the parts not rare, as in many variegated plants and plants which give dissimilar forms from adventitious buds, but there is now a large group in which the male and female organs of the same plant differ in the factors which they carry. Miss Saunders's stocks are the classical example, where the male side carries doubleness and cream plastid colour, whereas the ovules are mixed in these potentialities. Similar sex-linkage, as, following Miss Pellew's use, it may provisionally be called, has been shown to exist in Petunia, *Campanula carpatica, Begonia Davisii,* and in certain forms of Œnothera.

In all such examples segregation cannot be supposed to occur later than the constitution of the sexual organs. Collins's experiment, showing that in Funaria the scales surrounding the male organs by their vegetative growth give rise exclusively to male mosses, is another and very striking indication to the same effect. The genetics of "rogue" peas point to a similar conclusion in regard to the distinction between the rogues and the type from which they come. In some way not yet clear, the type-elements are wholly or partially excluded from the germ-lineage of the heterozygotes, being apparently relegated to the lower parts of the stem. Such facts raise a suspicion that, considered as genetic machines, plants may be fundamentally distinct from animals, an idea already suggested by the contrast between their modes of growth. In the animal the rudiments of the gametes are often visibly separated at an early embryonic stage, whereas in the plant they are given off from persistent growing points. Indeed, since Baur's work with variegated chimæras, which led to his brilliant interpretation of Winkler's "graft-hybrids," this possibility has inevitably been present to our minds.

In knowledge of the nature of sexual difference many very substantial advances have been made, which have much extended the original discovery that sex depends on a segregating Mendelian factor, in some forms the male, in others the female being the heterozygous member. In the fowl femaleness is dominant, and the hen is heterozygous in sex, from which Morgan drew the interesting corollary that the "henny" character of the Sebright cock is also a dominant. Not only has this been proved experimentally, but he has lately shown that after castration the Sebright cock acquires ordinary cock's plumage, much as hens do in ovarian disease. Perhaps we may regard the henny male as containing part of the large compound factor which normally constitutes femaleness. Conversely, we may interpret the spurs frequently present in normal Leghorn hens as indicating that they have lost that part of the female factor which inhibits the growth of the spur. Whether such transference involves actual detachment of chromosome material, as Morgan's theory would demand, is uncertain. Nevertheless, an approach to such evidence is provided by the extraordinarily interesting observation of Bridges of a condition which he calls non-disjunction. Certain crosses in Drosophila failed to exhibit the normal sex-limitation, and unexpected terms appeared. Bridges was able to show that in the families which behaved in this way an extra sex-chromosome sometimes occurred, carried over, as he imagines, by some error of division. Not improbably Doncaster's female-producing strains of *Abraxas grossulariata,* in which evidence of an extra chromosome was found, are an analogous case. Patterson with great probability proposes a similar explanation for the curious phenomenon which he has investigated in Copidosoma, where, by polyembryonic division of a single egg (almost certainly), males, females, and inter-sexes may result. The inter-sexes seen by Kuttner in Daphnia, and those produced by J. W. Harrison with considerable regularity in some hybrid combinations of species of Geometers, are obviously to be considered in this connection, and doubtless the sterile males, accompanied by fertile females, which Detlefsen found as the normal produce of a species cross in Cavia, will be investigated with such possibilities in view.

But though sex behaves in so many ways as a Mendelian allelomorph, showing, of course, frequent phenomena of linkage, it begins to be remarkable that no case of crossing-over in respect of these linkages has yet been established. Were the sex-chromosome always mateless, this fact would fit admirably with Morgan's views, but since the x-chromosome not rarely has a mate, a distinct problem is created. As bearing on the same question, we have also to remember Tanaka's observation that a certain linkage found in the male silkworm is absent in the female.

Another far-reaching discovery has been made by F. Lillie. When in horned cattle twins of opposite sexes occur, the female is sometimes sterile, being called a free-martin. We were inclined to interpret these twins as arising by division of one fertilised ovum, but Lillie, in a study of material from the Chicago stockyards, found that an ovum had dehisced from each ovary, and the twins were therefore originally distinct. Moreover, he showed that in some instances the twins have an actual anastomosis in the fœtal circulation. We are thus driven to believe that the presence of a male embryo may influence—in cattle—the development of a female embryo, poisoning it, in so far that the development of the generative organs is partially inhibited.

Many complex cases of interaction between factors have been successfully analysed. Punnett's elaborate experiments on the colours of rabbits and sweet peas, Emerson's studies in Phaseolus, and several more such investigations are gradually laying a solid foundation from which the mechanism of factorial determination may be deduced. The discovery made by Nilsson-Ehle, and independently by East, that in some forms there are several factors with identical powers, is another notable advance.

Controversy is proceeding respecting the divisibility of factors. When on segregation, either in the gametes of F_1 or in later generations, instead of two or three sharply differentiated classes of zygotes, much intergradation occurs, or when one of the parental types fails to reappear, the result may be interpreted either as showing imperfect segregation, or as an indication that the number of factors involved is very large. The balance of evidence perhaps suggests that many factors can, and on occasion do, break up (as the sex-factor almost certainly does), some commonly, others exceptionally, while others, again, seem to maintain their individuality indefinitely unimpaired.

As bearing on evolutionary theory, the new work leaves us much where we were. Progress in genetic physiology has been rather a restraining influence. The notion that Mendelian segregation applies to varieties and not to species has been often refuted. One of the most useful contributions to this subject is Heribert-Nilsson's evidence respecting Salix hybrids. Wichura believed himself to have proved that they and their derivatives are simple intermediates between the parental forms, and this statement, which has passed current for fifty years, is now shown to be a mistake due to insufficient material. Interest also attaches to Castle's recent withdrawal of his conclusion that by continued selection certain Mendelian characters in rats could be modified, an opinion which, though consistent with his own experimental work, has not stood a crucial test. We are still without any uncontrovertible example of co-derivatives from a single ancestral origin producing sterile offspring when intercrossed. This, one of the most serious obstacles to all evolutionary theories, remains. The late R. P. Gregory's evidence that tetraploid Primulas, derived from ordinary diploid plants, cannot breed with them, though fertile with each other, is the nearest approach to that phenomenon, but the case, though exceptionally interesting, does not, of course, touch this outstanding difficulty in any way.

Space does not suffice to enumerate the practical applications of genetic science to economic breeding, of which some have already matured and many are well advanced.

TELEGONY.

By Prof. J. Cossar Ewart, F.R.S.

THE belief in telegony is probably as old as the belief in maternal impressions, so intimately associated with Jacob's breeding experiments, recorded in the thirtieth chapter of the Book of Genesis. In prehistoric times, when breeds of sheep and cattle brought from the East by the Alpine race were crossed with the more recently formed European breeds striking new varieties would now and again appear. The ancient shepherds would doubtless endeavour to account for the differences between the cross-bred offspring and their pure-pred ancestors, and later biologists would be called upon to decide which of the views of the ancient breeders were most worthy of support.

The doctrine of the infection of the germ now known as telegony was more or less firmly believed in by men of science as well as by breeders up to the end of the nineteenth century. Beecher, writing at the close of the seventeenth century, says: "When a mare has had a mule by an ass and afterwards a foal by a horse there are evidently marks on the foal of the mother having retained some ideas of her former paramour, the ass." Agassiz held that the ovary was so modified by the first act of fecundation that "later impregnations do not efface that first impression." Similar views were entertained by Haller, Darwin, Herbert Spencer, Carpenter, Sir Everard Home, and others, and up to 1895, when I started my experiments, physiologists as a rule either admitted the possibility of the blood of a mare imbibing from that of the fœtus some of the attributes which it had derived from its male parent and thereafter handing them on to offspring by a different sire, or believed that some of the unused germ plasm of the first mate penetrated the immature ova and eventually took part in controlling the development of offspring by subsequent mates.

Up to the end of last century Lord Morton's experiments with a male quagga and a young chestnut seven-eighths Arabian mare were regarded as affording strong evidence of telegony. Hence at the outset I decided to repeat as accurately as possible Lord Morton's experiment. The quagga being extinct, a Burchell zebra was mated with Arab and other mares belonging to different breeds and strains. The mares, after producing one or more hybrids, were mated with Arab and other stallions.

In an account of my experiments, illustrated by numerous figures, published in the Transactions of the Highland and Agricultural Society of Scotland for 1902, it is pointed out that, though, to start with, I believed there was such a thing as telegony, I eventually came to the conclusion that "there never has been an undoubted instance of infection in either dogs, rabbits, or horses." Though a full account of my investigations, by Mr. Hermon C. Bumpus, appeared in the *American Naturalist* (December, 1899), and an abstract was published in the 1910 Report of the United States Bureau of Animal Industry, it is related in a recent American work on evolution[1] that the idea of telegony "rests mainly upon what are known as the Penycuik experiments (Ewart, 1899), the initial one of which was the impregnation of a mare, 'Mulatto,' by a quagga, a species of zebra which is now extinct. The offspring of this union was the foal 'Romulus,' which showed the quagga-stripes of his father very distinctly. Later, 'Mulatto' was bred to a pure Arab stallion and her second foal also showed traces of stripes, although by no means as distinctly as his half-brother 'Romulus.' . . . Definite instances are neither numerous nor well authenticated with the exception of the one in question, and even this may be due to some other cause."

It is scarcely necessary to say that I am not responsible for the idea of telegony—without going far afield, Lull might have discovered that the doctrine of "infection" had been dealt with by Agassiz and was especially associated with a mare belonging to Lord Morton—but it may be as well to point out that I used a Burchell zebra (the quagga had been extinct for nearly a quarter of a century); that the hybrid "Romulus," instead of being striped like his sire, approached in his markings the very richly striped zebra of Somaliland; and that the two subsequent foals of "Mulatto" were decidedly less suggestive of zebras than pure-bred foals of a near relative of "Mulatto" who had never even seen a zebra.

In 1910, when giving a course of lectures in Iowa, I gathered that the doctrine of telegony had few adherents in America. This view is supported by a statement in the recent work by Jordan and Kellogg, who "think it probable that the phenomena called telegony have no real existence."

PROGRESS OF CHEMISTRY.

By Sir Edward Thorpe, C.B., F.R.S.

THE half-century which has elapsed since the first issue of NATURE has witnessed an extraordinary development of science in general, but in no department has it been more marked, or the changes more profound, than in chemistry. Before dealing with the period over which the existence of this journal extends, it may not be uninteresting to indicate, in the broadest possible outline, the main features of progress in chemical science to which the growth we have witnessed during the last fifty years is in reality due.

The opening years of the nineteenth century constituted a new era in the history of chemical science. The revolution initiated by Lavoisier and his associates—Morveau, Laplace, Monge, Berthollet, and Fourcroy—was by this time accomplished, and its influence had extended throughout Europe. The French chemists, who emancipated chemistry from the thraldom of a false German doctrine, swept phlogistonism into the *limbus fatuorum* of extinct heresies. The early years of that century saw the passing of the more prominent adherents of Stahl's philosophy; of the English chemists, Priestley died in 1804, and Cavendish, who for some years previously had ceased to pursue chemical inquiry, followed him six years later.

Within the first quarter of the century appeared some of the most eminent of those who were destined to consolidate the principles upon which the New Chemistry was founded. Dumas and Wöhler were born in 1800, Liebig in 1803, Graham in 1805, Laurent in 1807, Gerhardt in 1816, Wurtz, Kopp, and Marignac in 1817, Kolbe and Hofmann in 1818, Pasteur in 1822, Alexander Williamson in 1824, and Edward Frankland in 1825. But there was already a generation at work the members of which, although not specially distinguished for their direct contributions to speculative chemistry, yet served by their labours to strengthen the foundations upon which it is based; among them were Wollaston and Davy, born in 1766, and Gay-Lussac, born in 1778. Berzelius, who was born in 1779, first published his electro-chemical theory in 1827. A revolution scarcely less momentous than that of Lavoisier had, moreover, by this time been effected by John Dalton; the enunciation of the atomic theory in 1807–8 wholly altered the aspect of chemistry; henceforth it was brought within the domain of mathematics, and its laws and processes were established on a quantitative basis. It consummated a change which Cavendish may be said to have originated. It can be proved that Cavendish was cognisant of the principles underlying what we term the "law of constant proportion" and the "law of reciprocal proportion"; that he foresaw that the facts embodied in these laws are at the foundation of all quantitative analytical work, and that in his practice he implicitly recognised their truth.

In spite of the widespread political and social disturbance which marked the early years of the last century, a tide in the affairs of chemistry then set in, which, with periods of ebb and flow, reached a high-water mark at the time this journal was founded.

The first two decades of the century not only witnessed the establishment of the fundamental laws of chemical combination and their rational explanation by means of the atomic theory; they also saw the enunciation of the gaseous laws; the discovery and application of voltaic electricity as an analytic agent; the isolation of the metals of the alkalis and alkaline earths; the determination of the nature of the halogens; and the discovery of many new metallic elements. In 1802 these were only twenty-three in number, as against sixty-three at the present time. They saw, too, the discovery of fulminating mercury and fulminating silver, acetylene, carbonic oxide, phosgene—some of which have played a large part in the Great War, but which when first made known were regarded as mere chemical curiosities, incapable of application. This period also saw the invention of the miner's safety lamp and the creation of the gas-lighting industry—two new departures of which it is impossible to exaggerate the consequences, immediate and remote. It witnessed also the discovery of isomorphism, the enunciation of the law of Dulong and Petit, and the first synthesis, by Wöhler, of an organic product.

The third decade brought us Faraday and the discovery by him of tetrachlorethylene and perchlorethane; the liquefaction of the gases; the isolation of benzene; the preparation of naphthalene sulphonic acids; and the formulation of the laws of electro-chemical decomposition. It witnessed also the activity of Graham; the promulgation of the law of gaseous diffusion; the recognition of the basicity of acids and the constitution of salts; the establishment of the doctrine of compound radicals by Liebig and Wöhler; the discovery by Dumas of chlorine substitution and the publication of his theory of types. It saw also the death of Wollaston and Davy, and the birth of Cannizzaro, Berthelot, Kekulé, and Lothar Meyer. The early 'thirties are memorable, too, for the attempts made to regularise chemical notation and for the gradual adoption of the system of Berzelius.

But, with the exception of the work of Graham and Faraday, the decade 1830–40 is not particularly remarkable for British contributions to chemical science. Although the volume of published work was no doubt considerable, it was not of the epoch-making order. As Edward Turner wrote, "the era of brilliant discovery in chemistry appeared to have terminated for the present." Thoughtful men deplored the condition of British science at this period, and they were concerned at the general apathy of the public with respect to it. One result of their action was the foundation, in 1831, of the British Association for the Advancement of Science. At the same time, it cannot be said that Continental workers were much more active. Apart from those already referred to, we find no noteworthy contribution to the theory of chemistry. The extent of the retrogression in this country may be judged from the fact that at this time the number of communications to the various societies, and to scientific periodicals dealing with chemistry, was not much more than half of what it was in 1802.

With the advent of the fourth decade there was a great awakening. It was signalised by the discovery of the first of the organo-metalloid radicals by Bunsen in 1841; the recognition of homology by Schiel in 1842; the early work of Pasteur on racemic acid; the synthesis of acetic acid by Kolbe; the dissociation of water by heat by Grove; the work of Frankland on ethyl and zinc-ethyl; the discovery by Wurtz of the compound ammonias and their synthetical formation by Hofmann; and the elucidation of the constitution of ether and the theory of etherification by Williamson. This decade was further made memorable by the creation, in 1841, of the Chemical Society of London, and by the foundation, in 1845, of the Royal College of Chemistry. At that time organic chemistry was scarcely studied in this country, and schools of practical chemistry were very few in number here. English chemists who sought instruction in operative chemistry and in the methods of original investigation for the most part resorted to Liebig at Giessen or to Wöhler at Göttingen. Liebig soon made his influence felt abroad, and his memorable English tour in 1842 gave a strong stimulus to the study of chemical science in this country. One of its immediate effects was the foundation of the Royal College of Chemistry, with Hofmann, one of Liebig's most brilliant pupils, as its director.

This was the first institution of its kind in Great Britain in which chemistry was studied for its own sake, and not merely as subordinate to other professional training. Space does not permit of any detailed account of its activities, or of the circumstances which led to its absorption into the School of Mines. It is only necessary to recall the names of Warren de la Rue, Abel, E. C. Nicholson, How, Bloxam, Blyth, Price, Rowney, Muspratt, Mansfield, Field, Noad, Brazier, Medlock, Crookes, Spiller, Tookey, Church, Perkin, Groves, Valentin, Vacher, O'Sullivan, Duppa, McLeod, Reynolds, Griess, Holzmann, Martius, Geyger—among the most distinguished of Hofmann's pupils and coadjutors—to indicate the influence he exercised on the development of chemistry in Great Britain during the twenty years of his residence amongst us. That he should have been allowed to depart was nothing short of a national calamity.

As regards British contributions to chemistry during this and the succeeding decade, the most noteworthy may be said to have emanated from the Oxford Street institution. Williamson, however, was still active at University College, and to this period belongs Frankland's recognition, in 1851, of the principle of valency. The synthetic colour industry originated in 1856 from Perkin's discovery of mauve, and Hofmann himself, with other of his pupils, contributed greatly to its development. As regards other workers, notable contributions to chemical theory at about this time were Clausius's work on electrolysis, Deville's studies on dissociation, Couper's conception of atomic linkage, and the resuscitation by Cannizzaro of Avogadro's hypothesis and his demonstration of its sufficiency at the memorable Congress of Karlsruhe in 1860. The introduction of spectrum analysis by Bunsen and Kirchhoff belongs also to this epoch.

NATURE was founded at a time of extraordinary development in chemistry. Kekulé had made known his fruitful conception of the constitution of benzene, and a host of workers, more particularly in Germany, were exploiting with feverish activity the chemistry of the so-called aromatic compounds. The synthetic colour industry received a remarkable impetus by the synthesis of alizarin. Newlands had already adumbrated Mendeléeff's great generalisation, of which the validity seemed to be established by the dramatic discovery, in quick succession, of the new elements it had predicted.

During the fifty years of its subsequent existence this journal has recorded and made intelligible to the general public every notable advance in chemistry. It has witnessed great and fundamental changes in the science. New conceptions have arisen and time-honoured doctrines have been modified or altogether supplanted. Chemical knowledge has been augmented by the inclusion of the theories of stereo-isomerism, desmotropy, the gaseous theory of solutions and free ions, and the Walden inversion. It has had to note and describe the methods of liquefaction of all the so-called permanent gases, and it has seen the universal recognition of the principles, first indicated by Andrews, on which the change of physical state depends. It has chronicled the discovery of argon by Rayleigh, and that of terrestrial helium, krypton, neon, and xenon by Ramsay. It has seen the rise and progress of radio-activity, the isolation of radium and its associates, and the discovery of isotopic elements. Lastly, it has seen a profound change in our conception of the Daltonian atom as an indivisible entity, and a strengthening of our belief in the intimate connection between matter and energy.

Throughout the whole of its existence NATURE has been true to the ideals which it established at its birth, and has been consistently faithful to the traditions it created. It has insisted from the outset that national progress must be based upon new ideas, and that the main source of new ideas is original research. It has shown that the greatest practical realities of our time have originated from the search for truth; that invention waits upon discovery—the most powerful of all agents of civilisation; and that new knowledge means new power. Hence it has with a uniform insistence pointed out that it is the duty of the State, in its own interest, to encourage and foster research and to remove the hindrances which beset the pursuit of science and impede its progress. Nor has its advocacy been based solely on the lower ground of material advantage, or on the fact that original research has proved to be the source of new industries and of wealth—that it creates employment and alleviates labour. It has striven to show that mental and moral progress have a scientific basis—that our knowledge of Nature and the universe, our modes of thought, our criteria of truth, our detection and avoidance of fallacies, are dependent upon that habit of mind we call "scientific"—a habit which can be cultivated and strengthened only by the study and pursuit of science.

It has a record of which it may justly be proud. By the manner in which it has discharged its functions and fulfilled its obligations, it has earned the gratitude of all men of science, and it now celebrates its jubilee with the knowledge that it has merited, and will receive, the unstinted appreciation of all true lovers of science.

CHEMISTRY IN THE MAKING.

By Prof. Henry E. Armstrong, F.R.S.

THE period covered by NATURE happens to be that which just comes within my ken. In chemistry, both pure and applied, it has been one of astounding progress and fulfilment. Frankland and I published our new method of water analysis—involving combustion *in vacuo* with the aid of the Sprengel pump—in the year of its birth: people then ran their sewage into a cesspit and drank the water from an adjoining well. Typhoid fever was rife throughout the land. Bacteriology was an unknown science. Frankland's work on the Rivers Commission gave the nation a pure-water supply and contributed greatly to a complete sanitary system, in this respect placing us ahead of the world. The systematic use of the Sprengel pump dates from our inquiry; Crookes afterwards used it in constructing his radiometers.

It is noteworthy that sulphuric anhydride was a laboratory curiosity at that time: when I prepared several pounds of it, in Leipzig, in the autumn of 1868, I was regarded with wonder: Squire and Messel began its manufacture here at Silvertown in 1873: it soon came into vogue, especially in the alizarin industry. During the war, many thousands of tons have been used in the production of propellants and high explosives. I then also made the chlorhydrol, SO_3HCl, in quantity, and suggested to my student friend, Karl Knapp, Liebig's nephew, that he should test its value as a sulphonating agent. He sulphonated benzene. I took up the work afterwards and first applied it to toluene, so laying the foundation of the method now preferred in manufacturing saccharin.

In 1868 chemists were waxing enthusiastic over Mendeléeff's great generalisation, brought home to us not only in his paper in the *Annalen* but also by Lothar Meyer's well-known book, then recently published, especially by Meyer's justly famed atomic volume curve. At that date those of us who could think in terms of systematic organic chemistry were possessed by the view that the "elements" must be compounds: the "periodic" inter-relationships were so similar to those manifest in homologous and isologous series. Soddy's "isotopes"—the word is unnecessary—are simply the chemist's homologues. That the two leads should be as like as the two Dromios—recent observation shows that they are perceptibly different—is in no way surprising: methane and ethane are all but indistinguishable chemically; we can also foresee isomeric as well as homologous primaries. Now that the "primaries" have been robbed of their position as "atomic" materials, by the appearance on the scene of radium, this view is proved to have been justified; but none of us ever dreamt that they would come to be regarded as made of lumps of electricity—still less that we should ever dare to think of energy in terms of quanta or to discard the doctrine of the other in favour of one of relativity.

All my life, I have regretted the aloofness of chemistry from physics: that the physicist shows so little real interest in chemistry. It is a welcome finish to find him at last entering upon the fringe of our domain and taking up our work, though it is a pity he cannot become one of us instead of a mere extrapolation; probably it cannot well be otherwise, as the mathematical habit of mind is required for the new work and chemist and mathematician are different natures. Ours must be the task of digesting the material to the point at which our mental enzymic machinery no longer suffices and that of the mathematician and physicist comes into play. The two recent lectures to the Chemical Society by Nicholson and Jeans—both astounding displays of eloquence and imaginative power—are demonstrative of the new departure. If fifty years hence the new field be as fully grasped as that has now been which I saw opening up in 1868, NATURE at its centenary will indeed have cause to congratulate its readers.

In 1868, we were only beginning to write $C=12$; our symbolic system was barely stabilised; the importance of Avogadro's theorem was but coming home to us, mainly through Cannizzaro's insistence. Structural constitutional chemistry was in its infancy. Frankland's theory of valency—it is now clear that he included carbon in his scheme—and Kekule's benzene symbol were new weapons; we were only beginning to interpret isomerism in terms of structure; we scarcely thought of position as its cause. A vast edifice has been erected in the interval but the foundations are simple: Frankland's postulates have but been supplemented by van't Hoff's extension of Pasteur's geometric conceptions. What is most noteworthy is the surprising simplicity and sufficiency of the system.

Latterly we have begun to think in terms of solid structure: it is already clear that the next advance will come from the geometric, crystallographic side: and having learnt to see through a brick wall, we are now beginning to peer directly into the molecular structure of crystalline solids. Low temperature phenomena have been probed to their depths, especially in this country; indeed, we have seen a series of important industries grow out of the work.

The growth of our knowledge of method, of our analytic and synthetic powers, has been marvellous—full use has been made of this development by the manufacturer, so that we can now not only reproduce natural colouring matters but match the rainbow in every tint. Although British chemists cannot claim the credit of much of the matching, they can at least rejoice in the fact that the foundations were laid in London—by Faraday's discovery of benzene in 1825, in Albemarle Street; and by Perkin's discovery of mauve, in Oxford Street and at Sudbury in 1856.

It is noteworthy that mauve was made in attempting to synthesise quinine: as we are not yet certain as to the structure of this alkaloid and in no way near to a method of producing it artificially, it is clear that even now our powers of interrogating and copying Nature are but limited: remarkable as our progress has been, she yet defies us in many directions. We stand ashamed before the unassuming ease with which she fabricates starch from glucose underground in the dark; indeed, cane-sugar, starch, cellulose and not a few other compounds of primary importance are still to be ranged with the Delphic mysteries.

But whilst, on the organic side, we have secured a wonderful mastery and the odds in favour of our structural conceptions are many thousands to one—because we have been able to ring the changes so often with success; on the inorganic side, almost complete ignorance prevails—because we have not been able to ring the changes. Thus we cannot say, with any approach to certainty, what is the structure of so simple a substance as sulphuric acid. In this and similar cases probably the clue will come through X-rays.

On the biological side the advance has been very great and it can no longer be said with truth that "Thierchemie ist Schmierchemie"—Emil

Fischer's expression; but physiologists are still far from being sufficiently schooled in our science and progress has been chiefly due to men such as Emil Fischer, who have had sympathy with biological problems and been alive to the fact that it is desirable to walk before running. It is strange that few chemists have biological leanings—but the biological is still further removed than the chemical from the mathematical habit of mind.

The chief feature of progress in later years has been the ongrowth of the physical school. This has had both its advantages and its disadvantages—for whilst we have been led to widen our vision and increase our grip on the philosophy of our subject, we have lost in manipulative skill, as we have given inadequate attention to the development of method and technique. This probably is one of the chief causes of our comparative failure on the industrial side. Though based on analysis, chemistry is mainly a constructive, practical science: our success has been in proportion to the extent to which we have been able to confirm analytic by synthetic results. The man who does always gets ahead of the man who doesn't—of the man who merely seeks to explain; though the latter is often more useful than is supposed in controlling practice. Still it is because fingers and artistry come first in the practice of chemistry, that the chemist proper is not and cannot often be a mathematician. The superior value of the preparative side has been so brought home to us during the war, that it is to be hoped that full attention will now be given to its development.

Our ill-balanced bookish system of examinations is one of the main causes of the incomplete practical training chemists have received of late years; we have yet to teach the real value of books, that they are meant for constant reference; to force students to memorise them is the worst of policies: thoughtful, dextrous fingers and knowledge of materials are the chemist's chief needs.

Much progress has been made, on the physical side, in correlating properties with structure. Also great attention has been paid to the problems of solutions: unfortunately the men who have dealt with this latter side of chemistry have not been working chemists—in fact, scarcely chemists at all—and the pseudo-mathematical treatment they have introduced has often savoured far too much of dogma. The result has been to introduce an unscientific, partial habit of mind into our subject. We are strangely behind in having no proper, accepted theory of chemical change in general. Our elementary text-books too are behind the times—full of half-truths and superficial when not inaccurate: there is no lack of detail but little philosophy and still less logic. Chemistry is the most fundamental of the sciences, the one by means of which it is alone possible to teach the principles and practice of scientific method in their entirety—and yet chemists are rarely trained to be masters of method.

To make chemistry a truly philosophical science, for the guidance of students, we need a man of giant mind, well versed in practice, who will survey and weigh the facts and give sympathetic consideration to all hypotheses, then summarise the situation in broad and simple terms which all can understand. Fitzgerald was a man of the type I have in mind.

Certainly the progress made during the fifty years is astounding—the extent of our collective knowledge is extraordinary. But we must be on our guard—there are too many "bits of chemist" about: the most pretentious member of the species is of modern invention—the "research chemist." No chemist is a chemist who is not fully imbued with the spirit of inquiry. Not a little of the work that is now called research is of a trivial character; the majority are incapable of original effort and far more careful direction of advanced work is required. If care be not taken, "research" will become a word of reproach. The effort of the future must be to produce the whole chemist—the man who will know his subject and be ever careful and modest, both in word and deed, being possessed by scientific method.

THE DISCOVERY OF CHEMICAL ELEMENTS SINCE 1869.

By Prof. H. B. Dixon, F.R.S., and H. Stephen, M.Sc.

A GLANCE at the history of the chemical elements reveals the fact that no fewer than fifty-three of them were recognised so early as 1818, and since that time some thirty more have been discovered. The search for new elements between 1818 and 1869 represents an empirical programme without considerations of marked theoretical interest, and the investigations were directed more particularly to an examination of minerals. The chief results were the isolation of new metallic elements, and the work of the great master, Berzelius, stands out pre-eminently during this period, and his quantitative work surely paved the way for future investigations.

The later period extending over the past fifty years marks out a new era in the history of the chemical elements, inasmuch as it opened with the discovery of the periodicity of the elements in connection with their atomic weights. The elaboration of the system in its final form was due to Mendeléeff in 1869, although Newlands had foreshadowed such a system in his law of octaves (1863).

Mendeléeff's system had a profound effect in bringing about radical changes in respect of the atomic weights of certain elements, notably beryllium, uranium, and indium; and in affording predictions of the existence and properties of new elements, which were confirmed with astonishing exactitude in the cases of scandium, gallium, and germanium.

Another factor which played an important *rôle* in the development of the chemistry of the elements in the early years of this period was the application of the spectroscope by Bunsen and Kirchhoff to chemical analysis, when, by a comparison of the bright lines in the spectra of the vapours of metallic elements with the dark lines in the solar spectrum, they showed that many terrestrial elements exist in the sun. During the last two decades the interest in spectroscopy has revived, and much of the valuable information which we now possess of the intra-atomic structures of the elements is due to the remarkable developments in the construction of diffraction gratings, and in particular the concave gratings of Rowland.

Notwithstanding the great possibilities for research opened up by Mendeléeff's periodic table, the latter remained only slightly modified until 1893, when a period of rapid development and continual progress began. The later discoveries with regard to the chemical elements fall in a remarkable way into three distinct groups: the rare earths, the inactive gases, and the radioactive elements, and it is to be lamented that the pioneers in the two first-named groups have passed away.

Much of our knowledge of the rare earths is due to the late Sir William Crookes, who was the first to advance the conception of the meta-elements—*i.e.* elements which show great resemblance to each other, and have many physical and chemical properties in common, and, in consequence, are not easy to separate. Such in a few words sums up the chief characteristics of the rare earths, which have found so far only a temporary resting place in the periodic table. Apart from their purely academic interest and the high degree of accuracy attained in their separation, the rare earths have found important technical application as catalytic agents and in the manufacture of the modern incandescent mantle. Our knowledge of them, however, remains in many respects incomplete.

Of the second group, the inactive gases, we possess a more complete history of their chemistry, due in no small measure to the brilliant achievements of Lord Rayleigh and Sir William Ramsay, who were the first (1894) to characterise the inert gas argon in the atmosphere, and so confirmed the almost forgotten work of Cavendish more than a century before. The discovery of helium in cleveite by Ramsay followed shortly after that of argon; his attention had been directed by Miers to Hillebrand's discovery of nitrogen in the mineral uraninite—and gas-containing minerals seemed to be a possible storehouse of condensed argon. He sought for argon and found helium, the presence of which in the sun's atmosphere had been detected by Lockyer twenty-five years before.

The proof that helium was an inert monatomic gas like argon led to many speculations as to the position of these new elements in the periodic system. Ramsay predicted the existence of another inert gas between, and forming a "triad" with, helium and argon, having an atomic weight between that of fluorine (19) and that of sodium (23), and he and his fellow-workers deliberately hunted for the missing element. They found it in the atmosphere, but besides the gas they sought—neon (20)—they also isolated the heavier elements krypton and xenon. All the inactive gases are colourless; they form no chemical compounds, and are monatomic. They have definite boiling points, give characteristic Geissler-tube spectra, and occupy a unique position in the periodic table—the neutral points in Crookes's descending figure of eight.

The last group of elements to be discovered include the remarkable and interesting series of radioactive elements, which originated in the discovery of radium by Mme. Curie in 1898. The development of this field of research has produced a profound effect upon chemical theory and given us entirely new conceptions of the structure and nature of the atom, foremost among which is the nuclear atom proposed by Sir E. Rutherford, and recently modified by Prof. Bohr.

The chief interest of the radioactive elements centres round two elements of highest atomic weights, uranium and thorium, which are continually decomposing into a series of other elements at definite rates over which we have at present no control. These new elements in a similar way undergo spontaneous changes into still another series of elements. Accompanying these changes in both cases there is a high-speed emission of three distinct kinds of rays, now designated the α-, β-, and γ-rays respectively. The first-mentioned have been identified as electrically charged atoms of helium, and it is now believed that all radio-elements are built up of lead and helium, a conclusion reached by Rutherford and others, and thus after the lapse of a century the hypothesis advanced by Prout (1815), concerning the existence of a primordial substance, makes a reappearance in modern guise.

The majority of the elements formed in the transformations associated with uranium and thorium (which are the progenitors of a long line of descendants) have not as yet been obtained in a pure condition, and are characterised at the present time solely in connection with radioactive properties. Two substances, radium and niton—the gaseous emanation from radium—have been definitely described, and their atomic weights and positions in the periodic table fixed. Niton belongs also to the group of inactive gases; its existence is transitory, since the gas disappears after a few days, during the course of which radioactive disintegration takes place. Its atomic weight being 222, four units less than radium, the difference is attributed to the loss of a helium atom from radium.

Based on a consideration of their researches, Rutherford and Soddy have formulated a theory of atomic disintegration (1902) in connection with which Soddy has recently introduced the term *isotope*, by which he defines very closely related elements which are chemically inseparable but have different atomic weights. The non-separability of isotopes by chemical methods has recently been confirmed by Richards and his co-workers, who found that the atomic weight of lead obtained from Australian carnotite (containing uranium-lead) was unaltered even after the nitrate into which the lead was converted had been subjected to more than a thousand fractional crystallisations. Furthermore, Richards has determined the atomic weight of uranium-lead, and the number found (206·08) is less by as much as 0·25 per cent. than that of ordinary lead, which differs from it in other physical properties involving weight. It is possible that lead descended from thorium (208) and lead descended from uranium (206) have enough in common to be each called lead, but are varieties or isotopes of the same element, common lead (207·2) being a mixture of the two.

We may conclude, therefore, that in radioactive substances there is a continual transformation of one element into another of lower atomic weight, such transformation (apparently quite independent of temperature and external electrical conditions) being accompanied by the liberation of enormous amounts of energy, compared with which the magnitudes of energy of chemical reactions fade to insignificance. Has the earth passed through its element-building epoch? Instead of spinning "for ever down the ringing grooves of change," are we mounting backwards up the spiral as our larger empires of matter disintegrate into smaller and perhaps more stable states?

Just as the beginning of the last half-century was marked by the epoch-making discovery of the periodic system of the elements, so in effect is the close of it marked with another—namely, Moseley's discovery of the atomic numbers of the elements, the importance of which we have as yet scarcely realised.

The atomic number of an element as suggested by van der Broek defines the place-number occupied by the element in the periodic table, and at the same time is the number of electrons in the atom or nuclear charge of it. Moseley showed from a spectroscopic examination of the frequencies of characteristic X-rays emitted when X-rays bombard anticathodes of various metals, that the square roots of the frequencies are proportional to the atomic numbers. The latter are known for all elements up to uranium—thus, hydrogen one, helium two, lithium three, and so on until finally uranium 92, and the anomalies which appear in Mendeléeff's table disappear, as in all cases the correct chemical order is maintained. The atomic numbers appear to be even more fundamental than the atomic weights.

PHYSICAL CHEMISTRY—PAST AND PRESENT.

By Prof. J. C. Philip, F.R.S.

THE cultivation of the border-lands between the various sciences, so actively prosecuted in the last few decades, has nowhere led to more notable results than on the frontiers of physics and chemistry. This particular field of investigation, covering phenomena in some measure common to both these sciences, has gradually taken shape, and has attracted crowds of workers, keen to apply the exact methods of physics to the wealth of problems and material presented by chemistry. With the passing of the years physical chemistry has ultimately emerged as a definite branch of natural knowledge, full of intrinsic interest, but comprising also much that is of value for other sciences.

Fifty years ago the foundations of physical chemistry had to some extent been already laid. Faraday's experiments on electrolysis and the liquefaction of gases, Graham's observations on gaseous and liquid diffusion, and Hittorf's investigations of electrolytic migration had been put on record, although in some cases, notably the last-mentioned, the full significance of the work was not to be realised for many years to come. Avogadro's hypothesis and the kinetic theory were also before the scientific world, and the Brownian movement of minute particles suspended in water, destined ultimately to figure so prominently in the physical chemistry of recent years, had been not only recorded but, for the time, forgotten.

During the period in which NATURE first appeared, new methods of investigating chemical change, and new conceptions of chemistry as a quantitative science were being developed. The work of Harcourt and Esson, of Guldberg and Waage, on the action of mass as a factor in equilibrium and velocity, as well as Horstmann's application of thermodynamics to chemistry, inaugurated a new epoch, with which, in both directions, the name of van't Hoff was afterwards so brilliantly associated. It was van't Hoff who put the science of chemical dynamics on a secure experimental basis, and thus prepared the way for a rational study of catalysis, a particular development of vital significance for the growth of important chemical industries. It represents part of the contribution which physical chemistry has made to the advance of chemical knowledge from the purely descriptive to the rational and quantitative stage.

Appreciable progress towards the recognition of physical chemistry as a distinct branch of knowledge resulted, at a somewhat later date, from van't Hoff's study of osmotic pressure, and his extension of the gas laws to solutions. This remarkable work was followed, at a short interval, by Arrhenius's hypothesis of electrolytic dissociation, a conception that has left its mark deep on the physico-chemical research records of the past thirty years. This hypothesis has been the guiding principle in countless investigations, and although it presents difficulties not yet satisfactorily solved, and appears to require modification in some respects, notably in regard to the *rôle* of hydration, it holds the ground to-day as the most acceptable and intelligible interpretation of the properties of electrolyte solutions. The history of the electrolytic dissociation theory may be fairly described in Larmor's words: "In the case of every successful scientific theory the time must come when its first easy triumphs become exhausted, and what prominently confronts the investigator are its outstanding defects and difficulties." Such is the present position in regard to the ionisation theory, and during recent years there has been a concentration of effort on such outstanding problems as the application of the mass action law to strong electrolytes, the catalytic action of ions, and the differences existing between the values of the ionisation ratio deduced for one and the same electrolyte by the osmotic and conductivity methods respectively.

The decade in which the theories of van't Hoff and Arrhenius were propounded saw also the establishment of the first journal exclusively devoted to the record of physico-chemical research. The first number of the *Zeitschrift für physikalische Chemie* appeared in 1887, and an inspection of the early volumes reveals the extraordinary variety and attractiveness of the problems that were being attacked under the ægis of the new science, and on the more definitely quantitative lines for which this branch of chemistry stands. It was not long before the influence of physical chemistry began to be apparent beyond its own borders in a renascence of inorganic chemistry which continues to the present day. Important reactions between well-known substances, regarded as completely worked out, have been explored afresh in the light of physico-chemical principles, and have yielded an extraordinary amount of valuable quantitative data. In this connection one might refer to the phase rule and its practical utility in connection with the conditions of existence of salt hydrates, the constitution of alloys, and various technical problems.

Prominent among the later developments of physical chemistry has been the examination of matter in a condition coarser than that corresponding with the molecular state. The study of mechanical suspensions, and the investigation of colloidal solutions with the aid of the ultramicroscope, have opened up a whole new world of fascinating phenomena, and bridged the gap between the visible particle and the molecule. Perrin's epoch-making count of the particles at different levels in a vertical column of a mechanical suspension, and the evaluation of the Avogadro constant which follows therefrom, have notably extended the validity of the gas laws, and supplied at the same time definite quantitative proof of the molecular movements postulated by the kinetic gas theory. Of extraordinary interest also in this connection is the fact that purely physical evidence, based on the atomic character of electricity and depending on measurements of the elementary electric charge, gives strong support to the Avogadro conception.

At the present moment fresh means of attacking the still unsolved problems of the physico-chemical field are being developed. Planck's quantum theory, for example, coupled with such experimental work as that on the heat capacity of solids at low temperatures, and on the origin and relationship of spectral lines, appears likely to have a notable influence on the future of physical chemistry. The thorough investigation of colloids along physico-chemical lines, which is actively proceeding to-day, promises to throw light on many problems which are of interest not only from the purely scientific point of view, but also to the industrial chemist. The sister sciences, too, are vitally concerned in the exploitation of this field, and, indeed, the physical chemist of to-day may point with legitimate pride to the fact that the principles of his science are welcomed by the metallurgist, the physiologist, the geologist, and others, as valuable aids in the elucidation of their respective problems. This ever-widening influence is the guarantee of the future vitality of physical chemistry.

THE INFLUENCE OF INVESTIGATIONS ON THE ELECTRICAL PROPERTIES OF GASES ON OUR CONCEPTIONS OF THE STRUCTURE OF MATTER.

By Sir J. J. Thomson, O.M., Pres. R.S.

All workers in science owe much to Nature, and so I am glad to comply with the request of its Editor to write a few words on the progress of some branch of physics in the fifty years since Nature was started. I shall confine myself to the effect which results obtained by investigations on the electrical properties of gases have had on our conceptions of the structure of matter and the potentiality of further applications of these results to increase our knowledge of physical and chemical problems. In these investigations we study atoms and molecules when they are charged with electricity, and the success which has been obtained is due in the main to the fact that the methods by which we can detect the existence and follow the behaviour of these charged particles are almost infinitely more powerful than those which are available when the particles are uncharged. We can by the aid of their charges detect the presence of a few thousand atoms, while the most delicate methods of chemical analysis will scarcely detect a million million. Again, when an atom or molecule is charged we can by acting upon it by electrical forces increase its energy a million-fold, and thus enable it to produce effects by which its presence can be detected. We obtain in this way very powerful and accurate methods for measuring some of the fundamental constants associated with atoms and molecules. We know now, for example, with great precision the masses of the molecules of the different gases; we owe this to the study of their electrical properties.

Again, the study of the positive rays has shown that all the atoms of an element have to a very high degree of approximation the same mass, and has disposed of the idea that the atomic weight only represented an average value taken over a considerable range. The positive rays, too, have demonstrated the existence in most gases of both atoms and molecules; not only have they shown that atoms exist, they have also proved the independent existence of the radicles of organic chemistry such as CH, CH_2, CH_3. These rays will, I think, in the future play a considerable part in the determination of the atomic weight of those elements which can exist in the gaseous form, as they furnish a method which is independent of impurities, and can distinguish between "isotopes," should such exist. The rays provide a powerful method for detecting new elements and compounds, as they demand only an infinitesimal amount of material and the atomic weight of the new body can be calculated at once from the position of its line in the positive ray spectrum. As a side issue the rays show the complexity of the conditions when electricity passes through compound gases. I have found cases in which there were as many as thirty-seven different types of positive carriers at work simultaneously.

The convection of negative electricity presents a remarkable contrast, for one of the most striking results of the study of the electrical properties of gases is that at very low pressures the carriers of negative electricity are not atoms or molecules, but electrons, the mass of which is only about 1/1700 of that of the smallest known atom, that of hydrogen; these carriers are unaltered in character whatever changes may take place in the nature of the gas through which the electricity is passing. These electrons can be obtained from atoms of every kind, so that they form an integral part of the normal atom. The number of electrons in an atom which are not fixed too rigidly to be shaken when struck by Röntgen rays has been determined, and it has been found that the number of such electrons in an atom of any element is equal to the atomic number of the element. The positive rays show that the atoms of elements other than hydrogen which occur in these rays must contain more than one electron, for atoms which have lost two or more electrons are a common feature in these rays; mercury atoms have been observed which have lost as many as eight electrons. The speed which the electrons may attain is very great; some of the electrons emitted by radio-active substances (the β-rays) travel at a speed only a few per cent. less than that of light.

The source of the mass of the electrons is interesting; it was known before they were discovered that a charged body had in virtue of its charge a larger mass than an uncharged one, the difference increasing as the size of the body diminished. The result at that time looked very academic, as even molecules were far too large for the effect to be appreciable; the result became of practical importance when electrons (the linear dimensions of which are only about one-hundred-thousandth part of those of atoms) were discovered; and the experiments indicate that the whole of the mass of an electron is due to its charge. Mass of this kind depends upon the velocity and becomes infinite when the velocity is that of light. The mass of the electrons accounts, however, for only a minute fraction of that of the atom of which they form a part.

Since we know the number of electrons in an atom, the problem of finding the structure of the atom is that of finding the configuration of these electrons when they are in equilibrium under their mutual repulsions and whatever forces may be exerted upon them by the positive charges. The solution of this problem would give representations of the structure of the atoms of the various elements. The consideration of the positions of equilibrium when two such atoms of the same or different kinds are brought near together would lead to clear views as to what constitutes chemical combination and the conditions under which it is possible. This is one of the problems which call most urgently for solution. It must be noticed, however, that we cannot explain the properties of the atoms of the elements by a system of positive and negative point charges exciting forces varying inversely as the square of the distance. These would not give rise to systems of atoms sharply limited to definite and distinct types, but to systems passing continuously from one type to another. To get the requisite definiteness in the model atom we must introduce some other condition, such, for example, as that the force between the positive and negative forces is not always an attraction varying inversely as the square of the distance, but that it changes from attraction to repulsion at definite distances (such distances giving a length to measure the size of the atom), or we may assume some condition such as is imposed by the quantum theory, which rules out all but a small fraction of the solutions otherwise possible.

RADIUM AND THE ELECTRON.

By Sir Ernest Rutherford, F.R.S.

WHEN we view in perspective the extraordinarily rapid progress of physics during the last twenty-five years, we cannot fail to be impressed with the great significance to be attached to the discovery of X-rays by Röntgen in 1895, not only from its intrinsic interest and importance, but also from the marked stimulus it gave to investigations in several directions. In fact, this discovery marks the beginning of a new and fruitful epoch in physical science, in which discoveries of fundamental importance have followed one another in almost unbroken sequence.

It does not fall within my province to discuss the great advances in our knowledge that have followed the close study of this penetrating type of radiation, but to indicate, I am afraid very inadequately, the progress in two other directions of advance which were opened up by the discovery of X-rays, and have revolutionised our ideas of the nature of electricity and the constitution of matter.

Following Röntgen's discovery, attention was concentrated on two aspects of the problem. On the one side it was thought that the excitation of the X-rays might be connected with the phosphorescence set up in the glass of the discharge tube by the impact of cathode rays, and experiments were consequently made by several observers to test whether substances which phosphoresced under ordinary light emitted a type of penetrating X-rays. By a fortunate combination of circumstances, H. Becquerel in 1896 tried the effect of a phosphorescent uranium salt, and this led to the discovery of the emission of a penetrating type of radiation, and thus laid the foundation of the new science of radioactivity, the further development of which has been attended by such momentous consequences.

On the other side, the problem of the nature and origin of the X-rays led to a much closer study of the cathode rays and to the definite proof, as Sir William Crookes had long before surmised, that the cathode rays consisted of swift charged particles of mass small compared with that of the hydrogen atom. It was soon shown that these corpuscles of small mass or negative electrons, as they are now termed, could be set free by a variety of agencies, by the action of ultra-violet light on metals and copiously from glowing bodies, while they were ejected with high speed spontaneously from the radioactive bodies.

The interpretation by Lorentz of the Zeeman effect in which the spectrum lines were displaced by placing the source of light in a magnetic field showed that electrons of the same small mass were present in all atoms, and that their vibrations constituted visible light. Sir J. J. Thomson early pointed out the significance of the electron as one of the units of atomic structure and its importance in the mechanism of ionisation in gases, and the rapid growth and acceptance of electronic ideas owes much to his work and teaching. An important stage in advance was the proof by Kaufmann that the mass of the electron was entirely electrical in origin. Sir J. J. Thomson had shown in 1881 that a charged particle acquired additional or electrical mass in virtue of its motion. The variation of mass with speed has been shown to be in accord with general theory, but is in best agreement with the formula based on the theory of relativity. It would be of great interest to compare theory with experiment for the highest attainable speed of the electron from radium which is so near to the velocity of light that the variation of mass with velocity is very rapid.

The proof that the electron was a disembodied atom of negative electricity was a great step in advance in electrical ideas. Information as to the nature of positive electricity is far less precise and definite, for no positive electron, the counterpart in mass of the negative electron, has ever been observed. In all experiments with positive rays and with radioactive transformations where the processes are very fundamental in character, no positive charge has ever been found associated with a mass less than that of the atom of hydrogen. While it is well to keep an open mind on this fundamental question, the evidence as a whole suggests that there is an essential difference in mass between the carriers of positive and negative electricity. In fact, such a difference seems to be essential to fit in with our knowledge of the structure of atoms. The nucleus of the lightest atom hydrogen may prove to be the positive electron and its much greater mass than that of the negative electron would then be ascribed to the greater concentration of the electrical charge in the former.

From consideration of the passage of electricity through gases, it had long been surmised that electricity, like matter, was atomic in character. The study of the deflection of the cathode rays and α-rays in magnetic and electric fields showed that the carriers of each type had all the same charge, and the atomic nature of electricity was implicitly assumed by all workers. Townsend showed that the charge carried by the ions in gases was equal to the charge carried by the hydrogen atom in the electrolysis of water and made the first measurements of this fundamental unit. Other methods of attack were developed by Sir J. J. Thomson and H. A. Wilson, and by a skilful adaptation of methods Millikan was able to demonstrate in a very direct way the unitary nature of electricity and to measure the value of the unit charge, probably the most important and fundamental constant in physics, with an accuracy, it is believed, of one in a thousand. By combining the value of this constant with electrochemical data, the number of molecules in a cubic centimetre of gas and the mass of the atoms can be deduced with equal accuracy. The convincing proof of the atomic nature of electricity and the accurate measure of the fundamental atomic and molecular magnitudes are two of the greatest triumphs of the new era.

One of the most important properties of X-rays is their power of making gases a temporary conductor of electricity. The study of this small conductivity led to a clear idea of the transfer of electricity through gases by means of charged ions, and the nature and difference of the positive and negative ions have been closely studied. The proof by Townsend of the production of ions by collision in electric fields opened up a new field of investigation and gave us for the first time a clear idea of the processes leading up to an electric spark. The ionisation theory was found to explain the conductivity produced by radium rays and the conductivity of flames. The laws controlling the escape of electricity from glowing bodies were closely examined by H. A. Wilson and O. W. Richardson.

It is a striking fact that these purely scientific researches on the conductivity of gases, which had their inception in the Cavendish Laboratory, and appeared at first to have only an academic interest, should so soon have resulted in important practical applications. We may instance the use of a hot filament in a low vacuum as a rectifier of alternating currents and a detector of electrical waves. The supply of electrons from a glowing filament coupled with the generation of ions by collision has led to the production of powerful electric oscillators and amplifiers for magnifying minute currents to any desired degree. These amplifiers have not only been of great service in war, but have also rendered possible radiotelephony across the Atlantic. Last, but not least, we have the invention of the Coolidge X-ray tube, which has played such an important part in research and in radiography.

While the mechanism of ionisation of gases by X-rays and radium rays and the transfer of electricity in ordinary electric fields is in the main well understood, it is a striking fact that the passage of the disruptive discharge through a vacuum tube, which was the starting point of so many discoveries, is still almost a mystery. While no doubt some of the main factors involved in the discharge are known, the phenomena in gases at low pressure are so complex that we are still far from a complete elucidation of the problem. This complexity is well instanced, for example, by the sign and magnitude of the charges communicated to atoms and molecules in the positive rays, which have been so closely studied by Wien and Sir J. J. Thomson, and in the hands of the latter have given us a very delicate method of chemical analysis of gases in a discharge tube.

The discovery of the electron as a mobile constituent of the atom of matter has exercised a wide influence on electrical theory, and has been the starting-point of attack on numerous electrical problems. In these theories the electron may be considered as a point charge with an appropriate mass associated with it, and in many cases no assumptions as to the nature and constitution of the electron itself are involved. One of the first problems to be attacked was the passage of electricity through metals where it was supposed that the negative electrons are continuously liberated from the atoms, and are in temperature equilibrium with the matter. While the theories as initially developed by Drude and Sir J. J. Thomson have been instrumental in accounting for a number of relationships, they are unsatisfactory on the quantitative side. These difficulties have been enhanced by the recent discoveries of Kamerlingh Onnes of the supra-conductivity of certain pure metals at very low temperatures and the marked departure from the law of Ohm under certain conditions. As in the case of the theory of radiation, it may be necessary for an ultimate explanation to introduce the ideas of quanta as recently proposed by Keesom. Langevin has applied the electron theory to the explanation of magnetism and diamagnetism, but there are still many difficulties. The suggestion, first proposed by Weiss, that there exists a natural unit of magnetism called the magneton, analogous in some respects to the atom of electricity, still lacks definite confirmation.

In this brief review reference can be made only to the apparently insoluble difficulties in the explanation of the facts of radiation brought to light in recent years, and to the application of the theory of quanta which has had such a large measure of success in many directions.

Radioactivity.

The rapid growth of the subject of radioactivity after the discovery by Becquerel of the radiating power of uranium was greatly influenced by the discovery and isolation of radium in 1899 by Mme. Curie, for the radioactive properties of this element were on such a scale of magnitude that they were difficult to explain and still more difficult to explain away. The systematic chemical analysis of uranium ores disclosed the presence of new radioactive substances like polonium and actinium, while the study of thorium, radium, and actinium disclosed the emission of radioactive emanations or gases and their apparently remarkable power of conferring temporary activity on all bodies in their neighbourhood. The changes in activity of these substances with time and the different types of radiation emitted at first gave an appearance of great complexity and confusion to the rapidly accumulating mass of facts, but the whole subject took on an orderly and systematic development after the transformation theory was put forward by Rutherford and Soddy in 1903 as an explanation of radioactivity. On this view radioactive matter is undergoing spontaneous transformation of its atoms with the appearance of a succession of new radioactive bodies, each marked by characteristic chemical and radioactive properties. The radiations accompany the transformation of atoms and are a measure of the rate of transformation. Guided by this theory, the whole sequence of changes in the uranium-radium series, the thorium and actinium series, were investigated in detail, and in a remarkably brief space of time more than thirty new radioactive elements were brought to light and their position in the scheme of radioactive changes determined. Special interest attaches to the discovery by Boltwood of the substance called ionium, which is directly transformed into radium. This afforded a direct experimental method of determining the average life of radium with a result that is in close accord with the value calculated from the rate of emission of α-particles. The position of actinium in the main scheme of changes has occupied much attention. The constancy of the relative amount of actinium and uranium in uranium minerals showed that it must be derived ultimately from uranium, but the activity of actinium is too small to be in the direct line of succession. This has led to the view that actinium is a branch product at some point of the uranium series where about 6 per cent. is transformed into the actinium branch and 94 per cent. into the main line of descent. The general evidence indicates that this branching occurs near to uranium, and possibly the branch product called uranium-Y by Antonoff is the first member of the family. Recently the intermediate parent substance of actinium itself has been discovered.

While in the majority of cases the atoms of a radioactive product break up in a very definite fashion and in only one way, certain cases are known where one substance breaks into two chemically distinct substances. Examples of this are: radium C, thorium C, and actinium C. Usually the transformation is mainly in one direction with a small fraction in the side branch. It is quite probable that further study may lead to the discovery of a number of such dual transformations. In the violent cataclysm that must accompany the transformation of an atom, it is not unexpected that the constituents of the residual atom may arrange themselves in more than one configuration of temporary equilibrium.

Much attention has been directed to the properties of the radium emanation—the radioactive gas constantly produced by the transformation of radium atoms. The equilibrium volume of this gas from one gram of pure radium is only six-tenths of a cubic millimetre, but contributes more than three-fourths of the total activity of radium. By concentration of purified emanation into fine glass tubes, very powerful sources of radiation have been obtained, which have proved of great utility both in the laboratory and for therapeutic purposes. Although only about one-tenth of a cubic millimetre of purified radium emanation has ordinarily been available for experiments, methods have been devised to determine its spectrum, molecular weight, freezing and boiling points.

We owe to Hahn the discovery of two fairly long-lived products of thorium called mesothorium and radiothorium. The mesothorium, which is separated with the radium from ores containing both thorium and uranium, is transformed into radiothorium. These products can be obtained of activity greater than radium for equal weights, and give us another source of powerful radiation.

The discovery of the production of helium from radium by Ramsay and Soddy was of great importance in emphasising the reality of the transformations occurring in radium. Rutherford showed that the α-rays which are shot out from radium consist of positively charged atoms of helium so that all radioactive substances which emit α-rays give rise to helium. The production of helium by radioactive substances explains the occurrence of large quantities of helium in uranium and thorium minerals, and indeed the prediction by Rutherford and Soddy that helium would prove to be a product of radioactive transformation was based in part on this fact.

The great majority of radioactive substances are transformed with the expulsion of helium atoms with great velocity, but in a few cases swift electrons appear. The appearance of helium in so many changes, coupled with the observation that many of the atomic weights of many known elements differ by four units—the atomic weight of helium—indicates that helium must be one of the secondary units of which many of the ordinary elements are built up. It is noteworthy that so far no definite evidence has been obtained that hydrogen is a direct product of radioactive transformation, although its complete absence would be very surprising.

The proof by the Curies of the rapid and continuous emission of heat from radium showed clearly the vast amount of energy that must be stored up in radioactive matter and released by its transformation. This heat emission has been shown to be a secondary effect of radioactivity, for it is a measure of the energy of the expelled radiations, the greater part being due to the energy of the expelled α-particles.

The transformation of an atom is the result of an explosion of intense violence in which a part of the atom, whether a helium atom or an electron, is shot out with great speed. In order to produce α-, β-, or γ-rays of equal energy to those emitted by radioactive substances, potential differences of about two million volts applied to a vacuum tube would be necessary. These spontaneous radiations have been of great utility in studying the ionisation, scattering, and other properties of particles moving at high speed, while in the very penetrating γ-rays we have a type of X-rays of much shorter wave-length than can be produced at present or is likely to be produced by laboratory methods.

The properties of the α-rays have been very closely studied and their speed and mass have been determined accurately. The definiteness of the range of α-particles, to which Bragg first directed attention, is a matter of remark, and so far the apparent disappearance of the α-particle while still moving with a high velocity has not been adequately explained. The analysis of the β-rays has disclosed the presence of groups of electrons emitted at a definite velocity, so that the pencil of β-rays deflected in a magnetic field shows a veritable magnetic spectrum. The presence of these groups of β-rays appears to be connected with the emission of characteristic X-radiation from the atom, and the evidence as a whole strongly supports the view that the γ-rays from radioactive substances, like the X-rays from a vacuum tube, contain rays of a wide range of frequency in which the characteristic rays from the atom predominate.

Space does not allow me to do more than mention the extraordinary delicacy and definiteness of the electrical methods devised for measuring minute quantities of radioactive matter. By their aid the chemical properties of the numerous radioactive elements have been studied and their position in the periodic table established. The orderly sequence of changes in the chemical properties of successive elements in the radioactive series has been shown to be intimately connected with the type of radiation, whether α- or β-ray, emitted by the preceding element. One of the most important fruits of these chemical investigations has been the proof of the existence of non-separable elements, named isotopes by Soddy, which are identical in ordinary physical and chemical properties, but have different atomic weights. In the case of lead, six isotopes are already known which differ from one another either in atomic or radioactive properties. On the nucleus theory of the atom, this indicates that the charges on the nuclei are the same, but that the masses differ. The proof of the presence of isotopes promises to open up a new and very fundamental field of chemical inquiry which must inevitably exercise a great influence on atomic weight determinations and also on our ideas of atomic constitution. In a recent letter to this journal Merton has indicated that the minute change in the wave-length of spectrum lines of isotopes may give us a simple method of attack on this problem.

While the subject of radioactivity belongs in essence to the border-line of physics and chemistry, with affiliations to both sciences, it has had numerous connections with other fields of work. The examination of the earth's crust has shown that radioactive matter is very widely distributed, and has disclosed, notably through the work of Strutt and Joly, that the heating effect due to this matter vitiates to a large extent the old arguments of the duration of the earth's heat. While showing that the old views are not tenable, radioactivity has at the same time supplied new methods of estimating the age of minerals and the duration of geological epochs. The minimum age of minerals can be deduced from the helium accumulated from the transformation of radioactive matter, and the maximum age from the accumulated lead which is the product of both uranium and thorium. Now that the atomic weights of the lead isotopes are well established, the atomic weight of the lead in a uranium mineral should serve as a definite guide to the fraction of lead present which is due to the transformation of uranium and thus give a trustworthy estimate of the age of the mineral. Joly has demonstrated in a striking way that the pleochroic haloes observed in mica are of radioactive origin, and he has also estimated their age. The presence of radioactive matter in the atmosphere has been shown to account for its electrical conductivity. Just before the war, evidence was obtained indicating the presence of a very penetrating type of γ-radiation in the upper atmosphere. It is to be hoped that soon a further study will be made to determine the nature and origin of this interesting radiation. Finally, numerous investigations have been carried out to determine the effects of the radioactive rays on living tissue and on the growth of plants and organisms. With the increased use of radium for therapeutic purposes, it is likely that our knowledge of this important field of inquiry will grow rapidly.

It is a matter of remark that while the study of radioactivity has disclosed in a striking way the transformation of heavy atoms through a long series of stages, it has at the same time provided us with indubitable proof of the correctness of the old atomic theory of matter. The electric method devised by Rutherford and Geiger of counting single α-particles allows us to count the total number of α-particles projected from one gram of radium per second. By determining the volume of helium produced by the collected α-particles, we have a simple and direct method of determining also the number of molecules in a cubic centimetre of helium at standard pressure and temperature. This number is in good agreement with the number found by Millikan by measuring the charge on the atom of electricity. On account of the great energy of motion, a single α-particle can be detected in a variety of ways, by the electrical method, by the scintillations produced in zinc sulphide or the diamond, and by its action on a photographic plate.

The most striking proof of the individuality of the electron, the α-particle, and the ion has been given by C. T. R. Wilson by his beautiful photographs showing the trails of α- and β-particles through gases. By a sudden expansion, each charged ion produced by the flying particle is rendered visible by becoming the centre of a visible drop of water. In the case of the swift electron, the number of ions per centimetre of path is so small that the number may be directly counted. These photographs bring out in a vivid and concrete way the phenomena accompanying the passage of ionising types of radiation through gases, and are, in a sense, the ultimate court of appeal of the accuracy of theories of the properties of these rays.

The discovery of the electron and of the property of radioactivity has given a great stimulus to attempts to deduce the structure of the atom itself, and numerous types of model atoms have been proposed. The great difficulty in these attempts is the uncertainty of the relative importance of the *rôle* played by positive and negative electricity. In the model atom proposed by Sir J. J. Thomson the electrons were supposed to be embedded in a sphere of positive electricity of about the dimension of the atom as ordinarily understood. Experiments on the scattering of α-particles through large angles as the result of a single collision with a heavy atom showed that this type of atom was not capable of accounting for the facts unless the positive sphere was much concentrated. This led to the nucleus atom of Rutherford, where the positive charge and also the mass of the atom are supposed to be concentrated on a nucleus of minute dimensions. The nucleus is surrounded at a distance by a distribution of negative electrons to make it electrically neutral. The distribution of the external electrons on which the ordinary physical and chemical properties of the atom depend is almost entirely governed by the magnitude of the positive charge. The experiments by Marsden and Geiger on the scattering of the α-particles, and also on the scattering of X-rays by Barkla, show that the resultant units of charge on the nucleus of an element is about equal to its atomic number when arranged in order of increasing atomic weight. Strong proof of the correctness of this point of view has been given by the work of Moseley on the X-ray spectra of the elements, for he has shown that the properties of an element are defined by a whole number which changes by unity in passing from one element to the next. It is believed that the lightest element, hydrogen, has a nuclear charge of one, helium of two, lithium of three, up to the heaviest element, uranium, of charge 92.

Radioactive evidence indicates that the nucleus contains both positively charged masses and negative electrons, the positive charge being in excess. Apart from the difficulty on the ordinary laws of electric forces of explaining why the nucleus holds together, there is a fundamental difficulty of accounting for the stability of the external electrons on the ordinary laws of dynamics. To overcome this difficulty, Bohr has applied the quantum theory to define the position of the electrons and to account for the spectra of the lighter atoms and has made suggestions of the structure of the simpler atoms and molecules. Space does not allow me to discuss the important developments that have followed from Bohr's theory by the work of Sommerfeld, Epstein, and others. The generalised theory has proved very fruitful in accounting in a formal way for many of the finer details of spectra, notably the doubling of the lines in the hydrogen spectrum and the explanation of the complex details of the Stark and Zeeman effects. In these theories of Bohr and his followers it is assumed that the electrons are in periodic orbital motion round the nucleus, and that radiation only arises when the orbit of the electron is disturbed in a certain way. Recently Langmuir, from a consideration of the general physical and chemical properties of the elements, has devised types of atom in which the electrons are more or less fixed in position relatively to the nucleus like the atoms of matter in a crystal. It appears necessary, in Langmuir's theory, to suppose that electrons, in addition to their electrical charges, are endowed with the properties of a magnetic doublet, so that at a certain distance the forces of attraction and repulsion between two electrons counterbalance one another.

The whole question of the possible arrangements and motion of the external electrons in an atom or molecule still remains a matter of much doubt and speculation. While there are strong indications that the conception of the nucleus atom is in the main correct, we are still very uncertain of the laws controlling the position of the external electrons on which the ordinary physical and chemical properties depend. The study of the light spectra and also of the X-ray spectra already promise to throw new light on this very difficult but fundamental problem.

From the above hurried survey of the progress of atomic physics, it will be seen that the investigations of the past twenty-five years have dealt mainly with three great outstanding problems, viz., the nature of electricity, the structure of the atom, and the nature of radiation. While great additions have been made to our knowledge of these questions leading to a much wider outlook, we cannot but recognise that much still remains to be done before we are certain that we are building on a firm foundation for the future. Notwithstanding the prolonged halt during the war, the scientific outlook is one of good augury for the immediate future, and there is every prospect that the vigorous attack on these outstanding problems will be continued.

ATOMS AND MOLECULES.

By PROF. FREDERICK SODDY, F.R.S.

IT may be doubted whether, fifty years ago, chemists and physicists believed very deeply in the actual reality of the molecules and atoms, which they used as convenient and simplifying conceptions to interpret the behaviour of matter. The half-century, indeed, has not passed without strong protest from the thermodynamical school of physical chemistry that the science should be so wedded to pure hypotheses and unverifiable assumptions, then, apparently, for ever beyond the power of being actually apprehended and demonstrated. That the modern student of physical science believes in the reality of the existence of his atoms and molecules, as much as he does in that of chairs, tables, and lamp-posts, probably sufficiently epitomises one of the most striking features of the change of outlook since NATURE made its first appearance in 1869. Vague ideas of their actual individual mass, size, shape, and constitution have been or are being replaced more and more by exact quantitative knowledge, which invites our literal acceptance and grows in fruitfulness the more implicitly it is used as the basis for further investigations.

But the latter half of the period under review witnessed an even greater change of outlook. The atom, since the discovery of radio-activity in 1896, has ceased to be the smallest coin of the realm of material change. The farthings of 1869 have proved to resemble 1000*l.* notes, and the potentialities of the world in consequence have been multiplied a million times. The change of the single atom of matter is well within the range of direct perception by the senses, and, stranger still, the change reveals that, under the image and superscription of the same Cæsar, coins of different mass and mintage have been circulating unsuspected in the chemist's currency.

As regards the physical reality of molecules, by no means the least important factor contributing to the result has been the recognition that, if the molecules were not the smallest parts of matter capable of free independent existence and motion, heat would not be the final permanent form which all kinetic energy liberated in the world assumes. The limit that fixes the physical sub-division of matter limits also the sub-division of motion. Though in the real world of matter in bulk, as contrasted with the ideal fictions of mathematics, friction and imperfect elasticity quickly reduce all moving masses to apparent rest, that "rest" is the perpetual heat motion of the molecules, which, literally and necessarily, must be perfectly frictionless and elastic because they are the smallest particles capable of free independent motion, and no smaller particles exist among which their motion can be further distributed.

Moreover, in accordance with the law of equipartition of energy, all molecules at the same temperature, whatever their mass, become, in consequence of their ceaseless mutual collisions, possessed of the same average amount of kinetic energy, and, therefore, of a velocity of translation inversely proportional to the square-root of their mass. This serves to clarify the conception of the real molecule from misnomers still unthinkingly retained.

For example, it is a pure survival of past confusion to speak of the molecule of a crystalline solid, if not of any solid, for in such the smallest parts are not free to move, but are anchored in fixed, unchanging positions in the crystal space-lattice, as the resolution of X-rays by the crystal structure has shown. It is, similarly, always a pure misnomer to give the name "molecule" to the least number of atoms which represent the chemical composition and properties of a substance, in the absence of experimental knowledge of the molecular magnitude, and therefore of any knowledge as to whether such a particle really exists in a form capable of free independent movement.

Cleared of these ambiguities, the conception of the individual molecule has become very real. We have been led by Perrin, and the mathematical physicists who paved the way for his experimental work, to recognise the Brownian movement as but one aspect of the perpetual motion of the molecules, which, though invisible to the naked eye, becomes swift and ceaseless for particles even of the scale of minuteness resolved by the microscope, and we can extrapolate with assurance to the minuter world which science had long before visualised by faith.

Or, again, we may follow Langmuir, with none of the feeling of hesitancy and diffidence that would have held back an earlier generation, into the explanation of catalysis, adsorption, and allied phenomena, as caused by surface layers of molecules "one molecule thick." Nor do we consider it fanciful to explain the spreading of animal and vegetable oils upon water and the non-spreading of mineral oils, as due to the attempt, in the first case, of the one end, the soluble glycerine ester end, of the rod-like molecule to dissolve in the water, and the refusal of the other end, the insoluble, hydro-carbon, or oily end, to do so. Wherefore the molecules of such oils stand up on end and cover the surface with a one-molecule thick layer of the oily ends of the molecules, whereas the mineral oils, with molecules oily at both ends, do not spread! Real in one sense as the structural formulæ of organic compounds have been for many decades, an earlier generation would scarcely have thought of this.

The discovery that the X-rays are of a character identical with light, but of wave-length of the order of one ten-thousandth of that of light of the visible spectrum, has made the structure of crystalline solids as open to direct examination as the ten-thousand-fold coarser structure of the Rowland grating, ruled by the dividing engine, is by means of ordinary light. In this way many of the space-lattices hitherto arrived at only by the aid of the second-sight of the mathematical crystallographer have been tested and found real.

Since the explanation by Le Bel and van't Hoff of optical isomerism as due to structural differences of the arrangement of the atoms in the molecule, of the kind that exist between an asymmetrical object and its mirror-image, and therefore only capable of representation in space of three dimensions, chemists have, not without reproach, used model carbon atoms in building up the structure of organic compounds, and have found them capable of accounting, for example, in cyclic structures, for many of the properties of these compounds far removed from the field of optical activity. That the real carbon atom should possess any resemblance to these little wooden balls bearing four spokes radiating symmetrically from the centre may have appeared to many too crude a conception for literal belief. Yet when the character of the space-lattice of the diamond crystal was elucidated by means of the X-rays, these very models were used to represent it—a striking proof, surely, of the basis of physical reality underlying the conceptions of stereo-chemistry.

But these triumphant vindications of what only a generation ago were described as purely hypothetical and unverifiable conceptions have been to some extent overshadowed and eclipsed by the startling progress made since the discovery of radio-activity in 1896 and its almost immediate interpretation as due to the explosive disintegration of the atoms of the radio-elements. This subject is being treated by Sir Ernest Rutherford in another article, and need be only briefly alluded to here. The change is attended by the liberation of energy a million times greater than is liberated in any previously known change of matter, and so it has come about, as for example in the spinthariscope, that the effect of each individual atom disintegrating can be perceived by the senses. The counting of the number of atoms disintegrating per minute has become one of the regularly used methods of investigation, whereas it requires, at least, some 25,000 times as many atoms as there are people alive in the world before an element can be detected by the spectroscope. The condensation of moisture on the columns of ions, lying in the tracks of the fragments of the atom after its explosion—both of the α- and β-particles, which may be likened to projectiles fired from a gun, and of the recoiling residue of the atom or gun itself—has in the hands of C. T. R. Wilson enabled the individual atomic explosions to be photographed. These permanent records, of extraordinary interest and value as they are as confirmatory evidence, yet revealed nothing new. Every detail of the whole phenomenon had been correctly comprehended and established without such direct aid. In particular, the photographs show well the almost rectilinear flight of the α-particle through the myriads of gas atoms in their path, and their rare and occasional wide-angle deviation when perchance they pass near enough to the heart of the atoms penetrated, which is the experimental basis for the present provisional representation of the internal structure of atoms.

The atom is regarded now as a solar system, but the massive central sun, comprising all but a negligible fraction of the whole mass, is an exceedingly minute positively charged nucleus, attended by numerous rings or shells of the almost mass-less electrons. In spite of its relatively great mass, the nucleus is so minute that the chance of an α-particle—which itself is the nucleus of a helium atom—in its passage through the atom approaching or colliding with the central nucleus, is exceedingly small. Mass and radio-activity alone seem to depend directly upon this hitherto unsuspected and all-important nucleus. The chemical and physical properties, including the light spectrum, are governed probably by the outermost shell or ring of valency electrons, which alone are variable in number. The coming and going of these seem to constitute chemical change and to give rise to ordinary light radiation. Barkla's various series of X-rays characteristic of each element probably originate in the successive completed rings or shells of electrons surrounding the nucleus.

All the properties of the atom, practically, save mass and radio-activity, depend solely upon the numerical value of the positive charge of the nucleus, which is equal to the number of the surrounding negative electrons. This number, which is known as the atomic number, increases unit by unit in passing from one place of the periodic table to the next. From numerical relationships between the wave-lengths of the characteristic X-rays, Moseley was able to determine or infer this atomic number for all the elements. So he called the roll of the elements for the first time and found between hydrogen, the first, and uranium, the last and ninety-second element in the table, only five still missing.

In the course of successive radio-active changes the radio-element expels from its nucleus an α- or β-particle, so losing two positive charges, or, relatively, gaining one, and shifting back two places or moving forward one in the periodic table. The expulsion of one α- and two β-particles produces an isotope of the parent, chemically and spectroscopically identical with it, but of atomic mass four units less. The ultimate products of uranium and thorium have been identified as isotopes of lead of atomic mass 206 and 208 respectively, and this has been confirmed by an examination of the atomic weight of the lead derived from uranium and thorium minerals. Of all strange consequences of the atom changing, this is perhaps the most subtle and hitherto unsuspected, for now nothing is more certain than that the analysis of matter into chemical elements depends on a superficial identity of the outer shell of the atom, and that the same type of outer shell may contain internal nuclei of different mass and different constitution.

Naturally, the many, at first separate and independent, lines of evidence which have led to the present results cannot all be even mentioned in an article of this length. The significant fact is that all the new and powerful methods of attack developed by physics and chemistry during the last quarter of a century are converging successfully on the problem of the internal constitution of the atoms. The prospects of successful accomplishment of artificial transmutation brighten almost daily. The ancients seem to have had something more than an inkling that the accomplishment of transmutation would confer upon men powers hitherto the prerogative of the gods. But now we know definitely that the material aspect of transmutation would be of small importance in comparison with the control over the inexhaustible stores of internal atomic energy to which its successful accomplishment would inevitably lead. It has become a problem, no longer redolent of the evil associations of the age of alchemy, but one big with the promise of a veritable physical renaissance of the whole world.

Even in the present year a further significant advance in this direction has been made. For it appears, from the latest results of Sir Ernest Rutherford on the passage of α-particles through nitrogen, as though the nuclei of an exceedingly minute proportion of the nitrogen atoms struck by the α-particle were shattered by the collision. If this is so, artificial transmutation on an infinitesimal scale has already been accomplished, though, it is true, only by the aid of a previous natural transmutation, still impossible artificially to imitate.

IONISATION OF GASES.

By Prof. J. S. Townsend, F.R.S.

During the last fifty years many physicists have been occupied in studying problems connected with electric currents in gases. The earlier work was principally confined to experimental investigations of the general outlines of the phenomena which occur in discharges obtained with high potentials. The large number of complicated and surprising properties of gases which were thus discovered naturally attracted much attention, and it is very interesting to read the accounts of the first experiments of the discharges in air and through vacuum tubes which were written before any special investigations of the theory of the conductivity were undertaken.

It would clearly have been extremely difficult to obtain from these experiments any general theory of electricity to explain what was taking place, as such a large number of different phenomena seemed to occur simultaneously. From the first, some physicists maintained that the currents through gases were carried by means of ions, as in liquids, although there were peculiar differences between the two cases, and it was not evident why under a given force a gas might act either as an insulator or as a conductor.

The greatest success in advancing the theory of electricity was obtained from careful studies of the discharges at very low pressures. In this direction some remarkable experiments on the cathode rays were made by Hittorf in 1869. He found that the rays travelled in straight lines from the cathode; when they fell on glass they caused the surface to fluoresce, and an obstacle in the path of the rays cast a shadow on the glass. He also found that the rays were deflected by a magnet into circles, or more generally into spirals, which were described in the direction which would be taken by negatively charged particles moving from the cathode. Notwithstanding these results, and further experiments made by Crookes, the projected particle theory of the rays was not at first universally accepted, and some physicists maintained that the rays were an undulatory motion of the ether. This question was decided by Perrin in 1895. He showed by direct experiment that the rays carried a negative charge, but thus far the origin of the rays, their velocity, and the mass and charge of each particle were unknown.

The question of the ratio of the charge to the mass was studied by Schuster in 1890, and he concluded that in gases it was of the same order as in liquids, but for negative ions it was larger than for positive. This was the first indication of the characteristic difference between positive and negative ions in gases.

A direct method of finding the ratio of the charge e to the mass m of the cathode particles, and the velocity of the particles, was devised by Wiechert, and in 1897 he described the experiments which showed that in some cases the velocity of the rays was about one-tenth of the velocity of light, and that the ratio e/m for the cathode rays was between 4000 and 2000 times as great as the corresponding quantity for a hydrogen atom. Thus, assuming the charges to be the same in the two cases, the experiments showed that the mass of a cathode particle is very small compared with the mass of an atom of hydrogen. This small cathode particle has been called the electron. Further experiments show that currents of negative electricity obtained from metal surfaces by other methods also consist of streams of electrons. Thus Sir J. J. Thomson investigated the charged particles set free from hot wires or from a metallic surface by the action of ultraviolet light, and found that in both cases the ratio e/m was the same as for cathode rays. The values of e/m afterwards found by various methods show that the ratio of the mass of the electron to the mass of an atom of hydrogen is 1 : 1830. This value of e/m is constant provided the velocity is small compared with the velocity of light, but with velocities of this order the effective mass of the electron increases, and Kaufmann found that the value of e/m diminishes in accordance with Lorentz's theory as the velocity approaches the velocity of light.

During the earlier part of this period some investigations were made of the currents that can be obtained with forces smaller than those required to produce discharges. The positive and negative ions produced in air at atmospheric pressure at the surface of incandescent metals, the conductivity of flames, and the charges obtained in newly prepared gases, or by bubbling air through water, were examined. In these cases the mass associated with the ions is comparatively large, and varies rather irregularly over wide ranges, so that it was difficult to formulate precise theories from the results of the experiments. These large ions have the property of condensing water vapour, and in a moist atmosphere small drops are easily obtained which form a visible cloud. This phenomenon led to the method of estimating the charge on each particle. The number of particles in a given volume was found by dividing the weight of the cloud by the weight of each particle estimated from the rate of fall of the cloud. The charge on each particle was then obtained by dividing the total charge by this number. Various corrections and improvements were later introduced by Millikan, and the charge on an ion in a gas has been found to be 4.7×10^{-10} electrostatic unit.

The remarkable discoveries made by Röntgen and Becquerel, which have led to so many advances in the knowledge of molecular physics, were of invaluable assistance in providing means of studying the properties of ions in gases. It was found that X-rays and the rays from radioactive substances made gases conduct, and it was possible to obtain ionisation at a uniform rate in gases under various conditions, with the advantage that the mass associated with the ions was not liable to irregular change.

Special experiments were devised to determine the rate of recombination of positive and negative ions, the velocity of the ions under electric forces and their rate of diffusion; and various properties of ions in gases were discovered.

The experiments on diffusion, for instance, led to a method of finding the number of molecules per cubic centimetre of a gas and of comparing the charges on ions in liquids and in gases. If N be the number of molecules per cubic centimetre of a gas at atmospheric pressure and 15° C., and e the charge on an ion in a gas, a direct determination of the product $N \times e$ is given by observing the lateral diffusion of a narrow stream of ions. The value of $N \times e$ thus found is 1.23×10^{10}, and as the charge e was also found by other experiments, the value of N is seen to be 2.6×10^{19}.

If E be the charge on a hydrogen ion in a liquid, the total charge $2N \times E$ carried by all the atoms in a cubic centimetre of the gas is equal to the quantity of electricity required to evolve that volume. When expressed in electrostatic units, the latter quantity is 2.46×10^{10}. Thus the two charges E and e are the same.

Another line of investigation was undertaken in order to discover how ions are generated in large numbers, as when small changes of force convert a gas from an insulator to a conductor. It was found that when ions are generated by Röntgen rays or by ultra-violet light a maximum current composed of ions generated by the rays was obtained with small forces, but as the force increased beyond a certain point new ions are generated in the gas by the motion of those produced initially by the rays. At first the new ions are produced by the collisions of negative ions, or electrons, with molecules of the gas, and as the force increases and approaches the value required to produce a discharge, the positive ions also acquire the property of generating others by collision.

The theory of ionisation by collision was found to be in accurate agreement with the experimental determinations of the forces required to produce spark discharges, brush discharges, and the corona discharge which is accompanied by a glow over the surface of a wire or cylinder.

Thus the various properties of ions which have been discovered in the last fifty years have already explained many phenomena connected with electric currents.

SPECTROSCOPIC ASTRONOMY.

By Prof. A. Fowler, F.R.S.

The science of celestial chemistry and physics was brought into existence in 1859, when Kirchhoff's famous experiment on the reversal of spectral lines furnished the key to the interpretation of the dark lines of the solar spectrum, and thence to the determination of the composition of the sun and stars. The new science developed with extraordinary rapidity, and within ten years the spectra of all the different classes of celestial bodies had been carefully observed. The gaseous nature of some of the nebulæ had been discovered by Huggins, and a spectroscopic classification of stars had been made on such sure foundations by Secchi that it still survives as one of the most convenient modes of describing the main features of stellar spectra. The memorable discovery by Lockyer and Janssen of the method of observing solar prominences without waiting for an eclipse of the sun was also made during this fruitful period, and the possible determination of the radial motions of stars by displacements of the spectral lines had been put to a practical test by Huggins. The demonstration that the immensely distant celestial bodies were composed, in part at least, of the same kinds of matter as the earth may well take rank among the greatest triumphs of science.

The half-century which has elapsed since the first issue of this journal has witnessed a progress which must far exceed the highest hopes of the earlier workers. Some of the advances have followed from the increased apertures of the telescopes which collect the light for spectroscopic examination, but many more are to be attributed to the substitution of photographic for visual methods of observation which was made practicable by the introduction of the gelatine dry plate.

Great observatories dedicated to astrophysics have been erected, notably in America, and observational methods have reached a high degree of refinement. In solar investigations, where the great intensity of the light allows of the use of instruments of high resolving power, velocities on the sun's surface can now be measured with a probable error of only a few metres per second; and even more remarkable is Hale's determination of the general magnetic field of the sun by observations of Zeeman effects involving displacements usually amounting to less than one-thousandth of an Ångström unit. Stellar spectroscopes have been improved by the provision of temperature control and other aids to efficiency, so that radial velocities are now measurable in the case of the brighter stars to within a quarter of a kilometre per second. With the exceptional resources of the Mount Wilson observatory, stellar spectra have even been photographed on a scale comparable with that of Rowland's great map of the solar spectrum, providing data for deductions, among other things, on such a delicate matter as that of the pressure in the atmosphere of a star.

Not less important has been the development of experimental researches bearing upon the interpretation of celestial spectra. The study of enhanced lines initiated by Lockyer has been especially productive, not only in relation to stellar temperatures, but also in leading to a satisfactory explanation of most of the lines which are met with in the spectra of the hotter stars, where we might well have expected that the reproduction of the conditions would be outside the range of our laboratory resources. The application to sun-spots of Zeeman's discovery of the effect upon spectrum lines of a strong magnetic field, and Ramsay's discovery of terrestrial helium following its previous detection in the sun's chromosphere, are familiar examples of the close bonds which unite astronomy with other sciences to their mutual advantage.

The spectrum of the sun has naturally been the subject of an immense amount of detailed study, and as the work has progressed it has become less and less probable that there are any substances in the sun which do not also exist on the earth. The spectra of sun-spots and of the chromosphere have also been minutely recorded, and most of their peculiarities have been satisfactorily accounted for. The bright lines of the coronal spectrum, however, have not yet been matched in any terrestrial source, but the precise knowledge of this spectrum which has been obtained during total eclipses has stimulated theoretical investigations, and some extremely suggestive relations have been deduced by Nicholson in his calculations of the spectra of atoms of assumed simple structure. Similar considerations have also been extended to the unidentified lines which occur in nebulæ.

As regards the stars, many of them have been photographed in great detail for minute analysis, and a multitude more for purposes of classification. Secchi's classification, at first merely empirical, soon came to be regarded as indicating the actual sequence of forms assumed by a star in the process of cooling, and the same idea is embodied in the Harvard system of classification, which has been most widely adopted by astronomers in recent years. Lockyer, however, has based a classification on the supposition that there must be stars which are becoming hotter as well as stars which are cooling down, in accordance with the theory of condensing masses of gas or meteorites, and this view has lately been greatly strengthened by the work of H. N. Russell on the densities of stars. In either case the impressive result is that the different types of stars are not to be looked upon as arising from fundamental differences of composition, but as representing successive stages in an orderly evolutionary progression.

The spectroscopic determination of the velocities of stars in the line-of-sight, irrespective of distance, has united the old and the new astronomy in the great task of deciphering the intricacies of structure of the sidereal universe. Besides contributing the velocities and spectral classes of individual stars, the spectroscope has revealed the existence of a large number of close binary systems, and has provided the most trustworthy means of investigating the sun's motion in space, the effect of which is to be eliminated in deducing the movements of the stars themselves.

An entirely new field for the spectroscope has been opened up by the remarkable discovery by Adams of a method of estimating the absolute brightnesses, and thence the distances, of the stars by mere inspection of photographs of their spectra. This novel method is full of promise, and encourages the hope that other equally unexpected applications of the spectroscope may yet be discovered.

Lack of space forbids even the enumeration of many other remarkable achievements, but sufficient may have been said to convey some impression of the enormous extension of the scope of astronomical research which has been brought about by the introduction of the spectroscope. It cannot be doubted that the spectroscope will continue to play a leading part in the advancement of our knowledge of the universe of which we form a part.

X-RAYS IN PHYSICAL SCIENCE.

By Prof. W. H. Bragg, F.R.S.

It is twenty-four years since Röntgen made the famous discovery which at once excited such immense and widespread interest. Everyone felt the fascination of the photograph which actually showed the bones of a living human hand. Surgeons seized on its obvious application to their craft; students of physical science realised that a new and most powerful means of investigation had been placed in their hands. And at the present day we see that the first expectations have been more than realised. We stand only at the beginning of what the Röntgen rays promise to accomplish for us.

Knowledge of the main properties of the X-rays grew rapidly under the labours of Röntgen himself and the many investigators who were attracted to the new field. Much was discovered respecting the power of penetrating various substances, the existence of different qualities, hard or penetrating, soft or less penetrating, the dependence of quality on the degree of evacuation, the construction and the applied potential of the X-ray bulb, the action on the photographic plate and on the fluorescent screen, and the power of producing ions in a gas. At the same time, the technique improved rapidly; bulbs, plates and screens, coils and interruptors were all designed afresh to meet the demands of an experiment which grew into an industry.

Notable advances were made by Barkla when he proved the existence of a polarisation which was to be expected on the hypothesis that the rays were ethereal waves or pulses, and when he showed that every element emitted its own special and characteristic X-rays under proper stimulus. The properties of characteristic radiation are most remarkable and instructive. The radiation of any element can excite the corresponding characteristic radiation in elements lighter than itself, but never in any element which is heavier. For example, "zinc rays" can excite the characteristic radiation of magnesium, potassium, or nickel, but not the characteristic radiation of bromine or silver, nor, indeed, of zinc itself. Since energy is necessarily spent in the excitation of radiations, the absorption coefficients of zinc rays by the various elements show a marked discontinuity; they increase steadily from magnesium upwards, but there is a sudden drop at zinc, the coefficient falling to about one-eighth of its previous value. After that the coefficient increases steadily with the atomic weight as before.

X-rays can excite an electron radiation in any substance on which they fall, and this effect has also been the subject of much investigation. The more penetrating the X-rays, the higher the velocity of the electron which it can cause to be emitted. This effect is carried to an extreme in the corresponding emission of very high-speed electrons under the stimulus of the γ-rays of radium, for the parallelism between all the properties of X-rays and γ-rays is an obvious indication of the similarity of their nature. There is a striking correspondence in the two processes—that of the excitation of X-rays by the moving electrons of the X-ray bulb, and that of the emission of electrons under the stimulus of X-rays. The quality of an X-ray depends on the velocity of the electron that excited it, and not at all on the number of electrons in the exciting stream; conversely, the velocity of an electron due to X-rays depends only on the quality of the rays, and not at all on their intensity. Some kind of matter is required to bring about either of the energy transformations, but the atomic weight of it has no influence on the principle just stated. Anomalies may appear when characteristic radiations are excited, but they can be explained as apparent only.

Many other remarkable properties, which cannot be described in so brief a notice as this, were discovered in the first period of X-ray investigation. All of them were examined with the greatest interest, because it was recognised that if X- and γ-rays were essentially of the same nature as light, their study must contribute to any true theory of light radiation, and, indeed, must be necessary thereto.

A new period of investigation began when von Laue and his collaborators demonstrated in 1912 that X-rays could be diffracted by the ordered array of the atoms of a crystal. From a simple interpretation of von Laue's principle, and from the results of its application to the study of crystals of sodium and potassium chloride, W. Laurence Bragg was able to discover the actual arrangement of the atoms of those crystals and the distances separating the atom-bearing planes. It thus became possible to find the actual length of an X-ray. The older and vaguer methods of defining the quality of an X-ray were at once replaced by a method of great precision. Previous work can now be revised under infinitely better conditions, and much has already been accomplished in that direction.

Moseley, making a careful survey of the wave-lengths of the radiations of all the elements available, showed that the wave-length of the characteristic radiation marched in perfectly even step with the increase of the atomic number, and, therefore, that the atomic number of an element defined it more fundamentally than its atomic weight. So all the elements were drawn together by a common tie as they had never been before; anomalies of position in the periodic table were explained, and the number and places of missing elements were made clear.

The examination of the interchange of energy between X-radiation and electron movement can now be made so effectively that it has been possible to use the experimental results for one of the best determinations of Planck's constant.

In another direction the new discoveries have opened out a wide road of advance into crystallography. In the first place, it is possible to determine the crystal lattice—that is to say, to measure the sides and angles of the rhomboid cell which contains the unit pattern of atomic assemblage and is repeated throughout the crystal without change of form or orientation. This is a comparatively easy task. It is a second and more difficult task to determine the arrangement of the atoms within the cell; it has been accomplished in a few single cases only. Lastly, the new researches will give us information concerning the position of the electrons or the diffracting centres within the atoms and about their normal movements. Something has already been done in this direction also.

Moreover, the new knowledge reacts on older information, shaping it for interpretation and making it more valuable. From a knowledge, for example, of the elastic constants of crystals, the forces between the atoms themselves may be calculated as soon as the architecture of the crystal is known. It will be possible to make use of facts concerning cleavage planes, occurrence of certain natural faces and not of others, etching figures, and the like. Light will be thrown on the meaning of valency and on all that lies at the root of chemical action. If the atomic forces can be calculated, an explanation of the form of the wave-surface of light within a crystal will be at hand.

X-rays have been applied with ever-increasing success to medicine and surgery; their extraordinary power of revealing the interior of a body without disturbing its exterior are beginning to be recognised as a trustworthy aid to industry, as, for example, in the detection of flaws of construction otherwise invisible; and their use in observing the crystalline state is already being considered as a probable and welcome aid to metallurgical problems. But still the richest mode of their employment is by the indirect methods of pure science. Their unique properties help as nothing else can to a knowledge of the relations between radiation and matter, ether-waves and electrons, atoms and the forces that bind them together, which are among the greatest of the fundamental problems of physics.

X-RAYS IN MEDICAL SCIENCE.

By A. C. Jordan, M.D., M.R.C.P.

The discovery of X-rays in 1895 was justly hailed as one of the greatest scientific marvels of any age. Medical men eagerly grasped the possibilities of these rays, which enabled them to see the internal organs of their patients actually at work, hitherto impossible even to surgeons, who in the course of their operations had the organs exposed to view, but only under conditions of anæsthesia.

The first practical uses to which X-rays were applied were: (1) In the detection and localisation of metallic foreign bodies, such as needles and bullets; (2) in the detection and localisation of metallic or other foreign bodies that had been swallowed; (3) in the diagnosis of fractures of bones: this branch of radiology has made enormous strides during the war, and has led to a vast improvement in the treatment of fractures and to the saving of countless limbs; (4) in the diagnosis of calculi in the urinary tract and elsewhere: these foreign bodies throw shadows which have to be distinguished from concretions in the bowel and calcareous deposits: many pitfalls lie in wait for the unwary observer, and the right interpretation of these shadows, even at the present time, calls for skill, patience, and discrimination; (5) in the diagnosis of diseases of the chest: the appearance of the normal movements of respiration and of the beating heart was closely observed, and as a result of these observations upon healthy subjects this branch of physiology has had, to a large extent, to be rewritten. The position of the heart and vessels in the chest—in the midst of the air-filled lungs—rendered accurate diagnosis difficult by the older methods of physical examination, but by means of X-ray examinations with the fluorescent screen the mechanism of the heart has been closely studied and its diseases accurately diagnosed.

In regard to diseases of the lungs, pneumonia, pleurisy, abscess of the lung, tumours, enlarged glands in the chest, and many other conditions produce characteristic shadows on the fluorescent screen, and enable the site, nature, and extent of the disease to be determined. In pulmonary tuberculosis the aid which X-rays have brought to its early diagnosis, and in defining its extent, has proved of such value that this means of diagnosing phthisis is playing an essential part in the campaign in progress for dealing with this scourge. X-ray study has shown that the first changes which occur in the lung in this disease lie so deeply buried in the chest—under cover of a thick layer of healthy lung—that they are quite beyond the reach of the older methods of detection by percussion and auscultation. By the time the stethoscope is able to discover the signs of consumption, the disease is probably so far advanced that the prospects of a cure are remote. The diagnostic utility of X-rays has increased steadily with the continued improvement in the apparatus and the increased skill and experience of those engaged in this branch of science.

The correct estimation of fractures and other injuries to bone and joints necessitated an accurate study of the form and texture of normal bones, as well as the individual variations that occur in the conformation of bones and their joint surfaces. This knowledge led at once to a most important extension of the diagnostic powers of X-rays—the recognition of disease in bone and the differential diagnosis of many diseases of bones and joints.

So far we have considered radio-diagnosis as dependent on differences of density among the tissues. Bone, with its lime salts, is far more opaque to X-rays than muscle: consolidated lung is more opaque than healthy, air-filled lung. At first sight this precludes from the range of radio-diagnosis a very important part of the body—the hollow viscera constituting the digestive tract. Very little information is to be gained from an ordinary X-ray inspection of the stomach and bowels, but the introduction of opaque substances into hollow organs with the object of determining their outlines and of observing abnormalities of size, shape, or function has opened up an entirely new extension of the science of radio-diagnosis.

An "opaque meal" consisting of a heavy insoluble salt, such as carbonate of bismuth, is given in a dose of 2–4 oz. Its progress is observed through the œsophagus into the stomach and duodenum, and observations are continued at intervals to note the position and behaviour of each part of the small and large intestine as the bismuth passes through. By this means much new information is being gained concerning the physiology and the diseases of the alimentary tract. Our views regarding the causation and nature of many of the affections of the digestive system have had to be reconsidered and modified.

Medical and surgical text-books of a few years ago contained separate chapters devoted to individual diseases, such as gastric ulcer, duodenal ulcer, gall-stones, and appendicitis, but when radiologists were called upon to aid in the diagnosis of these various diseases they tendered evidence that showed conclusively that these diseases were not isolated morbid affections of the organs concerned, but "end-results" of a more general derangement of the digestive system. In other words, the stomach or appendix does not "go wrong" by reason of any intrinsic vice, but because it is in an environment which has become vitiated or unhealthy.

An entirely different aspect of our subject is the application of X-rays to the treatment of disease. From observations upon the far-reaching consequences of undue exposure to the action of X-rays, radiologists were led to explore their possibilities for therapeutic purposes.

It is well known that the first workers in the field of radiology were destined to pay a heavy price for their devotion. The repeated exposure of the skin to the action of the new rays set up a disease in skin known as X-ray dermatitis. Gradually the skin and even the deeper tissues of the hands and other parts that had been exposed to the action of the rays were destroyed. Extensive and painful sores appeared which penetrated deeply and resisted all attempts to induce healing, and in some cases cancerous change set in, necessitating the loss of a limb, and unfortunately, in a few cases, leading to a fatal termination. It was natural to surmise that an agent with such terrible powers for evil as X-rays possess might, in suitable small doses, be converted into a means of salvation, in the same way as many deadly poisons—strychnine, opium, digitalis, and mercury—have become the physician's most potent and useful remedies when rightly administered.

It was found that certain diseases of the skin yielded very readily to carefully administered applications of X-rays; and to-day ringworm, so difficult to eradicate by ordinary methods of treatment, is almost universally treated by X-rays. Prior to this treatment primary schools were deprived of numbers of their pupils for long periods, averaging two years for each child, but now the disease is usually eradicated in three months.

Other diseases which have been treated with a large degree of success by irradiation are: Tuberculous glands; other gland enlargements, such as occur in lymphadenoma (Hodgkin's disease); uterine fibroids; exophthalmic goitre (Graves's disease); blood diseases, such as leukæmia; and some forms of gout, rheumatism, and neuritis: in these painful disorders X-ray treatment relieves pain even when it cannot achieve a cure.

In view of the successful application of X-rays in dispelling enlarged glands, the question naturally arose: Have we here a therapeutic agent which can cure that most dreaded of all diseases—cancer? The answer to this important question was sought with diligence, and at first with much promise. But its limitations soon became apparent, and to this day the results of X-ray treatment of cancer have not fulfilled our greatest hopes. True, many cancerous masses can be destroyed and made to disappear by this treatment, yet a genuine cure does not always follow. Other growths may appear in inaccessible places, or general dissemination of cancer may set in. Early removal by operation is still the safest method of dealing with a cancerous growth. The removal may, however, be advantageously followed by the systematic irradiation of the operation area, so as to destroy any cancerous cells that may have been left behind. We must not (nay, we dare not) despair of the successful treatment of cancer. Recent researches, however, lead to the conclusion that the road to salvation is in the prevention rather than in the cure of the disease. In these researches X-ray observations of the digestive system occupy a prominent place. They have taught us that particular sections or points in the gastro-intestinal tract become so altered from their healthy state as to be specially liable to take on a cancerous change. We have learnt that toxic products, absorbed from the intestinal canal into the general circulation, give rise to deterioration of the tissues and render them liable to become cancerous as the result of some slight source of continued irritation such as would do no harm to healthy tissues.

The effects of X-ray exposures on white blood corpuscles are receiving increased attention, and to-day results are being obtained which are of great interest. We know, for instance, that the white cells of the blood play a leading part in the struggle with invading microbes. If particular kinds of white cells can be increased in numbers and in activity, we shall have gained a notable step in treatment. Already there are reports from more than one part of the world of promising results from treatment on these lines in cases of pulmonary consumption.

It will be seen from the foregoing brief account that important developments in the functions of X-rays in the direction both of diagnosis and of therapeutic application can be hopefully awaited.

Every day we are learning more of the nature and properties of the various kinds of X-rays, the soft and hard primary rays, the homogeneous and other secondary rays; and knowledge is increasing regarding their action on the surface and within the body tissues.

It is safe to predict that in the coming years X-rays will play an increasingly important part in attaining the end and aim of all medical study—the prevention of disease and the maintenance of a high standard of health and efficiency in the community.

PROGRESS OF ELECTRICAL INVENTION.

By Prof. J. A. Fleming, F.R.S.

THE progress of electrical discovery and invention, and especially of electric lighting, telegraphy, and telephony, in the last fifty years is the theme on which the Editor of NATURE has asked me to make a short contribution to this jubilee issue. The chief difficulty, however, is in selecting from the enormous stores of accumulated knowledge the topics most worthy of notice in a space all too brief for any adequate treatment.

Casting our glances backward to 1869, we can, however, say that on the theoretical side electrical science was then beginning to emerge from the stage of a chiefly qualitative study of phenomena into an era of quantitative measurement, on which progress so much depends. The initial attempts to lay deep-sea submarine cables and the engineering aspects of land telegraphy had compelled attention to the exact measurement of electrical quantities. Advanced physicists had already appreciated the advantages of an absolute system of measurement based on the fundamental units of space, time, and mass; but practical electricians still employed vague phrases such as "quantity currents" and "intensity currents," and precise ideas on the subjects of potential, capacity, inductance, electric energy, and power were not widely diffused. Lord Kelvin (then Prof. W. Thomson) had, indeed, started into existence some years previously (in 1861) the famous British Association Committee on Electrical Units, and Maxwell, Balfour Stewart, and Fleeming Jenkin had commenced experiments on the practical determination of the ohm, or British Association unit of electric resistance, for which work Faraday, W. Thomson, and Maxwell in Great Britain, and Gauss, Weber, and Helmholtz in Germany had laid the foundations.

A new era began in 1873 with the publication of Maxwell's stimulating work on electricity and magnetism. Up to that time students of the subject for the most part obtained their knowledge from such descriptive non-mathematical works as de la Rive's great treatise on electricity and magnetism. When Maxwell was appointed professor of experimental physics at Cambridge in 1871, and the Cavendish Laboratory was opened for work about 1873, quantitative researches at once commenced with Hicks, Gordon, Chrystal, Fleming, Schuster, Glazebrook, and Shaw as early workers. After Maxwell's lamented death in 1879, the late Lord Rayleigh accepted the position as his successor and directed his attention and great abilities at once to the exact determination of practical electric units, in which he did magnificent service, a work very ably continued by Glazebrook, J. J. Thomson, Searle, and others. After the introduction of public electric lighting, the measurement of electric quantities became a commercial matter. In 1885 the writer of this article read a paper to the Institution of Electrical Engineers in London advocating "the necessity for a standardising laboratory for electrical testing instruments." Soon after, the Board of Trade established such a laboratory, later on the Germans started their "Reichsanstalt," and at a still later stage the National Physical Laboratory in England was organised and equipped.

The Cambridge physicists have always maintained the high standard of research which marked that of Kelvin, Maxwell, and Rayleigh, and much valuable quantitative electrical work has been done there, too extensive for detailed reference. When Sir J. J. Thomson succeeded Lord Rayleigh at the Cavendish Laboratory he began the epoch-making researches on the nature of electricity and matter which have revolutionised scientific concepts. His identification of the cathode-ray particle with the electron of Larmor and Johnstone Stoney, and his measurement of its charge and mass, are amongst the most brilliant achievements of experimental science, and opened up an entirely new era in electrical research. J. J. Thomson gathered round him a band of experimental investigators whose researches, coupled with his own, threw light on innumerable obscure phenomena. The discovery of X-rays by Röntgen in 1895 and of the Becquerel rays, and the discovery of radium by Mme. and Prof. Curie, stimulated the work of Rutherford, C. T. R. Wilson, Townsend, and others, which has resulted in immense accessions to our knowledge of the nature of electricity and atoms.

Side by side with this progress in pure scientific knowledge fruitful advances were made in electrotechnics. Faraday's great discovery of magneto-electric induction had been long before applied in the construction of machines with permanent magnets for generating, by rotation of coils of wire, an electric current. Henry Wilde had suggested the use of electromagnets for producing the magnetic field, and he, as well as Werner, Siemens, and Wheatstone, had discovered the self-exciting principle and applied it in machines, to which the term "dynamo" was later on applied. In 1870 Z. Gramme, a French electrician, re-invented a special form of armature construction, first suggested by Pacinotti, which enabled a dynamo to give a very uniform direct electric current; and Hefner Alteneck, in Germany in 1873, had patented another type of armature winding, now called the drum winding. The way was then opened for the production of electric currents by mechanical power on a large scale and for the solution of the problem of public electric lighting.

Paul Jablochkov invented in 1876 his "electric candle" and initiated public street electric lighting in Paris. C. F. Brush, in America, invented a simple form of arc lamp adapted for working in series with others and a type of series arc-lamp dynamo. This Brush system soon after 1878 was largely in operation for street lighting.

In the following year Edison, in America, and Swan, in England, solved the problem of the production of a practical carbon filament incandescent electric lamp and thus rendered domestic electric lighting possible on a large scale.

In the same year the writer of this article exhibited some of Edison's early carbon filament lamps in operation in Queen Victoria Street, London, though it was not until the Crystal Palace Electrical Exhibition of 1882 that the public saw the new illuminant used on a large scale. The invention of the metallic filament lamp about 1904 made an immense improvement in economy in electric illumination, and more recently the "half watt" gas-filled lamp threatens to displace arc lighting entirely from streets and buildings.

The utilisation of this lamp, however, required a public electric supply, and Edison was one of the first to work out all the practical details and provide a complete system. This was put into operation in New York and in London in 1882. Improvements in the dynamo rapidly followed, and in the hands of J. Hopkinson, Crompton, Siemens, and others it became a highly efficient machine. About 1883 attention began to be directed to alternating currents, and alternators and transformers were designed by Ferranti, Mordey, and Parker.

In or before 1890 or 1891 polyphase alternators were first produced by Ferraris, Tesla, and C. E. L. Brown. Large electric supply stations were then built, and a lively contest took place on the relative merits of direct and alternating currents. The polyphase alternating system has, however, enabled electric power transmission to be conducted over great distances, and in the last twenty-five years an immense utilisation of natural water-power has taken place by this means, beginning with the Niagara Falls Power Station in 1893. Electrification of urban tram lines and short-distance inter-urban railways has made enormous progress in the last quarter of a century.

Meanwhile, between 1876 and 1879 Graham Bell, Edison, and Elisha Gray, in the United States, had given us the speaking telephone, and D. E. Hughes, in England, had produced the microphone, which is the basis of all modern telephone transmitters. In 1876 Lord Kelvin astonished the British Association at Glasgow by the information that he had heard articulate speech transmitted over a wire by one of Bell's early telephones. In 1879 the first rudimentary telephone exchange was established in London.

When once the commercial possibilities of telephone exchanges and of domestic electric lighting had been realised, progress was assured, although that of the latter was retarded by the unwise Electric Lighting Act of 1882, not repealed until 1888, and telephonic improvements were hindered by the Government control of it established by the legal interpretation of the term "telegraph" to include "telephone," under the Telegraph Purchase Acts.

Limiting consideration, then, to improvements in telegraphy and telephony, we note very briefly the following stages of invention. In 1869 the British Government passed an Act for the acquirement of the electric telegraph companies, and made the transmission of paid messages a public service. This "nationalisation" has, however, put a burden on the taxpayer, although it resulted in great extension of the facilities. Improved methods of transmission, such as the Wheatstone automatic system, capable of sending 400 words a minute, were soon introduced for Press purposes.

So far back as 1855 D. E. Hughes had invented an ingenious printing telegraph, but immense improvements afterwards introduced by Baudot, Creed, and Murray now enable twelve messages to be sent simultaneously on a single wire, each being printed down on paper at the receiving end, the sending being done by a typist on a special typewriter at the rate of thirty to forty words a minute.

Most long telegraph lines are now worked multiplex, meaning that several messages can be sent in the same or opposite directions on the same wire simultaneously.

In submarine cable work Great Britain has always been pre-eminent. The first submarine cable was laid in 1851 by the Brothers Brett across the English Channel, and the first permanently successful Atlantic cable by Sir Charles Bright and Sir James Anderson in 1866 from the s.s. *Great Eastern*. Lord Kelvin, who had previously given to the world his mirror galvanometer, invented also in 1867 the syphon recorder which receives and records the feeble arrival currents, and later improvements have given to it its present form. Very sensitive relays and repeaters have been invented by Muirhead, Heurtley, S. G. Brown, and Axel Orling, which have vastly increased the speed of transmission. Lord Kelvin laid the firm foundations for the theory of the telegraph cable so far back as 1855. There are at present about 300,000 miles of working submarine cable in the world, most of which has been made and laid by British electricians. In connection with telephony, enormous inventive thought has been given since 1880 to perfecting the mechanism of telephone exchanges, and the difficulties of automatic exchanges, which require no telephone girls or operators to effect the connection between subscribers, have now been finally overcome. Another very great advance has been in the "loading" of telephone lines. In 1887 Oliver Heaviside first showed the importance of inductance in the line as a remedy for "distortion" in the wave form of the speech currents, but it was not until Pupin, in the United States in 1899, suggested the insertion of inductance or "loading" coils at certain proper intervals in the line that practical success was obtained. A Danish engineer, Krarup, introduced a system of uniform loading for submarine telephone lines. The Pupin type of loading has made telephony possible over very great distances, such as New York to San Francisco, and Berlin to Rome. The difficulties of loading submarine cables up to 100 miles or so in length have been overcome. The theory of the subject has been treated by Heaviside, Kennelly, and Fleming.

Wireless telegraphy has attracted the attention of electricians since 1842, but no important invention was made until Marconi in 1896 first showed how to employ electromagnetic waves for this purpose, generated by a special form of Hertzian oscillator, and detected by an improved form of Branly metallic filings coherer. Lodge then demonstrated the importance of syntony in connection with the subject, and it soon took very practical shape. Inventors all over the world were attracted to this new field, with the result that in a few years, chiefly by the work of Marconi and his co-workers, electric wave telegraphy between ships and shore became established as an indispensable aid to navigation. The construction of long-distance wireless stations, the first of which was erected at Poldhu, in Cornwall, in 1901, brought to notice many remarkable facts in connection with the propagation of long electric waves round the earth and through the atmosphere.

A very important factor in the recent developments of wireless telegraphy and telephony has been the invention of the thermionic detector and oscillator. The pioneer invention, according to judicial decisions, was made by the writer of this article in 1904 in applying for the first time an incandescent electric lamp with a metal plate sealed into the bulb as a detector of high-frequency electric oscillations. The "Fleming valve" led to the invention of the three-electrode amplifier and thermionic generator of oscillations. This has given us an instrument of marvellous sensibility for detecting electric waves, and made wireless telephony a success and wireless telegraphy half round the world an achievement. The importance of wireless telegraphy and telephony in the European War of 1914–18 has been the cause of wonderful developments of the subject owing to the number of able minds brought to bear upon it.

Turning, then, from the present and the past and directing our gaze upon the future, we can certainly see many achievements looming before us. The world will be covered with long-distance wireless stations which will effect instantaneous communication over thousands of miles. Long-distance wireless telephony will enable speech to be transmitted over great distances, and it is quite within the bounds of possibility that the business man of the near future in London may hold a five-minutes' conversation with a friend in New York or even South Africa with as much ease as we now telephone to Glasgow or Liverpool. Directional wireless telegraphy will be used to steer passenger-carrying aeroplanes through cloud or fog. The steam locomotive and engine will gradually be replaced by the electric motor, and the water-power of the world will be utilised by its means. There are large possibilities still latent in connection with electro-chemistry and electro-metallurgy, and one great problem of the future is to tap the illimitable stores of energy latent in every chemical atom for the use and benefit of man. As coal becomes exhausted or coal power is made too expensive by labour difficulties, the question of new sources of energy becomes pressing. The engine of the future may be an improved form of internal-combustion engine in which the combustible is not coal gas or oil vapour, but some form of explosive compound in which atomic energy is suddenly released and expended in heating air or other gas in a cylinder.

Of one thing we may be perfectly certain, namely, that it is only through the avenue of pure scientific research sedulously and disinterestedly pursued that we shall reach the solution of these technical problems of supreme importance to mankind. The last fifty years has been a period of extraordinary technical applications of ever-increasing electrical knowledge, and no one can see reason to think that we have yet reached finality in the possible utilisation of this physical agent for ameliorating the conditions of human life.

DEVELOPMENTS OF MECHANICAL SCIENCE.

By Dr. W. C. Unwin, F.R.S.

THE attempt here made to give a sketch of the mechanical side of progress in the last fifty years is necessarily slight. The year 1869 was the centenary of that in which Boulton and Watt took out their first patent for the steam engine. It is due to the application of steam-power to industrial operations, more than to anything else, that there has been so great an increase of population, of wealth, and of social prosperity, and indirectly also of scientific knowledge, during the last 150 years. Perhaps a review of some of the earlier advances already slipping out of knowledge, as well as of more recent and familiar discoveries, will be interesting.

Eighty years ago Dr. Lardner said it was due to the steam engine that reason had taken the place of force, the pen had superseded the sword, and that war had almost ceased on the earth. History does not confirm the prescience of this. The last war, largely an engineering war, owes its vast range and frightful devastation to means placed in the hands of armies and navies by mechanical science. To take one point, success in war depends chiefly on the rapidity with which large masses of men can be moved and served with ammunition and food. This must be accomplished by railways and motor trucks. At Verdun sixty million shells containing three million tons of steel were expended in thirty weeks.

During the last fifty years there has been a wide extension of research in mechanical science. Most large engineering works have their laboratory for testing materials, and the problems investigated are largely those suggested by industrial operations. This was specially important during the war, and it is now necessary to make permanent the more intelligent and active spirit thus aroused.

Hydraulics is a very old subject of research. Its problems are generally too complex for purely rational solution. Hence the need of continued experiment. A remarkable series of measurements of flow over weirs of different forms, under different conditions, with varying velocities of approach, and an investigation of the peculiar change of form of the water nappe on the weir crest at low discharges, was communicated by Bazin to the Ann. des Ponts et Chaussées in 1888–98.

In 1885 Froude gave the first direct determination of the frictional resistance of surfaces of different roughness in water (Brit. Assoc. Report). The most novel result was that the average friction per square foot depended on the length of the surface in the direction of motion. The friction of rotating discs was investigated by Unwin in 1880, and by Gibson in 1910. A research by Stanton and Pannell (Trans. R.S., 1914) has shown the conditions of similarity of motion in fluids, and extended the results to water and air and to high velocities. These results have been of service in discussing the resistance of aeroplanes as tested in wind channels. Osborne Reynolds's experiments in 1882 showed that in flow-in pipes there was a critical velocity below which the resistance varied as the velocity, and above nearly as the square of the velocity.

Froude applied his results to the extremely important subject of the calculation of the resistance of ships. The greater part of the resistance is due to skin friction, and can be calculated on the assumption that the wetted surface is equivalent to a plane of equal area and length in the direction of motion and equal roughness. The remainder of the resistance, due to waves and eddies, can be found by model experiments. There is an exact relation between wave and eddy resistance of the model and ship at corresponding speeds. The method of model tests of ships as a guide to design is now fully established. Sir Alfred Yarrow has generously established an admirable ship model tank at the National Physical Laboratory.

Water-power is one of the oldest sources of mechanical energy for industrial purposes. Its importance, looking to the fact of the limitations of coal supply and that in favourable circumstances it is cheaper than steam-power, can scarcely be over-estimated. Its use has greatly helped processes such as the fixation of atmospheric nitrogen, and the production of aluminium, calcic carbide, carborundum, caustic soda, etc., besides being an essential auxiliary in many great electric lighting installations. Thirty years ago no water turbine existed of 1000 h.p.; now turbines up to 20,000 h.p. have been made. The harnessing of Niagara, commenced in 1890, gave rise to a movement for utilising water-power on a great scale. The possibility of transmitting energy electrically to distances up to 200 miles, with little loss and commercial success, has greatly enhanced the availability of water-power. In the U.S.A. some seven million horse-power are utilised, in Norway more than one million, in Canada two millions, and in Italy one million. There are great possibilities in the British Dominions. In Canada and some other countries a Government survey of the water-power resources is in progress.

In 1869 the steam engine differed little from what it was as Watt left it, except in detail, size, and variety of application. One important modification since may be noted. Rankine and Clausius drew up a complete rational theory based on the mechanical equivalent of heat. But it appeared that actual engines used 40 to 60 per cent. more steam than was accounted for by the theory. In the late 'fifties Hirn, of Colmar, traced the discrepancy to the conductivity of the cylinder wall, which was cooled by evaporation to the condenser during exhaust, and then condensed part of the steam on admission. To remedy this he introduced superheated steam, used to some extent in the 'sixties with economical results, but not widely adopted until the 'nineties. Watt aimed at getting a dry, hot cylinder, but only partly succeeded. Superheating is a further step, only second in importance to the separate condenser.

The greatest change in the generation of power is due to the perfecting of the steam turbine by Sir Charles Parsons. The principle of the steam turbine is old, but it involved great scientific tenacity and courage and large, unremunerative expenditure before practical success was achieved. The first condensing turbine of 100 h.p. was made in 1892. Now in the latest cruiser, the *Raleigh*, there are turbines of 70,000 h.p. For large electric installations and for large and speedy ships the steam turbine has superseded the reciprocating engine. Lately Sir Charles Parsons has introduced gear for reducing the necessarily high turbine speed to one more suitable for the propeller, and this will much extend the use of the turbine in marine engineering.

The development of the internal-combustion engine belongs almost entirely to the last half-century. On it has depended all aircraft and submarines, and most mechanical road transport. The first satisfactory gas engine was that of Dr. Otto in 1876. Dowson, in 1878, introduced producer gas, emancipating the engine from dependence on illuminating or town gas; and Benier soon after invented the suction producer. The Germans developed the large-cylinder, high-powered gas engine chiefly for utilising blast-furnace and coke-oven gas—a waste product. Sir Dugald Clerk, who has led the way in this country in developing the gas engine, and especially in studying its theory, estimates that there were gas engines of $5\frac{3}{4}$ million h.p. at work in 1909.

The first paraffin engine was that of Priestman in 1885. The Diesel oil engine, introduced in 1893, has perhaps the greatest thermal efficiency of any heat engine.

The petrol engine, which has made the conquest of the air possible, was greatly improved during the war, and is the lightest of heat motors. An aeroplane engine of 850 h.p. is stated to weigh only 1·63 lb. per h.p.

The future of air transport has very great promise, but it looks as if for commercial purposes the airship has advantages over the aeroplane. In coastal patrol and anti-submarine work naval airships carried out 9000 patrols covering $1\frac{1}{2}$ million miles. Engineers interested believe that an airship capable of carrying 1000 persons at 80 miles an hour is in reach of present practice. Attempts are being made to produce helium to replace hydrogen in the envelope, removing one source of danger.

Mr. Lanchester has reminded us that, with Government help largely withdrawn, the aeronautical industry is in the position of a youth luxuriously brought up who finds himself face to face with the fact that he has to earn his own livelihood.

Structures and machines should be designed with adequate strength and at the same time with the least necessary material. In the old view the strength limit was the statical breaking weight, and the ratio of this to the working stress was termed the factor of safety. Wöhler's research in 1871 proved that, in ordinary conditions of continual variation of stress, fracture occurred with much less than the statical breaking weight, and depended on the range of variation of stress. Bauschinger showed that the position of the elastic limit changed with repetition of straining action, and that the range of elasticity appeared to be the same as the range of stress, which could be sustained indefinitely. Bairstow and Stanton have confirmed this. Osborne Reynolds constructed a machine in which continuous changes of stress in a test bar could be produced by the inertia of reciprocating weights.

In the period under consideration there has been a great extension of public and private mechanical testing laboratories. The National Physical Laboratory and the Bureau of Standards, Washington, are now Government institutions. In the U.S.A. very large testing machines have been constructed, several of 600 tons capacity, and one of 5000 tons at Pittsburgh. For testing full-size members such as bridge ties, reinforced concrete columns, etc., such machines are necessary. Though new tests of materials must be adopted with great caution, tests of hardness and tests of brittleness have been found useful. Guest, Scoble, and others have investigated compound stress, and found that in ductile materials the limit of resistance is the greatest shear stress. A very great advance has been made in the delicacy and accuracy of strain measuring instruments.

THE TREND OF MODERN METALLURGY.

By Prof. H. C. H. Carpenter, F.R.S.

METALLURGY is the art of extracting metals from their ores, refining them, and working them up into finished products for the use of mankind *at a profit*. The inevitable corollary of this is that the economic factor is always decisive as to the applicability or otherwise of any new scientific discovery which bears upon the industry. The art is one of the oldest in the world, but in spite of its highly diversified character and the profound influence that scientific methods have had upon its scope and technique, it does not differ to-day in essence from the ancient art except in the fact that to an ever-increasing extent the applications of science are found to be payable.

In attempting a survey of the present position and tendencies of the great metallurgical industries, only the broadest treatment is possible. Accordingly, no account will be taken of the usual subdivision of the subject into ferrous and non-ferrous metallurgy. Rather does there appear to be an advantage in omitting this distinction which has no scientific basis, but is purely one of custom.

The first stage in the passage from the mineral as mined to the manufactured metal is "ore-dressing," and here a very notable advance, made in the last few years, has to be recorded. The old method of "gravity" concentration, whereby the ore after being crushed was suspended in water and treated in a variety of machines for the concentration of the metallic contents, which, being specifically heavier, tended to sink, while the lighter gangue floated, never, at its best, gave an extraction of more than 82 per cent. In the "flotation" process of to-day the sulphide ore particles are made to float on a froth produced by the agitation of the pulp with the addition of a small amount of oil and acid, while the gangue, although specifically lighter, sinks. The flotative agent is air, the froth being stabilised by the particular oil mixture used. Surface tension and not gravity is the principle utilised in the separation. The method has been principally applied to the concentration of copper sulphide and mixed lead and zinc sulphide ores. Its largest application has been in copper reduction work in America, where many millions of tons of ore are being treated to-day. At Anaconda the total recoveries in the concentration process have been raised from 76 per cent. to as much as about 95 per cent. There can scarcely be any doubt that flotation has a great future as a concentrator of metal values. At the present, however, it is limited to sulphide materials. For that reason it has had no effect on the metallurgy of iron, where the mineral is either an oxide or a carbonate; but it seems likely to have a very wide application to the principal economic minerals of copper, lead, zinc, gold, and silver, especially when the two latter contain base metal values.

Thus far the concentration has been mechanical—*i.e.* there has been no change in the chemical composition of the mineral itself. In the next stage, in the great majority of cases, "smelting" or "reduction" begins, which has for its object the conversion of the ore into a metal, usually unrefined. Hitherto the shaft or blast furnace has held its own, with coke as the fuel. This furnace has had its principal recent development along the lines of better charge distribution, and, in the iron industry, more efficient hot blast stoves and more economical power plants. Fifteen years ago many furnacemen were satisfied with almost any distribution of charge they happened to get from the apparatus installed, but this most important operation cannot be ignored without causing low output and high coke consumption. Distributors are now in use which give the charge a columnar structure with alternate columns of coarse and fine ore, instead of uniform layers produced by most systems of filling. Highly beneficial results are claimed for this improvement.

Hitherto the reverberatory furnace has been markedly inferior to the shaft furnace from the point of view of thermal efficiency. For this reason only the ore which was in too fine a state of division for treatment in a shaft furnace was smelted in a reverberatory. The very extensive application of gravity and flotation concentration, particularly to copper ores, with the fine grinding which these processes involve, has, however, necessitated the smelting concentration of such materials in these furnaces. Until comparatively recently the best practice in the reverberatory furnace concentration of copper ores was about 4·8 tons of charge per ton of coal, against about 8 tons of charge per ton of coke in the blast furnace. Here, too, a remarkable improvement during the last five years has taken place. This is due, in the main, to three factors:—

(1) To the increased efficiency of burning coal in the form of dust as compared with burning it on a grate.

(2) To maintaining a very large mass of the charge piled along each side of the furnace, which increases the speed of heat absorption.

(3) To the augmented size of the hearth, which has now reached a length of about 143 ft. and a width of 30 ft.

For successful practice, the coal, before pulverising, must be dried to a maximum of 1 per cent. of moisture. It must be finely pulverised, since the increased surface thus obtained has a direct bearing on the efficiency. Upwards of 80 per cent. should be capable of passing through a 200-mesh sieve. The delivery of coal and air must be controlled so that the proper proportion between them is maintained, and the coal itself must contain enough volatile combustible matter to give the required combustion. Only a few years ago it used to be reckoned that to smelt from 230 to 270 tons of charge per 24 hours was good work. The current practice to-day in the new furnaces is to smelt between 600 and 700 tons, and the ratio of charge to fuel has been brought up to about 7 : 1, which raises the reverberatory furnace almost to a level with the blast furnace from the thermal efficiency point of view. Certain of these large reverberatories are fired with oil, and very satisfactory results, as regards both economy in fuel consumption and weight of charge smelted, have been obtained.

Passing next to the refining of the metal, it is here that "electric heat" is tending in some cases to supplement, in others to supplant, fuel heat. An instance is furnished by the refining of steel on a large scale in the so-called triplex process, in the second stage of which fuel heat, in the form of producer gas, is used (the charge being worked first in a converter and afterwards in an open-hearth furnace), while in the third stage an electric resistance furnace is utilised which permits the refining of the steel to a considerably further degree. It is widely held that the quality of steel which can be produced in this way is superior to that obtained in the open-hearth furnace. This is due to the fact that, owing to the high temperature employed, more refractory basic fluxes can be used which permit of a greater removal of sulphur and phosphorus, with a consequent improvement in the properties of the refined steel. Moreover, in the electric furnace the charge is decidedly less contaminated with gases. For high-grade materials, such as high-speed cutting tools, where quality is of paramount importance, the electric furnace seems to have a field all its own, and, owing to the fact that, under special conditions, current for it can be bought from public service companies during "off peak" periods, its installation cost is not necessarily high. This permits of its use in plants smaller than otherwise would be justified in making their own steel. The rapid growth of the electric furnace is shown by the fact that the total number in operation in March, 1910, was 114, and in January, 1917, 471.

As an alternative to flotation concentration and smelting operations, which, as mentioned, are particularly suitable for sulphide ores, the achievements of hydrometallurgy have also to be considered. The cyanide process, which has long been established as the most suitable method of extracting gold and silver from low-grade ores, depends on the fact that the dilute solutions employed exercise a selective solvent action on the precious metals, and is the best-known instance of the application of leaching on a large scale.

Recently the extraction and refining of copper by hydrometallurgical and electrolytic methods direct from the ore has become a commercial process. Many of the low-grade ores of copper, particularly the vast porphyry deposits in the highly mineralised mountainous country in the south-west of U.S.A. and Mexico, are oxidised and not amenable to flotation concentration. For their beneficiation leaching is the most suitable method. A famous example of this kind is the treatment of the ore obtained from the mine of the Chile Exploration Co. situated at Chuquicamata, which, as regards tonnage and contents of valuable metal, is one of the greatest known copper deposits in the world. The high point of the mine lies at an altitude of 9890 ft., while the extraction plant is situated at 9023 ft. on a plateau of the Andes, 160 miles north-east of Antofagasta. Here a plant of 10,000 tons daily capacity has been designed and erected in a desert 5000 miles away from the base of supplies. The ore, which carries about 2 per cent. of copper, is an oxysulphate known as "brochantite."

The process chosen utilises its sulphuric acid ion for the solution of the copper, and allows a percentage discard of the liquid after each operation, thus avoiding its fouling by continual use. The ore is crushed to about half-an-inch mesh and leached with sulphuric acid. The greater part of the chlorine is eliminated in tube mills by treatment with metallic copper. The remaining copper is precipitated from solution by electrolysis and the cathodes are melted and cast into commercial wire bars. In this way a high-grade commercial metal is produced direct from the ore in three operations, in only the last of which is a furnace treatment necessary. Against this the ordinary concentrating, smelting, and refining operations involve no fewer than seven stages. The output of refined copper from this plant is at the rate of 200 tons per day.

The refining of metals by electrolysis, of which the previous process is an illustration, is one of the most important features of the industry of to-day. It derives its importance from two considerations which are inter-related: first, that it permits the production of the commercial metal in a highly purified form; secondly, arising out of this, it allows the complete recovery of the precious metal values from base metal ores, which thus increases their commercial value. To-day, iron, copper, zinc, lead, aluminium, sodium, magnesium, nickel, gold, and silver are obtained in a marketable form by such methods. To take one instance only, upwards of 90 per cent. of the world's annual production of copper, which in 1913 was about a million tons, was refined by electrolysis within 20 miles of New York City. The cathode copper thus produced did not contain more than 2–3 parts of impurities in 10,000. As a by-product of this refining, there was obtained nearly 20 per cent. of the world's entire output of silver, a substantial amount of gold, small amounts of platinum and palladium, together with notable quantities of nickel, selenium, and tellurium.

Viewing the industry to-day, it is manifest that there is a notable trend towards the substitution of furnace- or pyro-metallurgy by hydro- and electro-metallurgy. Even where furnace operations still hold the field, attempts are being continually made towards the substitution of fuel heat by electric heat. Iron is being produced commercially in Sweden, Canada, and the U.S.A. by electric smelting and refining. There is a clear trend of a similar character in the metallurgy of certain ores of copper which are not amenable to direct flotation or leaching. Metals such as aluminium, sodium, and magnesium are produced direct by electrolysis. The great importance of this tendency, as already suggested, is that it permits of a more complete beneficiation of any given ore, and, indeed, brings a far wider range of raw materials within the scope of economic exploitation than otherwise would be the case. How clearly this is so may be seen from the following instances:—

Previous to the introduction of the cyanide process, it did not pay to extract gold from any sulphide ore unless it contained at least 0·5 oz. of this metal. By means of this process, however, the limit of such payable ores has been brought down to about .1 dwt. per ton, and in the case of clean gravel containing native gold to as low as 3 grains—*i.e.* 0·006 of an oz. of gold per ton. Similarly in the case of the sulphide ores of silver, the previous limit of 20 oz. has been lowered to about 2 oz. per ton by the same process. As regards copper, the economic percentage was about 5 per cent. down to the year 1890. By the introduction of leaching processes this figure was quickly reduced to about 2 per cent. Progress has been continuous in lowering the limit, and to-day tailings from concentrating tables containing only 0·5 per cent. of copper are being treated for extraction at Cananea (Mexico) and Anaconda (U.S.A.). In regard to such materials it is more than possible that the flotation process will lower the limit still further.

Limits of space prevent any reference to the trend of current practice in the mechanical and thermal treatment of metals and alloys and the ever-deepening influence of metallography on this great branch of the metallurgical industry.

POSITION AND PROSPECTS OF AVIATION.

By L. Bairstow, F.R.S.

The present phase of scientific development of aviation may be said to date from the period 1890–1900, and to have its most definite form given by the researches of Langley and Maxim. From Langley's book were taken the early data on which pioneer designs were prepared, and a protracted controversy arose between Blériot and Farman as to the relative merits of the biplane or the monoplane as a result of a statement by Langley which has since proved to need considerable modification.

The first notable flight in public appears to have been that of Santos Dumont in 1906, for which he was granted the Deutsch de la Meurthe prize; this was little more than a long hop, and for the next two years it was clear that one of the larger difficulties of flight was the control of aircraft in the air.

Flying with reasonable certainty dates from the exhibition flights of the Wright Brothers in France during 1908, and may fairly be ascribed to the introduction by them of wing warping for the purposes of lateral control. Since then progress, both scientifically and industrially, has been very rapid.

In 1909 the Advisory Committee for Aeronautics was formed by the then Prime Minister, Mr. Asquith, with the late Lord Rayleigh as its president. The Committee controlled the activities of the Aeronautical Research Departments of the National Physical Laboratory, and was closely informed of the full-scale research work carried on at the Royal Aircraft Factory.

The development of the best shape of aeroplane had approached finality somewhat closely in the years 1913–14; on the other hand, owing to the death in an aeroplane accident of Mr. E. Busk, preliminary experiments on the industrial application of the theory of stability came to a premature end. During the war the attention of scientific workers in aeronautics was devoted to the many applications of existing knowledge rather than to its extension, and it was pointed out by them that the performances of aeroplanes could be predicted approximately with little effort, and that these predictions could be made the basis for an appeal for new designs to meet the increasing exigencies connected with fighting in the air.

On the other hand, no such simple generalisation has been found possible for dealing with stability, with the unfortunate result that designs made to give the necessary speed and rate of climb have been put into use before their condition as to stability was fully understood. Defects of stability made themselves felt by a series of accidents peculiar to each type. The analysis of these accidents and suggestions as to remedies came from the existing scientific work on stability. Examination of the categories into which accidents fall gives, perhaps, the clearest idea as to the technical development possible in the next decade. Some 80 per cent. of the total accidents during training are due to loss of speed of the aeroplane and an attempt on the part of the pilot to turn his aeroplane towards suitable alighting ground. The remaining 20 per cent. are in large part accounted for by failure of the engine to continue to develop power and so to compel descent on unsuitable landing ground. The latter point scarcely needs more than passing comment, for the general history of development in machinery shows that many years are necessary after main ideas have been established before details are satisfactory. Progress made in understanding the phenomenon connected with fatigue suggests that a moderate reduction of the power expected from existing aeroplane engine designs would lead to an enormous increase in the length of their life. It may therefore be expected that the ordinary precautions taken in the development of an engine will lead to the practical elimination of accidents under the heading of forced landings; here, again, progress will be accelerated by use of the known scientific data.

The larger group of accidents mentioned above needs a consideration of design intimately associated with the pilot's power of control of the aeroplane and its inherent stability. It should not be forgotten that the relation between these two quantities in an aeroplane designed for fighting in the air may have little or no connection with the corresponding relation of the properties desirable for civil aeroplanes. This field is as yet comparatively unexplored, and there are strong grounds for believing that an aeroplane can be so designed that the dangerous consequences of error of control by the pilot are greatly reduced; it is not improbable that the accidents on the score of loss of flying speed can be reduced to some 5 or 10 per cent. of their present magnitude when the necessary skill in design has been acquired.

The most important of the many difficulties which make it impossible to forecast the future of aviation are not technical, but commercial. Development under the stress of a great war has left an industry capable of producing an enormous number of aircraft. Attention has been given solely to military uses, and aeroplanes are therefore not specifically designed for civil purposes. At the same time, the civil uses are not clear; how far aviation will be good for the purposes of carrying mails, passengers, or merchandise is at present almost wholly a matter for conjecture.

Pre-war experience was gained in the development of aircraft which could be flown with a moderate degree of ease and safety, and no lines of commercial communication had been inaugurated. The main asset of both the aeroplane and the airship is speed, and here the importance of long distances will be evident on little consideration. In a country like England, with well-organised railway trunk lines and journeys of the order of 500 miles, the saving of time in the carriage of mails is small, particularly since the mail trains travel by night, whereas aeroplanes wait for the dawn before commencing the journey.

Where the route includes a sea passage the advantages are much greater, and the enterprise of our two leading transport companies has shown the possibility of a remarkable degree of certainty in the service between London and Paris. It is, however, on much longer journeys than these that the saving of time by aerial transport presents its most attractive possibilities.

On the other hand, the initial outlay and running expenses are roughly proportional to the length of journey, and the inception therefore represents a formidable undertaking. The returns are problematical, and from the nature of the case it will be obvious that until the special facilities have existed for some time no estimate of value can be made as to the charges which will prove remunerative to an operating company and sufficiently attractive to the users of the new form of transport.

Civil aerial transport is therefore still in its infancy as an addition to our industrial life.

THE LIQUEFACTION OF GASES.

By Prof. C. H. Lees, F.R.S.

In 1869, when the first number of Nature appeared, Andrews had just completed his experiments on carbonic acid, and established the fact that for each gas there is a critical temperature above which it is impossible to liquefy the gas by pressure. Faraday, by using low temperatures and considerable pressures, had liquefied chlorine, sulphurous and hydrochloric acids, cyanogen, and ammonia in 1823, by 1844 had added eight other gases to the list, and had solidified sulphuretted hydrogen, ammonia, and nitrous oxide. Cailletet, in 1878, by suddenly reducing the pressure on oxygen, nitrogen, and carbonic oxide compressed to 300 atmospheres, obtained mists which he ascribed to fine drops of the liquefied gas. Pictet, about the same time, by employing greater pressures and cooling his apparatus with other liquefied gases, succeeded in obtaining a small quantity of liquid oxygen which was of a slightly blue colour.

In 1883, at Cracow, Wroblewski and Olszewski succeeded in obtaining small quantities of liquid oxygen, nitrogen, and air, which evaporated in a few seconds. By 1887 Olszewski could obtain a few c.c., and by 1900 100 c.c., of liquid oxygen before an audience of his students. Dewar had been able to produce quantities exceeding 20 c.c. since 1886, and had already made determinations of the properties of substances at the low temperatures thus attainable. In 1892 he introduced the double-walled vacuum vessels with a little mercury within to convert the internal surfaces into mirrors, now known as Dewar flasks. These reduced the rate of evaporation of a liquid gas stored in them to about a thirtieth of the rate for ordinary vessels. The utilisation of the Joule-Kelvin cooling effect by Linde and by Hampson in 1895 enabled each to produce a machine capable of liquefying air, oxygen, and nitrogen on a commercial scale. In 1898 Dewar produced for the first time liquid hydrogen, using the Joule-Kelvin effect in the gas pre-cooled to 68° A. by a bath of liquid air evaporating *in vacuo*. Next year he solidified it, and determined its melting point to be 14° A. In 1908, at Leyden, Kamerlingh Onnes liquefied helium and determined its boiling point to be 4° A. In the meantime, Olszewski had liquefied and solidified argon in 1895, and Ramsay and Travers had by 1900 liquefied krypton and xenon.

The commercial production of liquefied gases gave facilities for the examination of the physical properties of substances at low temperatures, and in this work Dewar and Kamerlingh Onnes and his pupils have played prominent parts. It is to the Leyden professor we owe the discovery of the disappearance of the electrical resistances of many metals at temperatures a few degrees above absolute zero attained by the use of liquid helium.

PROGRESS OF METEOROLOGY.

By W. H. Dines, F.R.S

The progress of meteorology during the last fifty years has been very marked, as may be seen by a casual reference to the current meteorological literature of the period 1865–75; to a great extent, it resembles the emergence of astronomy as an exact science from the old astrology, but it must be confessed that the Newton of meteorology has not yet appeared.

Fifty years back the student of meteorology spent much of his time in a vain hunt for weather sequences, and the principle of *post hoc propter hoc* held full sway; the laws of motion and the more recently discovered laws of thermodynamics were in most cases completely ignored, or at least considered as not being applicable to meteorology. This has been largely changed for the better, and one does not now expect to find a cold area explained as being due to the descent of air in an anticyclone from a higher and colder region. Perhaps the pendulum has swung too far the other way, and mathematical analysis may sometimes be used when it is not applicable. On the assumption that air is a perfect fluid, it follows from a strict mathematical analysis that a sphere exposed to a steady current of wind will offer no resistance to that wind—a result obviously inconsistent with the facts. The assumption made cannot be justified, and one cannot help feeling that great caution should be used in making assumptions if the result of a complex mathematical investigation into a meteorological question is to be trustworthy. Mathematics, however, afford a most useful and often indispensable aid to meteorology, and of late years especially, although far from exclusively, by their means many useful deductions have been drawn.

It is impossible in a brief article to give any full statement of the present position of meteorology, but a short account of the great access of knowledge that has come to us in the last fifteen years or so by means of observations in the upper air may be of interest, the more so because the great central problem of meteorologists who live in temperate latitudes has always been the genesis and motion of cyclones and anticyclones which bring us our various types of weather, and this problem is most intimately interwoven with the upper-air observations.

A mass of detail remains to be filled in, but the salient facts of the distribution of temperature in the upper air are well established, and, at least for Europe, where some 1500 observations are available, are beyond dispute. We have also observations from Canada, the United States, and Batavia, and a few from Central Africa and the tropical Atlantic.

It has been found that the atmosphere is divided into two parts: a lower part, the troposphere, in which there is a lapse rate—that is, a fall of temperature with height—of about 6° C. per kilometre (17° F. per mile); and an upper part, the stratosphere, in which there is no appreciable change of temperature with height. The boundary between the two parts is in these latitudes quite sharp and distinct, but is not so well defined in the tropics. Its height varies with the latitude: for the South of England the mean is 10·6 km.; for Scotland it is 9·8 km.; and for the equatorial regions it reaches 16 km. It has also for temperate latitudes an annual variation, rising in the summer, falling in the winter. It should be added that the usual lapse rate is less than 6° per kilometre in the first three or four kilometres, is more than 6° above that height, and in regions of excessive cold, such as Canada or Siberia in the winter, may be absent or reversed in the lower strata. With regard to temperature, over the equator the stratosphere may be as cold as −80° C.; over Europe it has about −54° C. for its mean, but may vary from −40° to −70° C.

Confining, now, our attention to Europe, there is very little or no correlation between the temperature and the barometric pressure of the air at the surface, but a totally different set of conditions is met with as soon as the very lowest stratum—the first 2000 ft., say—is passed. From 1 km. and upwards there is a very high correlation indeed between temperature and pressure; between 4 and 8 km. the correlation coefficients are more than 0·85; they then fall off rapidly, so that there is again no correlation at the boundary between the troposphere and stratosphere. Above this, in the lower part of the stratosphere, the correlation is negative and reaches −0·30, but falls off with increasing height. Also the correlation between the pressure at 9 km. and the temperature at any height excepting the surface and the common boundary is very high, being positive for the troposphere and negative above 12 km. Since a low-pressure area at the surface remains so up to nearly 20 km., the correlation defined above leads to the following rules. In a cyclone the troposphere is relatively cold and the stratosphere warm, and, it may be added, the boundary between the two is much lower than usual. In an anticyclone the troposphere is warm and the stratosphere cold; also the common boundary is raised. The actual differences of temperature between a well-marked cyclone and anticyclone in the British Isles are about 10° C., the cyclone being 10° cooler from 3 to 8 km., and the anticyclone 10° cooler from 12 km. height and upwards. In the cyclone the common boundary is 3 to 4 km. lower than in the anticyclone.

The cause of these differences is still more or less a matter of conjecture and controversy. In my opinion the changes of pressure at heights of 8 or 9 km. are in some way brought about by the accumulated momentum of the general circulation, and the temperature changes that follow are easily explained by the laws of mechanics and thermodynamics. Thus I think that temperature changes in the upper air are the results, and not the causes, of cyclones and anticyclones.

In addition to the results obtained by observations of temperature and humidity by means of registering balloons, much work in the last fifteen years has been done by means of pilot balloons. A large portion of this remains to be worked up. Also a considerable advance has been made from the theoretical side in our knowledge of the motion of the air particles near the centre of a cyclone, and meteorologists have good cause for congratulation in the steady progress that is taking place.

PROGRESS OF GEOGRAPHY.

By Sir John Scott Keltie.

During the past half-century marked advances have been made in all the departments now included under the head of Geography, which has to deal with certain problems dependent on the constitution, configuration, and distribution of the surface features of the earth. In attempting to take stock of the results of the exploration of the unknown and little-known regions of the globe during this period, I think it is safe to say that we have to go back to the half-century which followed 1492 (when Columbus stumbled upon a New World) before we find a period so prolific. The two Poles have been reached and large additions made to our knowledge of the deep island-girt ocean which covers the Arctic basin, and to the vast ice-bound, mountainous continent near the centre of which the South Pole is located. The unknown two-thirds of the no longer "Dark Continent" have been more or less provisionally charted, and all but an insignificant fraction partitioned among the Powers of Europe. Great areas of North America have been surveyed, charted, and occupied, while much has been done for the exploration of Central and South America. The map of Asia has, to a large extent, been reconstructed, while the vast unknown interior of Australia has been traversed in all directions. Even much of Europe has been re-surveyed. A new department essentially geographical—oceanography—has been created as the result of the *Challenger* and other oceanic surveys.

Survey work not only in the official surveys, but also among explorers, has become more and more accurate, while methods and instruments have been greatly improved. These improvements, combined with the more thorough training available at the Royal Geographical Society and certain of the universities by would-be explorers, have greatly enhanced the scientific value of the results of exploring expeditions. Many of these in recent years have been accompanied by specialists, not only in strictly geographical subjects, but also in other departments of science—geology, biology, meteorology, anthropology, etc.—certain of the data of which are required in working out some of the problems with which it is the business of geography to deal. For, to quote from the presidential address of Sir Richard Strachey to the Royal Geographical Society in May, 1887:—

> There is no greater difficulty in recognising the legitimate place of geography as one of the sciences of observation, because of the close relation that subsists between the matters with which it deals, and those that fall within the scope of other branches of science, such as geology or biology, than there is in assigning the like character to chemistry and electricity, because of the interaction of the forces with which they specially deal, with those that constitute the principal subject of inquiry in other specialised fields of human knowledge.

Of course, apart from the gains to geography as an observational science, the other departments of science represented on these expeditions have greatly profited by the opportunity thus afforded.

The results of all this activity have been vast additions to our knowledge of the great features of the earth's surface, their constitution, their morphology, their distribution, their mutual relations, their influence on the distribution of all that the surface sustains, mineral, vegetable, animal, and, most important of all, man, of whom all the other factors form the environment. If we compare the maps of to-day with those of fifty years ago, they will afford striking evidence of the great additions which have been made to our knowledge of the face of the earth. The entirely unmapped has been enormously decreased, while marked progress towards accuracy has been made on the imperfectly mapped features. Great improvements have been made, especially in the British Islands, in cartography, both in the symbols adopted for indicating the physical features and in execution and workmanship. At the International Geographical Congress of Geneva in 1891, a great scheme was initiated for an international map of the world on the scale of 1/1,000,000. At subsequent conferences a series of regulations was drawn up to be followed by each country in producing a map of its territories, and a certain amount of progress has been made, though it is feared that the war has been a serious interruption. On the other hand, one important result of the war has been the production by the Royal Geographical Society, under the direction of the Geographical Section of the General Staff, of a map of Europe and the Near East on the lines of the international map which not only has proved of great service in connection with the war, but also will be of permanent value as the standard map of the extensive region dealt with. In general, it may be said that the maps and atlases of the present day reflect the marked advance which has been made in geography generally during the past half-century.

In recent years considerable progress has been made in geodesy. In 1899–1902 an arc was measured in Spitsbergen, while under the direction of the late Sir David Gill there was initiated the measurement of a great arc in Africa along the meridian of 30° E. If these arcs are connected through Asia Minor and Europe, a continuous measured arc of 105° would be obtained. The arc of Quito (Peru) has been re-measured under the direction of the French Academy of

Sciences, and it is hoped may be connected with the great arc in 98° W. which has been undertaken by the U.S. Coast and Geodetic Survey. Other arcs of special importance have been measured in Europe and Asia.

One of the great problems with which geography has to deal is that of distribution. It is obvious, on the face of it, that the many types of features which are distributed over the surface of the earth must have a potent influence on the distribution and activities of humanity, which lives and moves and has its being among them. There can be no doubt as to the influence of geographical conditions on history and other human activities, and perhaps even on race; but, as Ellsworth Huntington points out, the claims in this respect are often too vague to convince the sceptical historian. What we want is a more precise statement as to the nature and amount, the quantity and quality, in each case in this environmental influence compared with various other elements. Several attempts have been made to deal with the problem in recent years; definite areas should be selected and the problem worked out in detail on the spot.

In what precedes we have dealt mainly with the geosphere; but the hydrosphere is an important section of geography, both in itself and in its influence on the former. Hydrography is a convenient term to include the various forms in which water is distributed over the face of the earth—rivers, lakes, and the ocean itself. Potamology, or the study of rivers and their *régime*, has attracted much attention in recent years. Limnology, the study of lakes—depth, movement of their waters, distribution of life, physical nature of their basins—initiated by Forel in the 'eighties and 'nineties on the Lake of Geneva, has been continued in the Scottish lochs with voluminous results of high scientific value. But it is in oceanography that the greatest advances have been made during the half-century. A certain amount of work on a limited scale had been done in oceanic research, but it remained for the great *Challenger* Expedition during its 1872–76 cruise over the oceans of the world to create a new department of science under the name of Oceanography. This was followed by other similar expeditions in the *Siboga*, the *Planet*, and the *Michael Sars*, the result being a vast accumulation of data on the ocean in all its aspects—its depths, the nature of its bed, distribution of life at all depths, saltness, temperature, its surface and under-currents, and other features.

As the result of a movement initiated by the Royal Geographical Society in 1884, geography has obtained a place in education in Great Britain which it had never held before, while the standard of the subject has been raised to a much higher level. The subject has at last received ample recognition at Oxford and Cambridge and other universities in the kingdom, while radical reforms have been made in schools of all grades. On the university programme we have such heads as the Principles of Geography; Survey of the Natural Regions of the Globe; Land Forms and Morphology of the Continents; Meteorology, Climatology, and Oceanography; Human Geography in its Various Phases; Geographical Methods of Notation, and so on. This will show how high is the standard and how wide the field of the subject compared with the position even thirty or forty years ago.

Such, briefly, is a review of the progress of geography during the past half-century and its present position in this country. It has made vast advances in all directions and risen far above the lowly position assigned to it fifty years ago. Still it has by no means reached the position claimed for it by the late Sir Joseph Hooker; "it must permeate," he said, "the whole of education to the termination of the university career, every subject taught having a geographical aspect." Notwithstanding all that has been accomplished in the more or less scientific exploration of the face of the earth, much still remains to be done before our knowledge of its features is adequate. The great blanks which disfigured the map of Africa fifty years ago have, no doubt, been filled up, but it is doubtful if more than one-tenth of its surface has been mapped with anything like accuracy. Of Australia, large areas have only been provisionally mapped, and the same may be said of Asia. Even in the case of Canada and the United States much remains to be accomplished before these countries are as thoroughly mapped as the United Kingdom, India, and even Japan. Of South America, only fragments have been adequately mapped, and probably a million square miles are entirely unexplored.

Oceanography has by no means completed its task, though when Amundsen returns in four or five years' time he may be able to tell us all we want to know about the Arctic basin. While there is no need for a network of mapping on the Antarctic continent, still we desire further additions to our knowledge of its great features, its geology, its meteorology, as well as its resources, if there are any of value accessible. There remains ample room for work by trained explorers in many of the islands of the ocean. It is thus evident that plenty of work still remains to be done in exploration, in survey, in mapping, and in collecting the varied material which will enable the trained geographer to work out those problems which bear on the relations between man and his geographical environment. Happily, the marked educational advance during the last thirty years in the status of geography, and the great improvement in geographical education, have resulted in producing an increasing number of young geographers capable of dealing on scientific lines with the problems presented; in this respect we are rapidly approaching the standard which has for long been almost a monopoly of Germany.

PROGRESS OF PHOTOGRAPHY.

By Chapman Jones.

To most people fifty years ago, photography was represented by the "carte-de-visite" which they exchanged with their friends, and a few "views" which they bought now and then as mementoes. Some who were rather better-to-do preferred the larger "cabinets" which had been fashionable for two or three years. But there were also, as there had been for the previous thirty years or more, an increasing number of those who were really interested in the art and the science of photography. The Royal Photographic Society, then the Photographic Society of London, was sixteen years old, and there had been journals devoted to photography for about as long. The rapid rectilinear lens, which has enjoyed a greater popularity than any other lens, had just been introduced. The carbon process had already been practised commercially, but in that very year it received its final simplification by the elimination of the use of a cement to hold the exposed tissue on to its support during development. Large photographs had been made, one, 12 ft. by 7 ft., having been recorded in 1868. Photography in natural colours had had its history written, the principles of three-colour photography were understood, the nature of the developable image had been much discussed, and an electrical theory had been proposed. Actinometers had been devised. The kinematograph was represented by the zoetrope, or "wheel of life," a mere toy.

Thus it is obvious that when NATURE first saw the light photography had made very considerable progress, but its applications were hampered by its limitations. There was no plate sensitive enough for a photographic zoetrope, and the three-colour method of colour photography was not practical, because the plates available were insensitive to red and nearly insensitive to green. But the keys to the removal of these two great barriers to progress were soon to be found. Vogel's fundamental discovery that silver haloids might be made sensitive to red and to green by treating them with certain colouring matters was made within four years, and within eight years, during which gelatine had been coming to the front as a medium to replace collodion, Bennett found that by keeping gelatine emulsion warm for a few days the general sensitiveness of the plates coated with it was increased very many times. It remained, of course, to develop the possibilities thus demonstrated, and, equally of course, they were developed. During the 'seventies there were other notable matters. Printing in platinum was introduced, the replacement of glass by films received attention, and the photographic zoetrope became an accomplished fact in the work of Mr. Muybridge, of California.

In the 'eighties hand-cameras began to appear, isochromatic plates (that is, plates sensitised for green) were commercially produced, films were made practical, plates and films were coated by machines instead of by hand, and developing agents, which had hitherto been restricted to two or three, began to increase in number.

In the next decade, the 'nineties, Carl Zeiss issued the first anastigmat, which was soon followed by the products of other firms, and the mechanical, photographic, and optical difficulties of kinematography were largely overcome. Many new developing agents were introduced, and the chemical constitution apparently necessary to confer the power of development was elucidated.

In the early years of the present century much superior colour sensitisers for gelatine plates were found, and panchromatic plates became practically a new power in dealing with colour. The autochrome plate provided the first commercially practical method of photography in natural colours on a single plate and by one series of operations.

This brief sketch of some of the chief items of the history of photography for the period under review is necessarily very incomplete, but it gives landmarks that may help to picture the general progress. The applications to scientific and pictorial work, as well as to matters of immediate commercial importance, followed close upon each step that increased the scope of photographic methods, until in many cases these took the first place instead of a very subordinate position. We have examples of this in astronomy, in surveying, and especially in photo-engraving and block-making, for in this last case the hand methods have been rendered commercially obsolete. With the increase of facility the popularity of photography increased until now one regards any person who can say that he has never taken a photograph as something akin to a person who is unable to write.

The Editor asks me to say something as to the "promise of future advance." Photography in its essence is a pictorial method of recording, and may therefore be fitly associated with writing, though photography has the great advantage of being automatic. Besides this it has so many advantages that it will form a necessary part of the training of every well-educated person. Whether it will be a college or a secondary-school subject the educationists must decide, but it will form a necessary adjunct to the study of almost all college subjects. In the professional and commercial world its importance will be increasingly recognised as a means of rapidly getting unbiased records. The kinematograph is a photographic method of recording movement whether slow or rapid, and will therefore be increasingly appreciated both for scientific purposes and as a means of education.

As to pure photography—that is, the study of photography itself—we do not know what change takes place in silver salts when they are rendered developable. Of late this matter seems to have passed into the domain of atomic or molecular physics. We know little enough about gelatine, and want to know a great deal more. Gelatine has proved to be a better medium than collodion, but there seems no reason to suppose that a better than gelatine may not be found. We seem to have realised the maximum aperture (or rapidity) in lenses, but there is no such absolute boundary to the sensitiveness of photographic plates, and here we look for continued progress. One fundamental question: Why should silver occupy such a unique position among all the elements with regard to the sensitiveness of its salts?

REPRODUCTION OF ILLUSTRATIONS, 1869–1919.

By EMERY WALKER.

FIFTY years ago illustrations for books or periodicals were printed either from engraved wood blocks, steel plates, or were lithographs. In the earliest numbers of NATURE examples may be seen of the first method—in that of January 20, 1870, we find a diagram of a section of the tube by which it was proposed to construct the Channel tunnel; and in that of February 17 an illustration of the Newall telescope at Gateshead: these could scarcely be bettered now. The map illustrating the main drainage of London, in the issue of March 31, is an example of the inadequacy of wood for such a purpose.

Two years later Mr. Alfred Dawson patented a method of engraving designed to supersede wood, and though his object was not attained in subjects requiring tone, diagrams and simple maps were found at once to be better and more cheaply engraved by his process.

Dawson's typographic etching, as he named it, is produced thus: A metal plate is coated with a ground of wax composition; the drawing is made upon the plate through the ground down to the surface of the plate with steel points, similar to those used in etching, but they are faceted to different dimensions at the points. If lettering is wanted, as for a map or a diagram, the letters are stamped in the wax with ordinary printer's type. The spaces between the lines and letters are then raised upon the plate by the addition of melted wax, which unites with the ground and runs up to the line, and in the hands of a skilful operator stops there, thus forming a mould. This is then blackleaded, and upon it copper is deposited by a galvanic battery. When the copper is about the thickness of fairly stout brown paper it is taken off the mould and the outer surface tinned and "backed up" with antimonial lead. The leaden surface is turned in a facing lathe and mounted upon wood or metal, which brings the printing surface of the block to the height of type. It is then practically a piece of type and can be "set up" and printed with the text of the page.

This process was a development, with some refinements, of a method patented by Edward Palmer about 1840, and called by him "glyphography"; it was used to a limited extent for book illustration.

Dawson's typographic etching is still in use, and it may be interesting to note that the line blocks for the maps in Fortescue's "History of the British Army," and the greater part of those for the last edition of the "Encyclopædia Britannica," were engraved in this way.

In France a method called, after its inventor, "Gillotage" had been in use a few years earlier than this, by which blocks for the cheaper kinds of newspapers were made by transferring to zinc drawings made in reverse upon lithographic transfer paper, and the "whites" bitten away with dilute nitric acid. This process was introduced into England after the suppression of the Commune in 1871. The application of photography to this process was the beginning of a revolution in book illustration. For though wood-engraving held its own for many years after this for subjects in which chiaroscuro was required, it was gradually disused for drawings made in line, and the art of pen-and-ink drawing for reproduction began.

Artists soon got used to the new method, and there was a general demand for a process which would reproduce not only drawings in line, but also those made in washes or body colour, and would be suitable for the direct reproduction in the printing press of a photograph from nature. This was met simultaneously by F. E. Ives, an American of great photographic distinction, and by a German inventor, Meisenbach. Ives's process, though beautiful results were obtained, was too complicated for general use, and Meisenbach's process, called in English "half-tone," held the field. The negative of the drawing to be reproduced was made by photographing through a screen of parallel lines placed close to, but not touching, the sensitive surface of the photographic plate, and when the exposure was half-completed the lens was covered and the screen turned round so that the lines ran in the opposite direction to that in which the screen was first placed, and the exposure completed.

This was in 1882. The result was rather crude and deficient in variety of tone. The real advance was made by the invention, by Max Levy, of Philadelphia, of a new screen composed of two ruled glasses placed in contact at right angles. Max Levy's screens were imported largely, and from this time England, which had been, in the earlier stages of the invention, dependent upon Vienna, and to a smaller extent upon Paris, for half-tone blocks, went ahead, and now half-tone work made here is not second to that of any country in the world. It is used, not only in books, but also for the illustration of daily papers.

The most important invention since Meisenbach's is the three-colour half-tone process. This was based upon James Clerk Maxwell's researches made so long ago as 1861. The drawing or object is photographed successively through three colour filters: for the red negative a green filter is used; for the blue, a red; and for the yellow, a violet or blue filter.

A half-tone block is made from each colour negative, an operation requiring the utmost accuracy to get register, and the screen is placed at different angles to get white into the interstices of the grain and to prevent an effect like that of "watered silk."

In all these processes intended for the letterpress machine, the metal plate, for rough work of zinc, and for more delicate work of copper, is mounted "type-high" in the manner described above.

A more recent invention obviates the use of the objectionable but necessary shiny coated paper: An impression is made from a half-tone plate upon an india-rubber roller and transferred to the paper, which may have an ordinary or even a slightly rough surface. Excellent work has been done with some subjects by the application of this method to the three-colour process, but so far the average results are not equal to those obtained by the use of blocks upon glossy paper. This is called "Off-set."

A very important photographic process, used until lately more on the Continent than in England, where it was first introduced in 1870, is collotype; or, as it was known in earlier days here, "heliotype." Mungo Ponton, in 1839, used bichromate of potassium, and Fox Talbot, in 1851, discovered the action of this chemical in making a gelatine film sensitive to light. When a negative is printed upon a film of gelatine so sensitised, it absorbs moisture in inverse ratio to the amount of light it has received, and when by means of a roller a greasy ink is applied to it, it takes the ink in the ratio of its dryness, and so gradation in the print is obtained. The advantage of this method of reproduction is that it is not necessary to use the glossy coated paper, which is essential if one is to obtain the best result from either a half-tone block in black or from a set printed in three colours. The disadvantage is that it cannot be printed on a letterpress machine in the same way as a block.

This process is unrivalled for facsimiles of documents and early manuscripts. But for the reproduction of pictures and illustrations requiring a greater depth of tone, photogravure remains without a rival at present. It is interesting to note that Niepce de Saint-Victor, in 1847, had produced a photogravure plate. He coated a copperplate with bitumen of Judea and exposed it to the action of the sun under a line engraving, which acted as a photographic positive, afterwards biting the protected lines into the copper, and etched a plate which could be printed on a copperplate press.

Since that time many modifications have been made, the more important being the process invented by Rousillon based upon a beautiful invention of Walter Bentley Woodbury, patented in 1866, and introduced by Messrs. Goupil, of Paris, early in the 'seventies, which was an electrotype from a gelatine mould in relief; and that by Klic, of Vienna, who invented the method now most generally used: A copperplate is covered with an aquatint ground made by dusting powdered resin or bitumen of Judea on it and then melting it with a gentle heat. This causes the particles to run together in little "hills," leaving minute "valleys" between them. Upon this plate an ordinary carbon positive made from a reversed negative is squeegeed down and developed. When it is dry it is placed in a bath of perchloride of iron. This acid bites through the gelatine of the carbon positive and into the copper, the depth being graduated by the varying thickness of the gelatine of the carbon positive. When the biting is completed the gelatine is cleaned off, the copperplate inked by filling the interstices or pits and the excess of ink wiped off, first with canvas and fine muslin, and, finally, with the printer's hand, and an impression taken upon damped paper in the same way as from a copperplate engraved by hand.

An adaptation of photogravure to machinery was made at Lancaster about twenty years ago. It consists in applying Klic's method to a copper cylinder by the use of a half-tone screen instead of a grain produced by bitumen or resin. After inking the surface of the cylinder it is wiped to remove the superfluous ink and impressions on paper are made by a rotary motion at a great rate. The process is now largely used for illustrations for weekly illustrated newspapers and magazines.

PROGRESS IN SCIENCE TEACHING.

By Sir William A. Tilden, F.R.S.

A MAN who remembers clearly the first Great International Exhibition in 1851, and was at school through the period of the Crimean War, can no longer claim to be ranked among young men or even the middle-aged. But, with all the disadvantages of age, there is something to be said for the satisfaction and practical use of personal reminiscence. The days of school life which I can recall were practically pre-scientific, for, though one or two schools, such as the Quaker School at Ackworth, included elementary science in their programme, the utmost attempted, as a rule, was a visit from a peripatetic teacher, who came, like the dancing-master and the drawing-master, once a week or a fortnight. This was the practice at a school in Norfolk at which

I was a pupil in 1856. It was kept by a kindly old clergyman, who would, in the occasional absence of the lecturer, quack a bit himself and sometimes show experiments, not always well chosen. I remember seeing the cruel operation of putting a mouse under the receiver of the air-pump and extracting the air. And though Stockhardt's "Experimental Chemistry" was the text-book, the boys made no experiments for themselves, but were required to commit to memory passages from the book, such as "iodine has a violet vapour." There were no school laboratories in those days, even in the great public schools, neither was natural science so much as mentioned in the great majority of the schools in the country.

There can be no doubt that the Great Exhibition in 1851 set many people thinking, for in 1853 the Department of Science and Art was created with the object of assisting in the establishment of local science schools and classes. Many of the first created schools failed, and in 1859 the only classes in actual operation under the Department were at Aberdeen, Birmingham, Bristol, and Wigan.

The difficulty at that time arose chiefly from the scarcity of competent teachers willing to undertake the work, and a system was therefore inaugurated by which persons who passed the examinations held by the Department were considered qualified to teach and to earn payment on results. The system, with modifications, grew to gigantic proportions, and, whatever may have been said in later years in the way of criticism by those who object to all kinds of examinations, there can be no doubt that the existence of these classes served to spread an elementary knowledge of physical and natural science very widely through the country, and especially among the industrial classes, who would otherwise never have found their way into any place of higher instruction.

With regard to the introduction of systematic teaching of science into public schools and others of similar rank, there is the evidence of the Rev. W. Tuckwell, headmaster of Taunton School, who, in a paper contributed to the British Association at Exeter in 1869, stated that science had been taught at Taunton "for the last five years" and at the rate of not less than three hours a week. This was, however, a marked exception, for from the first report of the Duke of Devonshire's Commission it appears that in 1864 science did not exist in the programme of the largest and most famous schools. Very soon after this, however, systematic teaching, associated with practical work, began at Clifton, Rugby, and the Manchester Grammar School, and this example was soon followed elsewhere. Nevertheless, the Commissioners reported that in 1875, of 128 endowed schools examined, not one half had even attempted to introduce it, while only thirteen had a laboratory, and only ten gave so much as four hours a week. It was uphill work. Obstruction was rampant, not only among the headmasters, but also in the old universities to which the schools passed on their boys. The distribution of scholarships at that time was most unfair, and mischief was done by the procedure of the Oxford and Cambridge Schools Examination Board, which sent down examiners, sometimes ill-qualified for their office, who set unsuitable questions from the text-books with very little reference to the teaching.

At the present day all the great schools are provided with spacious laboratories and an equipment generally superior to that which was to be found in many British universities fifty years ago. Moreover, there is now a large body of highly efficient and enthusiastic teachers, not only in the schools for boys, but also in the high schools for girls, which have sprung up since that day. The science masters have formed an association which includes representatives of all the great public schools and many others—in all, upwards of three hundred members. The science mistresses have a separate association of their own, and as the problems they have before them are very nearly the same as those which interest the masters, it seems a pity that the two associations are not amalgamated. The existence of these associations and the position of influence to which the Association of Science Masters has attained show the changed position of physical and natural science as a school subject. There are, however, schools still where the headmaster stands in the way of the development of science teaching; there is the persistent, ignorant demand on the part of the public for those subjects only which are supposed to lead immediately to remunerative business; there is the almost total ignorance in Whitehall, in Parliament, and in the Ministry of the commonplaces of physical science; there are the indifferent methods still employed in classical teaching whereby an enormous waste of time is incurred: all these are circumstances which operate perennially against that kind of recognition of physical science in education which is essential to national progress, and must continue to be the subject of conflict until a state of balance between the advocates of the old and of the new has been established.

From the schools we may now turn to see what has been accomplished at the universities. In the early sixties of the nineteenth century the position of science at Oxford is indicated by the fact that Dr. C. G. B. Daubeny occupied down to 1867 the chair of chemistry simultaneously with that of botany. An undergraduate who chose to "go in for stinks" could attain a degree, but it was B.A. Daubeny's successor, Sir Benjamin Brodie, was a distinguished chemist, and in his evidence before the Royal Commission in 1873 he plainly stated his view that Oxford did nothing to extend scientific knowledge—that is to say, that research was not encouraged. At Cambridge things were in much the same position. There were some distinguished scientific professors, of whom Stokes was one of the most eminent, but there was no university laboratory, though one had been opened at St. John's College. At this time and for many years afterwards serious students of chemistry and some other branches of science resorted to the German universities for the instruction which they could not obtain in their own country in the higher parts of their subjects and in research, usually returning with the Ph.D. degree. In London the only chemical laboratories for the reception of students were at the Pharmaceutical Society (opened in 1844), at the Royal College of Chemistry (opened in 1845), at University College, at King's College, and at the Royal School of Mines in Jermyn Street. But a great step forward was taken when in 1860 the University of London founded for the first time in England a Faculty of Science and began to hold examinations for the degrees of Bachelor and Doctor in that faculty. The effect was immediate and extensive. The programme put forth appeared formidable, but it provided at once a stimulus and a guide to all the numerous casual students scattered throughout the kingdom, some attending classes of the Science and Art Department or mechanics' institutes, some engaged privately in evening study after business. As a simple matter of autobiography, my case was one of the latter kind. I was then a young demonstrator in the laboratory of the Pharmaceutical Society, but I was fairly well up in the physics and chemistry of that day. I also held a Science and Art certificate as a teacher of botany. The matriculation was the chief obstacle, as I had practically learned no Greek at school. This, however, diligence enabled me to surmount, and by 1868 I got my B.Sc. with First Class Honours in chemistry.

My case must have been very similar to that of dozens of young men at that time to whom came the opportunity of getting a stamp or brand without the necessity of throwing up the occupation by which they were getting a living. But it did more than that, for the syllabus of subjects comprised the whole circle of the sciences, including, besides the various departments of natural and experimental science, logic and moral philosophy, so that candidates were required to show at least a rudimentary knowledge of the subject-matter of various branches of human knowledge of which they would otherwise have remained totally ignorant. My own experience leads me to think that this "little knowledge," which, according to Pope's mistaken aphorism, is "a dangerous thing," is of great value even to the specialist. A *Doctor* of Science ought, and is supposed, to be an expert in some direction or other, but not long ago I met a London D.Sc. who had never heard of Bishop Berkeley. This curious fact revealed a state of ignorance of all philosophy and much more which he would have escaped had the old regulations been retained. This is, of course, now past praying for, and research, which implies specialism, is the order of the day. It is only consolatory to reflect that anything which induces concentrated thought has an educative effect on the young mind.

One of the greatest movements for the promotion of education in general, and conspicuously in the encouragement given to scientific teaching and research, was the foundation of the university colleges and new universities distributed over the country. In Manchester the college which became the nucleus of the present Victoria University had been founded by John Owens in 1851, while in London University College (the original University of London), King's College, and Bedford College were already in existence. But in 1871 the first step was taken towards the extension of similar benefits to other parts of the country. In the first instance these institutions subsisted on endowments provided by private benefactors, supplemented by aid from local subscribers or such bodies as the Guilds of London. But in a very few years these were found to be insufficient, and serious financial embarrassment had to be faced. After repeated applications to the Government for assistance, and a long struggle, the battle was won, and in 1889 State aid was granted in the form of the very modest amount of 15,000*l.* per annum, to be divided among the English colleges. Sir William Ramsay was one of the most active promoters of the movement, and the full story is recorded in his "Life" (Macmillan).

As to the future of scientific discovery, who can tell? The wonders which have been successively revealed during the last fifty years should teach us not to be surprised at anything. Co-operation among workers and organisation may do something in the way of gathering up knowledge of Nature, but whatever is done by Governments, institutions, or individuals, one consideration should ever be kept in view, and that is that genius will find its own way, and it would be worse than useless to prescribe subjects, or methods, or opportunities to the man who has been gifted by the gods.

ASPECTS OF SCIENCE AT UNIVERSITIES.

BY DR. ALEX HILL.

DOUBTLESS the provision made by the universities of the United Kingdom for the teaching of science and for research is still inadequate. It always will be. The occupation of the field and its extension is a single process, not a process and its result; since the farther man explores, the wider is his vision of the unexplored. The improvement which has marked the past fifty years is roughly proportionate to the growth of knowledge and to the investigator's success in utilising it for the meeting of human needs.

Oxford, Cambridge, the four Scottish universities, Trinity College, Dublin, Durham (with no Newcastle College of Science), and London were the only universities in 1869. To these must be added Owens College, still in the house in Quay Street "to which a chemical laboratory and a large lecture-room had been added." In science Cambridge led the van with, possibly, University College, London, as her nearest rival. It is unsafe to adopt an order of merit. Much depends upon the point of view. Edinburgh, for example, in the biological aspect, might lay claim to precedence. We may take Cambridge and University College as examples of the provision made for science, then and now, seeing that space will not allow of a fuller treatment of the subject.

Science attained to the status of a department of knowledge when the Natural Sciences Tripos was established. The first examination was held in 1851. Yet for many years the various branches of natural science were regarded as possible substitutes for the humanities in the education of a gentleman, rather than as vehicles of a grim and strenuous discipline for the work of life. Science was Whewell's *forte,* omniscience his foible. The Tripos was reminiscent of his influence. All branches of science ranked alike. A candidate's place depended upon his aggregate of marks. To secure a first class he must show that his knowledge, like that of the stupendous Master of Trinity, ranged from zoology to mineralogy.

The institution of the Tripos was a powerful stimulus to scientific study. New buildings were erected in 1864 and 1865, yet the contrast between the accommodation and equipment of the various departments, in 1869 and to-day, is so marked as to be amusing. Salvin's building was a palace as compared with the hovel in the south-east corner of the old Botanic Garden, erected in 1786 by Mr. Bradwell, bricklayer, and Mr. Kaye, carpenter, both of Cambridge, in which, until 1864, all departments, with the exception of geology, had been lodged; a building which for several years after that date was shared by the professor of chemistry and the professor of anatomy (including comparative anatomy and comparative physiology). The lecture-room on the upper floor of this building was well lighted, but the metallurgical laboratory on the ground floor, and the cabinet in which, if possible, a body was dissected every year, were dark and inconvenient in such degree as seemed appropriate to the evil-smelling and repulsive rites to which they were devoted.

Salvin's building, which was enlarged later by the addition of an upper story, provided accommodation for mineralogy, botany, zoology, and natural philosophy. For long the block was known as the "New Museums," since the greater part of its space was given up to the housing of the herbarium and the collections of minerals and of zoological specimens. Museums, be it noted, were considered, in those days, as of far more importance than laboratories for the teaching of science. The geological collection was stored—it would be misleading to write "exhibited"—in Cockerell's building, now given up to the university library.

To-day the whole of the old Botanic Garden, with much surrounding property from which houses have been cleared, together with about six acres on the opposite side of Downing Street, is covered with noble buildings. Fortunately, they are not too noble. For the most part, they look as if they were intended for the purposes for which they are used. Cambridge is happier than some modern universities in this respect. The dignity of science is not enhanced by Gothic or Palladian architecture. Science looks to the future, not to the past. Steel girders and sheets of glass can be rearranged to meet new needs. The cotton-mill style is the only style appropriate to museums and laboratories. Proportion, light, ventilation, and convenience of access of the building as a whole and of its several parts are the only merits for which the man who designs them can lay claim to renown.

Excluding the professors of mathematics and astronomy, the scientific staff of the university comprised the professors of chemistry, anatomy, botany, geology, natural philosophy, and zoology, each of whom received a yearly stipend of 300*l.*, together with a demonstrator of anatomy, who received 100*l.*, and an attendant at the chemical laboratory. These officers alone were paid out of the University Chest. Additional assistants, lecturers, and demonstrators were to be found in some departments, but their employment was the professor's private affair. To the university staff must be added a lecturer in natural science at Trinity, two lecturers at St. John's, a medical lecturer at Caius, the superintendent of the laboratory at Sidney, and two lecturers in medicine and natural science at Downing. To-day we find nineteen professors of natural science and seventy-three readers, lecturers, and demonstrators on the university staff, and forty-three college lecturers.

The lures set in the gates of science were scarce likely to beguile a student from the broader ways. "Three-quarters of all university prizes and more than one-half of all college prizes are awarded for classics and English," the Calendar boasted in 1869. English might as well have been omitted. It could not stand alone. The only prize for natural science was the Sedgwick. Thirteen names appeared in the Natural Sciences Tripos, against 111 in the Mathematical and 73 in the Classical class-lists. In 1914, 153 men and women took honours in the Natural Sciences Tripos, against 121 in the Mathematical, 113 in the Classical, and 352 in the various other Triposes which have come into existence in recent years.

At University College, London, the laboratory accommodation was singularly modest, as, indeed, it remained until quite recent times. The steady flow of discovery which has issued from the cramped, dark, inconvenient chemical laboratory is testimony to the genius of the men who have successively occupied the chair. Students were not expected, in 1869, to do practical work, as understood to-day. The writer recalls sitting in a row of other students, in 1872, pulling petals from flowers and filling his notebook with floral diagrams; attending demonstrations in the physical laboratory; dissecting, when it came to his turn, a rabbit to be inspected by the class, whilst Prof. Grant, in the dress-coat, brocaded vest, and white cravat of the Georgian period, discoursed philosophy, with occasional reference to the rabbit. In the chemical laboratory students worked in relays, but so limited was its space that the lecture-theatre had to be fitted for the examination in practical chemistry by clamping a tray for each student on to the sloping board on which, during lectures, the notebooks rested. A similar description would apply to the laboratories at Edinburgh, Glasgow, Dublin.

Provision for teaching and research has kept step with the uses to which scientific knowledge has been turned. The distinction drawn between pure science and applied science is essentially unsound and wholly mischievous, as if the purity of science were sullied whenever the problem to be solved is suggested by an immediate human need. The discoveries made by an investigator who has a practical application in view are as truly additions to the sum of human knowledge as those which reward a worker who is following a line of research which can never, so far as he is aware, contribute to man's comfort. In most cases the practical man also advances the grasp of pure science by directing attention to gaps in theory, and by asking the professors questions which they cannot answer. The universities have been slow in realising their duty to the crafts and manufactures. It is greatly to be hoped that, in the near future, we shall cease to hear of independent bodies set up for the purpose of carrying out either "scientific" or "industrial" research. There is but one Science, and the universities are the instruments for extending its range.

FIFTY YEARS OF TECHNICAL EDUCATION.

BY J. H. REYNOLDS, M.Sc.

JUST fifty years ago there appeared a remarkable book, the fruit of much thought, experience, and wide travel, entitled "Systematic Technical Education for the English People." Its author was Mr. J. Scott Russell, F.R.S., the designer of the *Great Eastern*, the largest vessel of that time, which rendered singular service in the laying of the first Atlantic cable. The volume was dedicated to the Queen, and the purpose of the dedication was declared to be "to entreat her Majesty graciously to consider the case of the uneducated English folk who are now suffering great misfortune in their trade, commerce, and manufactures, as well as in their social, moral, and intellectual condition, through having been neglected and allowed to fall behind other nations better cared for by the men whose duty it was to lead as well as to govern the people." The Queen was urged "to issue her Most Gracious Majesty's commands to her Majesty's Ministers to see to it that for the future the dexterous, energetic, willing working people of England receive at the hands of the Government a practical education for useful life as thorough and systematic as the best-educated nation in Europe."

Mr. Scott Russell declared that the condition of English education, both general and scientific, compared very unfavourably with that prevailing in Continental countries, notably in Prussia, Saxony, Württemberg, and Switzerland, whilst no provision worthy of the name existed for technical education and training, which were abundantly provided for all grades of workers in industry and commerce in all the countries named. He called in evidence the lessons taught by the Great Exhibition of 1851, which owed its origin to the enlightened views of the Prince Consort, and in which the civilised nations of Europe received their first lessons in technical education. Our superiority in machinery and its products was manifest, whilst in articles demanding beauty and grace of design we were plainly lamentably far behind some Continental nations. Mr. J. Scott Russell concludes his book by pleading for the appointment "of a powerful statesman to be Minister of Public Education with a strong will; a complete organised plan of a people's teaching; a determination that, at whatever cost, the English people shall become in one generation the best-educated nation in Europe—and it will be done." We have at last such a man in the present President of the Board of Education, and it is to be hoped that he may so remain and be given the means to carry out the essential reforms embodied in the great Act of 1918.

The enormous progress made by the several important nations as a result of the object-lesson of 1851 was made clearly evident at the exhibition held at Paris in 1855. England was no longer, in consequence of the establishment of schools of design and the circulation of the best models in the areas affected, outstripped in pottery and glass, whilst, on the other hand, foreign nations, such as France and Germany, recognising the advantage which England enjoyed in the possession of abundant raw material, such as coal, iron, and steel, together with skill in adapting them to the purposes of industry, and realising that the only effective way of meeting it was to apply higher science and research in their treatment and application, had already, with this aim in view, established schools for the education and training of both masters and workmen, with the result that their engineering exhibits made a remarkable display.

The International Exhibition of 1862 held in London showed a further striking advance on the part of foreign nations: Switzerland with her aniline colours, Prussia with her ingots of Krupp steel, France with her steam-engines, and the United States with ingenious machinery for economising labour. But it was the Exhibition of 1867, held in Paris, which offered conclusive and disturbing evidence of the successful efforts of foreign nations in the application of organised scientific and technical education to manufactures, especially in the production of well-designed steam-engines, boilers, ships' armour, and artillery.

In the great ironworks at Creusot, in France, there was established a systematic organisation of technical schools such as could be found nowhere in England. It was the considered judgment of skilled observers and of representative workmen in various trades who visited the exhibition that England no longer held the preeminence in industry which was surely hers in 1851, due, as was declared, entirely to the absence of sufficient facilities of training in pure and applied science. The Science and Art Department, founded in its entirety in 1853, had encouraged the establishment of evening classes in science and art, but they reached only a fraction of the workers, and except in a few instances they had little bearing upon the technology of industry. It may safely be said that in 1869 out of 1,250,000 youths engaged in industry not more than 5 per cent. were receiving any training in applied science in the day and evening institutions of the kingdom.

The period of trade depression that followed after the year 1869 and the awakening of the nation to the serious industrial competition of certain foreign nations, largely due to better educational provision, notably of scientific education, especially for the leaders of industry, gave rise to earnest efforts to provide the means of scientific and technical training in this country. The Livery Companies of the City of London joined with the City in the creation of the City and Guilds of London Institute in 1879, the purpose of which it was to provide a day and evening technical college at Finsbury (opened in 1883) for boys purposing to enter upon industrial pursuits, together with a central college at South Kensington, opened in 1884, for the training of future industrial leaders and teachers of technology. In addition, the aim of the institute was to encourage the establishment of technological classes throughout the kingdom and to set up a system of examinations in the subjects. Large annual sums were subscribed in support of these objects, and certificates, prizes, and medals were awarded to successful students.

Considerable annual grants were given in aid of the establishment of technical schools in Manchester, Sheffield, and other places, and the Company of Clothworkers made itself responsible for the establishment and support of a textile department at the Yorkshire College, Leeds, whilst the Company of Drapers founded and supported the People's Palace, now the East London College. The interest aroused in the subject of technical education and the rising competition of Continental nations led the Government to appoint in July, 1881, a Royal Commission "to inquire into the instruction of the industrial classes of certain foreign countries in technical and other subjects for the purpose of comparison with that of the corresponding classes in this country, and into the influence of such instruction in manufacturing and other industries at home and abroad." The Commission presented in 1884 an exhaustive and highly informing and stimulating report after nearly three years' inquiry not only in Europe, but also in the United States, which had a profound effect upon public opinion, and led to the passing of the Technical Instruction Act of 1889, which empowered local authorities to rate themselves for the support of technical schools. This was followed by the Act of 1890, whereby nearly 800,000*l.* annually derived from the customs and excise duties was placed at the disposal of local authorities for purposes similar to those of the former Act.

This resulted in the establishment, chiefly by the local authorities, of technical schools and colleges throughout the kingdom, a few of which were effectively equipped and staffed for the training of qualified day students intended for leading positions in the various industries, and some of these schools, like those of certain London polytechnics, Manchester, Glasgow, Sheffield, Bristol, and Belfast, came into intimate relations with their respective universities. The Education Act of 1902, which placed all grades of education, exclusive of the university, under the control of the local authority, had a unifying effect which made it possible to correlate the various forms of education and to bring the opportunity of secondary and technical training within reach of the poor but capable scholar.

Meanwhile, many important industries, notably those producing scientific instruments, chemical ware, fine chemicals, and especially artificial dyestuffs, had passed largely into the hands of German and Swiss firms, as witness their exhibits in the Paris Exhibition of 1900, due entirely to the command on their part of an effective supply of efficient scientific workers, so that they held the "key" of our textile trades so far as printed and coloured goods were concerned. The course of the great war has made clear, however, the innate capacity and resource of the English manufacturer in these and other products of foreign origin, as well as in the fertility of his invention and in the success with which he has met and solved many technical problems arising during its course. Striking evidence of this was displayed in the exhibitions of British scientific products held in London and Manchester in 1918, and in London in 1919, under the auspices of the British Science Guild—an organisation established to further the cause of scientific and technical education and promote attention to scientific method in all national affairs.

Another fruit of the war is the awakened interest in the subject of education on the part of large employers, and especially of the importance of scientific training and research. A Committee of the Privy Council has been instituted for the purpose of encouraging scientific and industrial research, with numerous sub-committees dealing with various sections of industry and with special products. Ten research associations have been formed in respect of the chief industries, and twenty-eight important researches have been undertaken and aided from the fund of 1,000,000*l.* placed at the disposal of the Committee by Parliament.

The Education Act of 1918, which should be made operative without delay, will, when it comes into full effect, supply a far higher type of student for our arts and industries. As showing the advance within the last fifty years, there were at the beginning of that period only four universities which granted degrees in England and Wales, one of which (London) was merely an examining body. Now there are eleven duly incorporated, with numerous colleges attached to them, many of them chiefly concerned with technical training and education. These universities are all well equipped and staffed for the teaching of science and its applications, in the encouragement of which this journal has borne no small share since its foundation in 1869.

Yet we have still far to go if we would keep ourselves abreast of foreign educational enterprise. There were in 1914 twenty-one universities in Germany, with 68,000 students, against eighteen in the United Kingdom, with 27,000 students. There were also eleven technical high schools in Germany, and sixteen other special high schools for agriculture, mining, etc., with 21,000 students, as against 5000 in ours, and in both age and standard of education at entrance their students rank much higher than ours. The State grants to universities and colleges in the United Kingdom were about 500,000*l.*, in Germany nearly 2,000,000*l.*, and in the United States 7,000,000*l.*, but in addition there was given nearly 4,000,000*l.* in private benefactions, as compared with 200,000*l.* in the United Kingdom. To maintain our position as a leading nation in industry and commerce, we need to increase the potentiality of our manhood, to secure which will require a much larger expenditure of money and effort. We want accomplished leaders and a well-educated and highly trained rank and file.

THE PROMOTION OF RESEARCH.

By SIR RICHARD A. GREGORY.

The great inventions of former ages were made in countries where practical life, industry, and commerce were most advanced; but the great inventions of the last fifty years in chemistry and electricity and the science of heat have been made in the scientific laboratory: the former were stimulated by practical wants, the latter themselves produced new practical requirements, and created new spheres of labour, industry, and commerce.—J. T. MERZ.

THE recognition of the value of scientific research as a determining factor of progressive development has been a common note of many public utterances in recent years. Ministers and labour leaders, manufacturers and men of letters, are impressed with the results of experimental inquiry and do homage to those who devote their lives to it. Rarely, however, is the spirit which prompts most scientific investigations understood. "The quickening power of science, only he can know from whose soul it gushes free." It seeks not to use, but to know: its aim is not an engine of war or a profitable invention, but the discovery of new knowledge and the creation of new ideas for all mankind. Researches which have practical applications as their proximate or ultimate ends are not likely in these days to need much advocacy for their support, but those which have no such aims must, like virtue, carry their own reward with them. The standard of value to-day, more than ever it was, is worldly riches, and if all research had to be measured by it science might gain the whole world, but it would lose its own soul by so doing.

When the State or the manufacturer makes provision for research, tangible results are expected, and freedom to explore what, from a practical point of view, seem to be unpromising by-paths is discouraged. To a certain extent Mr. Gladstone was right when in 1872 he termed the intervention of the State as "interference" with science, calculated to discourage individual exertion and so obstruct discovery and progress. The view then taken was that the more science was left to itself the better for it. We are far from accepting this *laissez faire* principle entirely, but there is some truth in it so far as purely scientific research is concerned. Creative genius never has been, and never will be, willing to submit to bureaucratic control or industrial needs, yet it discovers the new lands in which rich fruits are afterwards cultivated for the benefit of the world. While, therefore, we acknowledge with much satisfaction the growing appreciation of research as a means of promoting industrial advance, we trust that the apparently useless and unpractical pursuits of purely scientific workers will be regarded as equally worthy of encouragement.

When the publication of NATURE was begun fifty years ago, experimental research received little or no support from the State. Astronomical work was carried on at the Royal Observatory, Greenwich, and natural history objects were displayed at the British Museum, but there was absolutely no provision in this country for the support of experimental investigation of a modern type. It was pointed out in these columns in 1872 that great laboratories had been erected in Berlin, Leipzig, Bonn, Aix-la-Chapelle, Karlsruhe, Stuttgart, Griefswald, and other places, at the expense of the State, and special provision had been made in them for original scientific research, but no like developments had taken place here. When a deputation of the Council of the British Association waited upon Earl Grey, Lord President of the Council, in 1870, to urge on the Government the issuing of a Royal Commission to inquire into the state of science in England, Lord Grey thought that the whole inquiry was fraught with difficulties, but the object was worthy of a statesman's ambition. The Commission was appointed in the same year, with the seventh Duke of Devonshire as president and Sir Norman Lockyer as secretary; and the volumes of its reports issued from 1871 to 1875 are filled with convincing evidence and far-seeing suggestions.

The terms of reference of the Commission were "to make inquiry with regard to scientific instruction and the advancement of science, and to inquire what aid thereto is derived from grants voted by Parliament, or from endowments belonging to the several universities in Great Britain and Ireland, and the colleges thereof, and whether such aid could be rendered in a manner more effectual for the purpose." The whole position of science in the United Kingdom was surveyed in the volumes of the report of the Commission; and had the recommendations of the Commissioners been acted upon, we should easily have been in advance of all other countries in the applications of science to industry, and have been strongly equipped for all eventualities of peace or of war. Our statesmen had not sufficient knowledge of science to understand its relation to national advancement, or sufficient faith in scientific discovery to believe that provision for it would ultimately benefit the community industrially and politically; and we lost ground in consequence of their neglect.

One of the recommendations of the Commission was that a special department of science should be entrusted with the duty of promoting the scientific interests of the country. It was proposed that a Ministry of Science should be constituted, with a permanent and well-paid scientific council to advise the Government on scientific questions, consider inventions tendered for the use of the State, and conduct or superintend experimental investigations relating to such matters. The Department of Research and Information outlined in the Report on the Machinery of Government issued by the Ministry of Reconstruction a few months ago is intended to serve much the same purposes as were contemplated by the Duke of Devonshire's Commission. It is permissible in this connection to recall a communication to NATURE of June 15, 1871, in which Lt.-Col. A. Strange described the work which a Ministry of Science could undertake, and added, in words which are as apt to-day as they were when they were written:

> When we have all scientific national institutions under one Minister of State, advised by a permanent, independent, and highly-qualified consultative body—when we have a similar body to advise the Ministers of War and Marine in strategical science—then the fact that, in accordance with our marvellous constitution, these ministers must almost necessarily be men without pretension to a knowledge of the affairs which they administer, need cause us no alarm. When these combinations have been, as they assuredly will be, sooner or later, effected, the wealth, resources, and intelligence of the nation, having due scope, will render us unapproachable in the arts of peace and unconquerable in war—but not till then.

Though the Ministry of Science advocated fifty years ago has not been realised, the Department of Scientific and Industrial Research established in 1916 fulfils many of its functions and is likely to undertake further work for the co-ordination and development of national scientific activities if the recommendations of the Report on the Machinery of Government are ever carried out. The Department has a fund of one million pounds voted by Parliament as a block grant to be expended over a period of five or six years. This fund is being used to make grants towards the foundation and maintenance of approved associations for research on a co-operative basis. In addition, the Department has at its disposal an annual Parliamentary vote to cover the cost of researches not undertaken by the research associations, to provide grants to research workers, and for administration. The Department also now administers the National Physical Laboratory, which was founded in 1899, and to which the sum of 155,000*l.* is allocated in the Civil Service Estimates for the current financial year.

National provision for scientific work has thus been considerably extended in recent years. The official attitude of earlier days was represented by a reply which the Lords Commissioners of H.M. Treasury made to an application from the British Association in 1872 for a grant of 150*l.* to secure the continuance of some important tidal observations. The reply was:

> I am to state that their Lordships have given their anxious attention to the memorial, and that they are fully sensible of the interesting nature of such investigations, but that they feel that if they acceded to this request it would be impossible to refuse to contribute towards the numerous other objects which men of eminence may desire to treat scientifically. Their Lordships must, therefore, though with regret, decline to make a promise of assistance towards the present object out of public funds.

It will be evident from this example of the position of State support for science in England in 1872 that much remained to be done in order to change the official mind which after "anxious attention" had to express "regret" that the Government of these islands could not provide the sum of 150*l.* for tidal observations because further demands might be made for the support of other investigations. It is not too much to say that NATURE has been largely responsible for bringing about a more encouraging attitude towards scientific research on the part both of statesmen and the public generally. Throughout its existence this journal has consistently and persistently advocated increased attention by the State to scientific investigation and the need for liberal endowment of all work by which natural knowledge is increased. It is gratifying to know that the principle of national responsibility for the fostering of these research activities has in recent years been officially accepted.

Fifty years ago the provision made by Parliament for the promotion of science in the United Kingdom was an annual grant of 1000*l*., which was administered by the Royal Society. In 1876 a further grant of 4000*l*. was voted for "the payment of personal allowances to gentlemen during the time they are engaged in their investigations." In 1882 the grant of 1000*l*. was discontinued, and that of 4000*l*. has been included since then in the Civil Service Estimates without increase. The Royal Society, which administers the grant, derives no pecuniary benefit from it, and it only shares to the extent of a few hundred pounds annually in the additional annual grant of 1000*l*. made to assist in defraying the expenses of scientific publication. If this grant were increased to ten times the amount it could be effectively used by scientific societies, for the costs of publication are now very heavy and the output of papers or other works worthy of publication is much greater than when the grant was originally made in 1894.

In the Estimates for 1869–70 a grant of 1000*l*. to the Royal Society, 500*l*. to the Royal Geographical Society, and 300*l*. to the Royal Society of Edinburgh, together with other grants for scientific investigation, were classified together as votes for learned societies, with a total of 12,300*l*. The total amount for scientific and other institutions in the Estimates for 1919–20 is about 114,000*l*., but this includes 47,000*l*. for the Meteorological Office, and 20,000*l*. for the National Museum of Wales. In addition, the grants for investigation and research under the Department of Scientific and Industrial Research are estimated at 93,570*l*., and there is a grant of 12,775*l*. for the Fuel Research Station.

State grants to Colleges of London and Manchester were recommended by the Devonshire Commission in 1874, but the first direct assistance of this kind from the National Exchequer was a grant of 4000*l*. to the University College of Wales in 1883. In 1889–90 a vote of 15,000*l*. was included in the Estimates for University Colleges in England, in addition to 12,000*l*. for the three University Colleges of Wales. The total grant under that vote was then 44,785*l*., and now—thirty years later—the total amount of the grants to be paid out of the Exchequer for the maintenance of university institutions in the United Kingdom during the year 1919–20 is 1,000,000*l*. Though the increase is substantial, there are more institutions to participate in the grant, and much larger staffs and more elaborate equipment are necessary, so that it cannot be said even now that adequate provision has been made by the State for university education.

In university grants and gifts, as in those for research, the tendency is to promote the applied sciences and to overlook the needs of departments concerned particularly with knowledge of no apparent practical value. It is forgotten that the great advances in the industrial sciences of modern times, those which have raised the industrial and commercial life of the community, and so enormously increased its wealth, have had their origin in university laboratories and like places of what may be termed academic study. Investigations and discoveries on the borderlands of science, and leading to no immediately useful results for mankind, are often in the end the most valuable. It is the duty of universities to provide encouragement and training for men and women who possess special capacities for carrying on work of this kind; and a wise State will see that these workers are provided with full facilities for the cultivation of their abilities, as well as freedom to follow what seem to them the most promising paths of investigation. A scientific research laboratory cannot be conducted on the lines of a business house in which each department has to justify its existence by profitable returns. It must be independent of its patron, whether this be represented by a State department or by a governing body of commercial men. Unless this is so, our university laboratories and our research workers in fields of pure science may be reduced to the condition of some of the universities in the United States, amusingly illustrated by President Maclaurin, of the Massachusetts Institute of Technology, as follows:

The superintendent of buildings and grounds, or other competent authority, calls upon Mr. Newton.

Superintendent: Your theory of gravitation is hanging fire unduly. The director insists upon a finished report, filed in his office by 9 a.m. Monday next; summarised on one page; typewritten, and the main points underlined. Also a careful estimate of the cost of research per student-hour.

Newton: But there is one difficulty which has been puzzling me for fourteen years, and I am not quite . . .

Superintendent (with snap and vigour). Guess you had better overcome that difficulty by Monday morning or quit.

The absurdity of the picture is manifest; yet there is a tendency to regard research as more or less routine work in which results can be ordered and measured as they can by methods of scientific efficiency in industry. This is the present danger, and it is the duty of all who cherish increase of knowledge to see that such inhibitory conditions are excluded in our laboratories of creative science.

RESEARCH AND ITS APPLICATION.[1]

RESEARCH in the distant past was the privilege of the few. In chemistry, during the Middle Ages, the alchemists were practically the only men pursuing it, and they in secret, and not always from the highest of motives. Working by themselves as they did, they had not the great advantage of meeting and discussing with others similarly engaged, and using their progress and mistakes to intensify their own increase in knowledge. Thus it has come about that the science of chemistry is little more than a century old, and its tremendous advances only a few decades.

As the foundation of all these advances research is firmly embedded. Without it the structure could not have arisen or the glowing anticipations of the future been even imagined. Twenty centuries ago we were told, "Seek, and ye shall find; knock, and it shall be opened unto you." No one can deny that there have been accidental discoveries, some of great moment; but this has not been, and will not be, a safe dependence. Accidental discoveries are not to be relied on, although they are not to be scorned. In chemistry the accidental good fortunes have usually come to those who were really seeking, although possibly for something far different; but, note this, they were usually made by men qualified to recognise an important discovery when it flashed across their vision.

Research, of course, is not of necessity to result in invention. It may in that respect terminate in a *cul-de-sac* from which with present knowledge there is no egress; or, what more frequently happens, it may lead to a line of reasoning which in time leads to another, and so on, until suddenly a bright light illumines the way and a goal of the greatest importance is attained. Many instances illustrative of this could be mentioned. One only need here be cited, and that because of the importance it has assumed in the light of recent developments.

As early as 1882 men of science rigidly established by chemical research what chemists call the "constitution" of the blue vegetable dye indigo, and clinched that scientific conclusion by preparing the identical material in the laboratory. This particular important addition to human knowledge has remained a discovery merely, yet it so stimulated the search for practicable methods of applying that discovery to human needs that voluminous researches in a number of European countries were undertaken almost at once for that purpose. It remained for a college professor, working in quite a different field, to hit upon the central idea of the successful indigo method of 1897, and to clinch it by appropriate laboratory methods. In 1901, however, one of the so-called "inorganic" chemists, in searching for new worlds to conquer, evolved an idea which he thought would make one of the discarded and discredited methods of making indigo a worthy rival of the only commercially successful indigo method of that day. And he was right! The owners of the 1897 method were forced to look to their laurels.

The chemical knowledge and research that enter into the synthetic production of indigo, as we know it to-day, come from more than three generations of chemists, scattered all over the globe, speaking many languages, researching on many different and separate problems which touch almost every phase of human endeavour; and the end is not yet.

True research must be intentional and intensive. We must really seek if we would find. We must really knock at the doors of the secret chambers of knowledge if they are to be opened to us. We must have imagination, it is true, but we must have more than that. There must be the foundation of sound education and the ability to extend it to embrace new and unexpected knowledge, and apply this in its turn as we progress upwards.

The importance of research is being more and more recognised and understood by the public. One of the most encouraging evidences of this is shown in the preamble and resolution adopted recently by the American Federation of Labour at Atlantic City, indicating as these do a clear appreciation by that great association of how much we all depend on what science will disclose to ameliorate the conditions of the future.

But let our friends of the federation not be content with what the Government can do in the line of their resolution, good as it has been and will be. Let them start a carefully planned series of researches themselves, and follow them up until the truth stands revealed. Employers of labour have been doing this for years. The shining goal of all research is the truth, the whole truth, and nothing but the truth. Thus, starting from different angles, with fairness and thoroughness, the various so-called interests will arrive at the same truth, for there can only be one truth concerning any question. Thus will it come to pass that capital and labour will discover that the true interest of one is the true interest of all, and instead of bickerings and suspicions we shall have that cordial co-operation which is absolutely essential if we are to get the best out of this world of ours.

Scientific discovery is really not a haphazard matter. The art of making it can be cultivated, and definite rules of research can be laid down. Many elements enter into the problem, and these have been very well tabulated by the late Dr. G. Gore in his book, "The Art of Scientific Discovery." He defines the difference between discovery and invention as follows:—"Discovery consists in finding new truths of Nature, whilst invention consists in applying those truths to some desired purpose"; and that definition is sufficiently accurate. Research does not always lead to discovery or discovery to invention, but the sequence is logical.

The application of research has always required a high order of talent. In the future a still higher order of talent will be necessary, but in addition this talent must be prepared by education to do this very thing. How can we produce the leaders who shall adequately combine both the scientific and the practical qualifications that are necessary? This is one of the greatest and most interesting problems awaiting solution by our educators, and on its correct solution depends, in a larger degree than many imagine, the future of successful and contented industry in this country.

The candidate for leadership should have a healthy body, good habits (which involves good character), and a good mind educated to the highest degree attainable. This education should be specialised in the desired direction, while good all round. He should have a thorough knowledge of human nature. To play on the "harp of a thousand strings" requires an unusual acquaintance with the instrument. How many men, otherwise great, have broken down here, sometimes because they have given too much confidence, sometimes not enough, sometimes because they did not know how to select assistants.

Let us proceed to fill our high places of every kind with the men and women specifically prepared to fill them, being assured that the effort to do so will produce an army of those not quite qualified for the top, but of the greatest value to assist those who are. Let us educate for living, certainly; but let us also educate for leadership—that superlative leadership of which civilisation will stand more and more in need as it increases in complexity and reaches higher and higher planes.

[1] Abstract of an address delivered by the President of the American Chemical Society, Dr. W. H. Nichols, at Philadelphia, September 4.

BRITISH BOTANIC GARDENS AND STATIONS.

A MARKED feature of the scientific activities of the past fifty years has been the extensive establishment throughout the British Empire of botanic gardens and botanic stations. The history of such institutions is a long one; it takes us back to the time of the Pharaohs. It is also wide; the Spaniards found, in the Mexico they devastated, establishments of this nature conducted with as much enlightenment and on as elaborate a scale as any then to be met with in Europe.

The motives underlying the creation of such gardens have varied at different times and in different countries. Up to the middle of the sixteenth century the scope of European botanical gardens was mainly confined to the technical task of illustrating as fully as possible what were believed to be the sources of classical simples. During the next hundred years this was extended so as to include such æsthetic and economic novelties as could be made to grow. But by the middle of the eighteenth century, when the Royal Garden at Kew (1759), and the Botanic Garden at St. Vincent in the West Indies (1764), were founded, the purpose of botanical collections had become largely limited to the assemblage of plants interesting because of their rarity.

Presently a healthy reaction against this rather narrow outlook arose, for we find the historical memorandum by Lt.-Col. Kyd, to which the establishment of the famous institution at Calcutta was due (1786), advocating "the propriety of establishing a botanical garden, not for the purpose of collecting rare plants (although they also have their uses) as things of mere curiosity or furnishing articles for the gratification of luxury, but for establishing a stock for disseminating such articles as may prove beneficial to the inhabitants as well as to the natives of Great Britain, and which ultimately may tend to the extension of the national commerce and riches." Already Sir Joseph Banks, with his practical mind, had made representations to the same effect with regard to Kew, urging the utilisation of the Royal Garden as a central institution where information regarding the vegetation of the globe and its economic uses could be accumulated; where useful plants from all quarters could be raised; and whence such plants could be distributed to the overseas possessions of the Crown. Before the close of the first generation of the nineteenth century, many important establishments of the kind had been provided; among these we may note the gardens at Peradeniya in Ceylon, Saharunpur in North-West India, Singapore and Penang in Malaya, Buitenzorg in Java (during the brief occupation of that island by the English), Trinidad in the West Indies, and Sydney in Australia.

The conversion of Kew into the national botanic garden for this country (1841) gave a new impetus to this salutary activity, and under the active guidance of three eminent directors—Sir W. J. Hooker (1841–65), Sir J. D. Hooker (1865–85), and Sir W. T. Thiselton-Dyer (1885–1905)—the tradition established by Banks was vigorously sustained. To this impetus we may attribute the establishment of the famous gardens of Melbourne (1846), Durban (1850), Adelaide (1855), Brisbane (1855); and Jamaica (1857), though in the last case the inability of the local legislature to appreciate the value of science ensured for the garden the fate which had befallen that founded a century earlier in St. Vincent. The great services rendered by Kew to all forms of botanical enterprise have been nowhere more manifest than in the training of those who have proceeded to every quarter of the globe to take charge of the botanic gardens and stations throughout the Empire.

Since 1869, when NATURE was founded, the activities in this direction have continued unimpaired. In 1870 the botanic garden at Wellington in New Zealand was founded. In 1871 the abandoned Jamaica garden was re-established and another was created in Bermuda. In 1879 an important botanic garden was founded at Georgetown, in British Guiana.

Between 1886 and 1890 the botanic garden at St. Vincent, which had long been allowed to lie in abeyance, was restored, and new botanic stations were opened in the islands of Barbados, Dominica, Grenada, St. Lucia, and the smaller islands. The last station to be established in this region was that of British Honduras (1892). Profiting by the experience gained in the West Indies, attention was directed to Africa, and Kew has been instrumental in the establishment of botanic stations in our West African Colonies at Lagos (1887), Aburi in the Gold Coast (1890), Old Calabar (1893), Sierra Leone (1895), and Kaduna in Northern Nigeria (1914). In East Africa the need for a botanic station in Nyasaland was urged by the authorities at Kew, and as a result that at Zomba was founded in 1891. This was followed by the establishment of the botanic garden at Entebbe in Uganda in 1898. The urgency of the need for such an institution in the East Africa Protectorate it has, for some reason, been more difficult to persuade the authorities concerned to realise. But at last (1918) the beginnings of such an institution as has long been called for have been created at Nairobi. The Government of the Sudan, with a keener appreciation of the value of science, lost no time in establishing a botanic garden at Khartum and a botanic station at Jebelin.

Notable additions to the list of botanic gardens were those founded at Hong Kong in 1871, and at Aberdeen in 1897. But the most important of the creations of recent years is that of a great national botanic garden at Kirstenbosch, Cape Town, in 1913. This science owes to the enlightened action of the Government of the Union of South Africa, and to the untiring advocacy and exertions of the late Prof. Pearson. This institution bids fair to become in time the "Kew" of South Africa, and gives promise to be one of the most interesting and valuable scientific gardens in the world.

THE SCIENTIFIC AND TECHNICAL DEPARTMENT OF THE IMPERIAL INSTITUTE.

IN furtherance of its principal object of promoting the utilisation of the resources of the Empire, and in order to supplement its other activities in this direction, the Imperial Institute established in 1896 a scientific and technical department under the direction of Prof. Wyndham Dunstan. The history of the formation of that department and of its work in early years was told by the late Sir Frederick Abel, at that time Director of the Imperial Institute, in the preface to a volume of technical reports and scientific papers published by the institute in 1903. From that account it will be seen that the inception of scientific work at the institute received strong support from his Majesty King Edward and from the Royal Commission of the 1851 Exhibition, whilst the late Lord Playfair was one of its most active supporters.

The principal purpose of the department was to investigate by laboratory researches and technical trials raw materials, and especially those derived from the Empire overseas, as the first step in their commercial utilisation. The work of the department rapidly increased in amount and importance, and the laboratories and staff have been greatly extended in recent years. It is obvious that in the wide sense the scientific investigation of raw materials provides an enormous field, and it was necessary to limit the work of the department to those materials which are considered to be of most importance from a commercial point of view and are best dealt with in this country, and also to a large extent to limit the scientific investigation of these selected materials to the subjects requiring elucidation from the commercial viewpoint. Even with these necessary limitations a large number of scientific papers have been communicated by the staff of the department to the Royal Society, Chemical Society, Society of Chemical Industry, and other societies, whilst a number of materials of promise in scientific research have been passed for investigation to workers in other institutions, including the Universities of Manchester, Liverpool, Leeds, Aberdeen, and London.

To the research laboratories, which are provided with the proper equipment for experimental research, have been added testing plant and machinery for enabling small-scale technical trials of certain raw materials to be carried out. Arrangements have also been made with manufacturers for trials on a commercial scale of materials which appear to be suitable for commercial employment, and the department is now utilised not only for such investigations as have been indicated, but by manufacturers and merchants in this country for obtaining information as to supplies of raw materials, their nature and composition, and also as to their uses and the means of overcoming technical difficulties in regard to their industrial employment.

The scientific results of investigation conducted by members of the staff are, as a rule, communicated to the special societies concerned, whilst records of some of the principal results obtained in their commercial bearings are printed in the quarterly Bulletin of the Imperial Institute.

THE LISTER INSTITUTE OF PREVENTIVE MEDICINE.

THE institute originated from a public meeting summoned by the Lord Mayor in July, 1889, to hear statements from scientific men as to the efficacy of Pasteur's treatment for hydrophobia. The lack of any institute in this country with objects similar to those of the Institut Pasteur in Paris was discussed, and it was pointed out that England should continue to take her share in the discovery of means to control disease and not be dependent upon the national laboratories of France and Germany.

A committee was formed, of which Lister became chairman, and in 1891 the British Institute of Preventive Medicine was founded.

During the first nine years of its existence the permanent income of the institute was hopelessly inadequate to the requirements, but in 1900 it received a gift of 250,000*l.* from Lord Iveagh, which for the first time placed it in possession of an assured income. In 1903 the title of Lister Institute was adopted.

The central institute is situated on the banks of the Thames at Chelsea. It contains laboratories equipped for the study of bacteriology, biochemistry, protozoology, experimental pathology, entomology, etc., and a library and theatre. These accommodate, in addition to the staff, 20–30 graduates who are engaged in researches in some subject pertaining to preventive medicine under the guidance of the staff. The institute is a school of the University of London, and graduates of any university may proceed to the degree of doctor of science after having satisfactorily conducted during two years a research under the direction of a member of the staff who is a recognised teacher in the University.

In addition to its central laboratories in London the institute has a branch where antitoxic sera, bacterial vaccines, and calf-vaccine lymph are manufactured, and where investigations into the improvement of these curative and prophylactic agents, their standardisation, etc., are carried out.

The institute is administered by a governing body of seven, upon which the Earl of Iveagh has three representatives and the Royal Society one. The remaining three are elected by the members.

The income of the institute is derived from two sources, about one-third from endowment and the remainder partly from the sale of antitoxins, etc., and partly from moneys received from Government Departments and municipal authorities as remuneration for investigations and diagnoses carried out at their request.

THE NATIONAL PHYSICAL LABORATORY.

IF fifty years ago a Government had proposed to allocate 150,000*l.* per annum for the furtherance of scientific research, it would have met with an unsympathetic response in Parliament, and in all probability would have been turned out of office as too visionary and unpractical. The growth of the belief in the influence of research on industry and commerce was slow in this country, and was due, perhaps, more to the successful application to the production of electricity and of light of the laws of electromagnetic induction discovered by Faraday than to any other fact. When Dr. (now Sir Oliver) Lodge urged the necessity of a National Physical Laboratory in his address to the Mathematical and Physical Section of the British Association in 1891, Berlin and Paris had already taken action. A committee of the association, under the chairmanship of Sir Douglas Galton, drew up a scheme for the foundation of such a laboratory, and, after a favourable report by a Treasury Committee under Lord Rayleigh appointed to consider the matter, the laboratory was founded in 1901, with Dr. (now Sir Richard) Glazebrook as director and an annual income of 5000*l.* The control was vested in the council of the Royal Society, who appointed an executive committee. Owing to the rapid growth of the work of the laboratory, the financial responsibility became too great for the Royal Society, and the financial control was taken over by the Government in 1918. So well has the laboratory justified its foundation that the Government is prepared not only to make the annual grant mentioned in the opening sentence, but also to support a Department of Scientific and Industrial Research, and National Chemical and Engineering Laboratories are not outside the bounds of possibility.

THE DAVY FARADAY RESEARCH LABORATORY OF THE ROYAL INSTITUTION.

THE Davy Faraday Research Laboratory of the Royal Institution was founded and endowed by the late Dr. Ludwig Mond, F.R.S., with the object of providing opportunity for original investigation to extend knowledge in the domain of pure chemical and physical science by persons (men and women of any nationality) who could satisfy the authorities of the laboratory of their scientific training and qualifications to conduct original research.

The laboratory was opened on December 22, 1896, by his Majesty King Edward VII., who took occasion to point out that "Dr. Mond's foundation was a most important accession to the resources which had been placed at the command of the institution for the advancement of chemical and physical science. The Royal Institution has long enjoyed a world-wide reputation, thanks to the marvellous work of the succession of illustrious men whose researches carried on within its walls have very largely contributed to secure and maintain for this country a foremost position as a source of great discoveries and important advances in science and its applications."

Mr. Robert Mond was nominated in the deed of trust honorary secretary for life.

The managers appointed the late Lord Rayleigh and Sir James Dewar the directors without remuneration.

The following is a selection of inquiries executed in the Davy-Faraday Research Laboratory communicated to scientific societies by fellows of the Royal Society:—Dr. H. Debus, "Contributions to the History of Glyoxalic Acid"; Hugo Muller, "Quercitol, Cocositol, Inositol, Flavon"; Horace T. Brown, "Starch: Its Transformations and Derivatives"; J. Y. Buchanan, "The Specific Gravity of Soluble Salts"; J. Emerson Reynolds, "Silicon Researches"; J. E. Petavel, "Standards of Light" and "Gaseous Explosive Mixtures"; A. Scott, "Atomic Weight of Carbon, etc."; W. J. Russell, "Action of Wood on Photographic Plates in the Dark, etc."

The following papers have been published:—A. Croft Hill, "Reversibility of Enzyme or Ferment Action, etc."; W. Wahl, "Optical Investigations of Solidified Gases, etc."; W. Gluud, "Derivatives of Allylamine, Phenylglycine, etc."; Sir J. C. Bose, "The Response of Inorganic Matter to Stimulus, etc."; Miss Ida Smedley, "Colour Derivatives of Fluorene"; and Miss A. Everett, "Colour Photometry."

THE INTERNATIONAL CATALOGUE OF SCIENTIFIC LITERATURE.

THE International Catalogue of Scientific Literature was constituted in 1900 at an International Conference held in London under the auspices of the Royal Society. It is a unique attempt to secure an accurate and exhaustive bibliography of pure science by international co-operation, each country being responsible for the indexing of its own literature. Each volume contains an author index and a subject index. An annual issue is composed of seventeen volumes indexing the seventeen branches into which science is divided for convenience of reference. The books and papers catalogued are those published since January 1, 1901, papers published before that date being indexed in the Royal Society's Catalogue of Scientific Papers.

The control of the catalogue is in the hands of an international council composed of one representative from each country taking part in the work. This council appoints an executive committee, which meets in London, but each of the countries co-operating has its own regional bureau to prepare index cards and send them to a central bureau in London for publication. Since the foundation of the catalogue about three million such cards have been received from the bureaux. More than two hundred volumes have been published.

Until the outbreak of the war in 1914 more than thirty countries were taking part in preparing the catalogue, and the harmony with which they worked together is one of the most remarkable features of the enterprise. Even the Russo-Japanese War did not hinder the delegates of Russia and Japan from meeting at the conferences.

Although the recent war and the present condition of Europe create a difficult position for all international undertakings, it is much to be hoped that means may be found for continuing the work of the catalogue on an international basis, and without sacrificing those distinctive features which have met with such widespread appreciation.

THE TROPICAL DISEASES BUREAU.

THE Tropical Diseases Bureau came into existence in July, 1912, as a development of the Sleeping Sickness Bureau founded in 1908. The main function of the bureau has been to review current papers on tropical diseases, *i.e.* exotic diseases occurring in the tropics and sub-tropics. The medium of publication is the *Tropical Diseases Bulletin*, now in its fourteenth volume. The *Bulletin*, which appears monthly, contains classified summaries of all papers within its scope which come under notice. Each subject is in charge of a "sectional editor," whose initials are appended to his summaries. Thus the results of the most recent researches on tropical disease in every country, new methods of treatment, and improved means of prevention quickly become available for the remote worker in the tropics. Critical reviews of books are also published.

The bureau issues also the *Tropical Veterinary Bulletin* quarterly, the object of which is to deal with the diseases of domestic animals in the tropics in the same way as the *Tropical Diseases Bulletin* does with the diseases of man.

The bureau maintains a library under the charge of Capt. R. L. Sheppard, which contains complete or nearly complete files of all the tropical medical journals, in addition to others, some two hundred series in all, and a large number of reports and reprints. Though the library is mainly intended for the use of the sectional editors, it is open to any inquirer without formality.

The bureau is under the management of a committee appointed by the Secretary of State for the Colonies, the expert members of which are Sir John Rose Bradford, Sir David Bruce, Sir Havelock Charles, Sir Wm. Leishman, Sir Patrick Manson, and, representing veterinary medicine, Sir John M'Fadyean and Sir Stewart Stockman. Dr. A. G. Bagshawe is the director. It is maintained by a grant in aid from the Imperial Treasury and by contributions from the Governments of India, the Sudan, the Union of South Africa, and certain colonies and protectorates, to which copies of its publications are supplied gratis. By the general public the *Tropical Diseases Bulletin* can be obtained at an annual subscription of a guinea, and the *Tropical Veterinary Bulletin* at 10s.

The offices of the bureau are at present situated at the Imperial Institute, South Kensington.

WOMEN AT CAMBRIDGE.

IN February, 1896, the council of the Senate reported the receipt of four memorials relating to the admission of women to degrees. A syndicate was appointed to consider the question, and in February, 1897, the majority reported recommending that degrees should be conferred on women by diploma, but not that they should become members of the University on the same terms as men. The liveliest interest in and opposition to these proposals were occasioned, and a discussion lasting three days took place in the Senate House. Finally, in May, 1897, the report was rejected by the Senate, amid scenes of enthusiasm and disorder, by a majority of 1707 to 661.

In May, 1919, the council reported the receipt of two memorials relating to the same subject, and proposed the appointment of a syndicate to consider it. The first memorial stated:—"We believe that the time has passed for the adoption of half-measures, and that women should be admitted to full membership of the University." In the second, objection was taken to the "attempt to force a hasty conclusion on a prejudged issue," and the suggestion made that a solution might be found by allowing women to obtain degrees without becoming full members of the University. This suggestion—which is made now by those who in 1897 opposed the granting of degrees to women at all—is practically the same as that which was rejected by a large majority then, and illustrates how far the attitude towards women has changed in twenty-two years. There are few now who would dare openly to advocate the exclusion of women from the recognition rightly due to their study and their services to learning.

On Thursday, October 30, a discussion on the subject was held in the Senate House. It is clear that a large progressive body of opinion is in favour of removing all restrictions on the studies of women and on their just recognition by the University. It is also clear, however, that there is still an underlying opposition to the idea of a mixed university, which will manifest itself in proposals designed to shelve the question temporarily by the adoption of half-measures. There can be little doubt that in the end all restrictions will be removed; and there are many who believe that it will be wiser and more generous for the University now to allow women the full membership they demand than to have the change forced upon it by outside influence, *e.g.* through the coming Royal Commission.

NOTES.

ANNOUNCEMENT of the approaching fiftieth anniversary of the foundation of NATURE was made in a letter sent a few weeks ago to the presidents of a number of scientific societies, official heads of British universities, and other representatives of progressive knowledge, most of whom are among the contributors to the columns of this journal. The result of this communication has been that we have received numerous cordial messages of congratulation, many of them containing interesting reminiscences associated with NATURE, and all most appreciative of the services it affords to scientific workers. It was hoped that space could have been found to publish these messages this week, but this has proved impracticable. We believe, however, that these testimonies to the close attention paid to the contents of NATURE will interest a wide scientific public, and therefore propose to place a selection from them before our readers in next week's issue.

THE general arrangement of Notes in these columns follows the principle of from man to machine; early paragraphs are concerned with current topics and events, and these are followed successively by Notes on subjects relating to biological, physical, and engineering sciences. The articles on scientific progress which we have been fortunate enough to secure for this issue are arranged in much the same order, so that each has a relationship to the contributions which precede and follow it. In addition to the descriptive articles concerned with different fields of scientific activity, short accounts are given of a few important British institutions established for research purposes since NATURE was first published. These articles will, we think, serve to increase the value of this jubilee number as an epitome of outstanding developments of scientific work during the past fifty years.

ON Wednesday, October 29, Mr. Balfour was inaugurated Chancellor of Cambridge University. In a letter to the Vice-Chancellor dated October 25 he had written:—"In so far as lifelong devotion to the University, unceasing interest in its welfare, and pride in its great services to learning be sufficient qualifications for that high post, I am not unfitted to fill it." His election was unopposed. In presenting the Letters Patent the Vice-Chancellor dwelt upon the needs of the University and upon the possibility of utilising the learning available in the University more fully in the service of the Empire. The new Chancellor agreed that it is the business of the community to make easier the path of those who have shown what the sound learning and scientific training of a university can do for a national cause, but at the same time he felt that, in the main, Cambridge would have to trust, and could well trust, its own powers in the coming arduous days of peace. In all departments of national activity, but especially in the scientific study of the mechanical, economic, chemical, medical, or physical problems of the last five years, our universities—and not least Cambridge—have earned a position in the national estimation which they have never held before. This position carries great opportunities and great obligations with it. The interest of the next few years and their influence on the future history of education and human knowledge are immense. There will undoubtedly be a strong tendency towards the adoption of a more technical education and towards the teaching of "practical" subjects in a university course; this tendency cannot, and must not, be opposed, but at the same time it is most earnestly to be desired that our universities should keep before the eyes of their students the three chief motives for the acquisition and improvement of knowledge: a pleasure in knowledge for its own sake, a sure faith that no attempt to acquire and improve knowledge is vain, and a reasoned belief in the power of knowledge to help and elevate mankind. Cambridge has chosen wisely in electing a Chancellor in whom these motives are so strong, and who possesses in a high degree the power and opportunity of keeping them before the eyes of the best of his countrymen.

MEMORIAL tablets to Lord Lister to be erected at University College, London, will be unveiled on Tuesday, November 11, by Sir George Makins, president of the Royal College of Surgeons, and Sir J. J. Thomson, president of the Royal Society. The Duke of Bedford, president of the Lister Memorial Committee, will preside.

THE VERY REV. W. R. INGE, Dean of St. Paul's, has been appointed Romanes lecturer for 1920 at the University of Oxford. The date and subject of his lecture will be announced later. The late Camden professor of ancient history, Mr. F. J. Haverfield, has bequeathed the residue of his estate, subject to certain charges, in trust to the University for the advancement of the study of Romano-British antiquities.

MR. W. R. COOPER has just retired from the editorial chair of the *Electrician*, having decided to devote the whole of his time to his consulting practice. He was appointed editor of our contemporary in 1906, and under his editorship the journal has represented electrical science at its best, as well as progressive practice. He will be succeeded by Mr. F. H. Masters, who was chief assistant editor at the outbreak of war in 1914.

AT the annual general meeting of the Cambridge Philosophical Society, held on October 27, the following were elected officers of the society for the ensuing session, 1919–20:—*President:* Mr. C. T. R. Wilson. *Vice-Presidents:* Sir W. J. Pope and Sir E. Rutherford. *Treasurer:* Prof. Hobson. *Secretaries:* Mr. A. Wood, Mr. G. H. Hardy, and Mr. H. H. Brindley. *New Members of the Council:* Prof. Inglis, Prof. Seward, Dr. Rivers, Dr. E. H. Griffiths, and Mr. F. A. Potts.

DR. O. L. BRADY, president of the National Union of Scientific Workers, took the chair at a meeting held on October 30 to inaugurate a London branch. He pointed out that the organisation of the union is by branches. Although there are already branches in South Kensington, the Board of Agriculture, the London County Council, and at Woolwich, it was felt that a more central branch should be formed to meet the needs of workers engaged in the City and in the central district of London. A resolution that a London branch of the National Union of Scientific Workers be forthwith formed was passed unanimously, and Dr. H. M. Atkinson and Mr. W. E. King were elected chairman and secretary respectively of the branch.

THE *Times* of November 4 publishes the following message from its New York correspondent, dated November 3:—"The gift of a further 2,000,000*l.* to the Rockefeller Institute by the founder, Mr. John D. Rockefeller, is announced to-day. The institute, which was founded in 1901, has become the largest endowed establishment in the world for medical research. It had already received from Mr. Rockefeller successive gifts to the amount of 5,500,000*l.* and real estate valued at 500,000*l.* The scientific staff numbers sixty-five, and in addition there are 310 persons employed in technical and general services. The latest gift will enable research to be conducted in new fields in biology, chemistry, and physics, as well as in medicine itself, and the study of practical problems relating to disease in men and animals."

AT the Philosophical Congress, held at Bedford College last July, particular interest centred round the physiological researches of Dr. Head and his fellow-workers into the nature of the function of the cortex cerebri. This work has been going on for the last eighteen years. It started with the now classical experiment performed by Dr. Head, with the aid of Dr. Rivers, on the innervation of his own forearm. Following the clue which that experiment afforded, the function of the cerebral cortex in regard to sensation has been more and more clearly elaborated. Injuries due to the war have afforded means of immediately testing theories such as we might have had to wait long for under other conditions. Some of our readers are anxious to know where they can obtain an account of this work. Unfortunately, it is not at present available in the form of a treatise or monograph; it exists only in articles in medical journals. A very clear epitome of the whole theory, however, with illustrative cases, and free from technical terms, is the article by Dr. Head himself on "Sensation and the Cerebral Cortex," which fills the whole number of *Brain*, vol. xli., part ii., issued in 1918. The philosophical interest in the theory was due to the complete scientific refutation it offers of all psychological theories which build up knowledge out of original sense-material. Sensations depend neither for their existence nor for their psychical quality on the cortex cerebri, which has a purely interpretative function in regard to them.

LAST July Sir Robert Hadfield invited a large party of his Sheffield workmen to London to visit the British Scientific Products Exhibition, and also the Science Museum at South Kensington. Included in the party were a number of apprentices, some from the Hadfield works in Sheffield and others from similar establishments in London. Prizes were offered to the boys for the best essays descriptive of the visit. The winning essays, which are now printed for private circulation, are a striking commentary on the interest taken in the visit. To many of the Sheffield boys, who were in London for the first time, the day was a red-letter one. Their keen powers of observation were not confined to the exhibitions only; one at least showed a truly surprising knowledge of the significance of the historical statues he saw on his way from and to the station. More human, perhaps, was the boy lost in admiration for the London 'bus drivers. It is no mean feat of endurance to visit two exhibitions in one day and carry off any sort of coherent idea of what has been seen. The novelty of the event must have given these boys added enthusiasm, for they describe with great clearness machinery and processes which interested them. The essays show the immense educational value of visits of this character, and they are, too, a real tribute to the work of the evening technical schools, where the boys study hard after a day's work.

PROF. FERNANDO SANFORD discusses in the *Scientific Monthly* for October the *ignis fatuus*, one of those "meteoric appearances which have puzzled man since he began to inquire into the relations of phenomena, and which are still unexplainable." He reviews the various theories which have been formulated to explain these appearances. His final suggestion is that "they are little swarms of luminous bacteria which are carried up from the bottom of the marsh by rising bubbles of gas. Many kinds of luminous bacteria are known, and the marshes from which these lights arise are known to be the favoured habitat of some of these kinds. Some at least of these bacteria do not become luminous until exposed to the oxygen of the air. This seems to be true of the bacteria which cause the luminosity of rotten wood, the 'foxfire' of our boyhood."

IN the *Scientific Monthly* for October Prof. J. H. Breasted, the eminent Egyptian scholar, publishes the first part of a lecture on the origin of civilisation, with special reference to the Nile Valley. Following the guidance of Blanckenhorn, he classifies the geology of the Nile Valley, in so far as it bears on the age of man there, into four chief periods:—(1) The Lacustrine Terraces, Pliocene and First Glacial; (2) the Upper River Terrace, Second Glacial; (3) the Lower River Terrace, Third Glacial; and (4) the Alluvium, Lower Fourth Glacial, Upper Post-Glacial. Far back in the European Glacial age the North African plateau was the home of early hunters, who have left signs of their presence not only in flint weapons, but also in a remarkable rock temple in the western desert. From this point he deals with burials and artefacts, including the marvellous ripple-flaked flint implements which are a mystery to craftsmen of the present day. Prof. Breasted leaves the later developments of the culture of prehistoric man in this region to a second article, which will complete a study of unusual interest.

UNDER the title of "The Linguistic Survey of India and the Census of 1911" Sir George Grierson has published a short summary of the great work which he has now brought to a successful termination. The Survey deals with a population amounting to 290,000,000, as compared with 312,000,000 recorded in the census of 1911, the difference being due to the fact that the census covered the whole of India, while large tracts, like Burma, were excluded from the operations of the Survey. In all, 872 different languages and dialects are recorded. The sub-family which contains the greatest number of languages, thirty-two in all, is the Tibeto-Burman, where the population is split up into numerous sections owing to their special environment in a mountainous region. On the other hand, there are only seventeen Indo-Aryan languages spoken by 226,000,000 in the wide northern plains, where facilities of intercommunication promoted fusion of races. If, as an example of similarly circumstanced Aryan groups, we take the Eranian languages spoken in and near India and the Dardic languages, we find that these two branches, like the Tibeto-Burman languages, are spoken in inhospitable mountain tracts, but that, unlike the Tibeto-Burman group, they have a power of persistence. If they do subdivide, the division is not into mutually unintelligible languages, but into mutually intelligible dialects, held together by a common grammatical basis. This summary of the work of a great scientific philologist may be warmly commended to the notice of all students of language.

IN the course of his presidential address to the North-East Coast Institution of Engineers and Shipbuilders on October 24, Mr. A. Ernest Doxford made strong references to the present economic position of the country, and said that much too little publicity has been given to this important matter. This has afforded the extremist his opportunity to inflame the minds of the uninformed, and lead the country perilously near to anarchy. Two great evils have to be fought—greed and ignorance—and both of these can be overcome by education. The first and most important point to consider in education is the qualification of the teacher. He must be sound in first principles, in his facts, and in his reasoning, and must be capable and willing to impart his knowledge to others. One would have thought that a common-sense nation, such as we certainly are, would have seen the absolute necessity of paying well for such qualities; but, instead, we find that the teaching profession is one of the worst paid, with the natural result that we get either inferior or discontented teachers. This discontent is bound to be reflected, to a greater or less extent, in the mind of the pupil, and is the source of a great deal of our social unrest. The brain-power of the teacher is often superior to that of many in other walks of life who are being better paid than he, and the injustice, in many cases, forces him into the band of extremists, where he thinks that a social upheaval may remedy his grievances. Mr. Doxford feels sure that if, in our reconstruction, we put education foremost, we shall remedy not only many of the evils that existed prior to the war, but also the more virulent types that have arisen since.

DR. MURRAY STUART describes, in the Records of the Geological Survey of India (vol. l., p. 28, 1919), the deposits of potash salts in the Punjab Salt Range and Kohat, and adds a paper on the probable origin and history of the rock-salt deposits in this region. The author believes that the salts were originally laid down from an evaporating saline solution, but that their present banded structure, of which a good illustration is given, is due to subsequent flow under pressure. The salt, in fact, is now not a sediment, but a schist. Included iron pyrites, liberating sulphuric acid, has led to the formation of gypsum as a product of contact with limestone, and is also responsible for the presence of mirabilite. The potash salts, whatever their original position in the series, now appear as patches and lenticles in the rearranged foliated mass, and no continuous bed can be expected. "The prospects of obtaining potash from the salt of the Salt Range are not promising."

ONE of the most definite tendencies in British agriculture is towards greater use of mechanical power, though the most satisfactory source of power remains to be ascertained. In the Journal of the Royal Society of Arts for September 26 and October 3 and 10, Dr. J. F. Crowley discusses the use of electricity in agriculture, with special reference to its development in Germany. Farm conditions make portability essential, and a limit is set to the power obtainable from steam or oil engines by their weight. These considerations led to the development of electrical power, which has been so notable a feature of German agriculture in recent years. By far the greater amount of power used on German farms is distributed from central stations by high-tension overhead lines. The transformers and motors may be either fixed or portable, and may be separated by considerable distances. Illustrated descriptions are given of the motors and their use in ordinary agricultural operations. Thinly populated rural districts in Germany secured the advantage of cheap electricity through the growth of numerous rural co-operative societies, which either produced electricity themselves or secured a cheap supply by guaranteeing a certain consumption. The author believes that considerable progress could be made if steps were taken to promote such co-operative movements in the rural districts of this country.

A SERIES of illustrated articles descriptive of the Hell Gate Bridge at New York has been appearing in recent issues of *Engineering*. The article in the issue for October 17 contains an interesting account of the span measurements. It was impossible to secure a satisfactory direct measurement, since no previous structure crossed the river at the site, and the distance between the skewbacks was determined by triangulation. To obtain a check a special steel tape about 1100 ft. long was made, and repeated measurements were taken, making calculated allowances for tension, deflection, and temperature. Difficulty was experienced in making the corrected measurements agree precisely on account of the unequal temperatures of different portions of the tape. There was, however, substantial agreement with the triangulation measurements. The day before the erection of the last panel of the arch-trusses was commenced, careful measurements showed a clearance of 1·75 in. between the extremities of the semi-trusses. A rise in temperature during the night produced a diminished clearance of 0·75 in. next morning. Work was therefore accelerated in order to have the lower chord inserted before the rising temperature eliminated the whole of the clearance. The first chord piece had to be lifted vertically into position rather than revolved from an oblique position in a vertical plane as is customary. The following day was rainy and cloudy, affording more favourable weather conditions.

AN interesting survey of the general position of chemical industries in the chief countries of the world, and especially in France, is contributed by M. René P. Duchemin to the *Revue Scientifique* for October 4. Due to war demands, there has been a considerable over-production of important "heavy" chemicals such as sulphuric acid, nitrogen compounds, chlorine, and bromine; and this not only by the belligerent nations, but by neutral countries also. Factories have been developed and extended, so that they now have much greater productive capacity than heretofore; and, moreover, large stocks were necessarily accumulated by the various Governments to provide for unforeseen contingencies during the progress of hostilities. In some branches of manufacture these stocks represent several years' normal output. Hence the position of the industry as regards the foregoing products is just now a difficult one. For France in particular, unless the industry is to dwindle and vanish, it will be necessary to devise measures for preventing destructive competition by indiscriminate admission of certain chemicals from other countries. The plan adopted by Great Britain, namely, limited importation, to prevent either undue lowering of prices by "dumping" or excessive charges by manufacturers here, is considered by the writer named to be the best for France to follow until something like normal conditions are again reached.

HARDNESS is an extremely important quality, but no satisfactory definition of it has yet been given. The geologist has his scale of hardness, and the engineer has his instruments for measuring the elusive quality. The tests employed by the engineer are good in their way, but they do not, as a rule, measure directly what the manufacturer wishes to obtain in the finished article. A manufacturer of cutlery, for example, is not directly interested in the way his steel gives when a steel ball is placed on it and pressed down with considerable force. But, in spite of the lack of direct applicability in the engineering tests, a good deal can be maintained in their favour, for there is doubtless some connection between the mechanical properties desired by the manufacturer and the readings of the sclerometer, as the instrument for measuring hardness is called. The interpretation of the readings may be difficult, and will probably require the acquisition of knowledge allied to that attained by the skilled craftsman; but, notwithstanding the difficulties, the regular use of a sclerometer can be productive of nothing but good. The Magnetic Sclerometer which has been put on the market by the Automatic and Electric Furnaces, Ltd., 281–283 Gray's Inn Road, London, W.C.1, may prove to be extremely useful in connection with a large and important class of material, viz. hard steels. As its action does not depend upon mechanical phenomena, its range is limited, and it cannot be used for non-magnetic substances. A rod of steel is placed in a yoke so as to form a complete magnetic circuit, and magnetised almost to saturation. The rod is then taken out of the yoke and the remanent magnetism, *i.e.* the magnetism which remains after the rod has been subjected to the demagnetising action of its own poles, is measured. To make the measurement the rod is placed in a coil connected to a ballistic galvanometer, and the kick of the galvanometer-needle is noted on the rapid removal of the rod from the coil. The throw of the needle, which indicates the amount of magnetic flux still remaining in the rod, may be taken as the reading of the sclerometer. In spite of its lack of direct applicability so far as hardness, in the ordinary sense of the word, is understood, the magnetic sclerometer should prove to be an extremely useful instrument in the hands of the trained researcher.

MESSRS. W. HEFFER AND SONS, LTD., Cambridge, have just issued a Catalogue (No. 182) of 1670 second-hand books dealing, among other subjects, with archæology, folk-lore, anthropology and kindred subjects, Egyptology, and philosophy; also with scientific serials. In the latter section we notice a set of the first 102 volumes of NATURE. The list includes the archæological and fine art library of the late Dr. Allen Sturge. A copy can be obtained free upon application.

OUR ASTRONOMICAL COLUMN.

COMETS.—Schaumasse's comet (1911 VII., 1919*d*) was detected on its return by M. Schaumasse at the Nice Observatory on October 29, being of magnitude 12. The observation indicates October 19 as the approximate date of perihelion. The following ephemeris is for Greenwich midnight (corrected approximately by the above observation):—

	R.A. h. m. s.	N. Decl. ° ′	Log r	Log Δ
Nov. 5 ...	12 27 23	6 28	0·0914	0·2610
9 ...	12 41 25	5 19	0·0951	0·2622
13 ...	12 55 13	4 11	0·0993	0·2634
17 ...	13 8 47	3 4	0·1038	0·2649
21 ...	13 22 5	1 58	0·1089	0·2666

As the distances from both sun and earth are increasing, the comet will remain faint.

Continuation of the ephemeris of comet 1919*c* for Greenwich midnight:—

	R.A. h. m. s.	S. Decl. ° ′		R.A. h. m. s.	S. Decl. ° ′
Nov. 7	17 0 44	10 30	Nov. 19	17 41 42	16 57
11	17 13 56	12 41	23	17 56 20	19 0
15	17 27 32	14 50	27	18 11 28	20 59

The comet is approaching perihelion and growing steadily brighter, but it is too near the sun for convenient observation.

THE SOURCES OF STELLAR ENERGY.—There have recently appeared two articles on this subject by Profs. Russell and Eddington. The first (Publications Ast. Soc. Pacific, August, 1919) points out the apparent inadequacy of the contraction hypothesis to explain the long duration of the output of energy (far in excess of Lord Kelvin's twenty million years) which is suggested by geology and by various other arguments. Hence it is concluded that there must be some unknown source of energy in the interior of giant stars, which dies down before the dwarf stage is reached. Making the supposition that the temperature is insufficient for the unknown source to come into action in the pre-M stage of giant stars, Prof. Russell shows that this stage would be short and extremely few stars would be in it at a time; he thus explains our failure to detect stars in this stage.

He also points out that the hypothesis would do away with the difficulty which Prof. Eddington expressed about the maintenance of the pulsations in Cepheid variables, viz. that the leakage of heat from the hotter to the colder regions would damp out the oscillations in a few thousand years. For the unknown source would supply heat to the interior at the greatest rate when it was hottest, thus making good the leakage.

Prof. Eddington (*Observatory*, October) makes a bold speculation as regards the unknown source of heat. He reminds us that a large proportion of the total energy of a star is locked up in its atoms, so that the energy would not be exhausted when the star cooled. It would need to be annihilated to liberate all the energy. He asks whether this annihilation of matter may not be going on in giant stars: "When a positive and negative charge collide centrally they go out of existence." He points out that at moderate temperatures the outer electrons of the atom form a protecting cushion; but in a very high temperature, ionisation is presumed to take place, robbing the nucleus of its protecting electrons and leaving it an exposed target. He makes an estimate that 1 atom out of 5×10^{18} must be annihilated each second. At this rate it would take about 2×10^{11} years to annihilate the whole star, so that the loss of mass in the periods usually assigned to the giant stage would be trifling.

BRITISH SCIENTIFIC SOCIETIES FOUNDED DURING THE PAST FIFTY YEARS.

1869.

Edinburgh Field Naturalists' and Microscopical Society.
Iron and Steel Institute.

1871.

Institution of Electrical Engineers.
Mathematical Association.
Royal Anthropological Institute of Great Britain and Ireland.

1873.
