Besides having to explore the east coast as far north as circumstances may permit, two of the members, viz. Lieut. Garde and Dr. Eberlin, have established a station at Nanortalik (lat. 60° N.), where they have, last winter, prosecuted meteorological, magnetical, and auroral observations, being a continuation of those effected during 1882-83 at Godthaab. Observations of ice and sea are also made. The two scientists who have wintered in some spot on the east coast, started, according to latest advice, from Fluidlek (lat 61½° N.), where a depot has been established, at the end of July last year, northwards, in the company of Greenlanders, eighty-two of whom lived on the east coast, and were on their way home from trading on the south coast. There were thirty-six boats in all. Late in July the great glacier Puisortok, which reaches down to the sea, and which in 1830 caused Graah, the only European who had hitherto visited it, so much trouble—was passed without much difficulty. Soon after Tingmiarmint (lat. 62° 40′ N.) was reached, the northernmost place whence we have news of the party. It was their intention to attempt to reach a place, Augmaksalik, in lat. 65½° N., before the winter, where there is a settlement of Greenlanders, but which has never been visited by Europeans. It lies near the place where Nordenskiöld landed in 1883 without seeing any natives. In the spring of the present year the coast will be explored, but we shall have no news of the party until they return home. Lieut. Holm states that the east Greenlanders were very kind and friendly. They were all heathens. They were particularly remarkable for their features, being tall people, generally with dark eyes and hair, and without any trace of the Eskimo. However, that they should be descendants of Norsemen seems hardly probable on account of their uncivilisation and want of religion, Norse language, and traditions. The party at Nanortalik have explored eight great fjords, between lat. 62½° and 60½° N., right to the bottom, without finding the least trace of Norse remains.

The expedition may be expected to return at the end of 1885. There is, however, great probability of the party under Lieut. Holm having to spend another year on these inhospitable shores, where the European, in order to exist, has to live like the Eskimo.

While the above-mentioned two expeditions were chiefly confined to explorations, the third one despatched last entered upon an almost unbroken field for research, viz., the sea on the west coast. Between 1876 and 1879 researches of the Denmark Sound—*i.e.*, the sea between Iceland and Greenland—were effected by the Danish Admiralty Expedition, whereas Davis Strait and Baffin's Bay have only been cursorily studied, as, for instance, by H.M.S. *Valorous* on its return journey in 1875, after having provisioned Sir George Nares, and by the Nordenskiöld Expedition of 1883.

The vessel employed for last year's researches was the *Fylla* gun-boat, in command of Capt. C. Normann. The scientific staff were—Prof. E. Warming, botanist; Mr. Th. Holm, zoologist; and Dr. H. Topsöe, chemist and mineralogist. The hydrographical researches were made by the officers; and for the purpose of examining the flora and fauna of the sea the expedition was provided with trawls and scrapers of most improved American pattern, and, for the deep-sea researches and measurements of temperature, with a Sigsbee's sounding-apparatus with wire rope and a good collection of the necessary instruments. For the determination of the temperature of the sea, thermometers by Negretti and Zambra were mostly used, some of which were fitted with the splendid automatic reversing apparatus invented by Capt. Magnaghi, of the Italian Navy, and some with one constructed by Capt. G. Rung, of the Copenhagen Meteorological Institute, by which the turning of the instruments is effected at a given time by the simultaneous freeing of a weight running in the line. The Miller-Casella thermometers, with which the expedition were furnished, were used very little, on account of the existing high bottom temperatures.

For fetching water from various depths, water-carriers on Sigsbee's (American), Ekman's (Swedish), and Rung's (Danish) principles were used, the latter being a new invention, which was very practicable for lesser depths, as it not only brings the sample of water required, but also gives the exact temperature, a thermometer being hidden in the axis of the vessel, the mercury column of which is broken as soon as it is full.

The *Fylla* left Copenhagen at the end of May, and arrived, at the end of June, at Godthaab, a colony with 300 to 400 Eskimo inhabitants, on the west coast of Greenland, in lat. 64¼° N. Hydrographical researches were commenced early by following the edge of the Polar ice from Cape Farewell, which, during the summer, filled the southern and eastern parts of Davis Strait in vast quantities, and by studying the position of the ice-belt and the composition of the water inside and outside the ice current.

We have no space to give a detailed account of the movements of the expedition in the Greenland seas; it must be sufficient to state that the expedition, being chiefly stationed at Holsteinborg (67° N. lat.), visited most of the Danish settlements in Central Greenland, its field of research lying between 64° and 70° N. lat., and from the innermost creek at Disco Bay (about 50° W. long.) to the middle of Davis Strait,—*i.e.*, to about 57½° W. long. An attempt to get further west, and, if possible, reach the coast of America at Cape Walsingham and Cumberland Bay, had to be abandoned on account of the enormous ice-masses which were encountered there in July, and which, in the middle of August, when the *Fylla* was on her return journey, had, in 67° N. lat., approached within 50 to 60 miles of the shores of Greenland, which is very unusual at that season.

The deep-sea researches consisted in sounding, trawling, and scraping, both on the extensive banks which, between 62° and 68° N. lat., nearly everywhere surround the shores of Greenland with a deep channel between them and the coast, and in the Davis Strait.

The researches did not extend to very low depths, the greatest found being only about 900 fathoms south-west of Godthaab, while on the *bridge* connecting Greenland with Cape Walsingham, at the place where Davis Strait is narrowest—in about lat. 67° N.—depths of 400 fathoms only were struck. In the Disco Bay, where no soundings had previously been taken, a depth varying from 200 to 270 fathoms was found, and it has been discovered by the *Fylla* Expedition that at the mouth, at a depth of 180 to 190 fathoms, a barrier separates this basin from Davis Strait, and thus prevents icebergs of a greater draught from passing from the great fjord of Jacobshavn into the ocean. Judging by the results of the measurements of icebergs effected during recent years in this fjord by Prof. Steenstrup and Lieut. Hammer for the purpose of ascertaining the proportion between the part above and the part below the surface of the water, it has been found that only icebergs with an *average* height above the surface of 150 feet can float over this threshold, the proportion between the part above and the part below water being 1 to 8·8—*i.e.* 1 : 8·41 for blistered glacier ice, and 1 : 9·23 for glacier ice without blisters. For sea-water ice with a water saltness of 3·3 per cent. the proportion is only 1 : 5·29.

The numerous samples of water taken from the surface, bottom, and intermediary depths, during the voyage have not yet been thoroughly analysed, and before this has been done, it is hardly possible to say anything definite as to the currents at various depths. This much is, however, certain—that a comparatively warm current of water fills the eastern and central parts of the narrowest portion of Davis Strait—as far as the western ice limit—but that the highest temperature of the same, when the depth is more than a couple of hundred fathoms, is not, as is generally the case, found at the surface, *but nearest the bottom*, and that the coldest layer seems to lie between 30 and 100 fathoms. As an example may be taken the following series of temperatures obtained in lat. 67° 07′ N. and long. 56° 31′ W. on July 8, 1884, the temperature of the air being ÷ 1°·9 C.

At the surface	+ 2°·8 C.
,, 10 fathoms	1·9
,, 30 ,, ...	0·9
,, 100 ,, ...	1·1
,, 200 ,, ...	3·6
,, 362 ,, (bottom)	4·2

Similar conditions were also found everywhere in Disco Bay, but the surface water in this confined basin was considerably warmer, while the bottom temperature was proportionately lower.

We will give an example from lat. 69° 14′ N. and long. 52° 54′ W., on the morning of July 23, the temperature of the air in calm sunny weather being + 10°·2 C. in the shade :—

At the surface	+ 7°·7 C.
,, 5 fathoms	7·1
,, 10 ,, ...	4·2
,, 20 ,, ...	1·4
,, 30 ,, ...	+ 0·1
,, 50 ,, ...	+ 0·2
,, 70 ,, ...	+ 0·1
,, 100 ,, ...	0·6
,, 130 ,, ...	0·9
,, 200 ,, ...	1·8
,, 264 ,, (bottom)	2·1

That the influence of the ice-fjord is here felt at the intermediary depths is obvious even without any chemical analysis of the water of the various layers. It is, however, very remarkable that the surface-temperature in such a high latitude, and in water constantly covered with enormous icebergs, *can*, in the short summer, reach such a height as the above series show. This is, by the bye, so far from being a solitary example that most serial temperatures from this locality, which were, however, all taken in calm weather, and extended over seven days, show a much higher surface-temperature.

The highest temperature was registered off the colony of Christianshaab, in the Disco Bay, in the south-eastern corner, viz. + 11°·4 C. at the surface. At five fathoms it fell, however, to 2°·8, and stood from 30 to 100 fathoms at + 0°·2 C. That the icebergs in these waters must melt rapidly, particularly at the water-line, is clear, which was also corroborated by experience, all being deeply furrowed and heeling over.

The trawlings and scrapings extended to a depth of 300 fathoms, and were effected as well in Davis Strait, Disco Bay, on the banks, as in the fjords. The result was considerable, and several varieties of fauna previously unknown in the Greenland seas were caught, as well as some entirely new species. Among the rarest forms may be mentioned *Amblyops abbreviata*, *Mysideis grandis*, and *Boreomysis nobilis*, which are only known in a few species from the west coast of Norway, and *Spirorbis cancellatus*.

The harvest was richest on the banks, as was the case under previous expeditions, and poorest in Disco Bay, where several hauls at a depth of 200 to 250 fathoms brought up absolutely nothing, or only a couple of specimens of the same species. The trawl worked here so far down in the soft black clay, which everywhere covers the bottom, that the line constantly threatened to break. The expedition has brought home a total of 300 specimens of the deep-sea fauna.

During the stay in port the officers of the vessel were engaged in hydrographical labours, chiefly the measuring of certain harbours, and the botanists in excursions into the long, narrow fjords, where the vegetation is richest, but neither the mountains nor the islands were forgotten. The harvest was very rich. Of phanerogams and higher cryptogams alone specimens of 230 varieties were obtained, and five new plants were discovered, among which a new species of Carex, while several were found in entirely new places, whereby their geographical distribution has been increased with several degrees of latitude. Thus, *Linnæa borealis*, for the first time, in 1883, discovered in Greenland, and then in lat. 61° 10′, was this year found as far north as 67°. Special attention was also given to the collecting of materials for illustrating the development of the Arctic fauna, which has hitherto been neglected. Great attention, too, was paid to the algæ fauna, although it is very poor in the places visited by the expedition.

The mineralogical harvest of the expedition was poor, for the reason that Greenland has already been thoroughly explored, geologically and geodetically, by such eminent scientific men as Sir C. L. Giesecke, Dr. Rink, Profs. Johnstrup, Steenstrup, and Nathorst, that little more is to be learnt. One object of interest was, however, brought home—viz. a block of ironstone found on the shore of the Disco Island at Uifak, in lat. 69° 20′ N., of the same kind as those discovered there by Baron Nordenskiöld some years ago, and which were at first believed to be meteorites, but whose terrestrial origin must now be said to be beyond question, in consequence of Prof. Steenstrup having discovered nickel iron in lumps of all sizes, of exactly the kind as that contained in these blocks in the great basalt strata of the Disco Island. The block which weighs about 1800 lbs., has been presented to the Mineralogical Museum at Copenhagen, where it will be mounted, with those already brought thither from the same locality.

The scientific material collected by the expedition is under treatment, but considerable time must elapse before the final result is ascertained.

This spring another expedition has been despatched to Greenland, being the tenth since 1876. It is commanded by Lieut. Jensen, and has for its object, besides natural history and photographical studies, the survey of the west coast between Sukkertoppen and Godthaab, lat 65½°—64° N. This is the last stretch of the west coast which remains to be surveyed, and if Lieut. Jensen succeeds in finishing the work this year, the entire west coast of Greenland from lat. 59¾° to 72¼° N. will have been surveyed and charted.

That the Danes are proud of the accomplishment of this great and difficult work is only natural.

THE ROYAL SOCIETY OF CANADA

THE fourth annual meeting was held at Ottawa on May 26 and following days to the 29th inclusive; the President, T. Sterry Hunt, LL.D., F.R.S., in the chair. The following papers were read in Section III. (Mathematical, Physical, and Chemical):—On the analysis of silk, by Dr. H. A. Bayne, Royal Military College. The author selected samples of pure silk and linen and cotton (their purity being carefully determined beforehand by the use of the microscope), and after removing dressing material, colouring matter, &c., by ether and dilute hydrochloric acid, submitted all four samples to the action of a large number of reagents in order to determine to what extent solvents of silks affect other fibres also. The result of a large number of analyses showed that, for mixtures of silk and wool, basic zinc chloride is the most reliable reagent; while for mixtures of silk and cotton or linen, Lœwe's alkaline glycerine solution of oxide of copper gives the most trustworthy indications.—Mémoire sur l'introduction et l'interprétation rationelle des quantités négatives et des quantités imaginaires dans le calcul, by Dr. D. Duval.—Classification of natural silicates, by Dr. T. Sterry Hunt, F.R.S.—Blowpipe reactions on plaster tablets, by Prof. Haanel. This was in continuation of previous investigations.—Note on the quantitative blowpipe assay of Cinnobar, by Prof. Haanel.—On the determination in terms of a definite integral of the value of the expression—

$$\frac{1}{\underline{|m+n}}\left\{\left(x+\frac{n}{2}\right)^{m+n} - n\left(x+\frac{n}{2}-1\right)^{m+n} + \ldots \right.$$
$$(-1)^r \frac{\underline{|n}}{\underline{|n-r}\,\underline{|r}}\left(x+\frac{n}{2}-r\right)^{m+n} + \ldots +$$
$$\left.(-1)^n\left(x-\frac{n}{2}\right)^{m+n}\right\}$$

the series to be continued only as long as the quantity raised to power $m + n$ is positive, n being a positive integer, and m a positive integer, zero, or a negative integer numerically less than n; and on the deduction therefrom of approximate values in certain cases, by C. Carpmael, M.A. In this paper, after pointing out that the investigation of M. Cauchy fails when m is zero or an integer, although he assumed without comment that it would hold, the author proceeds to determine the values of a number of "extraordinary integrals" and obtains results different from those obtained by M. Cauchy, although his final approximate values agree with them if we correct certain numerical errors in Cauchy's results. — The geognosy of crystalline rocks, by T. Sterry Hunt, F.R.S.—Concernant la théorie de M. Steckel sur la veine liquide contractée, by C. Baillargé.—On tidal observations in Canadian waters, by A. Johnson, L.H.D., showing the very imperfect state of our knowledge of the tides, and the need of systematic observations on both the Atlantic and Pacific coasts.—On iron ores from Central Ontario. This paper comprises a series of analyses of magnetic and other iron ores from the counties of Peterborough and Hastings in the province of Ontario, with brief references to the conditions of occurrence of the various deposits from which the ores were taken, by Prof. Chapman.—A commentary on section ix. of Newton's "Principia," by Prof. Cherriman, M.A.—The density of weak aqueous solutions of certain salts, by Prof. MacGregor, D.Sc.—Redetermination of the difference of longitude between the observatories of McGill College, Montreal, and Harvard Observatory, by Prof. W. A. Rogers (Harvard) and Prof. McLeod (McGill College).—Redetermination of the differences of longitudes of Montreal, Toronto, and Coburg, by Messrs. Carpmael, M.A., McLeod, M.E., and Chandler, M.A.—Notes on (1) Clausius's theory of the virial; (2) the motion of a rigid body with one point fixed; (3) the equation of energy in generalised coördinates.—Geometrical methods in optics, by Prof. Loudon.—Notes on the economic minerals of New Brunswick, with a revised list of mineral localities in the province, by Prof. Baily. This paper being of the nature of a catalogue of localities, was not read before the Section.—Geology of Cornwallis or McNab's Island, Halifax Harbour, by Rev. Dr. Honeyman. A study of the local geology in which special reference was made to the occurrence of amygdaloidal boulders which were considered to have been derived from the vicinity of Cape Blomidon.—A Catalogue of Canadian Butterflies, with notes on the distribution of the genera, by W. Saunders. Explained merely in a few remarks, not being suited for reading in full.

The following papers were read in Section IV. (Geological and Biological):—On the Mesozoic floras of the Rocky Mountain region of Canada, by Sir W. Dawson.—Fossil plants from the Trias and Permian of Prince Edward Island, by Sir W. Dawson.—Illustrations of the fauna of the St. John group (third part), by G. F. Matthew. This paper was in continuation of former communications. It describes a large number of Cambrian forms, particularly trilobites, and discusses the relations of the subdivisions of the Cambrian of the vicinity of St.

John with those of the same formation in Europe.—On the Wallbridge Hæmatite Mine, as illustrating the mode of occurrence of certain ore deposits, by Prof. Chapman. The particular mine referred to has been practically worked out, and in the process a clear idea of its character has been gained. It is found to be a "stockwork," or irregular mass, and not, as had been supposed, a vein. Prof. Chapman regards it as typical of a large class of deposits in the vicinity.—On Cambrian rocks of the Rocky Mountains, by Dr. G. M. Dawson. These rocks are the oldest of those shown in the mountains between the 49th parallel and the Bow River. They are of great thickness, and include at one horizon red beds with pseudomorphic salt crystals, suncracks, &c. Fossils have so far been obtained from four localities only, and these appear to indicate the horizon of the Prospect Mountain group as olevellus shales of Eureka, Nevada. —On the geology of South-Eastern Quebec, by Thos. Macfarlane.—On the geology of Thunder Cape, Lake Superior, by Thos. Macfarlane. The last two papers were read merely by title, Mr. Macfarlane adding a few explanatory remarks.—Notes on the geology and fossils of Prince Edward Island, by Francis Bain, communicated, with remarks on the fossils, by Geo. Wm. Dawson. The paper contained the results of explorations by Mr. Bain, with mention of fossil plants found by him in different parts of Prince Edward Island. It appeared from these observations and fossils that the red and grey sandstones and shales of which the island is composed are divisible by superposition and fossils into three groups: (1) the Permo carboniferous as originally established by Sir Wm. Dawson, with local additions made by subsequent observers; (2) a formation regarded by Mr. Bain as probably Permian, and corresponding to the Lower Triassic of Dawson and Warrington's report; (3) an overlying series, probably Triassic, and corresponding to the Upper Trias of the above report. Sir Wm. Dawson discussed the evidence of the fossil plants as bearing upon the above views.

In Sections I. and II. the following (among others of a more or less literary character) were read:—(1) Population française du Canada de 1608 à 1631; (2) A travers des registres du XVII. siècle, by the Abbé Tanguay.—The manifestation of the æsthetic faculty among primitive races, by Dr. Daniel Wilson. This paper discusses the evidence of the æsthetic faculty, and the practice of imitative art among ancient and modern uncivilised races. The archæological investigations in European prehistoric remains showed a nearly universal absence of imitative art throughout the whole Neolithic period and the subsequent age of bronze. But behind this lay the vastly more remote age of the Cave-men of Southern France, with their singular indications of remarkable artistic skill. This the author compared with such evidences of imitative art as are familiar to us in the work of many native American aborigines, and stated his reasons for tracing all alike to efforts at sign-language and ideographic expression of facts and thought. This was illustrated from an analysis of native Indian languages in their terms for giving expression to the language of art.—Palæolithic dexterity, by Dr. Daniel Wilson. In this paper Dr. Wilson drew attention to the ingenious profile drawings now familiar to us as the products of the ancient Cave-men of Southern France, and showed that by the direction of the profiles they were divisible into right and left-hand drawings. In so far as the examples can yet be adduced, the right-hand drawings are to those of the left hand as about two to one. The percentage of left-hand drawings is thus greatly in excess of what would now be found. But it probably shows at that extremely remote period the bias of prevalent usage which, however originating, has sufficed to determine the nearly universal predominance of the preference for the right hand within the whole historical period.

ON THE OBSERVATION OF EARTH-TIPS AND EARTH-TREMORS

IN a paper read before the Seismological Society of Japan on February 15, 1883, I collected together a number of facts which lead to the belief that districts in all quarters of the globe have from time to time been subject to slow changes in level.

Amongst these evidences may be mentioned the changes which have been recorded by many observers in the position of the bobs of pendulums. That pendulums had not always hung in the same vertical line was sometimes indicated by the position of a multiplying index, and sometimes by the position of the stile of a pendulum as seen through a microscope. Another class of observations have been made by recording the position of a spot of light reflected from a small mirror, the mirror being so suspended that it was caused to turn by the slightest displacement of the pendulum relatively to the earth. A third class of records have been made with horizontal pendulums, the multiplying indexes of which have been observed to move from side to side as if the foundation on which the pendulums rested was being slowly tilted.

A fourth order of observations have been those which have been made with delicate levels, the bubbles of which slowly move along the containing-tubes in a manner difficult to explain. A fifth class of records indicating changes in level are those which have been made by observing the displacement of an image reflected from the surface of mercury.

A sixth kind of records are the changes sometimes observed in the levels of lakes and ponds. At the time of great earthquakes, at places remote from its origin, where there was no perceptible motion of the ground, the water of lakes and ponds have been observed to slowly rise and fall as if the basin in which they rested was being slowly tilted.

To the above six classes of records a number of miscellaneous observations might be added, all of which find an easy explanation if we admit that from time to time there are slow tips in the soil.

Another phenomenon which has been observed is that the surface of the ground is from time to time in a state of tremulous motion. These movements have been noted by observing the stile of a pendulum with a microscope, the end of a light multiplying index attached to a pendulum, the quivering and erratic motion of a spot of light reflected from a mirror connected with a pendulum or reflected from the surface of mercury.

An historical account of the various observations which have been made upon earth-tips and earth-tremors may be found in the reports of George and Horace Darwin to the British Association in 1881 and 1882.

Detailed accounts of the observations made in Italy are contained in Rossi's "Meteorologica Endogena."

An account of a considerable portion of the work which has been accomplished in Japan may be found in the *Transactions* of the Seismological Society, in the reports which from time to time I have had the honour of forwarding to the British Association, and in the pages of NATURE.

As it seems that these phenomena are gradually attracting an increasing attention, it is my intention in the following notes to give a brief account, not so much of the results I have obtained by observing earth-tremors and pulsations, but of the methods by which these results have been obtained, trusting that my experiences may be of value to those who are desirous of experimenting in this direction.

Among the first instruments I employed were microphones in conjunction with telephones and delicately-suspended short-period light pendulums. From time to time the telephones emitted strange sounds. As to what was the cause of these noises I am unable to say. Unless you kept your ear continually at the telephone there did not appear to be any method of obtaining a satisfactory record, so that, after much labour, these instruments were eventually discarded. For very similar reasons the small pendulums which were often in a state of tremor were also discarded.

The next class of instrument which I employed was similar to an apparatus suggested by Sir William Thomson and used by George and Horace Darwin in the Cavendish Laboratory when experimenting on the lunar disturbance of gravity. Any one who has read Mr. Darwin's account of these experiments will recognise the unusually great care which is required by any one who undertakes to make observations with such instruments. As I was without either assistants or a laboratory, and as my instruments were of the roughest description, my attempts at making satisfactory observations altogether failed. I certainly saw that the spots of light were continually shifting in position, but whether this was due to a tip of the soil or simply to contractions and expansions in portions of my instrument, I was unable to determine.

After much trouble and considerable expense, I very reluctantly gave up the pendulums and mirrors, and sought for apparatus of a still simpler kind. Having accidentally read an account of Plantamour's observations with levels, the simplicity of the apparatus induced me to borrow a pair of astronomical levels from the Imperial Observatory and follow his example.

For a long time these levels were installed beneath cases on a column kindly lent to me by the Professor of Natural Philosophy in the Imperial College of Engineering. Here they remained for over a year, after which they made many journeys. At one time they were nearly 13,000 feet above sea-level on the top of the conical Fujisan. At another time they were some hundreds of feet below sea-level at the bottom of the Takashima mine. These observations attracted the attention of the authorities at the Imperial Observatory, who, recognising the bearing they might have upon work which was going on in the observatory, they supplemented my observations with a second set of levels. All the usual precautions were taken to guard against the effects of temperature, and observations were carried out every three hours both day and night for more than a year. As the books of records accumulated, and the curves grew until some of them were 30 to 40 feet in length, experience showed that the errors chiefly due to changes in temperature might be equal to and even exceed the effects which were being sought. Now, I am inclined to an opinion communicated to me in a letter from M. d'Abbadie, who remarked that two levels upon the same column might be parallel, and yet their bubbles might move in

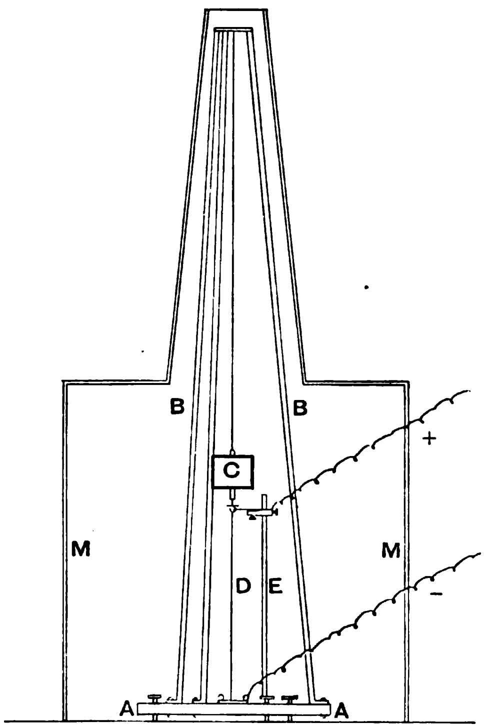

Fig. 1.

opposite directions. Notwithstanding this, the observations of levels have led to some interesting results.

First, there is the fact that level bubbles may wander without there necessarily being a change of level. Second, that level bubbles continue to move long after the sensible motion of an earthquake has ceased, thus giving us a means of observing the movements of long periods which usually bring the phenomenon of an earthquake to a close. After the earthquake the bubble will sometimes take up a position slightly different to that which it had before. Changes in the position of bubbles have been observed a short time before some of our earthquakes. Another result is the fact that the greatest irregularities in the curves showing the position of the bubbles of a level occur when earthquakes are most numerous. This is during the winter months. A last result is the fact that during a typhoon, or when the barometer is unusually low and fluctuating, a level bubble may be distinctly seen to pulsate through a small range, as if there were continuous changes of level going on.

While working with the levels another kind of instrument which I employed was a pendulum suspended from an iron stand, and so arranged that its stile could be viewed in the field of a microscope. By placing a prism beneath the end of the stile, the image of its end could be looked at horizontally, and the motion of the pendulum could be seen in any azimuth. At first I employed two microscopes placed at right angles, but by the adoption of the prism one microscope became sufficient. With these instruments, which are similar to those employed by Messrs. Bertelli, M. de Rossi, and other Italian observers, I verified for myself some of the more important results which had been noted in Europe.

For instance, it was seen that the pendulum was seldom at rest. Storms of tremors would take place with a low barometer. The pendulum did not always vibrate over the same point. It appeared as if there had been a tip in the soil, and the stand of the apparatus had been slightly inclined. These, together with other results which in many respects are little more than repetitions of results obtained by Bertelli, Rossi, and other observers, I have already published. Without attempting to describe other experiments which I have instituted, I will now give a brief description of an instrument which has been reached gradually, and which has given me the greatest satisfaction. From a letter received from M. d'Abbadie, whose researches regarding the change of vertical are amongst the most important yet instituted, I learn that my instrument has many points in common with one employed by M. Bouquet de la Grye. When I first set up this instrument, it was simply as a contrivance intended to make electrical contact, and set certain machines in action at the time of an earthquake. I next employed it as an instrument to record the occurrence of slight earthquakes. In its third form it was used to indicate earth-tremors and devia-

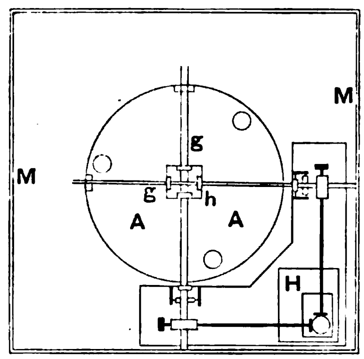

Fig. 2.

tions in the vertical. It will be readily understood from the accompanying sketches, Figs. 1 and 2: A A is a circular disk of cast iron about ¾ inches in thickness, resting on levelling screws. Bolted to this is a tripod of angle iron about 5 feet high, B B. This forms the support for a pendulum, C. The bob of this pendulum weighs about 7 lbs. It is made of a brass tube (3 m. diameter and 2¼ m. long) filled with lead. This is carried by a fine iron wire 3 feet 3½ inches long, soldered into a small hole in a plate at the top of the tripod. A spike, C, projects from the base of the bob (see Fig. 3). As the bob with its spike were turned in a lathe, the end of the spike, the point of support and the centre of figure of the bob are fairly in a straight line.

A long, light pointer, D, made of a strip of bamboo which has been varnished, is kept in contact with the base of the pointer, as shown in Fig. 3. At the top of the pointer there is a light brass ring, *c*; at the top of this there are two fine needle-points, *a* and *b*. The point *a* is kept in contact with the base of the pendulum by turning the screw T, which raises the flat spring S on which *b* rests. T is carried by a strong stand, E, which rests at three points on A; *ff* is a disk of lead which is nearly equal in weight to that of the pointer below *b*.

In one instrument *a b* is 6 mm. whilst the total length of D is 415 mm. With these dimensions we may suppose that if the base pendulum moved, say, 1 mm., then the lower end of the pointer would move about 68 mm. The values to be given to the defections observed in the pointer have also been estimated by giving a slight turn to one of the levelling screws of the base plate, and thus tipping the plate through a known angle.

Records were at first made by reading a scale of millimetres placed beneath the end of the pointer. Experience showed this method to be inconvenient and without satisfaction. What occurred between the hours of observation was unknown, whilst the records which were made were liable to greater or less errors due to the observer. This led me to seek for some method which would render the observations automatic. To attach a hair to the end of the pointer and let it be dragged across the surface of a smoked glass created too great friction. The necessary appliances for photographic registration were too costly and too troublesome to be employed as I was situated in Japan. A very near approximation to frictionless registration was obtained by sending a current down the pointer, the end of which trailed on the surface of a thick film of iodised starch covering a strip of paper. The strip of paper, which was on a metal tray, moved slowly by clockwork beneath the lower end of the pointer. On taking out the paper I found that the film of starch, with its blue line, could be dried down to form a brown line on the paper. The process was troublesome and the line subject to distortion by the flow of the starch. The next idea was to discharge a spark from the end of the pointer and perforate a band of paper moving beneath the end of the pointer at the distance of about 5 mm. This feature in the apparatus, M. d'Abbadie writes me, is an essential feature in the apparatus of M. Bouquet de la Grye. To avoid losing a record, should the pointer move parallel to the length of the paper, two bands of paper, *gg*, moving at right angles (by means of the clock, H), are employed (Fig. 2). One band passes beneath the other over the surface of a brass plate, *h*. The paper used is the ordinary paper employed in a Morse telegraph instrument. By allowing the hand of a clock to pass every five minutes across a wire the current from two of Thomson's tray-cells is sent through an indirection coil which yields the sparks to perforate the paper. Every hour the hand of the clock makes a long contact by

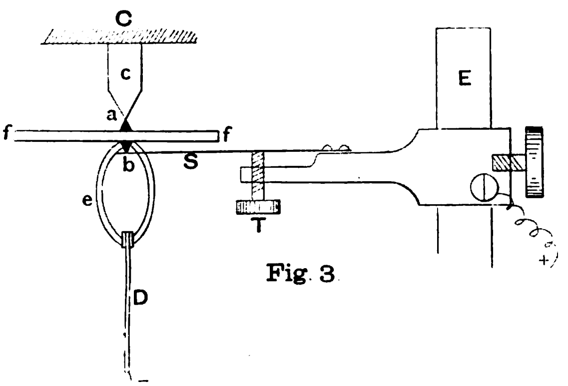

Fig. 3

passing across a small strip of platinum. In this way a large hole is made in the moving bands of paper and the hours are recorded.

To secure myself against error the same secondary current which perforates the paper of one machine is carried by wires to perforate the paper of a second instrument of slightly different construction placed on a stone column in a distant room.

The only work required is to wind the clocks which pull the paper and the clock which makes the contacts. This being done, records are automatically made every five minutes.

Up to the present the records which have been obtained have not been analysed, but certain of the results which they indicate are evident. These are as follows:—

1. Sometimes for days the pointers remain stationary, as is indicated by the sparks being regular and in a straight line (see Fig. 4).

2. Sometimes the pointers are in a state of tremor, and the sparks perforate the paper at many points, giving a line of several millimetres in breadth (see Fig. 5). These tremors may continue for ten or twelve hours. From the diagram, the duration of these tremors and the range of motion can be accurately measured. The instruments in both rooms agree as to the occurrence of tremors and periods of rest.

3. Sometimes the pointer will slowly wander from the straight line, and then slowly return. This usually takes place two or three times in succession. It would seem as if the ground had been slowly tipped through one or two seconds of arc, the period of each tip being from fifteen to sixty minutes (Fig. 6).

In regard to the occurrence of these tips, the instruments in the two rooms only occasionally coincide.

As to whether they are really to be regarded as true disturbances of level, or simply as movements due to local causes, I shall be better able to speak after a more carefal examination of the records.

4. Sometimes I find the bands of paper perforated over their whole breadth by sparks in all directions. This indicates that an earthquake has occurred and the pointer has been swinging (see Fig. 5, about 9.15 p.m.). All these figures have been produced by pricking through from the original diagrams. The clocks which I have used are made from small American spring clocks costing in Japan about 12*s*. each. The total cost of the portion of the apparatus figured, including the case, M, the doors of which and the parts which come in contact with the column are edged with flannel, is about 25 yen, or £4 10. In Europe an instrument of better construction would cost more. One of the columns on which an instrument is placed measures 6 feet by 3 feet and 5 feet high. It is constructed of brick and rests on concrete. The other column, which also rests on concrete, is made of stone. It measures 2 feet 2 inches × 2 feet 2 inches and is also 5 feet in height.

This latter column is rather too slight, as I found that even the pressure of my thumb is sufficient to cause the pointer of the instrument to move several millimetres.

Amongst those who may possibly have a practical interest in this matter are those who have to deal with mines—especially, perhaps, coal-mines.

In the columns of the *Japan Gazette*, in NATURE, in the *Mining Journal*, and other papers, references have been made to the attempt to observe earth-tremors and other phenomena in the Takashima Colliery near Nagasaki. At the conclusion of a

Fig. 5.

report to the British Association, 1884, on the earthquakes of Japan, a letter from Mr. John Stoddart, the chief engineer at that mine, tells us that, owing to the working of the mine and other causes, he finds it impossible to make observations with delicate instruments. He therefore proposes to move the instruments to some distant station, assuming that any natural cause which would cause tremors in the mine will be generally felt over a considerable area. As to whether there is a connection between earth-tremors and the escape of gas in collieries, we do not yet know. Mr. Walter Browne, in a paper to the North of England Institute of Mining and Mechanical Engineers, thinks it desirable that investigation on this subject ought to be made, and quotes what is being done at Takashima. Mr. Galloway, writing in NATURE of February 5, if I read him correctly, does not encourage Mr. Brown's suggestions, and enters into an argument about the possibility of an earth-tremor forming a fissure. Earthquakes often form fissures on the surface, but these effects in mines are usually nothing. I make this statement on the authority of personal inquiry in many mining districts.

With the exception of the disturbances near an epicentrum, the movements due to ordinary earthquakes are so superficial that the range of motion at the depth of 10 feet is sometimes only one-fortieth of what it is at the surface. Earth-tremors are phenomena usually lasting many hours, and they certainly occur with low barometers. That they could by any possibility form fissures it is difficult to imagine.

As to what may be the cause of earth-tremors I am not prepared to offer a definite opinion; but, inasmuch as their association with barometric fluctuations renders it possible that in their occurrence they may also be associated with the escape of fire-damp, about which we have so little knowledge of practical value, it seems impossible that their study should be neglected.

Whether the results of such a study would be of practical value to the miner is not known, but that results of scientific value would be obtained is indisputable.

As the making of such observations are neither a matter of trouble or serious expense, I sincerely trust that they may be undertaken. On some future occasion I hope to describe the experiments which I made with one of these instruments on the summit of Fujiyama (13,365 feet), where movements were of a very marked and decided character.

Tokio, Japan JOHN MILNE

SOCIETIES AND ACADEMIES

LONDON

Royal Society, June 18.—"The Removal of Micro-organisms from Water." By Percy F. Frankland, Ph.D., B.Sc., F.C.S., Associate of the Royal School of Mines.

The author has investigated the efficiency, as regards the removal of micro-organisms, of methods of water-purification depending upon

(*a*) Filtration.
(*b*) Agitation with solid particles.
(*c*) Precipitation.

The method of investigation consisted in determining the number of organisms present in a given volume of the water before and after treatment, the determinations being made by Koch's process of gelatine-culture on glass-plates.

Treatment of Water by Filtration.—The filtering materials examined were greensand, silver sand, powdered glass, brick-dust, coke, animal charcoal, and spongy iron. These materials were all used in the same state of division, being made to pass through a sieve of 40 meshes to the inch, and in columns of 6 inches in depth. The following results were obtained:—

	No. of organisms in 1 c.c. of water before filtration	Ditto after filtration
Greensand	80	0
ditto (after 13 days)	8,193	1,071
ditto (after 1 month)	1,281	779
Silver Sand	11,232	1,012
Powdered Glass	11,232	792
Brickdust	3,112	732
ditto (after 5 weeks)	5,937	406
Coke	3,112	0
ditto (after 5 weeks)	5,932	86
Animal Charcoal	very numerous	0
ditto (after 12 days)	2,792	0
ditto (after 1 month)	1,281	6,958
Spongy Iron	80	0
ditto (after 12 days)	2,792	0
ditto (after 1 month)	1,281	2

Thus greensand, coke, animal charcoal, and spongy iron wer at first successful in removing all organisms from the water pass ing through them, but after 1 month's continuous action this power was in every case lost, the improvement still effected, however, by spongy iron and coke was very great indeed, whilst the greensand and brickdust were much less efficient, and the number of organisms in the water that had been filtered through animal charcoal was greater than in the unfiltered water.

Treatment of Water by Agitation with Solid Particles.—Water was agitated with various substances (in the same state of division as above) and after the subsidence of the suspended particles, the number of organisms in the water before and after treatment was determined. 1 grm. of substance was in nearly each case shaken up with 50 c.c. of water. The agitation was in nearly all cases continued for 15 minutes, but the duration of subsidence was varied according to the length of time which it required for the water to become clear. The following results were obtained:—

	No. of organisms in 1 c.c. of water before treatment	Ditto after treatment
Spongy Iron (1 minute agitation, ½ hour subsidence; 5 grms. used)	609	28
Spongy Iron (15 minutes' agitation, ½ hour subsidence; 5 grms. used)	609	63
Chalk (15 minutes' agitation, 5 hours' subsidence)	8,325	274
Animal Charcoal (15 minutes' agitation, 5 hours' subsidence)	8,325	60
Coke (15 minutes' agitation, 48 hours' subsidence)	Too numerous to be counted	0
China Clay (15 minutes' agitation, 5 days' subsidence)	—	Too numerous to be counted

In order to ascertain whether subsidence alone would diminish the number of organisms contained in the upper strata of water, bottles containing infected water were allowed to remain at perfect rest, and then the upper layers in the several bottles were tested for organisms at different intervals of time. Thus:—

Hours of rest	No. of organisms found in 1 c.c. of water
0	1,073
6	6,028
24	7,262
48	48,100

Thus, without agitation with solid particles and subsequent subsidence of the latter, there is no diminution, but on the contrary an increase in the number of organisms in the upper strata of water.

Treatment of Water by Chemical Precipitation.—The effect of "Clark's process" in removing organisms from water was investigated both in the laboratory and on the large scale. In the laboratory experiments the following results were obtained:—

	Organisms in 1 c.c.
Untreated water	85
ditto (after 18 hours' rest)	1,922
Water after Clark's process and 18 hours' subsidence	42

In a second series of experiments the following results were obtained:—

	Organisms in 1 c.c.
Untreated water	37
ditto (after 21 hours' rest)	42
ditto (after 48 hours' rest)	298
Water after Clark's process and 21 hours' subsidence	22
ditto (after 48 hours' subsidence)	166

On the large scale the efficiency of the process was examined at the Colne Valley Waterworks, Bushey:—

	Organisms in 1 c.c.
Hard water	322
Water after softening and 2 days' subsidence	4

A recent modification of Clark's process devised by Gaillet and Huet was also examined:—

	Organisms in 1 c.c.
Hard water	182
Soft water	4

Thus a very great reduction in the number of organisms present in a water may be effected by submitting it to Clark's process. It appears also that the clear water should be removed as rapidly as possible from the precipitated carbonate of lime, as otherwise the organisms may become again distributed through the water.

Micro-organisms in Potable Water.—The number of organisms in natural waters of various origin has been determined by the author, who appends the results of a monthly examination, in this respect, of the various waters supplied to London during the first three months of the present year:—

	1885 No. of organisms in 1 c.c. of water Jan.		Feb.		March
Chelsea	8	...	23	...	10
West Middlesex ...	2	...	16	...	7
Southwark	13	...	26	...	246
Grand Junction ...	382	...	57	...	28
Lambeth	10	...	5	...	69
New River	7	...	7	...	95
East London	25	...	39	..	17
Kent...	10	...	41	...	9

General Conclusions.—Of the substances experimented with only greensand, coke, animal charcoal, and spongy iron were found to wholly remove the micro-organisms from water filtering through them, and this power was in every case lost after the filters had been in operation for one month. With the exception of the animal charcoal, however, all these substances, even after being in action for one month, continued to remove a very considerable proportion of the organisms present in the unfiltered water, and in this respect coke and spongy iron occupy the first place.

The results obtained by agitating water with various solid materials show that a very great reduction in the number of suspended organisms may be accomplished by this mode of treatment, and the complete removal of all organisms by agitation with coke is especially worthy of notice.

Again, the results obtained with Clark's process show that we possess in this simple and useful mode of treating water a means of greatly reducing the number of suspended organisms.

Thus, although the production in large quantities of sterilised potable water is a matter of great difficulty, involving the continual renewal of filtering materials, there are numerous and simple methods of treatment which secure a large reduction in the number of organisms present in water.

Physical Society, June 27.—Prof. Guthrie, President, in the chair.—Dr. Ramsay, Messrs. T. Hands, F. W. Sanderson, W. A. Shenstone, and T. H. Nalder were elected Members of the Society.—The following communications were read:—On the specific refraction and dispersion of the alums, by Dr. J. H. Gladstone. The refraction, dispersion, and specific gravity of nineteen different alums in the crystalline form were published by M. Charles Soret, of Geneva, in the *Comptes rendus* for last November. These, together with some additional data from Soret, Topsöe, and Christiansen, were employed by the author for comparison with certain experimental results of his own and of Kannonikof. In this way additional proof was obtained that a salt has the same specific refraction, whether it be crystallised or dissolved, and that the refraction equivalent of a compound body is the sum of the refraction equivalents of its components. The refraction equivalents of the alkalies in these alums are in the following ascending order—sodium, potassium, ammonium, rubidium, methylamine, calcium, and thallium; and of the other metals—aluminium, chromium, and iron. This is in accordance with what was previously known, but Soret's observations do not afford the means of determining the equivalents more accurately than before. The refraction equivalents of iridium and gallium were determined for the first time, giving respectively 17·4 and 14·8. The specific dispersion of the same compounds, measured by the difference between the specific refractions for the lines A and C, was also examined. The differences of dispersion are much greater comparatively than the differences of refraction. The order was also determined, but not the actual dispersion equivalents of the different elements.—On a form of standard Daniell cell, and its application for measuring large currents, by Dr. J. A. Fleming. The author first referred to the careful and thorough investigation of the circumstances affecting the electromotive force of Daniell's and allied cells by Dr. Alder Wright. He then described a form of all that had been found most convenient and reliable in practice. It consists of a U-tube in the two limbs of which are the two solutions of sulphate of copper and sulphate of zinc of the same specific gravity. Electrodes consisting of freshly electro-deposited copper and pure zinc that has been twice distilled dip into the two limbs. The E.M.F. of this cell is 1·102, and the variation of E.M.F. with temperature is practically *nil*.—On the phenomenon of molecular radiation in incandescent lamps, by Dr. J. A. Fleming. Some years ago Dr. Fleming had called attention to a phenomenon in incandescent lamps very analogous to that of discharge in high vacua observed by Mr. Crookes. The inner surface of the lamp-glass was sometimes found to be coated with a deposit of carbon, with the exception of a clear line marking the intersection of the glass with the plane of the loop, and being in fact a shadow of the loop apparently caused by an emission of matter from the terminals. Dr. Fleming has since found how to produce this appearance at pleasure by passing a very strong current momentarily through a lamp, and has succeeded in obtaining similar deposits of various metals that had been used as terminals. These deposits show colours by transmitted light, and as a general result the author concludes that red metals such as gold and copper appear green by transmitted light, whereas white metals like silver and platinum appear brown, a conclusion which, however, was challenged by Capt. Abney in the discussion ensuing.—On problems in networks of conductors, by Dr. J. A. Fleming.—Lecture experiments on colour mixtures, by Capt. Abney. The apparatus employed by Capt. Abney is a modification of Maxwell's colour-box: the spectrum, instead of being formed upon a screen, is received upon a convex lens which forms an image of the face of the prism upon a screen. If all the light from the prism falls upon the lens this image is colourless, but by interposing a screen with a slit in the spectrum close to the lens, so as only to allow light of a given colour to fall on the lens, the image appears coloured with that light. By using two or more slits different lights may be mixed in any required proportions.—On stream-lines of moving vortex-rings, by Prof. O. J. Lodge. The communication described a method of drawing vortex stream-lines, consisting in superposing uniform motion represented by a series of parallel lines upon the lines of a stationary vortex as given by Sir W. Thomson in his memoir on vortex motion, and joining up the corners of the quadrangles so formed. This operation is very simple, and by its application a number of the more remarkable properties of vortex-rings may be obtained, the general analytical investigation of which involves mathematical methods of the highest order. Drawings were exhibited showing the nature and behaviour of a single vortex-ring moving with different velocities, a vortex-ring approaching a large distant obstacle, the chase of two unequal rings, and many other cases.—On the thermo-electric position of carbon, by Mr. J. Buchanan. It having been observed that the carbon filaments of incandescent lamps usually gave way at the negative end, experiments were instituted to find if the destruction could be due to the "Peltier effect" causing a local generation of heat. Observations on a platinum-carbon thermo-couple showed that a generation of heat would result from a current passing from carbon to platinum, but the effect was too small to account for the observed phenomenon. It was found that a couple of carbon-iron rose considerably in E.M.F. by maintaining the hot joint for some time at 250° C.—On some further experiments with sulphur cells, by Mr. Shelford Bidwell. The paper contains (1) a description of a class of cells which give a constant voltaic current, the electrolyte consisting of a solid metallic sulphide; (2) an explanation of the unilateral conductivity exhibited by selenium and by sulphur cells; and (3) a description of a cell which gives, as the result of passing a current through it, a current in the same direction as the primary current.

EDINBURGH

Mathematical Society, July 10.—Mr. A. J. G. Barclay, president, in the chair.—Mr. R. E. Allardice gave an account of a paper by Mr. Charles Chree on physical applicatious of polar co-ordinates to the displacement of elastic solid and fluid bodies, and contributed some notes of his own on solid geometry.—Mr. J. S. Mackay submitted a paper by Mr. Robert J. Dallas on the method of orthogonal projection.—Mr. A. Y. Fraser, the hon. secretary, and Dr. Rennet, of Aberdeen, were appointed by the Society to represent it at the ensuing meeting of the British Association.—The president, in his closing remarks, stated that the membership of the Society at the end of its first session was 58, at the end of its second 92, and now, at the end of its third, 147.

PARIS

Academy of Sciences, July 6.—M. Bouley, president, in the chair.—New methods for determining the absolute coordinates of the polar stars without the necessity of ascertaining the instrumental constants, by M. Lœwy.—On the movement of a heavy revolving body fixed at a point in its axis, by M. G. Darboux.—On some new properties of the differential parameter of the second order for the functions of any number of independent variables, by M. Haton de la Goupillière.—A reply to

M. Mascart's recent note on the great movements of the atmosphere, by M. Faye.—Researches on vegetation: on the carbonates in living plants, by MM. Berthelot and André. In this paper the authors explain the methods followed by them in determining the quantity of the simple organic salts now known to be largely, if not universally, diffused throughout the vegetable kingdom.—Anatomy and physiology of Phœnicurus, a remarkable parasite found largely associated with certain mollusks, by M. de Lacaze-Duthiers.—On the homography of two solid bodies, by M. Sylvester.—Report on the experiments made in Holland and Belgium on an application of the large movable tubes of the hydraulic system constructed at the sluices of the Aubois; further modifications of that system, by M. A. de Caligny.—Spectrum of ammonia obtained by reversal of the induced current, by M. Lecoq de Boisbaudran.—A process of prophylactic inoculation against splenetic or charbon fever, by M. A. Chauveau. The peculiarity of this process consists in the method adopted for attenuating the cultivated virus, which is effected by means of compressed oxygen. Three points are established: (1) that it suffices to inoculate animals a single time in order efficiently to protect them both from experimental inoculations with strong, unattenuated virus and from the effects of spontaneous contagion; (2) that the virus attenuated by means of compressed oxygen is as harmless as that obtained by other methods constituting what is known as the first charbon vaccine; (3) that the most attenuated virus continues still active and serviceable long after its preparation.—Remarkable solar protuberances observed at diametrically opposite points of the disk on June 26, in Paris, by M. E. L. Trouvelot.—On some formulas in the theory of left curves, by M. Ph. Gilbert.—On the reductive properties of pyrogallol; its action on the salts of iron and copper, by MM. P. Cazeneuve and G. Linossier. The authors' experiments establish a complete parallelism between the reactions of ferric and cupric salts.—On the action of acetic acid in decomposing the hyposulphites of sodium and potassium, by M. E. Mathieu-Plessy.—Description of a new method of quantitative analysis for cadmium, by MM. Ad. Carnot and P. M. Proromant.—A new process for detecting and rapidly analysing small quantities of nitric acid in the air, water, earth, &c., by MM. Al. Grandval and H. Lajoux.—On the formation of large deposits of nitrates in Venezuela, the Andes, the Orinoco Basin, and other intertropical regions, by MM. A. Muntz and V. Marcano. From their observations the authors conclude that these nitrates have a purely animal origin, developed without the intervention of atmospheric electricity. Their position, the constant presence of large quantities of sulphates and of the nitrifying organism, combined with the study of the phenomena observed in deposits now in process of formation, all tends to exclude the recently advanced hypothesis of electric influences.—On the composition and fermentation of interverted sugar; a reply to M. Maumené, by M. Em. Bourguelot.—On the fermentation of the jéquirity plant, by MM. J. Béchamp and A. Dujardin.—On the production of the hydrate of crystallised magnesium (artificial brucite) and of the hydrate of crystallised cadmium, by M. A. de Schulten.—On the determination of the mineral group of zeolites in the absence of determinable crystalline forms, by M. A. Lacroix.—On a new group of felspar rocks in the district of Four-la-Brougue, Puy-de-Dôme, by M. F. Gounard.—On the position of some serpentine rocks on the road between Granada and Jaen in the north of the province of Granada, Spain, by M. W. Kilian.—On the augite and hornblende eruptive formations (diorites and serpentines) in the Sierra de Peñaflor, Andalusia, and on the genesis and dissemination of gold throughout these rocks, by M. A. F. Nogués.—Contributions to the study of the oolitic flora of West France, by M. L. Crié.—On the structure and growth of whalebone in the Balenopteræ, by M. Y. Delage.—On the structure and action of the stylets in the sting of the bee, by M. G. Carlet.—On the respective toxic properties of the organic and saline matters present in the urine, by MM. R. Lépine and P. Aubert.—Epilepsy of auricular origin: a contribution to the study of otopiesis (auricular compression), by M. Boucheron.—New metalloscopic processes applicable especially to cases of lethargy, catalepsy, and somnambulism, by M. Moricourt. The author shows that patients subject to these morbid affections are peculiarly sensitive to the action of metals, many cases having been successively treated by his new metallotherapic processes.—Clinical studies on the leprosy still surviving in the rural districts of Norway, by M. Paul Bert.—On the passage of pathogenic microbes from the mother to the fœtus, by M. Koubassoff.—M. Grandidier was elected a member of the Section for Geography and Navigation in place of the late M. Dupuy de Lôme.

SYDNEY

Royal Society of New South Wales, May 6.—Annual Meeting.—H. C. Russell, B.A., F R.A.S., President, in the chair.—The report of the Council stated that 34 new members had been elected during the year, making the total on the roll 494. Sir G. B. Airy, K.C.B., F.R.S., and Prof. John Tyndall, F.R.S., had been elected Honorary Members in the room of Sir F. B. Barlee, K.C.M.G., and George Bentham, C.M.G., F.R.S., deceased. The sum of 380*l.* had been expended on books and periodicals during the year. The Clarke Memorial Medal for 1885 had been awarded to Sir J. D. Hooker, K.C.S.I., C.B., and the Society's Medal and a prize of 25*l.* to Mr. W. E. Abbott for his paper on the water-supply in the interior of New South Wales. The Society had presented its *Journal* to 313 kindred societies and institutions, and received 1147 volumes and pamphlets in return. The following papers had been read at its monthly meetings:—Presidential Address, by Hon. Prof. Smith, C.M.G.; the removal of bars from the entrances to our rivers, by W. Shellshear, A.M.I.C.E.; notes on gold, by Dr. Leibius, M.A.; some minerals new to New South Wales, by Prof. Liversidge, F.R.S.; the oven-mounds of aborigines in Victoria, by Rev. P. MacPherson, M.A.; notes on the trochoided plane, by L. Hargrave; a new form of actinometer, by H. C. Russell, B.A.; notes on some mineral localities in the northern districts of New South Wales, by D. A. Porter; notes on Doryanthus, by C. Moore, F.L.S.; water-supply in the interior of New South Wales, by W. E. Abbott; notes on a new self-registering anemometer, by H. C. Russell, B.A.; researches upon the embryology and development of the Marsupials, Monotremes, and Ceratodus, by W. H. Caldwell, M.A. —A *conversazione* was held on October 8 in the Great Hall of the University, attended by about 900 members and their friends. The Council had issued the following list of subjects with the offer of the Society's Bronze Medal and a prize of 25*l.* for each of the best researches, if of sufficient merit (to be sent in not later than May 1, 1886):—On the chemistry of the Australian gums and resins; on the tin deposits of New South Wales; on the iron ore deposits of New South Wales; list of the marine fauna of Port Jackson, with descriptive notes as to habits, distribution, &c. (to be sent in not later than May 1, 1887); on the silver ore deposits of New South Wales; origin and mode of occurrence of gold-bearing veins and of the associated minerals; influence of the Australian climate in producing modifications of diseases; on the Infusoria peculiar to Australia.—The Chairman delivered the Presidential Address, and the officers were elected for the ensuing year.

THURSDAY, JULY 23, 1885

A NEW DEPARTURE FOR THE UNIVERSITY OF LONDON

THE influential movement which has grown out of the Educational Congress held during the Health Exhibition last year at South Kensington, and which has for its object the establishment of a Teaching University for London, has placed the existing University on the horns of a dilemma. Either it must be content to see itself altogether outdistanced by a new organisation which of necessity would absorb into itself all the teaching eminence of London, or it must rise to the occasion, and, bursting the cramped limits of its present contracted sphere of activity, show itself competent to the performance of larger duties.

The Convocation of the University, composed of the general body of graduates, has for its part shown at any rate a disposition to choose the latter alternative. After two successive debates it appointed a committee of forty of its members to see how far the proposals of the Association for a Teaching University could be carried into effect by the existing University. The report of the Committee has now been issued, and was printed by us in last week's NATURE. It will be submitted to an extraordinary meeting of Convocation to be held on Tuesday next.

What the action of the graduates will be it is of course impossible to predict with certainty. But it is hardly conceivable that, having assented to the principle of developing the University in the direction proposed by the Association, they will find much difficulty in accepting the scheme of reorganisation presented to them by Lord Justice Fry.

The scheme itself is necessarily cast in a somewhat technical form, and it is unaccompanied by any memorandum explanatory of its leading principles. These, however, it is not difficult to glean from it, and some account of them will, we think, be not without interest to many of our readers.

A priori the name of the University of London would call up to the mind of any one unfamiliar with the reality the image of a very splendid institution. This enormous city, which sooner or later absorbs into its life everything and everybody that rivets attention in the mind of the nation at large, might be expected to possess in its university a seat of learning where all the best of its intellectual activity would, as it were, be brought to a focus. That is the ideal. The reality is quite different. It is, in fact, a Government office which only by a kind of grim jest bears the name of a university. It is true it gives degrees; its graduates array themselves in gowns of surpassing brilliancy; it has a library and portraits of vice-chancellors; it has even a member of Parliament, But these are the mere accidents of its nature. Pierce below these insignificant academic symbols, and you find nothing but a mere State examination board supported by a Parliamentary grant; its expenditure controlled by the Treasury; its accounts audited by the Audit Office; and every academic regulation requiring the approval of the Home Secretary. Of any provision for the advancement and cultivation of knowledge there is none.

London however abounds with institutions of more or less eminence, in which studies of an academic kind are pursued. The first step which the Association saw to be necessary was to endeavour in some way to federate these. The task is one of no small difficulty. No educational establishment of any standing would care to sacrifice any portion of its autonomy, or to see taken from it any possible field of activity to which it might legitimately aspire. On the other hand, universal experience has shown that it is only those who are actually engaged in the higher kind of teaching who can be counted upon to supply the propulsive force needed for a real University activity. It is only those who work in the ultimate allotments of the fields of learning who can say how the achieved results in each area can be adapted to educational needs, and what help a University can give in securing harvests still ungrown and unreaped.

The leading feature of the scheme is—frankly following the principle on which the examining staff is secured—to bring into the University, irrespective of their previous connection with it, the best of the London teachers of University rank. These are to be obtained as representatives of Colleges who have agreed to come into the scheme. What these bodies sacrifice by so doing is scarcely appreciable. What they may gain may be very considerable. The teaching representatives so obtained (with some additional members) are to be grouped into four Faculties. In these Faculties the teaching arrangements of the several constituent Colleges may, though not necessarily, be brought into discussion. The result, it may be hoped, will be a better division by amicable arrangement of the higher educational appliances of the metropolis. And where (with the approval of the faculty) any particular constituent College undertakes the charge of some slenderly-supported branch of learning, it can hardly be doubted that the approval of the faculty will at least go a long way to securing public interest in the venture.

The faculties, then, can hardly fail to promote cooperation among the University teachers in London, and to better organise the attack on ignorance. But besides this they will enable the teaching bodies to gain for the first time a direct influence upon the examinations. Each Faculty will appoint a Board of Studies, and this will be charged with the duty of watching the examinations, keeping up something like a continuous tradition, and seeing that examination and teaching are in reasonable adjustment. Furthermore the Faculties will have direct representation on the Senate and that august body will in time be no longer a mere assemblage of notables holding their seats for life, but a real Academic Council for London at large, the members of which, being removable after a term of years, will always be in touch with their constituents.

These are the main outlines of the scheme. They appear to us to have been dexterously drawn between interference which the Colleges would resent and responsibility for their administration which the University could not accept. But though all this is admirable, it would not satisfy us if it were to be regarded as the final outcome of the scheme. Its great merit in our eyes is the provision we see in it for continuous development. The Faculties, the Boards of Studies, the Senate, are all under the scheme subject to provisions for renewing their composition. There will be therefore, we hope, a properly controlled flow of new life through every branch of the governing authority of the University. The present condition of crystalline rigidity will dissolve. As new objects of University enterprise come to the surface and assume definite shape, the men who advocate them will find their way to the Faculties and succeed in making their voices heard. At the same time there is sufficient opportunity for discussion to prevent the University being launched unadvisedly in any rash development.

We do not conceal our own hope that the most important outcome of the new scheme will be the ultimate provision of appliances for the prosecution of the higher studies in London. These never can be self-supporting, and never can, therefore, be properly undertaken by the constituent colleges. Ths voice of the faculties must be in the long run the voice of the men who compose them. That they will, therefore, if constituted, take some action in the matter, can scarcely be doubted. But instead of individual voices crying in the wilderness, there will be the mature utterances of a responsible body carefully guarding the interests of the constituent colleges on the one hand, and looking to the distinction and influence of the University on the other. Properly considered schemes will be put forward, and whether their execution devolves on the State, or is undertaken by private munificence, the public will for the first time have in the Faculties an authority competent to advise it in such matters, and whom it can listen to with confidence. The ultimate expansion of the University into all that can be desired, appears to us the inevitable outcome of Lord Justice Fry's scheme, if it is carried into effect.

THE WOOL FIBRE

The Structure of the Wool Fibre in its Relation to the Use of Wool for Technical Purposes. By F. H. Bowman, D.Sc., F.R.S.E., F.L.S., &c. (Manchester: Palmer and Howe; London: Simpkin Marshall and Co., 1885.)

THIS is a series of lectures delivered by Dr. Bowman to the students of the Bradford Technical College and the members of the Dyers' and Colourists' Society, and is in continuation of a similar series on the "Cotton Fibre."

The subject is one of so great importance that Dr. Bowman is amply justified in concluding that the information contained in his lectures ought to be accessible to others than students; for, if there is anything to learn with respect to a great national industry like the woollen trade, it is highly desirable that no time should be lost in communicating it to those who are now engaged in the trade, rather than that we should wait half a generation for the knowledge to become available in the hands of the students.

It is no doubt very difficult to introduce new methods and to banish old ones, except by the introduction of young blood; but even so, something may be done in the way of preparing the minds of the older workers to receive the new ideas of the young ones, and this at least Dr. Bowman's work is likely to do.

Whether Dr. Bowman has been wise in preserving the lectures in their original form in his book we take leave to doubt. It makes the book very much larger than it would otherwise have been, owing to the unnecessary recapitulation at the commencement of each lecture, and not only so, but the labour and attention which would have been required to remodel the lectures would have prevented some glaring errors and defects of style which are by no means creditable to a writer of Dr. Bowman's attainments. A careful perusal of the proof-sheets would surely have removed such errors as "the appearance of the bulbous parts are very similar;" "the Exmoor sheep are the smallest of the two;" and the vulgarism, "some of the sheep in the northern districts have four and even six horns, *the same as* the Iceland sheep."

These literary defects notwithstanding, the book is most opportune and valuable. The key-note of the whole is perhaps to be found in the following sentence:—"All our machines and processes are only a means to an end, and the correct method of proceeding is ever to have the end in view from the beginning. Strange as this may appear, such is not always the case in our manufactures, and especially in those where the materials pass through many hands in different works before reaching the final stage. How often do we find the farmer, for example, quite careless in regard to the nature of the dips, and washes, and smears which he uses for his sheep, in utter forgetfulness of the fact that, although he may gain a temporary advantage, he is spoiling the wool for future use in spinning and dyeing."

Dr. Bowman puts forcibly before his readers the fact that wool is a part of the skin of the animal on which it grows, and is capable of being modified to a very great extent indeed—much more than most people are aware—by change of climate, food, and other surroundings, and especially by judicious breeding. One-sixth of the book is devoted to an enumeration of the various breeds of sheep to be found in the world, for the purpose of illustrating this. Perhaps, if we may be permitted to say so, this division of the work might have been judiciously shortened by the omission of details respecting numerous breeds of sheep which are now of little more than historical importance, especially as Dr. Bowman appears to be of opinion that the course which has been followed is the right one, and that we are now in possession of practically the best breeds of sheep which we could have for wool-producing purposes.

The lectures are five in number, of which the first is chiefly introductory. In it the author discusses the difference in composition and structure of animal and vegetable fibres and minutely describes the structure of cotton, silk, and wool as disclosed by the microscope. He points out the distinction between hair and wool so far as any real difference exists, and describes the constitution of the skin and the mode of production and growth of hair or wool.

The second lecture is chiefly devoted to a description of the various breeds of sheep and of the results of cross-breeding.

In the third lecture the author describes the typical structure of wool fibre under the two heads: (*a*) in regard to the mechanical arrangement of its ultimate parts; (*b*) in regard to its chemical composition.

The fourth and fifth lectures deal with, first, the variations from the typical structure found in fibres taken from the same animal and grown at the same time, in fibres from the same animal grown in different years, in fibres from the same animal grown under different climatic and other conditions, and in fibres from different breeds of sheep grown in different countries; and, secondly, the effect of these variations in the manufacturing processes.

There are a number of excellent illustrations which materially assist the reader.

It has hitherto been too commonly supposed that the sheep might be turned out upon our bleak and barren hillsides, of which no other use could be made, and left to its own resources; but this is doubtful economy, even as regards the land, and Dr. Bowman shows that as to the sheep it simply ruins the wool. "The wool and its character depend very largely not only on the health of the sheep, but also upon climatic and other influences. The mildness or severity of the season and the plenty or scarcity of food very largely affect the character of the wool. In very severe seasons there is a tendency to a thickening of the fibres, with greater irregularity in the length of the general staple and a greater rankness of the fleece, with undergrowth of short fibres and a greater irregularity in the diameters of the individual fibres and the different parts of the same fibre. The general character of the wool is also affected because from constant wetting and drying in the bad seasons the wool becomes tender and rotten and loses its brilliancy and lustre." "When examined under the microscope the individual fibres are found to be injured in their structure by the want of proper nourishment and the deficiency in the natural suint or grease, a great part of which is soluble in water, and when removed leaves the fibres dry and hask. Of course amongst well tended flocks these variations are reduced to a minimum, because they are supplied with suitable shelters from the storms and fed artificially when there is a scarcity of pasture." Most farmers think more of the mutton than of the wool, but whatever improves the one improves the other, and it would pay them well to devote more attention to the comforts of our hillside sheep, and even of those which are pastured in more favourable situations.

Great improvements have, we believe, been effected in apparatus for washing wool, but perhaps Dr. Bowman is right in saying that even yet sufficient attention is not paid to the temperature of the water. It seems to be forgotten that wool is an animal matter and that "the real base of the wool fibre is a body which very closely resembles, and is allied to, the albumenoids, and all these bodies are subject to very great changes in molecular condition when subjected even to moderate degrees of heat." Dr. Bowman made a number of experiments with "a bright-haired wool" to determine the effect on its lustre and strength of washing at different temperatures in pure water. He found that "wool which looked quite bright when well washed with tepid water was decidedly duller when kept for some time in water at a temperature of 160° F.; and the same wool, when subjected to boiling water 212° F., became quite dull and lustreless." As Dr Bowman elsewhere says, when water is heated by blowing in jets of steam, as is not unusual in wool-washing, the temperature varies in different parts, being nearly or quite 212° close to the steam jet, whilst very much lower at a little distance.

W. H. S. W.

PHYSIOLOGY OF THE EMBRYO

Specielle Physiologie des Embryo. Untersuchungen über die Lebenserscheinungen vor der Geburt. Von W. Preyer. (Leipzig: Th. Grieben's Verlag, 1885.)

THE vital processes of the embryo present so many difficulties in their investigation that, in spite of their great interest, they have hitherto received only a small share of the physiologist's attention. Prof. Preyer's new book will therefore be received with welcome as an important contribution to our knowledge of the subject; and is likely, on account of its completeness, to become a standard text-book.

The work is an almost exhaustive summary (extending to more than 600 pp. 8vo) of the results of investigations into this branch of physiology from the time of Aristotle downwards. Indeed, so large a proportion of other men's researches are included, that the title "Untersuchungen . . . von W. Preyer" would seem to require modification.

The reader may be a little disappointed with the earlier portion of the book, on account of the trite nature of some subjects which could hardly have been omitted; but the matter increases in interest with the progress of the work, and especially where the author's own researches are described. The style is not as condensed as could be wished: but this fault is not uncommon in scientific writings.

Although the common chick most rightly receives a large share of attention, yet other animals—mammalia, reptiles, and fishes—are not in any way neglected, and even invertebrates are occasionally touched upon. The most valuable observations are those on the guinea-pig, dog, &c. The author laments the scarcity of material and of opportunities for observation on the human subject; and recommends that in foundling hospitals and lying-in institutions a supply of apparatus should be kept ready for observing the physiology and pathology of the new-born; since much may be learnt from the phenomena, especially the changes, which occur within the first minutes or hours after birth.

In the first section, which treats of the embryonic circulation, Prof. Preyer shows the probability that in the chick the primitive blood, or hæmolymph, begins to move before the occurrence of the first heart-beat. This he attributes to the effect of heat, the heart occupying a higher position in the embryo than the vessels, so that by convection the blood tends to rise towards the heart and distend it. This explanation is not satisfactory on physical grounds: for it is difficult to realise that there can be a difference of temperature between the contents of a minute vessel and its surroundings sufficient to cause such a movement. Is it not equally probable that the change of specific gravity may be due to chemical changes in the hæmolymph; or, more probable than either, that the fluid is formed in the peripheral vessels and driven onwards by the pressure of osmosis?

Among the most important results of experiments are those connected with the effect of temperature and of chemical agents on the embryo; especially the very potent action of quinine and atropine on the primitive heart; and the comparative inertness of strychnia, curarin, and hydrocyanic acid on the more advanced fœtus. These results, considered with those relating to the diffusion of substances between mother and fœtus, have a practical bearing on the medical use of the various drugs during pregnancy. No less important therapeutically are the effects of change of blood-pressure in the uterine vessels; and a very practical though old question is fully discussed—namely, whether the umbilical cord should be divided early or late after delivery.

In certain experiments the coagulation of blood from the embryo was observed to be very slow. It would be interesting if it were shown that coagulability is acquired only shortly before the birth of the animal, when it first needs this property of the blood to guard it against hæmorrhage.

The most interesting section of the book is that which deals with the secretions of the embryo. The experiments of the author and other observers are collated, with the result of showing the early appearance and activity of some of the digestive fluids, and the comparatively late acquirement of the amylolytic faculty, particularly in the human species. The origin of the amniotic fluid is here discussed—how far it is derived from the maternal or from the fœtal blood, and whether and to what extent the fœtal urine contributes to its formation.

Prof. Preyer endeavours to find a satisfactory derivation for the word *amnion*. It does not appear to him possible to connect it with ἀμνίον, a receptacle for the blood of a victim in a sacrifice, with ἀμνός, a lamb, or other proposed sources; so he suggests an origin from α-, and μένος, strength, because of the delicacy and lacerability of this membrane. This may be physiological, but it is hardly philological. If we cannot be satisfied with the explanation that ἀμνίον in either sense was something which appertained to a lamb, we may conjecture an earlier origin from the root *am*-, around, seen in ἀμ-φί, *amputare*, and German *um*; in which case ἀμνίον may mean a receptacle or envelope.

There is no doubt that spontaneous movements of the embryo take place long before its maturity, and Prof. Preyer considers that muscular action occurs earlier than is generally supposed. He adduces the fact that the umbilical cord has already begun to twist in the human embryo at the eighth week, and asks, "How else could this take place, if not through the fœtal movements?" Now it seems improbable that the muscular movements should be entirely or even mostly in one direction; and therefore some more satisfactory explanation must be sought. We would suggest that the twisting may be due to the excessive growth of the umbilical arteries, so that they are obliged to take a tortuous course: and, when a slight obliquity has once been established, every pulsation will tend to increase the spiral, and every movement of the fœtus or of the mother will be taken advantage of; the cord and fœtus revolving together until, with the growth of the fœtus, the friction of the amnion puts an end to the rotation.

The section dealing with the senses of the embryo is scarcely less interesting than that on the secretions. In connection with this we find a discussion on the state of the nervous system before maturity: whether it be in a waking or a sleeping condition, or whether these conditions alternate with one another.

Among the appendices is one, by Dr. R. Ziegenspeck, of Jena, treating of the fœtal circulation. There are also several coloured plates illustrating the circulation and other subjects. The usefulness of the book is much enhanced by the addition of a list of the literature on the special physiology of the embryo. The books and papers in this list (552 in all) are numbered and indexed; and, whenever either of them is quoted in the text, its corresponding number is given in the margin for reference.

F. J. ALLEN

OUR BOOK SHELF

The Animal Parasites of the Sugar Cane. By H. Ling Roth, late Hon. Sec. to the Mackay Planters' Association. Reprinted from *Sugar Cane*, March and April, 1885. (London: Trübner.)

It is within the knowledge of most people that when a matter of this kind is under consideration, there are never wanting those who are ready with suggestions—for the most part based upon a foundation anything but practical or logical. Quacks are always at hand with their "cures," greedy for the gain which it is the object of their impositions to intercept. Experience and common sense alike show that but two courses here lie open: either the cane-crop must be rooted up and something else substituted in its place, or the most searching inquiries must be instituted into the life-histories and conditions of existence of the organisms working the mischief.

The value of any publication on such a subject must, from the above considerations, be proportionate to the extent to which it assists the farmer in dealing experimentally with his enemies. Looked at from this standpoint, Mr. Roth's modest little pamphlet cannot fail to be of great service to the intelligent planter, for it embodies, together with the results of the author's practical experience, a bibliography of all that has been written on the subject.

Planters are beyond doubt largely a conservative body, and it is well known that years ago when first the failures of the Ceylon coffee-crops became disastrous, the attention of the grower was in vain directed to the tea-plant—then flourishing as an ornamental shrub in the gardens of certain residents. The deaf ear has since been opened, and the mourning of the disappointed coffee-grower is now being turned into the joy of the successful tea-planter. Unfortunately the conditions of growth of the sugar-cane will not admit of so easy a solution of the problem as that available in the above cited case, but the refrain of the paper before us is *more biology*. Nothing whatever can be done until the world is fully familiarised with the life-cycles and conditions necessary for the existence of the said parasites. The success which has recently attended the study of the liver-rot among sheep may be instanced as an example of what can be done in the field of applied biology, and there are among us young and competent workers ready to take the task in hand should opportunity offer.

The facts narrated on p. 2 of the paper are anything but encouraging to those who would seek Government aid. Much can be done by Governments, and it may be that when corporate bodies realise that pests of the category of those now occupying our notice are formidable even as an armed force, they will see fit to turn attention to them.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Nomenclature in Elasticity

In reference to a communication of mine which you published not long ago (see Nature, vol. xxxi. p. 504) on this subject, I have pleasure in enclosing for publication, should you think fit, photos from three automatically recorded stress-and-strain diagrams made in my laboratory. The originals were traced on smoked glass, the glass plate then varnished to fix it, and used at once as a negative. Test-piece No. 9461, of which Fig. 1 shows the behaviour, was a very ductile piece of Swedish bar-iron, turned to ¾-inch diameter. The extensions were measured

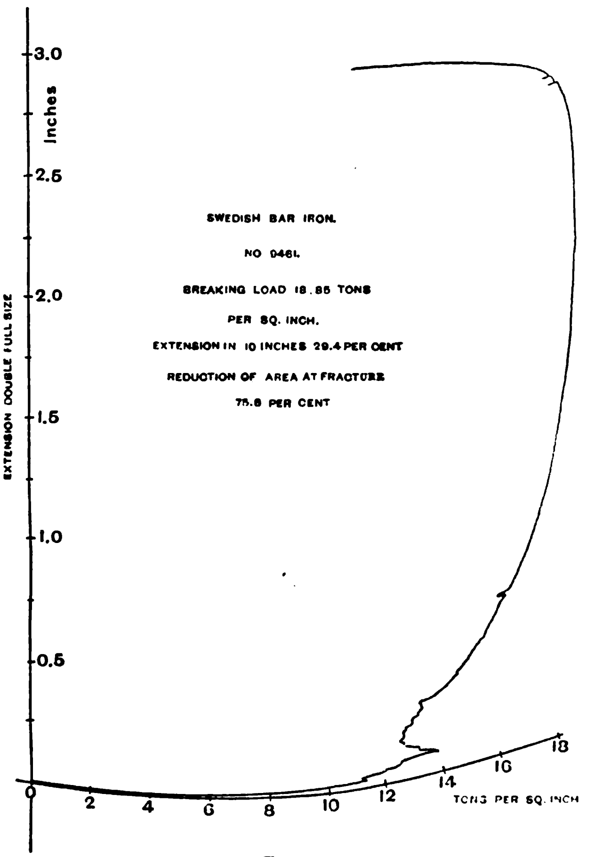

Fig. 1.

on a length of 10 inches, and recorded *double* full size; they are to be measured from the curved base-line, distances along which measure the total load on the piece (on a scale, as recorded, of about 1·9 tons per inch), and therefore the load per unit area (or, as I prefer to call it, the *intensity of stress*) up to the limit of elasticity, to which point the cross-section remains practically unchanged. The point where *instability* comes in is very marked, and also the release or going back of the stress after the material has "broken down." Lastly, the condition of local flow, or whatever it is to be called, is excellently shown. The material draws down in one place, so that the increase of extension, being confined to that place, is very small, and the total load diminishes, although the intensity of stress, on the now greatly reduced area, is much increased, as is shown further on in Fig. 4.

Fig. 2 is an autographic diagram similar to the last, taken from a piece of soft steel (No. 8397) 0·60 inch diameter and 10 inches long. It shows most of the same characteristics, except that the breaking-down is not preceded by any intermediate stage; the loss of elasticity comes very suddenly. The whole load was taken off the piece and then reapplied a number of times during the experiment, after the limit was passed, and the curves show most distinctly by their parallelism the (practical) constancy of the modulus of elasticity even up to the very maximum load. The curves show also the curious phenomenon—which I have often noticed in this form, and which, in some of its aspects, has been most carefully examined by Bauschinger and others—of increase of load borne, for a very limited time, after the material has been allowed a short rest—here only a few seconds. If the rest be for hours or days a similar thing occurs in a much more marked fashion.

Fig. 3 is a similar diagram from a piece of "S. C. Crown" iron, showing the same features, although in a less marked degree. In this case the load was removed and reapplied after the piece had begun to draw down visibly, and the curve to turn back, with the result of showing the piece to be still elastic up to the load it had just borne.

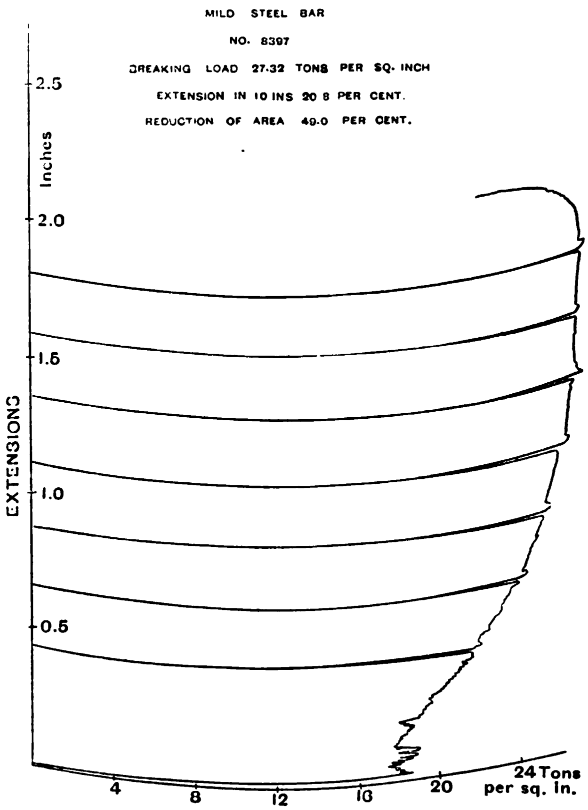

Fig. 2.

Fig. 4, which is a copy of a diagram obtained by consecutive measurements, not automatically, illustrates a question asked, I think, by Mr. Ibbetson. The diameter of the bar under test was measured each time the extension was noted, and the curve of actual stress on actual area (II.) is plotted out, as well as the usual load and strain curve (I.). The most interesting point about it is perhaps the way in which the curve ends nearly parallel to the axis, an excessively small additional extension corresponding to a very great additional intensity of stress. This arises, of course, from the fact that the extension is here confined to a very small length of the bar, the diameter and length of the main part of the bar remaining practically unaltered. If the extensions were plotted to stresses in this main part of the bar, the curve would take the shape (III.).

All these curves illustrate distinctly, I think, a point not very generally known, that the non-elastic extensions form really a curve passing through the zero point of stress and strain, just as do the elastic ones. It appears as if the *non-elastic*, the flowing or plastic state, were the *real* state of the material, the *elastic* condition being something consequent on the treatment which

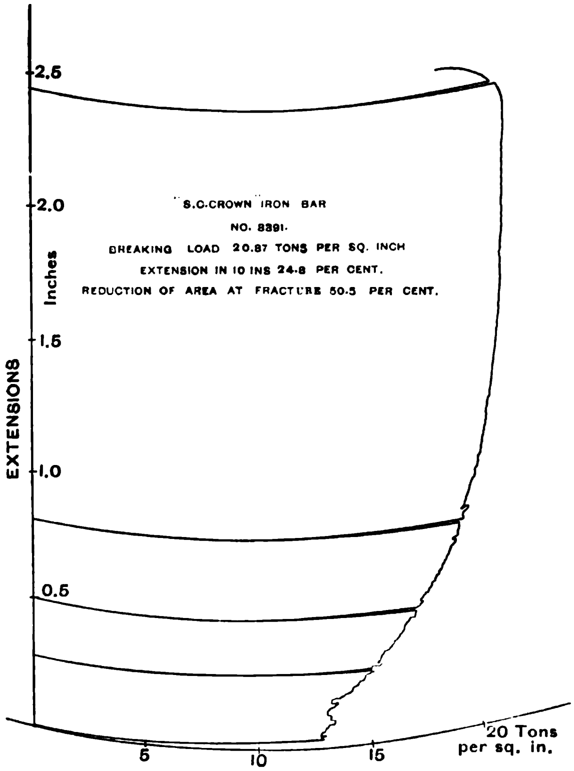

FIG. 3.

the material had undergone. I am bound to say, however, that I have no distinct evidence connecting the ratio $\frac{\text{limit of elasticity}}{\text{maximum load}}$ with the amount of previous work done on a material in manufacture.

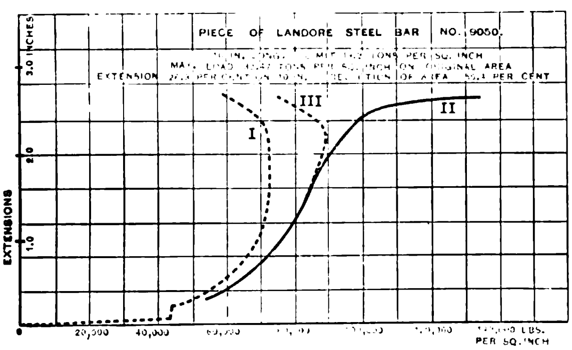

FIG. 4.

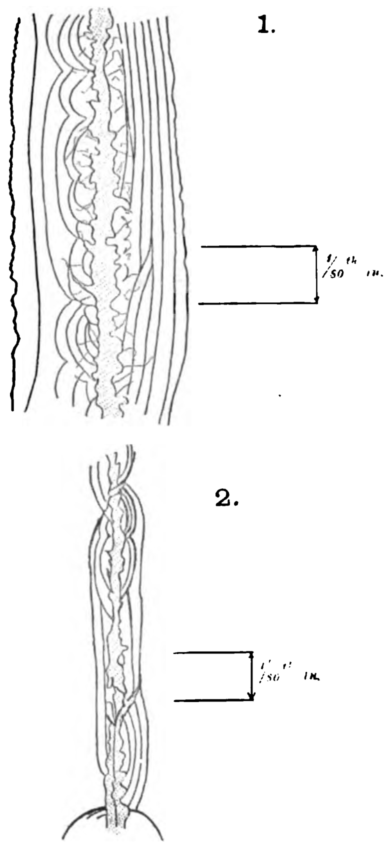
I should like to add that the credit of scheming and working out the very ingenious apparatus by which the autographic diagrams figured above were recorded belongs almost entirely to my friend Mr. A. G. Ashcroft, who has been working at the matter for me for some time. ALEX. B. W. KENNEDY

Spectra Produced in Glass by Scratching

A FEW weeks ago, while examining under the microscope a piece of glass on which a coarse scratch had been made by a file, in order to serve as a focussing mark in the determination of refractive index, I noticed a number of narrow, somewhat faintly coloured spectra running along both sides of the scratch. As I can find no account of such an appearance, and an examination of it seemed to throw a little light on the effects of a combined tangential stress and pressure on a brittle medium such as glass, I thought a short description of the phenomena might be interesting to the readers of NATURE.

The spectra (Figs. 1 and 2) run for the most part approximately parallel to the scratch, but those near the scratch are very much curved, the concavity being inwards, and often appear to commence and terminate at irregularities in the scratch. If the glass be left to itself after scratching, the spectra sometimes remain stationary, but not unfrequently spread outwards from the scratch; this process I have watched in three instances. In any case, sooner or later, the glass splits internally along the edge of the outermost spectrum, and sometimes along the others also. I was fortunate enough to watch this splitting in one instance: immediately before it took place the glass gave signs of great activity, the spectra waving about in the field of



FIGS. 1 and 2.—The shaded part in all the figures epresents the scratch.

view about three times in as many seconds, oscillating between two extreme positions (*a* and *b* in Fig. 3), and finally coming to rest in the position *b*, while the split developed with great rapidity from above downwards in the field of view. After this splitting has taken place, the spreading of the spectra ceases, and they generally, though not invariably, remain apparently unaltered. The time which elapses between the infliction of the scratch and the development of the split varies from a few minutes to several days or weeks.

The appearance is not shown by all scratches, but only by such as have produced considerable disturbance in the glass: thus they must be fairly deep and must produce some slight amount of splintering.

Next, as to the explanation of the phenomenon. Diffraction from the scratch is negatived by the great distance from the scratch to the spectra, and still more by the fact that they are farther apart the greater their distance from the slit; this important point was determined by careful measurement with a micrometer, using sodium light. They are clearly not due to polarisation, and examination between crossed Nicols failed to elicit any appearance indicating strains in the glass. The spectra seemed to be identical with the colours of thin plates, with which they agree in being much brighter in reflected than in transmitted light. The colours are also complementary in the two cases, as can easily be shown by the use of a micrometer eyepiece; the colour of the band lying on a certain division being noted, the moving of a suitably arranged screen cuts off the light from the mirror under the stage and allows that from a condensing lens above the stage to fall on the glass; the

3.

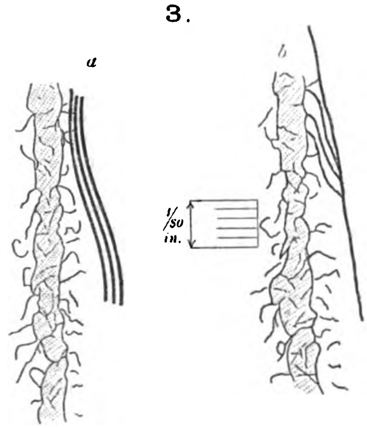


Fig. 3.

colour is then seen to change into its complementary, passing through white if the two lights are of suitable relative brightness. If the surface layers of the glass near the scratch are separated somewhat from those below, the interval forms a thin plate, and this would suffice to account for the spectra, as the separation would necessarily reach a maximum at the scratch, and we there find the spectra nearest together; moreover, along the edge of the outermost spectrum, the black of the first order is quite distinct wherever the spectra are broad enough to allow their colours to be distinguished. The splitting perpendicularly to the cleavage plane would then be quite analogous to that seen in other brittle

4.

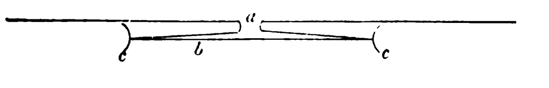

Fig. 4.—a = the scratch; b = the cleft under the torn-up surface layer; $c\,c$ = the splits.

substances, and as every one must have repeatedly observed it in cutting such substances as camphor, paraffin, or ice (Fig. 4 shows the condition of the glass on this supposition). That a tendency really exists in scratched glass for the surface layers to tear up we know from the fact that splinters of glass near the scratch will often keep peeling off for days together.

Birmingham, July 14

Prof. Sylvester's Article on "A New Example of the Use of the Infinite and Imaginary in the Service of the Finite and Real"

I should like to be allowed to mention that Mr. Buchheim has drawn my attention to the fact that one of the theorems in the postscript to my recent article in Nature contained in the formula—

$$P' : Q = \frac{P : Q}{\sqrt{P : P}\ \sqrt{Q : Q}}$$

is virtually given under a slightly different notation in the second edition of Grassmann's "Ausdehnungslehre," p. 141.

July 12 J. J. Sylvester

Rainfall of N.W. England

The rainfall on the coast-line of the Dee and the sea from Chester to Llandudno in the spring and summer months presents some interesting features. As a rule the amount of rain is the greatest at the Chester end in the spring months (April to June), and at the Llandudno end in the summer months (July to September). This is shown by the following table:—

	1882		1883		1884	
	Colwyn Bay[1] In.	Chester In.	Colwyn Bay In.	Chester In.	Colwyn Bay In.	Chester In.
April	3·01	3·59	0·68	0·79	1·32	0·92
May	1·54	2·16	1·86	1·09	1·37	0·94
June	3·39	3·95	2·15	2·94	1·15	2·06
	7·94	9·70	4·69	4·82	3·84	3·92
July	3·20	3·52	1·13	1·86	4·43	4·08
Aug.	3·47	2·52	2·19	2·64	1·35	1·05
Sept.	2·45	1·80	4·34	5·07	1·67	1·95
	9·12	7·84	7·66	8·57	7·45	7·08

That this result is not a mere coincidence will be gathered from the following statement of the rainfall last month (June, 1885) at Chester, Colwyn Bay, and Bagillt, this last being between the other two places, at a distance of fifteen miles from the former or twenty-five miles from the latter:—

June	Chester In.	Bagillt In.	Colwyn Bay In.
5	0·12	0·07	0·18
6	·38	·21	·20
7	·33	·29	·24
8	·11	·05	·01
16	·18	·15	·03
18	·10	·06	·05
19	·04	·02	·02
20	·16	·09	·03
23	·79	·46	·32
24	·13	·08	·02
29	—	·02	—
	2·34	1·50	1·10

It will be seen that on every day, except one, the rainfall was highest at Chester, Bagillt coming next, and Colwin Bay being the lowest. There must therefore be some definite law which governs this gradual decrease from east to west; and in the hope of drawing out the opinions of more skillful meteorologists on the subject, I venture to suggest the following explanation.

It is generally admitted that atmospheric currents travelling across the Atlantic from the south-west reach our islands charged with aqueous vapour almost to saturation. These, meeting the mountains of Wales and Cumberland, are driven up into a higher and colder region where the moisture is condensed into rain, causing a very heavy rainfall on the *western* slopes. Now if a line be drawn south-west from Colwin Bay, it will be found to pass over some of the highest mountains in Wales, so that *in spring*, when the air above these mountains is still cold, the moisture is so effectually condensed that there is little left to fall on the north-east side. But if a parallel line be drawn south-west from Chester it passes over no very high region, and the moisture is therefore less completely drained from the atmosphere. But, as the summer goes on, the mountain-tops become warmer and the condensation on them less complete, and then more rain is left to fall on the north-east side, *i e.*, at Colwyn Bay. And as the *summer* day temperature is higher at Chester than Colwyn Bay, less rain is condensed at the former place.

Chester, July 18 Alfred O. Walker

"Foul Water"

My attention has just been called to Mr. Shrubsole's letter under above title. Having been for several weeks past engaged in dredging off the North Wales coast, I have continuously noticed the profuse amount of gelatinous bodies diffused throughout the sea, evidently of the same character as observed by Mr. Shrubsole off Sheerness. They appeared here early in June.

The little bodies are distinctly visible on holding a bottle of sea-water up to the light. They vary in size from 1/16th to

[1] Colwyn Bay is about five miles east of Llandudno.

1/10th of an inch in diameter, and are spherical or oblong in form, the translucent membrane appearing under the microscope to be composed of minute particles and spicules imbedded therein.

As my observations included the examination of surface-life, the tow-net was continuously employed, and was always rapidly filled with so much gelatinous substance that it was difficult to pick out the Copepoda or other pelagic life. But although all of the bodies were perfect in form when taken in a bottle, the rush of water into the tow-net was sufficient to fracture them, the result being a mass of broken gelatinous *débris* (apparently vegetable) which clung tenaciously to the muslin of the net.

They appeared to be most numerous a few feet below the surface, and are distinctly visible on looking down into the water from the boat-side. Weather does not seem to affect them, being apparently equally prevalent on a calm or a rough day; but I noticed while rowing across from Penmaenmaur to Puffin Island, a distance of seven miles, that they were less plentiful about the middle of the entrance to the Menai Straits than nearer each side.

Early in June they were in profusion about the mouth of the Dee. Associated with them I have invariably found quantities of *Noctiluca*, which soon congregated about the surface of the collecting-jar, while the gelatinous spheres remained suspended in the water, and the *débris* from the tow-net fell to the bottom.

Any light that can be thrown upon the nature and appearance of these curious bodies will be much esteemed.

Liverpool, July 16 ISAAC C. THOMPSON

The Banner System of Drainage

OUR attention has been called to a paragraph in NATURE (p. 221) in which you review, "Hygiene, a Manual of Personal and Public Health," by A. Newsholme, M.D., Lond. In your review or criticism you state that you "do not agree with Dr. Newsholme in thinking the 'Banner system of drainage one to be recommended,'" and you say your system coincides with that of *several practical sanitarians*. Now, as this is calculated to do harm, and as our system *has* been *approved* of by the *most* eminent sanitarians, and has also obtained the highest awards at all the most important exhibitions, including a Gold Medal at the Health Exhibition, 1884, and has been successfully applied to many noblemen's mansions, hospitals, and other important public buildings, as well as to thousands of houses, we hope you will think we are justified in asking you to tell us your reasons for expressing the unfavourable opinion you have, and that you will oblige us with the names of the "practical sanitarians" you refer to.

We are unacquainted with Dr. Newsholme, and until the paragraph in NATURE was pointed out to us we were not aware of the existence of such a gentleman. Nevertheless, in fairness to him as well as to the public, we will thank you to insert this in your next issue.

BANNER BROTHERS AND CO.,
per MANAGER

11, Billiter Square, E.C., July 14

[Exception having been taken by Messrs. Banner & Co. to a statement which appeared in our last issue in the review of the Elementary Text-books of hygiene, having reference to this system, we have no objection to state that (in the opinion of our reviewer) the Banner system, although correct in principle, is unnecessarily complicated in the details of its working. The "Banner Patent Closet" shown in diagram in the book referred to is a modification of the pan-closet, a closet which has been universally condemned and as almost universally acknowledged to be incapable of improvement.—ED.]

ON THE USE OF CARBON BISULPHIDE IN PRISMS[1]

IN the *American Journal of Science* for April, 1885, there is an account of some experiments of Dr. Draper's which will be read with great interest by all who have used liquid prisms in a spectroscope. The following is an abstract of the article:—

The photographs which were taken in the research on the presence of oxygen in the sun were obtained by the use of two hollow prisms filled with carbon bisulphide. The same prisms had been used by Mr. Rutherford to produce his celebrated solar prismatic spectrum. The photographic work for the oxygen research was done in New York in a back room of the third storey of Dr. Draper's residence. The temperature of the room was remarkably uniform and the definition was all that could be desired. When, however, the research was continued in the new physical laboratory which Dr. Draper completed in 1880, it was found practically impossible to use carbon bisulphide prisms in the room owing to the rapid variations of temperature. No definition whatever could be obtained with the same prisms which had performed so well previously. In consequence the use of these prisms had to be abandoned and a series of experiments made to obtain the spectrum by other means. A Rutherford silvered glass grating of 8640 lines to the inch and a train of six flint glass prisms made by Steinheil were each tried. The grating was not found satisfactory, partly because want of light rendered long exposure necessary, partly because the definition was not so good as had been originally obtained from the bisulphide prisms. The flint prisms gave excellent definition, quite as good as had been obtained with the bisulphide prisms, but there was less light, and it was found impossible to get the line H on the photographic plate, through the train. The dispersion between G and H with the six flint prisms was not quite so great as with the two bisulphide of carbon prisms.

Among the earliest experiments which were undertaken in the new laboratory was a series made to test the performance of a bisulphide prism of Thollon's construction, made by Hilger, of London. This prisms consists of a glass bottle having two plane sides, making an angle of 90° with one another, upon which are cemented two prisms of flint glass 4 by 2 inches on the face, having each a refracting angle of 18°. The refracting edges of these glass prisms are opposed to that of the bisulphide prism. Hence the refracting angle of the compound prism is 54°. The same difficulties were experienced with this prism as with the Rutherford bisulphide prism. Owing to the temperature variations the lines were "woolly" and no definition was possible. It was found that the dispersion power of the Thollon prism was equal to that of about four of the Steinheil flint prisms; and this fact, together with the unsatisfactory character of the results obtained with the train of prisms as well as with the grating, led Dr. Draper to undertake an investigation into the cause of this unsteadiness of the bisulphide with a view to remedying it if practicable.

While using these prisms Mr. Rutherford made an important observation. He noticed that if a good prism which, with a high power, refuses to define the soda line (a more stringent test than soda lines), is violently shaken and then placed in position, it will for a few minutes define beautifully, but gradually settle to its former condition.

It occurred to Dr. Draper, therefore, that possibly the striæ caused by convection-currents produced by inequalities of temperature, and which caused the bad definition, might be destroyed by an active agitation of the liquid. He therefore placed a small propeller wheel in the bisulphide contained in the Thollon prism, passing its shaft through the stopper so that he could drive it at any desired speed by an electro-motor. The result was marvellous: by thus keeping the liquid in agitation all inequalities in its density were prevented, and the definition became excellent. Thus arranged, the Thollon prism was found to be superior, especially in quantity of light, to the Steinheil train of prisms.

Now another source of error was developed. Although when the propeller was running the definition of the bisulphide was not affected by changes of temperature, yet now these changes of temperature, by changing the refractive index of the liquid, caused a continual shifting of

[1] Being an account of experiments made by the late Dr. Henry Draper, of New York.

the position of the lines in the spectrum. It is obvious, therefore, that during an exposure of any considerable duration, such as is often necessary with faint spectra, this change of position of the lines due to temperature-change would absolutely destroy the definition n othe photographic plate. The shifting of the lines on the plate were found to amount to 0·1 inch for 1° F. An even-temperature box of metal containing cotton was made, and the prism arranged within it. The temperature was regulated by a thermostat contained within the box, consisting of a compound bar of brass and ebonite, which turned on or off the gas as necessary. Afterwards one even-temperature box was placed within another, and it was then found that the temperature could be kept uniform for a long time within 0°·1 F., and then the lines did not shift at all so much as the distance between the sodium lines. With this arrangement many hours were taken by the box to settle down to a new temperature, so that, if a change of over 10° F. is to be made in the temperature of the box, it is doubtful whether the spectrum would become stationary in less than twenty-four hours.

The results have a two-fold bearing. In the first place they prove that, by the simple expedient of stirring the liquid in the prism, all striæ may be prevented and the definition rendered perfect. The practical value of this simple expedient is very considerable. The Thollon bisulphide prism, while giving seven-eighths as much dispersion as six flint prisms, gives four times the light in the entire spectrum and eight times the light in the region near G. For photographic purposes, now that the definition can be made permanently sharp and the shifting of the lines prevented, this prism must replace trains of glass prisms, and even gratings, unless these are of large size and are used with telescopes of proportional aperture.

In the second place, this investigation has called attention in a very marked manner to the change in refracting power with change of temperature. This subject has already been discussed by several authors, who agree with the statement of Arago and Neumann, that for glass the law is the reverse of that given for liquids, and that the refractive index increases with the temperature. In the case of the Thollon prism the refractive index increases as the temperature diminishes. As Mendenhall has shown that no change takes place in the angle of the prism with change of temperature, it follows that the observed change of refractive power of the Thollon prism is a differential result due to the excess of the index of the bisulphide in one direction over that of the glass in the other.

It will ever be a source of regret that Dr. Draper did not live to complete the research to which the foregoing investigation was preliminary. With his new and admirably equipped laboratory and with this powerful and thoroughly corrected photographic spectroscope at his command, no one can doubt that he would have secured with it results of the highest value to astronomical, and especially to solar, physics.

PREVENTING COLLISIONS WITH ICEBERGS IN A FOG[1]

THE recent accident to the steamer *City of Berlin* emphasises the importance of devising practical methods of ascertaining the proximity of icebergs in a fog. The precautions adopted by Capt. Laud, though they saved the lives of more than 1400 passengers, and prevented serious damage to the vessel, did not prevent contact with the berg. Even the "look-outs" were unaware of the proximity of the iceberg until it was actually upon them.

Under these circumstances the method proposed by Mr. Frank Della Torre, of Baltimore, deserves consideration. His experiments indicate the possibility of obtaining an echo from an iceberg when in dangerous proximity to a ship. Mr. Della Torre believes that even an object offering so small a surface as a floating wreck may in this way be detected during a fog in time to prevent collision. However this may be, it is certain that his method is worthy of a careful trial at sea, and that preliminary experiments, recently made in the presence of Prof. Rowland, of Johns Hopkins University, and the present writer, have demonstrated the feasibility of producing well-marked echoes from sailing-vessels and steamboats at considerable distances away.

These experiments were made on the River Patapsco, near the head of Chesapeake Bay, at a point about seven miles from the City of Baltimore. The party proceeded down the river in a steam-launch to the selected place, where the distance from shore to shore appeared to be about three miles.

The launch was kept so far from land as to prevent the possibility of mistaking an echo from the shore for one produced by a passing vessel.

The apparatus employed consisted of a musket, to the muzzle of which a speaking-trumpet had been attached. This gun was aimed at passing vessels, while blank cartridges were fired. After a longer or shorter time, according to the distance of the vessel, an echo was returned.

The ordinary river-steamboats, and schooners with large sails, returned perfectly distinct echoes, even when apparently about a mile distant. At shorter distances the effects were, of course, still more striking.

In order to test the effects under the most disadvantageous circumstances, blank cartridges were fired in the direction of an approaching tug-boat. The surface presented was, of course, much smaller than if the boat had presented its broadside to the launch. As the boat approached bow on it corresponded to a target somewhere about six feet square, presenting a convex surface to the impinging sound-wave. Even in this case a feeble echo was perceived when the boat was at a considerable distance (estimated to be nearly one-quarter of a mile). That any echo should have been perceived at all under such circumstances was a surprise. The sound was heard only by the closest attention, but in the case of larger vessels the effects were very distinct and striking.

Experiments were made which demonstrated the fact that the speaking-trumpet attached to the gun was of material assistance in giving direction to the sound-impulse, and in intensifying the audible effect.

Mr. Della Torre claims that a steam-whistle or siren, combined with a projecting apparatus like a speaking-trumpet, will prove as efficient as the gun.

During the experiments on the Patapsco River a curious rumbling effect like the rolling of thunder was often observed, which continued for some seconds. A similar sound was also noticed, as an echo from a well-wooded shore; but the effect alluded to above could not have been due in any way to the land, as the sound commenced immediately upon the firing of the gun, whereas the shore was distant at least a mile or a mile and a half.

The sound was probably due to the presence of ripples on the surface of the water, as the effect was much less marked when the surface was smooth. Such a sound might prove a disturbing element of importance in a rough sea, but would hardly be sufficient to prevent the detection of an echo from a large iceberg. Had shots been fired periodically from the bow of the *City of Berlin* it can hardly be doubted that the presence of an obstacle ahead would have been discovered in time to prevent the collision that actually occurred.

ALEXANDER GRAHAM BELL

[1] From *Science*

THE AURORA[1]

I.

MR. TROMHOLT has rendered a great service to science by the travels and observations recorded in these volumes; indeed, it would not perhaps be going too far to say that we have here, brought before us in the most interesting manner, one of the best organised attempts to study the aurora that has been made for many years, the credit for which must be given to the organisers of the International Polar Research Expedition of 1882-83. Mr. Tromholt's duty was to observe all auroral phenomena in the Lapp settlement of Koutokæino, and above and beyond this to observe in such a way that, in combination with other observations arranged for at the Norwegian station at Bossekop in Finmarken and the Finnish one at Sodankylä in the centre of Finland, certain conclusions might be arrived at regarding the height at which the various displays take place.

The results, however, recorded in these volumes are by no means limited to the height of the aurora. The constant study afforded to Mr. Tromholt and his *confrères* at the other stations of one of the most awe-inspiring phenomena which it is given to man to witness have permitted generalisations to be reached and hypotheses to be broached of the greatest scientific interest; and this must be our excuse for dwelling on the general results of this recent work in the present article, including also a notice of those of Nordenskjöld in the *Vega* Expedition 1878-79.

Let us begin by considering the general phenomenon of an aurora as seen in Northern Europe. Mr. Tromholt gives the following general description of a great display:—

"It is a lovely evening in spring or autumn. The light is fast fading away in the west, and one star after another comes out of the azure sky. Suddenly a peculiar vibrating luminosity appears high up in N.E., now with a soft purple tinge, and now diffused with long narrow streamers, reaching to the Pole star, or beyond. It is wafted to and fro like a curtain before a light breeze, and its light becomes more and more intense as Night spreads her dark veil over the sky. Suddenly the luminous cloud is furrowed from one end to another by a bunch of streamers, the lower, emerald-green ends of which rest almost on the horizon, while the upper diffuse points, which flame with a purple lustre, reach right up to the Zenith. Streamer oscillates by streamer, more and more follow, and, with a rapidity almost startling, the aurora expands westwards, and shortly after the whole northern sky is a bath of fire. Like a curtain woven of light and colour the streamers hang fairy-like in the air; here and there they form large graceful folds and sway to and fro in wonderful beauty, as if the wind played on the radiating drapery. Red and green play alternately in the lower border of the curtain. For a few minutes longer the marvellous play of light lasts, the varying forms, colours, and motions charm the mind as much as the eye—the forces are then exhausted, the lovely picture grows more and more obscure, and the forms are dissolved into large soft clouds of light, covering nearly the entire northern half of the heavens.

"Down by the horizon there is still, however, great activity, as here a couple of arcs have formed, the constant-changing play of which enchains the spectator during the *entr'acte* between the past and coming scene of the sublime drama which Nature performs on the great stage of heaven: now faint, then strong, soon symmetrical, soon serpent-like, in one moment split into three or four arcs, and again gathering into one, now woven with all the lovely colours of the rainbow, now throwing forth rays and resembling the ornamental pipes in an enormous organ—such is the spectacle I gaze on.

"At this moment a narrow, white streamer suddenly leaps up from the horizon in the east, a similar one appears in the west; they both grow rapidly in length, their points meet, and a grand arc spans the sky right above the observer. Simultaneously two long and broad sheafs of streamers, woven of white and red filaments, develop at the bases of the arc. The luminosities on the northern sky again catch fire, and soon after the whole heavens in the north is again ablaze. Quicker and quicker the motions become and intenser the colours, higher and higher the streamers travel, the points approaching the great arc, which is moving slowly southwards. Other groups of streamers form at greater altitudes, in east and west, and the luminous masses cover more and more of the sky. Now a number of white bands suddenly appear overhead, shoot right across the sky from east to west, and then rush southwards, and vanish. By this time the luminous masses have crossed the zenith, the points of the streamers meet in a spot high in the southern sky, while in the east and west the sphere of the streamers moves gradually southwards. A wonderful spectacle is now presented to view. In every direction the whole sky is covered with bunches of streamers, all of which point to this spot—the magnetic zenith—and transform the vault of heaven into one gigantic lustrous cupola, the beauty of which no pen can describe, no brush depict. All the marvellous *nuances* of colour of the rainbow contribute to ornament the vault; here is the tender green of the emerald, the grand purple of the ruby, and the charming blue of the sapphire, all blended together in a thousand shades. Here gamble a flock of yellow-green flames, and there mighty pillars rise as if to support the luminous vault, while yonder the sky is covered with a transparent drapery shot with red, behind which dazzling white streamers stand forth. It is the auroral corona.

"A lovelier spectacle is not given the human eye to behold; he who has not seen it cannot form an idea of its magnificence—it defies description.

"For a moment the glorious, luminous vault remains thus in majestic beauty, then the supporting arches tremble for a moment, and fall, the faint light-clouds remaining in the southern sky vanish, and the aurora recedes to the northern sky. Here the streaming and play of colour continues for a while in manifold variation; but the area of the luminosity grows smaller and smaller, and moves steadily downwards to the horizon. A remarkable phenomenon now occurs in the soft luminosities, which still stand high in the northern sky: they appear to leap upwards with the rapidity of lightning, and then disappear; in several other spots similar clouds come forward and chase each other over the sky. The eye is hardly able to follow their strange gambols. Again the streamers grow in length, the light-clouds cease their play, and once more the streamers approach the zenith. But now they do not cross it; they remain in majestic rest for a few seconds, and then slowly disappear.

"Hour after hour this marvellous display continues in the northern sky, now stronger now fainter, and often it does not cease before the first streaks of dawn appear in the east."

It must not be imagined, however, that the displays generally are of this brilliancy; auroræ are generally much weaker, and in these cases the phenomena are different. Here is a general description of a weak aurora:—

"The sun set some hours ago. The purple glow in the west has disappeared, myriads of stars stud the dark canopy. Far down on the horizon, in north-west and north, lies a faint vague cloud of light, upwards and downwards fading into the sky . . .

"Soon after, tiny spots of intense light begin to appear in the luminous cloud, while at times the entire oscillating luminosity disappears from the sky. But still the light is

[1] "Under the Rays of the Aurora Borealis." By S. Tromholt. Edited by Carl Siewers. (London: Sampson Low and Co., 1885.)

increasing in force, and in a few moments a broad arc of light stretches along the north-western sky, resting both its bases on the horizon in north-east and west, and whose highest point lies a few degrees above the horizon in north-north-west. Upwards the light is gradually lost in the sky, downwards the intensity is greatest, and the lower edge stands sharply out. Solitary, stronger spots of light, now here, now there, travel, with an unsteady motion, at times right or left through the arc, again to disappear in the cloud. Following the arc attentively it will be seen to rise gradually, its point of culmination travels upwards, and the distance between the two bases becomes greater and greater. The colour of the light is nearly white, with a weak yellow-green tinge, which is easily discovered by comparing it with the cold, white light of the Milky Way. Suddenly energy and life become manifest in the phenomenon. The lower edge of the arc changes in an instant into a small, intense stream of light, which is sharply defined by the dark space below —the 'dark segment'—appearing black or faintly violet. Higher up the luminosity gathers into a broad, but fainter arc, running parallel with the other. Only for a moment does the aurora retain this distinct form; stronger waves of light begin to appear in the lower arc, which soon generate groups of intense, short, and perpendicular streamers, reaching the upper arc, which sway right and left, at the same time travelling east or west. Below, the ends, strong in light, cut down into the dark segment, whose sharp curve is thereby broken. Of the upper arc only fragments now remain, while the lower is dissolved into quivering bunches of streamers, which die out one after another as new ones are being lit in their place. They move, here slowly, there quickly, oscillating apparently to the right or left, but it is impossible to say whether it is really the streamers which move horizontally, or merely the light which passes from streamer to streamer without the latter shifting their position.

"But this display is only of short duration, the streamers soon lose their motion and light, and in a few minutes there remain only some pale, diffuse luminosities. Slowly these now gather, until another arc is formed. It is not so symmetrical, and does not possess the classical rest of

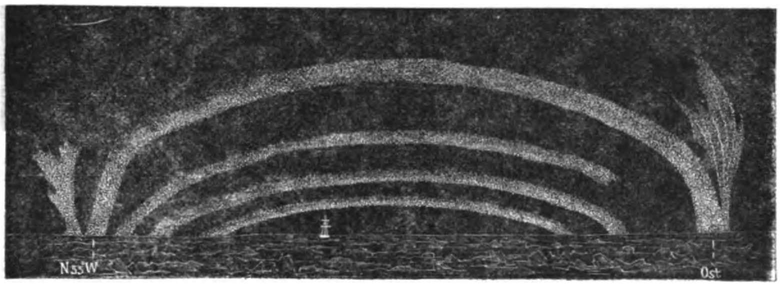

FIG. 1.—Auroral Arcs, Nordenskjöld.

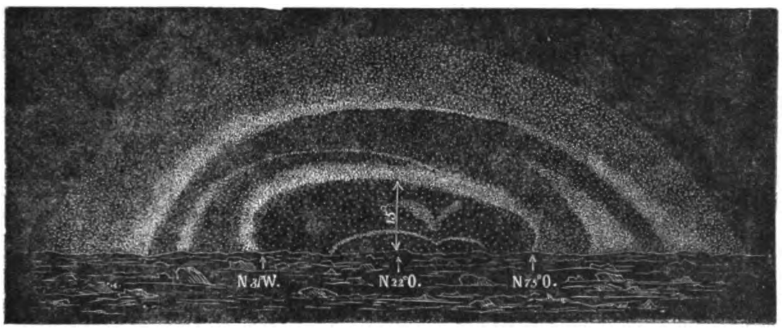

FIG. 2.—Auroral Arcs, Nordenskjöld.

the former. Constantly it changes form, position, and intensity until a fresh burst of streamers occurs; in two or three places the light shoots up into bunches of long streamers between which the space is nearly dark; in another second the streamers are isolated in groups, which, like the former, gracefully sway to and fro, their faint points reaching nearly up to the Pole star. The lower ends are broken at various heights, and develop as they move the soft colours of the rainbow. The culminating point in the display has been reached. The streamers vanish one by one, the light pales, and the remnants in the sky again form into a long, low-lying arc. Only for a short time it retains this pronounced form, the edges become obscure, the centre follows, and finally the last faint indications of the aurora sink into the unfathomable darkness of space."

Now the great variety in the appearance of the aurora depends to a great extent upon the various mixtures of certain component features. These have been designated *auroral arcs*, often very narrow, often degenerating into broad bands; *auroral streamers*, single or multiple shafts of light of various colours, nearly always vertical in direction, and long or short, with lateral and vertical motions; the *auroral corona*, a brilliant point near the zenith, from which, in most brilliant displays, streamers seem to radiate in every direction, the heavens putting on the appearance of a bright ribbed dome; and, finally, *auroral clouds*, which are amorphous and most irregular in their distribution.

Before we proceed further with more detailed descriptions of these various features, each of which in the main is seen more richly from certain positions on the earth's surface than in others, or puts on different aspects, a word must be said about the magnetic basis of the whole phenomenon, since it has long been known to be connected with the *magnetic* poles of the earth.

In the first place, the mariner's compass or declination-needle indicates the direction of the magnetic pole. At the present time in London the needle points 18° to the west of true or astronomical north; hence, if auroral arcs were seen here to-night, their highest points would be nearly certain to be west of north. Next, the dipping- or inclination-needle (a very cheap and admirable form of which is now sold by Mr. Casella) points to the magnetic zenith, which now in London lies 22° north of the true or astronomical zenith, in the magnetic meridian joining the north and south magnetic points of the horizon. Hence, if an auroral corona were seen here to-night, it would be nearly certain to lie in a point 22° north of the zenith.

Let us limit ourselves for the present to the arc. In our latitudes, as has been said, it is seen to the west of north, generally low down near the horizon; but in the far north on the same magnetic meridian as ourselves it is seen east of south, while also in the far north, but in a widely different longitude—that of Behring's Straits—it is seen north-north-east.

Evidently, then, this arc—this "common auroral arc," as it has been called by Nordenskjöld—is produced by a ring at some height between us and the north pole, but its centre does not lie at the north pole. Putting such observations as those referred to together, Nordenskjöld inferred the centre to be near the magnetic pole but not at it, in 81° N. lat. and 80° W. long., the thin ring of light having a radius of 18° and a height of 200 kilometres.

This, then, was Nordenskjöld's main conception—an immovable common arc (a permanent stria, to speak in vacuum-tube language), though he acknowledged additional ones sometimes, and shows by his observations that they are not always concentric.

He also attempted to explain the frequency and positions of arc auroræ in different places by dividing the polar lands into five concentric regions (see NATURE, vol. xxv. p. 368).

In Mr. Tromholt's volume we find what may prove to be an immense advance on this view. He holds that *the auroral zone moves northwards and southwards daily, yearly, and eleven-yearly.*

Again, to speak in vacuum-tube language, instead of one rigid stria, we may have many striæ, and these moving towards or away from the auroral pole as ordinary striæ move towards or away from the negative pole.

Next, as to the proofs of this movement, some more quotations from Mr. Tromholt may be given:—

"The daily period is apparent by a maximum of frequency and development which in most places in the globe occurs one to two, or three hours before midnight. This maximum seems, however, to occur *later* the nearer we approach the magnetic pole. This will be clear from the following series, in which the figure in parenthesis denotes the geographical latitude and the other the hour when the aurora attains its maximum in the place named:—

"Prague (50), 8¾; Oxford (52), 9¼; Kendall (54), 9¾; Makerston (56), 9⅓; Upsala (60), 9½; Christiania (60), 10; Bergen (60), 9⅘; Bossekop (70), 10½; Pustosersk (70), 11-12; Quebec (47), 10⅓; Fort Carlton (53), 12¼; Fort Simpson (62), 12; Point Barrow (71), 13½.

"For the Aurora Australis continuous series of observations are almost entirely wanting. It seems, however, from the fragmentary material which we possess, that the daily period for this does not differ from that of the Aurora Borealis.

"The individual types of the Aurora Borealis seem, like the phenomenon itself, to be confined to periods, and to attain their greatest frequency and highest development at certain periods. Thus, it appears from the observation of the previously mentioned French expedition to Bossekop, that the arcs appear on an average at 7h. 25m.; the streamers at 8h. 26m.; the auroral clouds at 11h. 18m.; the auroral waves between 13h. 12m. and 13h. 53m.; the intensest colours at 10h. 11m., and the greatest brilliancy between 10h. and 11h."

Next as to the yearly change.

Weyprecht was the first to advance the view that the auroral zone is furthest south at the equinoxes, and furthest north at the solstices. On this point Mr. Tromholt writes:—

"My researches have led me to endorse Weyprecht's theory. I feel satisfied that the *Aurora Borealis moves towards the autumnal equinox southwards, and then northwards, reaching its furthest northern limit about solstice. After this it again moves southwards, being in its most southern position at the vernal equinox, when the movement is again in a northerly direction.*

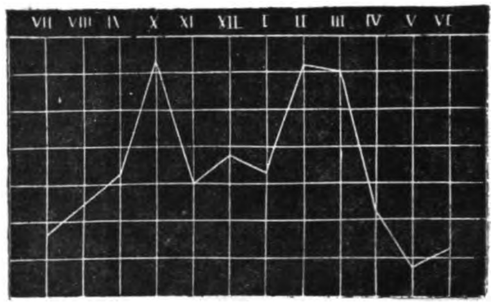

FIG. 3.—Curve of yearly auroral frequencies, Fritz. The Roman figures indicate the months.

"From this it follows that the two maxima occurring in the Temperate Zone at the equinoxes must approach each other more the further north the point of observation is situated. This is, in fact, the case. As some examples, I may mention that, whilst the two maxima occur in March and September in St. Petersburg, Åbo, Stockholm, Christiania, Worcester (Mass.), and New Haven, they occur in February and October in Aalesund, Newberry, Quebec, and Newfoundland; in December to January in Hammerfest and in January at Fort Reliance. Very instructive in this respect are also the observations from the three Greenland stations: Upernivik, Jacobshavn, and Ivigtut. At Ivigtut, the southernmost of the stations, the yearly maximum must certainly be said to occur in January, but there is a second maximum towards the autumnal equinox. At Jacobshavn, eight degrees further north, there is but one distinctly marked maximum, in January, and at Upernivik, the northernmost of the stations, the maximum falls at the winter solstice more marked and dominant than anywhere else in the world."

(*To be continued.*)

THE ECLIPSE OF CHUNG K'ANG

IN China an eclipse of the sun is, and has in all ages been, considered as a bad omen. Indeed anything which disturbs the regularity of the movements or appearances of the heavenly bodies is so considered. "On the first day of the last month of autumn the sun and moon did not meet harmoniously in Fang." This passage occurs in the ancient classic, the "Shu Ching," in the "Yin Cheng," one of the books of the Hsia dynasty. Chinese commentators say that this passage refers to an eclipse of the sun in Fang, the fourth of the Chinese twenty-eight constellations. The last month of autumn, according to the Hsia Calendar, is the ninth month, the month after that month which contains the autumnal equinox.

The constellation Fang extends from about π to σ Scorpii, a distance measured along the ecliptic almost equal to 5°. Approximately the limits of Fang were as follows:—

2250 B.C.	between	184° 12′	and	189° 12′
2150 ,,	,,	185 34	,,	190 34
2053 ,,	,,	186 56	,,	191 56

An eclipse near the constellation Fang will satisfy the conditions of the text, as at that early period, and for a great many centuries after, the Chinese were unable accurately to determine the position of the sun among the stars.

The date of the accession of the Emperor Chung K'ang, during whose reign this eclipse is said to have occurred, is unknown. Indeed all the dates in Chinese history before the Chou dynasty are unknown, the dates given in the common chronology being erroneous. The great importance of fixing the date of this eclipse is therefore apparent.

In all probability Chung K'ang reigned some time between the years 2050 B.C and 2158 B.C. I have therefore examined all years between these two dates on which an eclipse of the sun, in the constellation Fang, and on the first day of the ninth moon might be looked for.

Mr. Newcomb has published tables for the calculation of eclipses between the limiting dates 700 B.C. and 2200 A.D. I have extended these tables so as to embrace all eclipses of the sun between the dates 2200 B.C. and 2200 A.D. These tables thus extended I have used in the examination of this eclipse.

We might expect such an eclipse on or near the following dates:—

−2154 + ·64	years.	...	...	−2164 + ·82	years.
−2135 + ·25	,,	...	...	−2145 + ·43	,,

The dates on the left are the years and fractions of a year on which the ascending node is in longitude 180°, those on the right the years on which the descending node is in longitude 180°. The minus sign indicates B.C.

The situation of the capital of Chung K'ang is a disputed point. Some hold it was at An Yi Hsien, in Shan Hsi, latitude 35° 8′ N., and longitude about 111° 30′ E. of Greenwich; others say it was at T'ai K'ang Hsien, in Honan, latitude 34° 7′ N., and longitude about 115° E. of Greenwich.

Gaubil calculated the eclipse of the year 2154 B.C. to be the one in question. During this eclipse, however, it was night in China.

On October 22, 2136 B.C., the ninth of the cycle of days, the day Yen Shen, there was an eclipse of the sun, visible in the north of China. At An Yi Hsien it commenced about 10 a.m., and was over about half an hour after noon. The magnitude was about ·5. The longitude of the sun at the moment of true conjunction was 191°·38, so that the eclipse took place very near Fang. The day was the first of the ninth moon.

In the following year, 2135 B.C., on October 11, the third of the cycle of days, the day Ping Yin, there was an eclipse of the sun, also visible in the northern hemisphere. At An Yi Hsien the eclipse began about 4.30 p.m., and lasted till about 7 p.m. The magnitude was ·58. At the time of conjunction the longitude of the sun was 180°·28, so that the eclipse took place near Fang. Strictly speaking, October 11 was the first day of the eighth moon, but we need not expect the Chinese at that early date to have been able to determine the time of the equinox to a few hours.

We meet with no other eclipse visible in the north of China, and fulfilling the required conditions, till the year 2071 B.C. On October 23, the fifty-first of the cycle of days, the day Chia Yin of this year, there was an eclipse of the sun. At T'ai K'ang Hsien it began a few minutes after seven in the morning, and was over about 9.30 a.m. The magnitude was ·34. At conjunction the longitude of the sun was 193°·2. This eclipse also satisfies the required conditions near Fang, and occurring on the first day of the ninth moon.

The eclipse of the year 2127 B.C. deserves consideration, as it is generally considered to have been the eclipse in question. On October 13 of this year, the forty-seventh of the cycle of days, the day Keng Hsii (all dates are given according to the Julian calendar), there was an eclipse of the sun. The "Bamboo Books" say that this eclipse took place in the fifth year of Chung K'ang, the thirtieth of the cycle of years in the An Sunn and on the first day of the ninth month, the day Keng Hsii (forty-seventh of cycle). This account of the eclipse must have been the result of an after-calculation, and is a proof of the wonderful accuracy to which the Chinese astronomers attained in calculating back past eclipses. In this eclipse they are right in every particular. However, this eclipse was not visible in China so far south as either An Yior T'ai K'ang. The following table, which approximately gives the southern line of simple contact of the eclipse, shows this clearly:—

Latitude	Longitude
66° 14′ N.	96° 10′ E.
60 23 N.	139 27 E.
55 33 N.	152 28 E.
52 7 N.	158 35 E.

From the above investigation we see that the eclipse referred to in the "Shu Ching" in all probability must be that of one of the years 2136 B.C., 2135 B.C., or 2071 B.C.; which of these dates is to be taken must be determined by other considerations. The eclipse of the year 2136 B.C. may be the one in question. It occurred in the middle, the busiest part, of the day. A total eclipse would agree better with the accounts as given in the "Shu Ching." The hurry and bustle occasioned by the total want of preparation to perform the customary rites, and the penalty of death inflicted on the two astronomers, Hsi and Ho, seem to point to some adequate cause. However, I believe a great part of the account as given in the "Shu Ching" is legendary. It is taken for granted that Hsi and Ho were able to predict eclipses, and it is stated they were put to death because, giving themselves up to pleasure, they neglected their proper duties. But the Chinese at that early period, and for many centuries after, were not able to predict eclipses. They were not even able to observe the place of the sun with any degree of accuracy, which is proved by their Calendar so often falling into confusion. That the account of the eclipse itself is true, there is no reason to doubt. It is referred to in the "Tso Chuan," a book written about the time of Confucius. However, that the astronomers Hsi and Ho were put to death because they failed to predict the eclipse, appears very doubtful. It is much likelier they were put to death for rebellion, or some other political reason. Summing up the above investigation, we see that between the years 2164 B.C. and 2042 B.C. no eclipses of the sun in Fang, and on the first day of the ninth moon, were seen in the north of China, except in the years 2136 B.C., 2135 B.C., and 2071 B.C.

P.S.—In NATURE, vol. xxxi., p. 91, the eclipse of Thucydides is mentioned as having occurred on August 3, 431 B.C., and that, calculating this eclipse with Hansen's tables, the greatest phase falls at 5h. 9m. p.m., and the magnitude is ·75. Using Newcomb's tables of eclipses, I find the greatest phase falls at 6h. p.m., and that the magnitude was ·91. S. N. K.

NOTES

SIR L. PLAYFAIR asked the Secretary to the Treasury on Monday whether any answer had been given to the application of the Marine Biological Association for aid in establishing a station on Plymouth Sound to investigate the marine fauna and flora, especially in their relation to the food-fishes of these islands, and for which station 8000*l.* had already been subscribed from private resources. Sir H. Holland in reply stated that this application had received much consideration both from the present Government and its predecessors, and a letter was written to the association a fortnight since in which the Treasury undertook in general terms to ask Parliament for an annual grant for a term of years in aid of their undertaking, on condition that their work should be carried on in full concert with the Scotch Fishery Board, to whom Parliament has already granted considerable sums for similar objects. In the view of the Government these two bodies must be considered as working together towards the common benefit of the fishermen and fish consumers of the three kingdoms. On the whole this is satisfactory. No doubt it is desirable to form a central authority for dealing with fishery statistics and the scientific problems of fisheries for the three kingdoms. But this will take time; and in the meanwhile it is to be expected that the Marine Biological Association will receive Government aid so as not to delay its useful work. The condition as to common action and harmony with the Scotch Fishery Board is very proper and is not likely to give rise to any difficulty. The leading and we believe only scientific member of the Scotch Fishery Board, Prof. Cossar Ewart, is a member of the Biological Association, and will no doubt co-operate in every way with that body. The Marine Biological Association is now a very large and weighty body, comprising all British zoologists. It is not to be expected that it should be controlled in any way by the Scotch Board, nor are we sure it would desire to interfere with Prof. Ewart's valuable researches. But there need be no difficulty, we should think, about consultation and harmonious action. With the expected Government aid the Biological Association will be able to spend the greater part of its 8000*l.* on building and equipping a first-rate laboratory on the splendid site granted to it by the War Office. It will be able to carry out a definite series of investigations under the guidance of Profs. Moseley, Lankester, Günther, Huxley, and other leaders of the Association, and may be expected, step by step, to build up that knowledge of sea-fishes which is so much needed. The work to be done will no doubt be thoroughly systematised and apportioned to different workers. It should be remembered that the Marine Biological Association is not local: it aims at carrying on work on various parts of the English, Scotch, and Irish coasts, and in time, indeed, may become in all respects a national Association.

THE Astronomische Gesellschaft meets this year at Geneva from August 19 to 22. The first meeting will be held at 10 a.m. on the 19th, in the hall of the Aula of Geneva University. Geneva has been chosen for the eleventh meeting of this Association on account of its central situation. Although founded at Heidelberg twenty-two years ago, the Association includes among its members astronomers of nearly all civilised countries.

THE Paris students are making extensive preparations for celebrating the 100th birthday of M. Chevreul, the veteran chemist, who has been a member of the Academy of Sciences since 1826.

THE third session of the International Geological Congress, which was postponed last year on account of the cholera on the Continent, is fixed to be held this year on Sept. 28 at Berlin, under the honorary presidency of the veteran geologist of Rhineland, Dr. H. von Dechen. The President of the Organising Committee is Prof. Beyrich, and the General Secretary M. Hauchecorne, 44, Invalidenstrasse, Berlin.

To meet the requirements of ladies going up for the Preliminary Scientific or the Intermediate or Full B.Sc. examination at the University of London, under the new regulations, the Council of Bedford College, York Place, Baker Street, London, have arranged for a complete course of instruction in biology, to commence next October. Mr. A. G. Bourne will give lectures in animal biology, and will also have classes for demonstration. Mr. A. W. Bennett will lecture on vegetable biology, and Miss Mary Forster, of Newnham College, will give practical demonstrations twice a week. Provision is also made for adequate instruction in other branches of science required for the same examinations—viz. mathematics, physics and chemistry, the two latter including laboratory work.

THE secretary of the Royal Horticultural Society writes to say that the council of his society are prepared to offer their co-operation and assistance to such of the colonies as may desire as a feature of their courts examples of the indigenous flora in vestibules or plant-houses. The council, believing that collections of ornamental and economic plants in a growing state, and of fruits, would be of much interest and value, will be ready to give advice and practical assistance in preparing, arranging, and carrying out such illustrations, to any of the colonies who may apply to them.

THIS season the rains have set in early and with unusual force in Southern India and Burmah, and about the usual time in Lower Bengal, while in Western India they have been later in commencing and are deficient in amount. Thus far, therefore, Mr. Blanford's forecast of this year's south-west monsoon, founded on last winter's snowfall on the Himalayas, has been amply justified.

AN invention, which it is anticipated will be of importance in future warfare, was on Monday night exhibited in the grounds of the Albert Palace by Mr. Eric S. Bruce, the inventor. It consists of the application of electric lighting to balloons, by means of which signals may be flashed at night over very wide areas. Before giving a practical demonstration of the working of his invention, Mr. Bruce delivered a brief lecture in the concert hall of the Albert Palace, in which he stated the results of his experiments and explained the manner in which he had arrived at them. The invention consists of an ordinary balloon made of a material as translucent as possible (in the case of the one at present on exhibition the material is cambric) in which are fixed a number of incandescent lamps. The balloon is a captive one, and the rope which secures it is also utilised for conveying the electric current to the lamps inside the balloon. The Morse system of telegraphy is employed for the signalling, which illuminates the balloon with flashes of light of longer or shorter duration. The invention dates back only two months, and the experiments were made with a large balloon for the first time last night, and were completely successful. It is proposed to continue the exhibitions of signalling for a month. The chief obstacle to be overcome in introducing the electric light into the balloon was that occasioned by the highly inflammable nature of the gas with which the balloon is inflated. This has, however, been successfully surmounted. During the evening several sentences, including "God Save the Queen," "Rule Britannia," and "Health and Happiness to Princess Beatrice," were flashed from the balloon.

ON Thursday evening last, July 16, Finsbury Technical College was *en fête*, the students having organised a *conversazione* to mark the conclusion of the work of the session. The programme was of a very varied character, including, in addition to a large number of scientific items, a concert given in the Chemical Lecture Theatre, and a play and dance in the large hall of the Middle Class Schools in Cowper Street, which had been kindly lent for the occasion. The evening's entertainment proved most successful in every way, great credit being due to the secretaries of the various Committees, and especially to Mr. H. Newman Lawrence, the general and organising secretary, for the efficient manner in which all the arrangements were carried out. Most of the rooms were filled with exhibits of apparatus, the whole building being lighted by electricity, and the machinery, workshops, &c., in full action. In the course of the evening a lantern exhibition of polariscopic objects was given in the Physical Lecture Theatre by Prof. S. P. Thompson, who had also lent for exhibition various telephones, a phonograph, an "electric light compass" for detecting the direction of a current in a wire, a "cymatograph" (an instrument for compounding the resultant of two parallel, simple, harmonic waves), and a collection of historical electric-telegraph apparatus. In the Chemical Department Prof. Meldola exhibited a series of new organic products obtained in the course of recent researches. Messrs. Hopkins and Williams exhibited a series of chemical preparations. A large number of microscopes with objects were exhibited in one of the rooms by Mr. Beck. Amongst the electrical exhibits were a model telpher line by the Telpherage Company, the valve telephone lent by the New Telephone Company, Cardew's voltmeter lent by Messrs. Paterson and Cooper, a selection of ammeters, switches, incandescent lamps, &c., lent by Messrs. Woodhouse and Rawson and by Mr. Swan; and accumulators, dynamos, &c., made by the students of the Electrical Engineering Department. In the Trade Classes Department Mr. C. T. Millis exhibited some new geometrical models and students' paintings; models, and drawings were exhibited by the Applied Art Department. It is proposed to form an "Old Students' Association" in connection with the College, and the success which attended the first attempt at a public entertainment has encouraged the professors and students to make an annual institution of it.

Mr. Hele Shaw has been unanimously appointed to the new Chair of Engineering in University College, Liverpool. Mr. Shaw began his career by taking the Senior Whitworth Scholarship in 1876, which was followed by many other honours while pursuing his engineering studies. In the present year he was awarded the Watt Gold Medal and Telford Premium by the Institution of Civil Engineers.

According to the *Times* Roman correspondent an interesting discovery, illustrating the commerce and the luxury of ancient Rome, has been made close to Monte Testaccio and the English cemetery. The whole of the district to the west of the Aventine outside the Porta Tregemina was occupied by granaries and warehouses for the storage of imports of all kinds. Between the northern side of Monte Testaccio and the Tiber there still exist colossal remains of the great emporium built by Marcus Emilius Lepidus and Emilius Paulus nearly 200 years before the Christian era. In the year 1868 a considerable portion of the quays was discovered, together with some 600 blocks, many of them of large size, of rare, variegated marbles of all kinds, lying just where they were landed from the galleys which had brought them from Numidia, the Grecian Islands, and Asia Minor fifteen centuries ago. Now, in the course of the building operations in this locality, two warehouses have been discovered, one filled with elephants' tusks and the other with lentils. It is curious to find such products stored side by side; but as bags of lentils were sometimes shipped as ballast, they may have served that purpose. The discovery would have been a very valuable one if, unfortunately, the ivory had not been much decayed.

We have received from the Bureau des Longitudes ephemerides of circumpolar and moon culminating stars for the present year and an account of the determination of longitude between Paris and Bregenz, a town situated near the western boundary of the Austro-Hungarian Empire; a high value is claimed for the result.

Mr. Cleveland, the President of the United States, has given his assent to the nomination as American Ambassador at Rome of Mr. Stallo, a German by birth, but long since a naturalised American citizen. He devoted himself exclusively to scientific pursuits in his younger years, but was persuaded by his friend Draper to join the Bar, where he distinguished himself without relinquishing his former avocation. He is the author of several scientific works; the last was on "The Concepts and Theories of Modern Physics," noticed in Nature, vol. xxiv. p. 321.

Owing to the frequency of tornadoes in some parts of the valley of the Mississippi, we understand that a number of caves have been bored in some parts of the country to afford shelter to travellers chancing to meet such dangerous phenomena on their way.

On July 10, at about noon, a wonderful mirage was seen on Lake Wettern, in Sweden, by a number of people between the villages of Fogelsta and Vadstena. A small island in the lake appeared as if covered with the most gorgeous flora and tall gigantic trees, forming great groves, between which buildings having the appearance of the most splendid palaces were seen. The Sandö, another little island, seemed to rise out of the sea many times its actual height, its sandy shores looking like lofty castellated walls. It had the exact appearance of a mediæval fortress enclosed by four walls. Two other little islands, Åholmen and Risön, appeared also as lofty towers above the water. The mirage lasted for nearly half an hour, when it disappeared somewhat rapidly.

Mr. Clement L. Wragge is arranging for the establishment of a meteorological station in Northern Queensland and New Guinea. He hopes to establish an observing station at Port Moresby. An assistant will carry on the work of the Torrens Observatory. Mr. Wragge is also arranging for the continuance of his observatory on Mount Lofty.

On Tuesday morning last week an earthquake occurred in Eastern and Central Bengal which is said to have been the severest one experienced by the inhabitants for forty years. The shocks lasted for nearly a minute. In Calcutta the houses rocked and cracked and the plaster fell in large quantities. There was general consternation, the people all rushing out of doors. A wave was raised in the river like a bore, causing some anxiety with respect to the shipping. Luckily no accident occurred, and no damage was done beyond the cracking of the walls of some old houses; but had the shocks lasted some seconds longer the city would probably have been laid in ruins. Some of the up-country stations were less fortunate. At Serajgunge a chimney belonging to some jute mills fell. In many other places some of the houses fell and people were killed. Twenty-five deaths are reported to have occurred at Aheripore, five at Bogara, eleven at Azimgunge, and several at Dacca. The following morning another shock was felt in Cashmere which did some injury. According to the latest reports the earthquake caused altogether seventy deaths in Bengal.

A shock of earthquake occurred at Velez-Malaga on Monday night last week, but no damage was caused. A smart shock of earthquake occurred at Smyrna at 1.30 a.m. on July 15. The vibration was also slightly felt at Chesmé.

On June 30, at about 10 a.m., after a severe thunderstorm with heavy rain had passed over Stockholm, a little bright cloud was seen sailing in an easterly direction about 30° above the horizon, which at about 11 o'clock was suddenly illuminated by the intensest bright forked lightning, illuminating the cloud and the clear sky for upwards of half an hour, without any thunder being heard. The light was brighter than the electric light. Similar phenomena are very rare in these latitudes, and are believed to augur a good harvest. On the 12th inst. another phenomenon, perhaps of volcanic origin, was observed at Norrköping, the water in the river being seen suddenly to rise, and three large waves with frothy crests to roll thunderingly up the stream. After the lapse of a few minutes three smaller followed, of which the first only was froth-crested. Five minutes later it was observed that the water in the river had fallen quite four inches. The waves did not reach as far as the shore, and no earthquake or subterranean noise was felt or heard. After a quarter of an hour the river had resumed its wonted appearance. The phenomenon, it is suggested, may also have been caused by a sudden subsidence in the river basin.

A MOVEMENT is on foot in Christiania, at the instance of the Society for the Promotion of the Norwegian Fisheries, for the establishment in the Christiania fjord, near Dröbak, of a biological station for the hatching of sea-water food-fish and salmon, in consequence of the great success of other stations along the coast. In a report on this subject by Herr A. Landmark, Chief Inspector of the Norwegian Fisheries, he draws special attention to the great development of the salmon and trout fisheries of Great Britain and Ireland, in consequence of the care and attention paid to them in this country.

UPSALA UNIVERSITY has just received a somewhat valuable present in the shape of a collection of Scandinavian, Icelandic, and Greenland eggs, specially remarkable for its completeness and excellent preparation. Among some of the rarest are eggs of *Tringa islandica*, *Phalaropus platyrhinchus*, and *Lestris pomerina*.

AN automatic bichromate battery has recently been produced by Messrs. Woodhouse and Rawson, the dimensions of which are only 7½″ × 1¾″ × 8½″, and weight 6 lbs. One charge will light a 5-candle power lamp for about two hours. The electrodes are attached to an ebonite plate supported in position over the liquid by the upper edge of the containing case, within which is placed a more shallow case, constituting the liquid reservoir. The reservoir itself is free to move up and down without any possibility of disarrangement, and rests upon a small roller connected with a lever at the bottom of the case. By moving this latter the liquid reservoir is raised, and its contents "immerse" the electrodes. A ratchet arrangement prevents disconnection being made until the battery is out of use. By this arrangement, requiring the use of one hand only, an accurate regulation of the electrodes can be obtained. Further, it is easy, when using ordinary bichromate solution, to raise or lower the liquid reservoir from time to time while the battery is in use, and so displace the gas which gathers upon the surface of the electrodes in consequence of their polarisation.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus* ♂) from India, presented by Mrs. Cooper; an Erxleben's Monkey (*Cercopithecus erxlebeni*) from West Africa, presented by Miss Peers; a Blue-fronted Amazon (*Chrysotis æstiva*) from South America, presented by Lady Kensington; a Rendall's Guinea-fowl (*Numida rendalli*) from West Africa, presented by Mr. F. Le Sueur; three Razorbills (*Alca torda*), eight Puffins (*Fratercula arctica*) from Ireland, presented by the Rev. Ed. Weldon; a Long-eared Owl (*Asio otus*), European, presented by Mr. F. Allen; three Angulated Tortoises (*Chersina angulata*), an Areolated Tortoise (*Homopus areolatus*) from South Africa, a Black Sternothere (*Sternothærus niger*) from West Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; two King Vultures (*Gypagus papa*) from Tropical America, deposited; an Axis Deer (*Cervus axis* ♂), a Duyker-bok (*Cephalophus mergens* ♂), born in the Gardens.

OUR ASTRONOMICAL COLUMN

THE ASTRONOMISCHE GESELLSCHAFT. — The first and second parts of the twentieth year of the *Vierteljahrschrift*, issued by this Society, have been published as a single number. It contains reports from some thirty of the Continental observatories, detailing the astronomical work accomplished during the year 1884, and a Report from the Bureau of Calculation at Berlin, on the part of the Transit of Venus Commission, describing the progress made in the reduction of the observations of the transit of 1882. Dr. B. A. Gould, with the authority of the Government of the Argentine Republic, has offered the stereotype plates of the Catalogue formed from the Cordoba zones, to the Society, the gift carrying with it the sanction of the Government to a new edition being printed therefrom at such time as may be desirable. All the errors detected up to the time of Dr. Gould's communication have been corrected on the plates. It is almost needless to add that this valuable gift has been accepted by the Society, who will preserve the collection of plates at Leipsic.—The death is announced of Dr. T. Clausen, late director of the Observatory of Dorpat; amongst many other important contributions to astronomical science, his masterly discussion of the observations of Lexell's comet of 1770 will be remembered; his prize-memoir thereupon published in the *Astronomische Nachrichten* elicited from Bessel the eulogising remark—"Welche herrliche, oder richtiger, meisterhafte Arbeit ist die von Clausen über den Cometen von 1770; sie ist eine Leistung unsere Zeit, welche unsere Nachkommen ihr anzurechnen nicht vergessen werden."

The next meeting of this Society will be held at Geneva, from August 19 to 22, under the presidency of Prof. Auwers.

THE NEW COMET.—Mr. Bainard of Nashville, U.S., having notified his discovery of a small telescopic comet, on July 7, to Prof. Pickering, it was observed at Harvard College on July 9, the resulting position being—

July 9, 12h 33m 0s M.T.; R.A. 17h 17m 48s·4; Decl. −6° 1′ 8″

Prof. Millosevich communicates the following observations made at the Collegio Romano, in Rome:—

July 12, 9h 56m 29s; Rome M.T.; R.A. 17h 12m 52s·35;

Decl. − 7° 32′ 15″·6.

He remarks that the comet had a nucleus 11m. in the preceding part of the small nebulosity.

The elements of the comet's orbit are yet uncertain, from the case not being a favourable one for calculation. The Dun Echt Circular of July 16 has an orbit computed by Mr. Chandler from observations between July 9 and 11; the resulting date of perihelion passage is May 16. But on combining the above observations on July 9 and 12 with one on July 15, made by Col. Tupman at Harrow, it would appear that the comet may not arrive at perihelion till September. In this uncertainty we defer printing elements till next week. In any case the comet can hardly be one possessing much interest. The theoretical intensity of light seems to be decreasing.

TUTTLE'S COMET.—At the time of writing, no ephemeris to facilitate the re-observation of this comet at its approaching perihelion passage has, to our knowledge, been published, beyond the few positions which have been given in this column, on the assumption that the perturbations during the actual revolution have not been very sensible. If it should prove that no computation of the perturbations has been effected, it will be desirable to make a close examination of the north-eastern heavens during the absence of the moon in August, and just before morning twilight. The period of revolution of this comet at its last perihelion passage in December 1871, was 5045 days, which, without perturbation, would indicate September 24 as near the date of next perihelion passage.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, *JULY* 26 *TO AUGUST* 1

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on July 26

Sun rises, 4h. 17m.; souths, 12h. 6m. 14·3s.; sets, 19h. 55m.; decl. on meridian, 19° 22′ N.: Sidereal Time at Sunset, 16h. 14m.

Moon (Full on July 27) rises, 19h. 15m.; souths, 23h. 58m.; sets, 4h. 46m.*; decl. on meridian, 15° 30′ S.

Planet	Rises	Souths	Sets	Decl. on meridian

GEOGRAPHICAL NOTES

The Rev. G. Grenfell has recently explored the Mobangi, which enters the right bank of the Congo, forming a great delta, between 26′ and 42′ S. lat., nearly opposite Equator Station, and is probably its greatest tributary. Mr. Grenfell navigated the Mobangi in the little steamer *Peace*, on a mean course of north by east, from the equator to 4° 30′ N. lat., and left it still an open waterway. At 4° 23′ N., just below the second rapids, he found it 673 yards wide; at no point lower was it less in width. Its mean depth is 25 feet, and although the current runs not more than 80 to 100 feet per minute, it means an immense volume of water to find running south at a point, as Mr. Grenfell puts it, so near the supposed sources of the Binné, the great affluent of the Niger. Where does it all comes from? he asks. The "trumbashes" of the Chad Basin (Schweinfurth) are common, while they are not known on the Congo. The opinion of Mr. Grenfell and of his Congo colleagues, we believe, is that the Mobangi is probably the lower part of the Welle, a river whose course is one of the unsolved problems of African geography. This is certainly a more likely solution than to connect the Welle with the useless Aruwimi, as Stanley is inclined to do. From the notes sent home by Mr. Grenfell, it would seem that the Mobangi is navigable the whole way from the Congo to 4° 30′ N., a distance of probably 400 to 450 miles, taking account of the bends. A large map, in ten sheets, of the explored part of the river has just been received at the Royal Geographical Society. It is hoped that a full narrative of Mr. Grenfell's explorations will reach England in time to be read at the Aberdeen meeting of the British Association. The Mobangi, Mr. Grenfell writes, is far more populous than any equal length of the Congo, and to his mind the country is more promising. Whether the Mobangi is the Welle or not, it must form an important connecting link between the basin of the Congo and the basins of the Niger, the Shari, and the Nile. Mr. Stanley has always maintained that the region lying between the Congo and the Nile is probably the richest and most promising in Africa, and his belief seems likely to be amply confirmed. Besides the Mobangi, Mr. Grenfell has explored 300 miles of river courses debouching into the Congo, and, as he is a trained and careful surveyor, he will be able to plot them with precision. The most northerly point of the Congo bend he found to be 2° 11′ N. lat., near the mouth of the Ukere or Dujangi.

At the last meeting of the French Geographical Society, held on Friday night, M. Ferdinand de Lesseps gave an account of the recent success of the operations conducted with the object of finding water in the desert tracts of Southern Tunis. After the death of Col. Roudaire the French Minister of War authorised Commandant Landais to resign his duties at the Military School at Saint Cyr, in order that he might continue the schemes set on foot in the region of the Tunisian Shotts. At this time those who believed in the success of these undertakings directed their attention chiefly to the establishment of a harbour at Gabes. The necessity for a port where vessels could put in on the southern coast, and for a town through which the traffic of Tunis and Tripoli could be conducted, was apparent. It was determined to commence operations at the mouth of the Wady Melah, and to make the station established at this point the basis of future and more extensive operations. Two years ago M. de Lesseps, in company with M. Roudaire, visited the region of the Shotts. They observed there, on the banks of the Wady Melah, a lake in which the level of the water never sinks. This water was excellent. M. de Lesseps thought, although there was no visible confirmation of the fact, that this water might be in communication with a deep sheet of water. In consequence he requested the engineers to make borings, or to sink a well at that spot. They have succeeded admirably. At a depth of 91 metres they reached the sheet of water sought for. The flood rushed from the ground with such velocity that it raised with it stones weighing 12 kilogrammes, and threw them to a great height into the air. The well yields 8000 cubic metres of water a minute.

ANNUAL REPORT OF THE FISHERY BOARD FOR SCOTLAND, 1884

The third Report of the New Fishery Board for Scotland, which was recently presented to Parliament, contains, amongst other useful information, valuable statistics of the fish captured during 1884, and a record of the scientific work carried on under the direction of Prof. Ewart, the energetic convener of the Scientific Committee of the Board. From the Report it appears that the herring fishing of 1884 was the most abundant ever known. Unfortunately, it was largely composed of immature and small fish, and consequently it was of much less value than it would otherwise have been. Great shoals of young herrings were found far out at sea much earlier than usual, and heavy takes were made before they had time to mature. The curers were often unable to overtake the hauls of mature fish, and hence much good food was wasted. The haddock and sprat fishings were also successful, and large quantities of halibuts were taken off Shetland. The salmon fishing was not so productive as in 1883, which was a singularly good year. The most important fish taken and sold fresh is the haddock, of which the value is nearly three times as great as any of the others. The total estimated value of the white fish amounted to 716,295*l.*, and of the shell-fish, 80,939*l.* Beam trawling was carried on to a much greater extent than formerly, and with a fair amount of success. Telegraphic communication has been extended to the fishery stations at Castle Bay, Island of Barra, St. Mary's Burra, St. Margaret Hope, Orkney, Reawick, and Vaila Sound (Walls), Shetland, and this is much appreciated by the fishermen and other persons engaged in the fishing industry. Several harbours have also received grants to aid in construction or improvement. The Board, having recognised that great progress had been made in practical fish-culture in America, requested Prof. Cossar Ewart to visit Canada and the United States and report on the methods adopted there for improving the fisheries. Prof. Ewart accordingly visited first the fish-hatching stations in Canada, and afterwards the principal fishing-stations and laboratories of the United States Fish Commission. In addition to visiting the central station and the carp ponds in Washington, Prof. Ewart was able to study the appliances for carrying on hatching and other operations at Wood's Holl. He also visited the Bucksport and other stations for hatching salmon and trout, studied the arrangements for receiving and preserving fresh fish at Gloucester, Boston, and New York, and the methods of utilising the by-products of the fisheries. He likewise examined the boats and fishing appliances in use among the American fishermen and also the splendid vessel *Albatross*, recently constructed for the scientific work of the Fish Commission. It seems the Commission considers that "the best policy is to expend a small amount of public money in making fish so abundant by artificial means that they can be got without restriction and serve as cheap food for the people at large, rather than to expend a much larger amount in trying to prevent people from catching the few which remain after years of improvidence." In order to carry on investigations and hatching operations on the lines which have proved so successful in America, the Board will require to be provided with (1) a well-equipped laboratory with suitable hatching-tanks and at least one large sea-water pond; (2) a cruiser adapted for carrying on dredging and other operations; (3) two small steam tenders adapted for inshore work; (4) a sufficient annual sum of money to meet the working expenses of hatching and other operations and to provide the necessary apparatus. From information gained in America the Board feels that, if provided with sufficient funds and with increased powers, it might be able greatly to increase the number of useful food fishes in the firths, bays, and other waters around the coast. The marine station at St. Andrews is now in working order and an assistant naturalist has been sent to carry on investigations under the direction of Prof. McIntosh, F.R.S. A number of interesting inquiries have been instituted, especially on the nature of the eggs and rate of growth of fishes and the life-history of the common mussel. The Scientific Committee, who felt the assistance of an experienced naturalist devoting his whole time to the work of inquiry to be not merely expedient but necessary, have been so fortunate as to secure the services of Mr. Brook, F.L.S., of Huddersfield, who had been studying for some time the history and habits of fish, and gained considerable experience in organising and carrying on a marine laboratory. A temporary laboratory has been erected at East Tarbert, a convenient situation for studying the west coast fishing and from which it is possible to study not only the herring-fishing in Loch Fyne, but, with a good steamboat, to embrace the whole area of the Firth of Clyde. Mr. Brook is engaged in studying the development of the herring, and the result of his experiments will be described in detail in papers the first of which is now appended—the others to be presented to the Board in the autumn. Mr. Brook has also in hand a paper on the "Food of the Herring," to be completed in the autumn. The Directors of the Rothesay Aquarium have very kindly placed the tanks of their institution at the service of the Board, and this will be of great assistance in the study of the life-history of various food fishes, especially during the winter months. There is now at the service of the Board a small laboratory in the Cromarty Firth, and it is hoped that a marine laboratory may soon be established near the mouth of the Firth of Forth.

The most important paper in the scientific appendices contains "Observations on the Spawning of the Cod," by Prof. Cossar Ewart and Mr. George Brook. The authors say that it is now twenty years since G. O. Sars discovered, what our fishermen still decline to believe, that the eggs of the cod float on the surface of the sea, and only sink when dead. Sars's after-investigations showed that the eggs and the milt are of less specific gravity than the sea water, and consequently float, also that the micropyle lies near the lower portion of the egg. The experiments reported were carried on in Rothesay Aquarium on fish which had been in the tanks for four years. In February several cod appeared to be reaching maturity; early in March the fish refused food, and a few days afterwards eggs in an early stage of development were floating on the surface of the water, so abundantly that hundreds were collected in a few minutes by means of a piece of muslin placed over the overflow of the tanks. The temperature of the water was 43° F., and the specific gravity a little over 1·024. The eggs were usually found during the first few days in from the 2- to 8-cell stage at 8 a.m., so that they were most probably shed about daybreak. Later batches shed between 6 and 7.30 p.m. were found at the latter hour with the disk already forming. The great transparency of the living eggs makes it almost impossible to notice them as they rise through the water, whilst the dead eggs, being slightly opaque, are easily recognised as they are carried to and fro by the currents. For some time before the first eggs reach maturity, and during the early part of the spawning period, the fish not only refuse food, but give up their regular movements around the tank and swim about in small groups or rest together at the bottom, swimming and resting alternately. Sometimes a single female would swim leisurely about for a few minutes attended by a single male, and often settle down in a corner of the tank and rest till disturbed by her attendant. The activity of the males was specially evident at dusk and in the early morning, and it was apparently during these periods of activity that the eggs were shed and fertilised. One day, for example, there were no eggs visible on the surface of the water at 6 p.m., while a considerable number were obtained at 7.30, which, as the germinal disk was not completely formed, had in all probability been quite recently shed while the fish had been swimming about the tank in groups. From the observations made, it seems, as suggested by Sars, that the eggs and milt are shed while the fish are swimming freely about in the water. The males swim indiscriminately among the females, sometimes over, sometimes under them, fertilising the water through which the shed eggs are slowly rising to the surface. Eggs were pressed from a ripe female and fertilised artificially. They developed normally, but it was found that a few kept for some hours in a small glass cell in a warm room, for observation under the microscope, began to show similar abnormalities to those figured by Ryder ("Embryology of Osseous Fishes," Report U.S. Fish Commission, 1882). Too high a temperature has a similar effect on other eggs, but those which float on the surface are naturally more sensitive. The females, like the Salmonidæ, are capable of withholding the flow of ripe eggs to a certain extent. A limited number only are ripe at one time, and if the unripe be forced out they sink to the bottom and are incapable of being fertilised. The ripe unfertilised egg has a milky appearance and is moreover not so transparent as the fertilised one, so that by a little practice the two can be distinguished without the aid of a microscope. As soon as an egg begins to die or to develop abnormally, the milkiness returns and it sinks to the bottom. Whether fertilised or not, the eggs float immediately after extrusion, but in the latter case they die and sink to the bottom in twelve to fourteen hours. During this time no change was observed to take place in the unfertilised egg, the small oil-vesicles around the yolk remaining constantly in their primitive condition. In perfectly still water (sp. 1·024) the eggs float in a dense mass; when carried along by a strong current they become suspended at various depths, but none that are living lie at the bottom. At any rate all found there were either dead or dying. It seems that large numbers of the pelagic fish eggs have been dredged at the Fishery Board Station at Tarbet. With the sea perfectly calm, most eggs were obtained on the surface; with a slight ripple the net had to be kept just under the surface and in other states of the weather to be lowered two or three feet under the surface. The eggs having a specific gravity only slightly less than that of water, do not rise to the surface very rapidly. In one case noted it took an egg four minutes to rise through 1¼ inches of water. The milt also has less specific gravity than sea-water, and rises to the surface when shed. If forced down, it gradually rises again, disseminating as it does so. During the spawning process the water in the tank became slightly clouded by the spermatazoa, which were spread through it. The milt is, however, shed in such a thin stream under natural conditions that it is difficult to detect it. The eggs are capable of being fertilised a considerable time after the fish is dead, and also some time after they have been shed. Light appears to have considerable influence on the spawning process, and under natural conditions the eggs seem to be shed at daybreak or dusk, when the light is not strong. The observations made justify the conclusion that the spawn is shed while the fishes are swimming about freely in the water, and that the eggs are fertilised at, or as they rise to the surface, this being facilitated by the position of the micropyle, which is always found in the lower hemisphere of pelagic fish ova. To show the facility with which some fish ova are fertilised, an experiment on herring ova may be here mentioned. Three batches of ova secured from a living female were placed in tumblers, and water added from an adjoining tank. It was intended to fertilise each batch separately, and at fixed intervals, but it was found that though no milt had been intentionally added to the second or third tumblers, the water not being from the tank in which the herring were kept, spermatozoa must have been introduced with the water, as the second and third batch of eggs developed exactly like the first, and were ultimately hatched out. As Kupfer points out, it is necessary, in order to keep eggs unfertilised, to get a fresh supply of water direct from the sea.

Mr. Brook's first paper on the "Development of the Herring" gives a *résumé* of what is already known on the subject, as preliminary to the result of his own investigations. He also sends notes of rare and curious fishes sent to the Board. Dr. M'Intosh details the work done by himself and by his scientific visitors to the St. Andrew's Laboratory. Prof. Cossar Ewart reports on the progress of Fish-culture in America, and Mr. Young on the Northern and Western Salmon Rivers. The Report is both interesting and encouraging. It is difficult to form an adequate idea of the immense importance of their sea-fisheries to the people of Scotland. But it may be stated that about half a million of people, or about one-seventh of the entire population of Scotland, are connected with this industry, and more or less dependent upon it. Happily the country is now beginning to realise the importance of the matter, and when the Government places at the disposal of the Board sufficient money to carry on the necessary investigations, the produce of the Scottish fisheries, great as it now is, may be still largely increased.

RADIANT MATTER SPECTROSCOPY

THE following paper on this subject was read by Mr. Crookes at the Royal Society, June 18:—

In the concluding sentence of the Bakerian lecture which I had the honour to deliver before the Royal Society, May 31, 1883, I said that the new method of radiant matter spectroscopy there described had given me not only spectrum indications of the presence of yttrium as an almost invariabl:, though very minute, constituent of a large number of minerals, but had likewise revealed signs of another spectrum-yielding element. I stated that I had repeatedly seen indications of another very beautiful spectrum characterised by a strong red and a double orange band.

Elimination of Mercury Vapour from Vacuum Tubes.—It is much more difficult than is generally supposed to keep mercury vapour from diffusing into the experimental tubes.

The following plan answers perfectly so far as my experiments have yet gone:—Sulphur is first prepared by keeping it fused at a high temperature till bubbles cease to come off, so as to get rid of water and hydrogen compounds. It is then allowed to cool, and is pounded and sifted so as to get it in the form of granules averaging a millimetre in diameter. A glass tube, a centimetre in diameter and about 2 feet long, is lightly packed for half its length with this sulphur, and next about 2 inches of iodide of sulphur (I_2S_2) is added, and the rest of the tube is then filled up with sulphur. Ignited asbestos is packed in at each end to keep the sulphur from blowing out whilst the vacuum is being made, or from being sucked through when air is suddenly let in. This contrivance entirely keeps mercury vapour from passing through, since the iodide of sulphur holds its iodine very loosely, and fixes the mercury in the form of non-volatile red iodide. A glass tube containing finely-divided copper must follow in order to keep the sulphur out. With this blockade interposed between the pump and experimental tubes I have been unable to detect mercury vapour in any of the tubes, whether in the cold or on heating them.

The "Orange Band" Spectrum.—Since the date of my last paper I have devoted myself to the task of solving the problem presented by the double orange band first observed in 1881. With the yttrium experience as a guide it might be thought that this would not be a difficult task, but in truth it helped me little beyond increasing my confidence that the new, like the old spectrum, was characteristic of an element. The extreme sensitiveness of the test is a drawback rather than a help. To the in xperienced eye one part of "orange band" substance in ten thousand gives as good an indication as one part in ten, and by far the greater part of the chemical work undertaken in the hunt for the spectrum-forming element has been performed upon material which later knowledge shows does not contain sufficient to respond to any known chemical test.

Chemistry, except in few instances, as water-analysis and the detection of poisons, where necessity has stimulated minute research, takes little account of "traces;" and when an analysis adds up to 99·99, the odd 0·01 per cent. is conveniently put down to "impurities," "loss," or "errors of analysis." When, however, the 99·99 per cent. constitutes the impurity and this exiguous 0·01 is the precious material to be extracted, and when, moreover, its chemistry is absolutely unknown, the difficulties of the problem become enormously enhanced. Insolubility as ordinarily understood, is a fiction, and separation by precipitants is nearly impossible. A new chemistry has to be slowly built up, taking for data uncertain and deceptive indications, marred by the interfering power of mass in withdrawing soluble salts from a solution, and by the solubility of nearly all precipitates in water or in ammoniacal salts, when present in traces only. What is here meant by "traces" will be better understood if I give an instance. After six months' work I obtained the earth didymia in a state which most chemists would call absolutely pure, for it contained probably not more than one part of impurity in five hundred thousand parts of didymia. But this one part in half a million profoundly altered the character of didymia from a radiant matter spectroscopic point of view, and the persistence of this very minute quantity of interfering impurity entailed another six months' extra labour to eliminate these final "traces," and to ascertain the real reaction of didymia pure and simple.

Chemistry of the Orange Band-forming Substance.—At first it was necessary to take stock, as it were, of all the facts regarding the supposed new substance, provisionally termed *x*, which had turned up during the search for the orange band. In the first place *x* is almost as widely distributed as yttria, frequently occurring with the latter earth. It is almost certainly one of the earthy metals, as it occurs in the insoluble oxalates, in the insoluble double sulphates, and in the precipitate with ammonia. It is not precipitated by sodic thiosulphate, and moreover it must be present in very minute quantities, since the ammonia precipitate is always extremely small, and as a rule *x* is not found in the filtrate from this precipitate.

At this stage of the inquiry the chemical reactions of *x* were much more puzzling than with yttria. At the outset an anomaly presented itself. The orange band was prone to vanish in a puzzling manner. Frequently an accumulation of precipitates tolerably rich in *x* was worked up for purposes of concentration, when the spectrum reaction suddenly disappeared, showing itself neither in precipitate or filtrate; whilst on other occasions, when following apparently the same procedure, the orange band became intensified and concentrated with no apparent loss. The behaviour of the sulphate to water was also very contradictory; on some occasions it appeared to be almost insoluble, whilst occasionally it dissolved in water readily.

Is "x" a Mixture?—A very large series of experiments, which need not here be described in detail, resulted ultimately in establishing the remarkable fact that the *x* I sought was an earth which of itself could give no phosphorescent spectrum in the radiant matter tube, but became immediately endowed with this property by admixture with some other substance, which substance likewise by itself had no power of phosphorescing with a discontinuous spectrum.

"x" in Cerite.—In the corresponding yttrium research I was aided materially by the fact that the sought-for earth did not give an absorption spectrum. This enabled me to throw out a large number of obscurely known elements, and I therefore early endeavoured to ascertain whether the supposed new earth, *x*, did or did not give an absorption spectrum. Gradually it was noticed that whenever the didymium absorption bands were strong, the orange band spectrum was also particularly brilliant. Moreover, amongst the earths previously enumerated as mixed with lime in the quest for *x*, I have mentioned that some of them gave the orange band spectrum with increased intensity; the earths of the cerium group were the most noteworthy, and these considerations made it probable that here would be found the location of *x*.

Analysis of Cerite.—The cerium group consists of cerium, lanthanum, didymium, and samarium.

The first necessity was to get the earths ceria, lanthana, and the mixture hitherto called didymia, in a pure state; for my so-called pure earths of this group all showed the orange band in more or less degree.

The separation from each other of ceria, lanthana, didymia, and samaria is a most laborious process, and the amounts of these earths, obtainable in anything like a pure state, is small, compared with the mass of material worked up. Full particulars are given in the paper as to the method adopted to obtain each of them in a state of purity.

Ceria.—The ceric oxide obtained was almost pure white. A considerable thickness of a strong solution did not show a trace of absorption spectru n. The atomic weight of the metal was taken and yielded the number 141·1.

The ceric oxide gave no orange band spectrum in the radiant matter tube, either with or without the addition of lime.

Lanthana.—Lanthana is more difficult to purify than ceria. Long after the lanthana appeared pure it gave in the radiant matter tube a good orange band spectrum when mixed with lime and treated as usual, although without lime it gave no spectrum. Ultimately, however, a lanthana was obtained which, mixed with lime and treated in the usual manner, gave no orange band spectrum whatever. This lanthana was snow-white, and had an atomic weight of 138·3.

Didymia.—The earth formerly called didymia is now known to be a mixture of didymia and samaria, and systematic operations were now commenced with the object of obtaining the didymia and the samaria in a state of purity—that is to say, in such a condition that one of them should show no orange band spectrum at all, whilst the other should give the spectrum in its highest degree of intensity.

I commenced the purification of didymia in the latter part of the year 1883, and the operations have been going on since almost daily in my laboratory. At intervals of some weeks the didymia in the then stage of purification was tested in the radiant matter tube, a little lime having previously been added to bring out the discontinuous phosphorescence. During the first month or two the intensity of the orange band spectrum scarcely diminished. After this it began to fade, but the last traces of orange band were very stubborn, and not till the last few weeks could I obtain a didymia to show no trace of the orange band spectrum; and this result has not been accomplished without sacrifice. My 1000 grammes have dwindled away bit by bit, till now less than half a gramme represents all my store.

Samaria.—The foregoing experiments left little doubt that *x*, the orange-band-forming body, was samarium; the last problem was, therefore, to get this earth in a pure state. The general plan of operations was the same as I adopted in getting didymium free from samarium, only attention was now directed to the portions richest in samarium which had been formerly set aside. The colour of samaria, as pure as I have been able to prepare it, is white with the faintest possible tinge of yellow. The absorption spectrum of samarium salts is much more feeble than the spectrum of didymium.

The Phosphorescent Spectrum of Samarium.—Pure samaric sulphate by itself gives a very feeble phosphorescent spectrum. When, however, the samaria is mixed with lime before examination in the radiant matter tube, the spectrum is, if anything, more beautiful than that of yttrium. The bands are not so numerous, but the contrasts are sharper. Examined with a somewhat broad slit, and disregarding the fainter bands, which require care to bring them out, the spectrum is seen to consist of three bright bands—red, orange, and green—nearly equidistant, the orange being the brightest. With a narrower slit the orange and green bands are seen to be double, and on closer examination faint wings are seen, like shadows to the orange and green bands.

Preliminary experiments had shown me that lime was one of the best materials to mix with samaria in order to bring out its phosphorescent spectrum, but it was by no means the only body which would have the desired effect.

The samarium spectra, modified by other metals, may be divided into three groups. The first group comprises the spectra given when glucinum, magnesium, zinc, cadmium, lanthanum, bismuth, or antimony is mixed with the samarium. It consists simply of three coloured bands—red, orange, and green; as a typical illustration I will select the lanthanum-samarium spectra (Fig. 1).

The second type of spectrum gives a single red and orange and a double green band. This is produced when barium, strontium, thorium, or lead are mixed with samarium. The lead-samarium spectrum (Fig. 2) illustrates this type.

The third kind of spectrum is given by calcium mixed with samarium. Here the red and green are single, and the orange double. Aluminium would also fall into this class were it not that the broad, ill-defined green band is also doubled. The calcium-samarium spectrum (Fig. 3) is a good illustration of this type.

Mixed Samarium and Yttrium Spectra.—It was interesting to ascertain what spectrum a mixture of samarium and yttrium would give. A mixture of 90 parts of samaria to 10 of yttria was treated with sulphuric acid and then ignited, and afterwards examined in the radiant matter tube. The result was as remarkable as it was unexpected. Not a trace of the yttrium spectrum could be detected. The powder phosphoresced with moderate intensity, but the spectrum was almost the facsimile of that given by pure samaric sulphate, except that the sharp orange line, which in the spectrum of pure samaric sulphate is only just visible, had gained sufficiently in intensity to be measurable, and was found to lie at 2693, on the $\frac{1}{\lambda^2}$ scale. A large number of experiments were next tried on mixtures of samaria and yttria in different proportions, and the results are given in full in the paper.

Up to mixtures of 43 parts samaria and 57 parts yttria the spectrum nearly resembled the lead-samarium spectrum. Not a band of the yttria spectrum could be detected, and the brilliant orange line stood out sharply in the whole series. This spectrum is represented in Fig. 4.

After that proportion had been reached a change rapidly came over the spectra, and in the next trial mixture—samaria 35, yttria 65—the only indication of the samarium spectrum that could now be found was seen in the two faint green bands next to the citron line of yttria, and the new orange line, which shone out as brightly and sharply as ever.

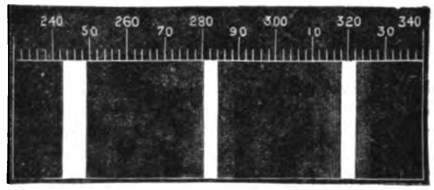

FIG. 1.

It will be remarked that a sudden change of spectrum occurs between very narrow limits of mixture.

The spectrum of a mixture of 44 parts samaria and 56 parts yttria, except for the orange line, is the pure samarium spectrum. The spectrum of 42 samaria and 58 yttria is built up of some of the component bands of the spectrum of each earth; whilst the

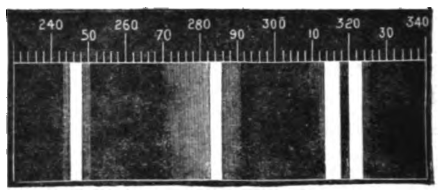

FIG. 2.

spectrum of 39 samaria and 61 yttria is almost a pure yttria spectrum, the sharp orange line running across them all.

The Delicacy of the Spectrum Test for Samarium.—Experiments were now commenced with the object of getting some approach to a quantitative estimate of how small a quantity of samarium could be detected.

A mixture was first made in the proportion of 1 part sama-

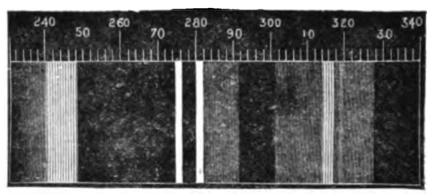

FIG. 3.

rium to 100 parts of calcium. The spectrum is very brilliant, and but little inferior in sharpness to the spectrum given by a 50 per cent. mixture.

A mixture was now prepared containing 1 part of samarium to 1000 parts of calcium. Very little difference can be detected between the spectrum of this mixture and that of the last. The bands are, however, a little less sharp.

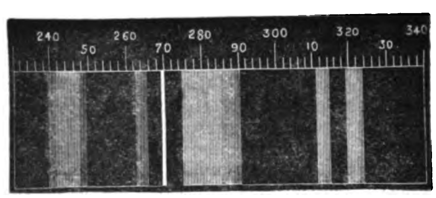

FIG. 4.

A mixture containing 1 part of samarium to 10,000 parts of calcium was now tested. The bands are now getting fainter, the second green band is fading out, and the continuous spectrum of calcic sulphate is getting brighter.

The next mixture tried contained one part of samarium in 100,000 parts of calcium. Here the green is almost gone, being overshadowed by the continuous spectrum of calcium which has spread over it. The red band has likewise almost disappeared in the greater brightness of the continuous red of the calcic spectrum. The double orange band is still very prominent, and the black space, 2942, between it and the green is very marked.

The next mixture, one part of samarium to 500,000 parts of calcium, gives a spectrum which is fainter than the last, but the orange bands are still distinctly visible. The blank space between the yellow and green is strongly marked, but narrower than before.

A mixture of one part of samarium in 1,000,000 parts of calcium was next subjected to experiment. In this the samarium spectrum is very feeble, and the orange bands are only to be seen with difficulty. Now the most striking characteristic of this spectrum is the black space which still cuts out the greater portion of the yellow.

A mixture of one of samarium in 2,500,000 parts of calcium was now taken. In the spectrum shown by this mixture the bands of samarium have entirely gone, and its presence now is apparent only by the darkening in the yellow portion of what otherwise would be a continuous spectrum.

The calcium phosphorescent spectrum by itself is continuous, with no break, lines, or bands in it.

The Anomalous Line $\frac{1}{\lambda^2}$ 2693.—On several occasions I have spoken of an orange line, 2693, which by its brilliancy and sharpness is a prominent object in most of the samarium-yttrium spectra. With pure samaric sulphate it is exceeding faint. With samaria containing 5 per cent. of yttria it is very little brighter; with 10 per cent of yttria it gains a little; with 15 per cent. it is brighter still, and with a mixture of 80 parts samaria and 20 parts yttria it is at its maximum intensity. It continues to be the most striking feature in the spectra of the various mixtures of samaria and yttria until the proportion becomes samaria 3, yttria 97, when it begins to get less bright, and only when pure yttria is reached does it altogether vanish.

It is noteworthy that so long as this bright line is a component of the spectrum, the other bands manifest decidedly less intensity, and many of them are suppressed. The profound modification in the spectra of samaria and yttria developed by their mixture is, I believe, without precedent in spectrum analysis. It is difficult to realise the character of the modification which converts somewhat faint diffused bands into one intensely sharp and brilliant line.

One important lesson taught by the many anomalies unearthed in these researches is that inferences drawn from spectrum analysis *per se* are liable to grave doubt, unless at every step the spectroscopist goes hand in hand with the chemist. Spectroscopy may give valuable indications, but chemistry must after all be the court of final appeal.

The following paper (reprinted from the *Chemical News*) is so intimately connected with Mr. Crookes's work, that it may be appropriately appended to his paper:—

AT the meeting of the Académie des Sciences on June 8, 1885, M. Lecoq de Boisbaudran requested that a sealed packet which he had deposited June 30, 1884, might be opened. The packet was opened by the Permanent Secretary during the meeting, and contained the following note:—

"When the electric spectrum of a solution *with a metallic base* is produced it is customary to make the outside platinum wire (whence the induction spark strikes) positive, the liquid consequently forming the negative pole.[1] If the direction of the current is reversed, the metallic rays (due to the free metal or to one of its compounds) are scarcely or not at all visible, at at all events so long as the exterior platinum wire now forming the negative pole is not coated with a deposit.

"Having again last year taken up my researches on the rare earths belonging to the didymium and yttrium family, I had occasion to observe with many of my preparations the formation of spectrum bands, nebulous, but sometimes tolerably brilliant, having their origin in a thin layer of a beautiful green colour, which was seen to appear at the surface of the liquid (a solution of a chloride) when it was rendered *positive*.

"These are the approximate positions of the principal bands:—

[1] This rule, hitherto general for *metallic* solutions, is not always applicable to liquids containing *metalloid* bodies, as I have already had occasion to notify (see my "Spectres Lumineux," p. 38).

Micrometer		λ	Observations
91¾	About the middle.	620½	A narrow band, somewhat hazy. Rather faint. About 1½ divisions wide. (Due to calcium??)
101	Approximately about the middle.	585¾	A nebulous band slightly connected with the following one. About 3 divisions wide. Slight intensity, but generally stronger than 91¾.
104 9/10	Approximately about the middle.	573	A nebulous band. Intensity varying with the state of the liquid and strength of spark. It seems to be fainter in the earths obtained from the sulphates which are very slightly soluble in potassic sulphate than in the earths obtained from the more soluble double sulphates. In some cases it has been seen as brilliant as *α* 115⅓, but it has almost always been seen *much* more feeble than 115⅓ in the earth obtained from the very slightly soluble double sulphate. It has, indeed, on several occasions been seen fainter than 101.
From 111½ to 112	About the beginning. Very indistinct.		A nebulous band, shading off from right to left. Rather strong, and generally much the most brilliant in the spectrum of the yellow earth whose double potassic sulphate is very slightly soluble.
115⅓	About the middle of maximum of light.	543⅓	
117	About the end. Very indistinct.		
About 141⅓	Apparent centre.	487	A very hazy band, appearing somewhat shaded from right to left when the spectrum is brilliant. About 4 or 4½ divisions wide. Somewhat joined to the following. Generally of very moderate intensity.
About 147⅓ to 147½	Apparent centre.	476½	Faint band, very hazy. About 6 divisions wide.

"On comparing in the different products the relative intensities of this new reversion spectrum and of the already known direct rays, I have come to the conclusion that the body producing the band *α* 115½ is very probably *not* one of the following:—

"Didymium, erbium, Y*α* (of M. de Marignac), lanthanum, samarium, zirconium, scandium, thulium, ytterbium, yttrium.

"Cerium and thorium are also excluded for chemical reasons.

"I have not yet obtained the new spectrum with a substance altogether free from holmium, but I have good reasons to think that this metal is not the cause of the observed phenomena.

"The treatment undergone by the earths which give most sharply the reversion spectrum hardly admits in my preparations of the presence of such bodies as phosphoric, boric, &c., acids.

"The band *α* 115⅓ (and most of the others which, except perhaps the band 104 9/10, follow in their intensities the same variations as *α* 115⅓) appears, therefore, only to be attributable to terbia, unless, indeed, it be due to some new analogous earth not hitherto defined.[1]

"The treatment of a yellow earth obtained from samarskite, and much resembling that which is now called *terbia*, has already

[1] There remains to be examined the earth decipia (of M. Delafontaine), the existence of which appears to be confirmed by the researches of M. Clève.

given me interesting results, which, however, it will be difficult to describe in this short preliminary note. I will only say that all the bands specified above (except sometimes $104\frac{9}{10}$) are especially very marked in the earth which is most easily precipitated by ammonia, which has a sulphate least soluble in potassic sulphate, and whose chloride, very soluble in pure water, is difficultly soluble in concentrated hydrochloric acid.

"Shall we find two earths respectively characterised by the bands $104\frac{9}{10}$ and α $115\frac{1}{5}$?

"The production of my reversion spectrum appears to be analogous physically with the formation of the phosphorescence spectra obtained by Mr. Crookes at the positive pole in his high vacuum tubes containing certain compounds of yttria. The conditions of the two experiments are, however, very different practically speaking.

"It is a singular fact that the positions of the phosphorescence bands observed by Mr. Crookes with very pure compounds of yttrium, are sufficiently near those which I, on my part, have obtained with hydrochloric solutions of the earths separated as widely as possible from yttria, chemically as well as spectroscopically. My reversion spectrum cannot, I think, be attributed to yttrium, for on the one hand it is seen *brilliantly* with products which give no trace of yttrium rays by the direct spark, and on the other hand I have found it impossible to obtain it sharply from certain earths extremely rich in yttria.

"As soon as my work is sufficiently advanced to enable me to arrive at some definite conclusion, I shall have the honour of informing the Academy of it."

M. Lecoq de Boisbaudran added the following additional note:—

I have not yet finished the very long work undertaken in the hope of determining the nature of the above described phosphorescence spectrum.

This spectrum is now recognised as being identical with that which is ascribed to pure yttria by Mr. Crookes, and which this *savant* obtained under experimental conditions very different to mine. Nevertheless my latest observations, as well as the older ones, lead to the conclusion that yttria is not the cause of the spectrum bands observed. In my fractionations the phosphorescence spectrum regularly gets weaker as I advance towards the yttria end. With almost pure yttria the phosphorescence bands show themselves faintly or not at all, whilst they are brilliant with the earths which do not give by the direct spark the rays of yttrium to an appreciable extent.

The prodigious sensibility of Mr. Crookes's reaction, which detects a millionth part of his purified yttria, makes very singular this divergence which I am obliged to point out between the conclusions of the eminent English chemist and myself. Mr. Crookes has willingly undertaken to examine some of my products in his high-vacuum tubes; and, on the other hand, he has promised to send me the earths prepared by himself, so that I can examine them by my process. A comparison of these cross experiments, it is hoped, will throw some light on the question of the origin of the phosphorescence spectrum.

Another conclusion from my researches, a conclusion which I publish with a certain reserve because my work is not yet finished, is that the bands 105 and 115 do not belong to the same element. On this hypothesis, based on the fact that some of my products give 105 notably stronger than 115, whilst others show 115 brightly and 105 faintly, I will provisionally call $Z\alpha$ the earth characterised by 105, and $Z\beta$ the earth giving 115.

Space does not allow me to describe to-day the principal experiments or observations undertaken to find out what are $Z\alpha$ and $Z\beta$; this will form the subject of another memoir.

I should acknowledge here that Mr. Crookes was the first to see the phosphorescence spectrum of samarium. During the past year only this spectrum was pointed out to me by my learned friend M. Demarçay, to whom I had confided the secret of my method for the production of phosphorescence spectra by the reversion of the induced current. I then made a drawing of it.—*Comptes Rendus*, vol. c. p. 1437, June 8, 1885.

SOCIETIES AND ACADEMIES

London

Chemical Society, June 18.—Dr. Hugo Müller, F.R.S., President, in the chair.—Messrs. Jos. F. Burnett and Harry M. Freear were formally admitted Fellows of the Society.—The following gentlemen were duly elected Fellows of the Society:—Messrs. Harry Haslett, Thomas Cradock Hepworth, Leonard de Koningh, Charles Langer, Arthur Richardson, James Sharp, James Pender Smith, James Spilsbury.—The following papers were read:—On the decomposition and genesis of hydrocarbons at high temperatures: I., the products of the manufacture of gas from petroleum, by Henry E. Armstrong and A. K. Miller, Ph.D. Having carried the examination of the various products of the decomposition of petroleum effected at high temperatures, in the manufacture of oil-gas (see paper in the *Journal* of the Society of Chemical Industry, September, 1884), as far as can usefully be done with the material originally dealt with, the authors now describe their methods and results; they remark, however, that these must be regarded as little more than preliminary, and that it will be necessary to repeat the investigation on a much larger scale, and to introduce new and improved methods. The products examined are (1) the portion of the compressed gas which combines with bromine; (2) the liquid deposited during compression of the gas to about ten atmospheres; (3) the portion of the tar which is volatile in steam. (1) By far the chief constituents of the mixture of bromides obtained by scrubbing the compressed gas by bromine are ethylene bromide and crotonylene tetrabromide, $C_4H_6Br_4$; propylene and butylene bromides have also been separated from it. The gas is practically free from hydrocarbons of the acetylene series capable of producing a precipitate in an ammoniacal cuprous solution. (2) The liquid deposited during compression of the gas is a complex mixture of olefines, of hydrocarbons of the C_nH_{2n-2} series, and of benzenes. The presence in it of *normal* amylene, hexylene, and heptylene has been demonstrated by the study of the products of oxidation of the various fractions. It is saturated with crotonylene, and contains a considerable quantity of the next homologue, C_5H_8; this latter hydrocarbon has not been previously described; it boils at 45°, and yields a tetrabromide which crystallises from alcohol in long flat prisms melting at 114°. All attempts to separate a hydrocarbon having the properties of Schorlemmer's hexoylene from the fraction boiling at 80°–82° have hitherto been unsuccessful, the statement previously made by one of the authors that this hydrocarbon was present having been based on determinations which have since been discovered to be faulty. The liquid deposited during compression of oil-gas is rich in benzene and toluene, but contains only traces of higher benzenes. (3) The steam distillate from the tar contains the less volatile hydrocarbons present in the liquid deposited during compression of the gas, together with a great variety of others. It is rich in hydrocarbons which are readily polymerised by sulphuric acid; these appear to be mainly members of the C_nH_{2n-2} series, such as Schorlemmer discovered in the light oils from cannel and boghead coal, and which yield no acid higher than acetic on oxidation. The three xylenes and mesitylene and pseudocumene are present in about the same relative proportions as in ordinary coal-tar; but in addition, the oil-gas tar contains certainly one—probably two—*higher* members of the benzene series: the amount obtained has not been sufficient, however, to permit of the precise determination of its nature. A very considerable amount of naphthalene may be separated from the tar; benzenoid hydrocarbons of higher boiling point than napthalene have also been obtained in small quantity. A certain, although relatively small, amount of a complex mixture of saturated hydrocarbons has also been separated from the tar: the quantity of material at their disposal has not enabled the authors to separate these to their satisfaction, and in a state sufficiently approaching purity; they are inclined to believe, however, that the mixture does not consist of paraffins, but of hydrocarbons of the C_nH_{2n} series—such as form the chief constituents of Russian petroleum. The hydrocarbons mentioned are by no means the sole constituents of the material examined, but merely those which have been proved to be present. The theoretical conclusions to be deduced from the results are in some respects interesting. It would appear that *only normal* olefines are present, and it is also remarkable that apparently this series is not represented by terms higher than heptylene. No true acetylenes have been detected; the crotonylene obtained is either *methylallene*, $CH_3{\cdot}CH{\cdot}C{\cdot}CH_2$, or *dimethylene-ethane*, $C_2H_2(CH_2)_2$, and from their behaviour on oxidation it is probable that the homologous hydrocarbons are closely related to it. Hence it may be inferred that in the formation of hydrocarbons of the C_nH_{2n-2} series at high temperatures from normal olefines of the formula $C_nH_{2n+1}{\cdot}CH{\cdot}CH_2$ two atoms of hydrogen are removed in such a way that the terminal $CH_2{\cdot}CH_2$ radicle in the formula becomes either

$CH_3 \cdot CH$ or $CH_3 \cdot CH$; although the production of acetic acid on oxidation of the hydrocarbons favours the former hypothesis, it is not safe to accept it until several of the hydrocarbons of the C_nH_{2n-2} series have been isolated and more completely studied. The possibility that *saturated* hydrocarbons of the C_nH_{2n} series are among the products is especially noteworthy, although it must not be forgotten that such hydrocarbons might have been original constituents of the petroleum used in making gas. To settle this and other questions, it is proposed to prepare oil-gas from *solid* paraffin on a sufficient scale to obtain the quantity of material required for the investigation.—On the non-crystallisable products of the action of diastase upon starch, by Horace T. Brown and G. H. Morris, Ph.D.—Decomposition of carbonic acid gas by the electric spark, by H. B. Dixon, M.A., and H. F. Lowe, B.A. Various chemists have investigated the decomposition of carbonic acid by the electric spark. Experiments having shown that no explosion is propagated by a spark in a mixture of carbonic oxide and oxygen dried by standing over anhydrous phosphoric acid, it seemed of interest to repeat the experiments on the decomposition of carbonic acid when dried in a similar manner. Carbonic acid dried over anhydrous phosphoric acid was submitted to a series of induction sparks in an eudiometer by means of a chain composed of short pieces of platinum fused into small glass bulbs. The amount of decomposition varied from time to time, approaching no fixed limit. Similar results were found on introducing a Leyden jar into the secondary circuit of the Ruhmkorff, but the amount of decomposition was less. On passing a series of induction sparks through a dried mixture of carbonic oxide and oxygen, partial combination gradually took place, but no fixed limit was reached. Two similar eudiometers were prepared and fitted with wires made of an alloy of platinum and iridium, each wire ending in a bulb about 2 mm. in diameter. The bulbs were brought to the same distance apart in the two tubes. On bringing an equal volume of dried carbonic acid into the two tubes, and sending a series of sparks from one Ruhmkorff coil through both tubes at the same time, the gases in the two vessels were found to be equally affected, their volumes varying exactly together so long as the pressure was kept the same in the two tubes. The more feeble the spark, the greater was the decomposition of the carbonic acid found to be. When 100 volumes of dried carbonic acid were brought into one tube, and 150 volumes of a dried mixture of carbonic oxide and oxygen were brought into the other, and a series of sparks were passed through both from the same coil, the volume of carbonic acid increased, and the volume of carbonic oxide and oxygen diminished, until after some hours they became equal. On a further prolonged passage of the spark the two volumes altered together, sometimes increasing and sometimes diminishing, as the nature of the spark varied. A coil of fine platinum wire was heated by an electric current to whiteness in dried carbonic acid. No permanent alteration of volume was produced. When a similar coil of platinum wire was heated in a mixture of dried carbonic oxide and oxygen, it glowed intensely for some minutes, and complete combustion was found to have taken place between the two gases. No flame was visible around the wires.—On the influence of silicon upon the properties of cast iron, by Thomas Turner, Assoc.R.S.M.—Eleven months' experience with toughened glass beakers, by R. J. Friswell.—Bromo-derivatives of diphenyl, tolylphenyl, and ditolyl, by Prof. Carnelley and Andrew Thomson.—Note on the influence of strain upon chemical action, by Prof. Carnelley and James Schlerschmann.—On the non-existence of gaseous nitrous anhydride, by William Ramsay, Ph.D.—On the causes of the decrepitations in samples of so-called explosive pyrites, by B. Blount.—On the specific action of a mixture of sulphuric and nitric acids upon zinc in the production of hydroxyamine, by E. Divers, M.D., F.R.S., and T. Shimidzu, M.E.—On the action of pyrosulphuric acid upon certain metals, by E. Divers, M.D., F.R.S., and T. Shimidzu, M.E.—On the constitution and reactions of liquid nitric peroxides, by E. Divers, M.D., F.R.S., and T. Schmidzu, M.E.—On the behaviour of stannous chloride towards nitric oxide and towards nitric acid, by E. Divers, M.D., F.R.S., and T. Haga.—Preliminary note on the reaction between mercurous nitrate and nitric oxide, and between mercurous nitrate and nitrites, by Edward Divers, M.D., F.R.S., and Tamemasa Haga.—On some derivatives of anthraquinones, by A. G. Perkin and Dr. W. H. Perkin, jun.

Royal Microscopical Society, June 10.—Rev. Dr. Dallinger, F.R.S., President, in the chair.—Mr. Suffolk exhibited a collecting bottle (made by Mr. Stanley) with flat sides, which had been worked to a true surface, through which an ordinary objective could be focussed with perfect definition.—Prof. Stewart called attention to a specimen he exhibited under the microscope, and a model showing the special eyes of Chitonidæ described by Prof. Moseley.—Mr. Wright's letter with reference to Dr. Anthony's criticism on his note on the structure of the tongue of the blow-fly was read, in which he gave all the credit of the discovery of the suctorial organs to Dr. Anthony, whose paper on the subject had been previously unknown to him. He also sent a slide of the blow-fly proboscis, mounted by Mr. Sharp, whose method of preparation and mounting in the biniodide of mercury solution was described.—Mr. Suffolk said he had examined Mr. Wright's first specimen, and he had also made a similar specimen of his own; but the conclusion he came to was that the appearances described were due to some sort of diffractive effect and that they were in fact out-of-focus appearances.—Mr. J. Mayall, jun., called attention to the fact that a Nobert 19-band test-plate had been successfully mounted in Prof. Hamilton Smith's medium, having a refractive index of 2·4, the results being to render the lines very much more visible than had been the case before The preparation was made by Dr. van Heurck, and was attended with considerable difficulty. He now thought it possible to improve upon the photomicrographs of the late Dr. Woodward of Washington, for, the lines being mounted in the highly refractive medium, could be illuminated by immersion means, so that an objective of higher aperture than any employed by Dr. Woodward could be used to resolve them. He hoped to try some experiments in photographing the test-plate by means of Powell and Lealand's new homogeneous immersion, 1/12th of 1·5 N.A.—Mr. Crisp said that they had received from Prof. W. A. Rogers, of Cambridge, U.S.A., a collection of upwards of 60 slides, showing the action of a diamond in ruling lines upon glass. The series was accompanied by a descriptive paper, which, when printed in the *Journal*, would enable the Fellows to compare it with the slides. The President said that Prof. Rogers had expressed the hope that some one might feel sufficiently interested in the subject to make a careful study of the slides. They had not yet had any opportunity either of examining the slides or reading the paper, but their best thanks were due to Prof. Rogers for his valuable donation.—Theiler's "Universal Pocket Microscope" was exhibited by Mr. Crisp.—Dr. Maddox said that since the last meeting he had continued his experiments on the feeding of insects with bacilli, and had fed both the wasp and the blow-fly with the Anthrax bacillus. They had lived on through the month until that very hot day when the thermometer rose to 136° in the sun, when they succumbed to what he believed was heat asphyxia, so that he was unable to attribute their deaths to any effect of the bacilli.—Mr. Waters read his paper on the use of the avicularian mandible in classification, the subject being illustrated by drawings.—Mr. Cheshire described a method of mounting in glycerine, which he had found of great advantage with the particular class of preparations (insect anatomy) with which he had lately been engaged; he further illustrated his meaning by drawings upon the blackboard and by the exhibition of specimens which were handed around for inspection.—Prof. M. N. Dutt's letter was read, accompanying some unknown powdery substance found near Delhi.

SYDNEY

Linnean Society of New South Wales, May 27.—Prof. W. J. Stephens, F.G.S., President, in the chair.—The following papers were read:—Note on the brain of *Halicore australis*, Owen, by N. de Miklouho-Maclay.—On a new species of *Haloragis* from New South Wales, by Baron F. von Müller, K.C.M.G., &c.—Two new Australian Lucanidæ, by William Macleay, F.L.S., &c.—A list of the *Cucujidæ* of Australia, with notes and descriptions of new species, by A. Sidney Olliff, Assistant-Zoologist, Australian Museum. In this paper, which is a preliminary contribution towards a monograph of the family, fourteen species are added to the Australian fauna. Ten new species are described, including five belonging to the genus *Læmophlœus*. A fine new *Brontes* from Port Darwin and the Richmond River, measuring 14 mm. in length, is characterised under the name of *B. macleayi*. It is distinguished from all the Australian species of the genus by its rather convex elytra, and in having the prothorax with the anterior angles very prominent and the sides feebly serrate. A table showing the geographical distribution of the species is added.—Description of some new fishes from Port Jackson, by J. Douglas-Ogilby, Assistant Zoologist, Australian Museum. Four fishes are here described—a new genus and species of Blenniidæ—*Petraites heptaolus*, also *Platycephalus macrodon*, *Percisnova-cambria*, and *Latris ramsayi*, the latter remarkable in its want of villiform teeth.—Note on *Neoanthias guntheri*, Cast, by J. Douglas-Ogilby, Assistant Zoologist, Australian Museum.—Notes on the geology and water supply of the interior of New South Wales, by the Rev. J. Milne Curran, F.G.S. The author points out the conditions under which the plains of the western interior have been formed, explains the river system or drainage of the level country, and indicates the sources of the subterranean waters which are met with in the gravel formations generally known as "drifts."—Some remarks on the fertilisation of the genus *Goodenia*, by E. Haviland.—Notes on a medusa from the tropical Pacific, by R. von Lendenfeld, Ph.D.—Contributions to the zoology of New Guinea; notes on birds from the Astrolabe Range, with descriptions of some new species, by E. P. Ramsay, F.R.S.E., &c. In this paper two new forms of Paradise birds, *Parotia lawesii* and *Lophorina superba minor*, are described, the former differing chiefly from its ally from Mount Arfak in the shape of the frontal crest and olive-coloured shield, the latter chiefly in size; measurements of specimens from both districts are given. The remaining portion of the paper gives a list of species hitherto only recorded from Mount Arfak.—Description of a new species of Collyriocincla, from Queensland, by E. P. Ramsay, F.R.S.E., &c.

PARIS

Academy of Sciences, July 13.—M. Bouley, President, in the chair.—A method of determining the absolute co-ordinates of the polar stars without the necessity of ascertaining the instrumental constants (declinations), by M. Lœwy.—Telluric spectra, by M. J. Janssen. The author reports the completion of the apparatus prepared in M. Ducretet's *ateliers* for the study of the gases in the terrestrial atmosphere and of the vapour of water.—Note in reference to M. Stieltjes' communication on a uniform function, by M. Hermite.—On the motion of a heavy revolving body attached by a point of its axis (continued), by M. G. Darboux.—On the theoretic aim of the late M. Henri Tresca's chief studies in the field of mechanics, by M. de Saint-Venant.—A study of the action of dust-particles left to themselves, by M. Chevreult. The particles in question came from a factory in Paris, where the hair of cows and calves is prepared for the spinning-mills of England. They have been left for a twelvemonth on a sheet of red paper in a cylindrical vessel, where they have presented certain mechanical, physical, and chemical phenomena studied and photographed by the author.—Fundamental principles of the new science of dynamic meteorology: reply to M. Mascart's note of June 29 (second part), by M. H. Faye.—Remarks on the same subject in reply to M. Faye, by M. Mascart.—Magnesia; its preparation from sea-water and application to various branches of industry, by M. Th. Schlœsing.—On the central nervous system of *Tethys leporina*, by M. H. de Lacaze-Duthiers.—Note on the homography of two infinitely-extended solids, by M. Sylvester.—On the nature of the transformations undergone by extenuated charbon virus cultivated in compressed oxygen, by M. A. Chauveau.—Remarks on Dr. Brouardel's report on his recent mission to Spain, by M. Pasteur. If Dr. Ferran has really discovered a remedy against cholera he will stand in no need of any Minister's signature; all mankind will welcome a guarantee of the moral and material value of his discovery. To persist in refusing to see this would justify all suspicions, as has become evident since the publication of the replies made to the French Mission in Spain. Dr. Ferran now wishes to withdraw from the position taken up by him, as appears from his fresh note addressed to the Academy. On this issue Dr. Brouardel will be the first to congratulate himself.—Remarks accompanying the presentation of the second edition of his work on the origin of the world, by M. H. Faye.—Protection against cholera by means of hypodermic injections of pure cultivations of the comma bacillus, by M. Jaime Ferran. The Spanish physician describes the results obtained from his method as quite astounding, and maintains that it offers an absolute remedy against cholera. The dangers of attack and death begin to disappear five days after vaccination, and the immunity from further attack increases with each successive injection. The period of immunity cannot yet be accurately determined, but a minimum of two months may already be confidently anticipated.—Observations of Barnard's new comet made at the Paris Observatory (equatorial of the West Tower), by M. G. Bigourdan.—On a law of reciprocity in the theory of displacement of a solid body, by M. A. Schœnflies.—On a uniform function in mathematical analysis, by M. Hermite.—Observation of a cloud of black particles which were seen to cross the solar disk with varying velocity on August 28, 1871, by M. E. L. Trouvelot.—Indices of refraction for some crystallised alums, by M. Ch. Soret.—On the spectra of absorption of some colouring matters, by MM. Ch. Girard and Pabst.—On the electric resistance of copper at a temperature of 200° C. below zero, and on the isolating point of liquid oxygen and nitrogen, by M. S. Wroblewski.—Heat of formation of the bromide and iodide of antimony, by M. Guntz.—On the double bromides of gold and phosphorus, and on a chlorobromide, by M. L. Lindet.—On a method of producing the alkaline earthy manganites, by M. G. Rousseau.—On the development of the Hematodes, and especially of *Ascaris megalocephala*, by M. de Lacaze-Duthiers.—On *Adamsia pallatia* and its association with *Eupagurus Prideauxi*; a hitherto unrecorded instance of symbiosis, by M. Faurot.—On the parasites of *Mæna vulgaris*, by M. R. Saint-Loup.—First traces of the presence of Permian rocks in Brittany, by M. Ed. Bureau.—On the Permian formations occurring in the departments of Aveyron and Hérault, by M. J. Bergeron.—On the distribution of luminous intensity and visual intensity in the solar spectrum, by M. Aug. Charpentier.—On a case of cebocephaly (atrophy of the nasal process), complicated with partial anencephaly, observed in a foal, by M. Dareste.—Attenuation of the cholera virus, by MM. Nicati and Reitsch. From a series of experiments made on the guinea-pig the authors conclude that the cultivated virus loses all efficacy after a few weeks.—Photographic experiments in a balloon, by M. G. Tissandier. During an ascent on June 19, 1885, in Paris, the author, aided by M. J. Ducom, obtained some excellent photographs at elevations ranging from 605 to 1100 metres. By the new processes of instantaneous photography these operations have been greatly facilitated, and may render effective service in time of war.—Remarks on a partial earthquake felt only on the surface of the ground in the Department du Nord, by M. Virlet d'Aoust.—Note on the microzymas of the Jequirity plant, by MM. J. Béchamp and A. Dujardin.

CONTENTS

THURSDAY, JULY 30, 1885

THE UNIVERSITY OF LONDON

CONVOCATION met on Tuesday to consider the report and draft scheme submitted to it by Lord Justice Fry's Committee. After a somewhat lengthened debate the House adjourned till November 3, when no doubt their consideration will be resumed.

We do not think much is lost by the delay. As we pointed out last week, the scheme has at first sight an aspect of complexity. But this arises in great measure from the technical form and language with which it is necessary to invest provisions intended to receive legislative effect. We do not think the underlying principles are difficult to disentangle, but it could hardly be expected that such a body as Convocation would grasp them without considerable opportunity for explanation and discussion.

The particular date which the accident of circumstance determined for the meeting was in some respects unfortunate. Many of the medical graduates who might be expected to support the scheme were drawn away by the meeting of the British Medical Association at Cardiff. In November all the medical schools will be in full activity, the leading teachers in every faculty will be in town, and the preliminary ventilation which the scheme has now received, followed, as it will be, by the discussion and reflection of the vacation, will prepare Convocation for a definitive decision in the autumn.

What that decision should be there can hardly be any doubt in the mind of any reasonable person. The remarkable attention bestowed by the leading journals on a purely academic question goes far to prove that the ear of the public is ready to entertain any reasonable proposals for the development of real university work in London. It is for the graduates in Burlington Gardens to decide whether they will approach the task or leave it to some new organisation which may be created for the purpose. That the thing sooner or later in some shape or other will be done we have not ourselves a shadow of a doubt.

The Association for promoting a Teaching University for London has suspended to some extent its own efforts, pending the action of Convocation, to which in its first report it has given its cordial support. The Association and the Committee of Convocation do not, however, seek to attain their objects quite on the same lines, and the identification by some of the speakers on Tuesday of the views put out on behalf of the two perfectly distinct bodies introduced a certain amount of confusion into the debate which no doubt the present opportunity for further consideration will go far to remove.

Of the debate itself little is to be said. Lord Justice Fry's speech explanatory of the scheme had the quality of lucidity which every one expected from him. But more than this, he exhibited a largeness of view in contemplating the possible future of the University which might have been expected to carry with it a more enthusiastic sympathy from Convocation than it obtained. The criticisms which followed were mostly on points of detail, and, on the whole Convocation, without being adverse, evidently felt that it should like more time for reflection.

THE EVOLUTION OF THE PHANEROGAMS

L'Evolution du Règne Végétal. Les Phanerogames. Par MM. Marion et Saporta. (Bibliothèque Scientifique Internationale, 1885.)

SINCE the appearance of the first volume of this important work the views of the authors have been subjected to more than one attack, and they have turned aside to vindicate the correctness of their interpretation of the often obscure fossils upon which our knowledge of the earliest forms of plants is based. The wisdom of the delay is unquestionable, for it would have been useless to continue a work whose foundations had been shaken by adverse criticism. It is not to be expected that their views will even yet be universally acceptable, for the difficulties attending the study of fossil plants are such that its most experienced professors are still scarcely agreed upon some of the fundamental questions. It is well known that Prof. Williamson is opposed to the French school as to the gymnospermous nature of several groups of Carboniferous plants, and in addressing the British Association in 1883 (NATURE, September 20, 1884) he criticised in advance some of the main facts dwelt upon in this work. In contrast to the divergent views of English investigators, the greatest workers in France, including the honoured names of the late Adolphe Brongniart, and of MM. Grand'-Eury, B. Renault, Marion, and de Saporta, are in complete accord. Their work presents for the first time a complete outline of the evolution of the vegetable kingdom, and its importance and novelty are such as to demand a critical as well as friendly examination.

In the former volume it will be remembered (NATURE, May 26, 1881) the authors endeavoured to trace the development of vegetable life from the protoplasmic body, differentiated from animal life in no way other than through the conversion of a portion of its protoplasm into chlorophyll, to the heterosporous cryptogams. The present volumes prove that there is an almost direct passage from the latter to the far higher phanerogams.

There is no need to argue at the present day that if phanerogams were differentiated from cryptogams this must have taken place in very remote times; and it is equally certain that evolutionists will be disposed to anticipate that the initial differences between them must at first have been relatively imperceptible. An heterosporous cryptogam in which the microspores penetrate to a solitary macrospore in order to effect fertilisation, and in which the prothallus is enclosed and germination takes place *in situ*, is well on the road to become a phanerogam and, moreover, a gymnospermous one, if the macrosporangium be not protected by any leaf modified into a tegumentum. The change in the reproductive organs was accompanied and preceded by modifications in the vegetative organs, and the transformation is actually found to have progressed through three distinct stages—the *progymnospermous*, the *gymnospermous*, and the *metagymnospermous*.

The Progymnosperms are among the earliest plants known, and already occupied an important position in Carboniferous floras. Though they are now completely extinct, the Cycads have to some extent preserved their characteristics. They retained many characteristics of the cryptogamic stock whence they originated, which are completely lost to remote descendants of the present day. As the earliest connecting links between Cryptogams and Phanerogams their morphology is peculiarly interesting, and the exquisite preservation of many of their silicified or calcareous stems permits the minutest details of this part of their structure to be studied.

That Cryptogams reached a far higher stage of development in the Palæozoic time than exists in any living representative is one of the few facts that has not been disputed. One of the best-known of these is Lepidodendron, a tree-like plant allied to the Lycopodiaceæ. Its structure has frequently been described, and presents nothing unusual to Cryptogams. But in Sigillaria, a plant strongly resembling it in nearly every other respect, we find a radiating vascular cylinder or woody zone in the cellular stem, with unmistakeable exogenous growth. It is richly supplied with medullary rays, and, Prof. Williamson allows, presents clear evidence of interruptions to growth, succeeded by periods of renewed vital activity. The same writer also describes the prosenchymatous and the parenchymatous structure investing the woody zone as a bark, and remarks that, although not divisible into three layers, the enormous development of the elongated prosenchymatous fibres or bast-tissue in the inner layers of the epidermis of the fossil stems is a manifest foreshadowing of the presence of that same tissue in the bark of living exogens, especially the Cycads. In Diploxylon there is a further development, the woody zone being made up of an inner or medullary vascular cylinder, either interrupted or continuous, composed of large scalariform vessels without definite order, and an outer cylinder of scalariform vessels of smaller size arranged in radiating fasciculi. There is no difference of opinion as to the exogenous nature of the woody zone, which bears a relatively small proportion to the diameter of the stem, and as to the presence of medulla or pith and bark; but while Adolphe Brongniart and our authors class Sigillaria in consequence as a low form of exogen, a progymnosperm, Prof. Williamson and some of the German authors prefer to regard it as a highly-developed Cryptogam. He possesses specimens which conclusively prove to him that the exogenous wood is undeveloped in the young stages, and that young stems of Sigillaria are indistinguishable from Lepidodendrons; but though there is a gradual passage from one to another, the typical Lepidodendron never produced a ligneous zone. Sir J. W. Dawson, who has done much to elucidate this subject, believes that even some Lepidodendrons are exogenous, and that all Sigillarias are so. The evidence goes to prove that unquestionable Lepidodendrons in youth gradually acquire the internal features, notably the exogenous ring, characteristic of Brongniart's gymnospermous family of Sigillariæ. So far as its bearing on evolution is concerned, the differences of opinion scarcely affect the question. Whether they are looked upon as Cryptogams with exogenous growth, or exogens with cryptogamic characters, they are equally valuable as connecting-links, and if we agree with Prof. Williamson that they pass direct into true Lycopodiaceæ, the chain only becomes so much the more direct and complete. During growth the woody or exogenous zone increased for a certain period, but this was quickly arrested by the absorption or destruction in some way of the Cambium layer. The subsequent increase in diameter took place mainly in the cortical system, and to it the growth and solidity of the stem was principally due. The exogenous element in the oldest known trees is thus seen to have been transitory and subordinate, for had it persisted indefinitely, the continued generation of fresh layers or new rings of growth would have produced true dicotyledonous stems. It is suggested that until seasons, or alternations of activity and repose, replaced the earlier uniformity of climate, an exogenous growth would have been of relatively little use to the plant.

Sir J. W. Dawson has observed specimens of Sigillarian stems possessing still more definite exogenous characters, and in Poroxylon M. Rénault finds that the wood is dotted with areolated punctæ similar to those distinguishing the spiral vessels of Cycads and Araucariæ. Still the structure of their stems agree in so many respects with those of the highest heterosporous Cryptogams, the Lepidodendrons, that the difference between them remains almost insensible. Moreover, the Sigillarias are not supposed to be in the direct line of the evolution of Gymnosperms, but an offshoot which was quickly extinguished, and even in the Carboniferous time exogenous trunks were growing side by side with them. The construction of their stems was greatly varied, and it is evident that their plan of growth was susceptible of very considerable modification and development. It is now universally acknowledged that some Stigmarias are the roots of Sigillaria, yet here again we find a remarkable divergence of opinion, for while our authors regard them as rhizomes capable of bearing leaves as well as roots, Prof. Williamson contends that they are merely roots with rootlets. The Stigmarian rhizomes were procumbent and vegetated in the soft mud, Sigillarian stems budding from them occasionally, erect and cylindric, and crowned with a mass of long and linear leaves whose scars, impressed upon the bark, give rise to complex and beautiful tesselated designs. To how great an extent their fruiting organs preserved their cryptogamic attributes is unfortunately even yet imperfectly known.

The next type of progymnospermous stems, that of Calamodendron, is more remarkable because more abnormal, for it possessed a hollow fistular stem with verticillate leaves, closely resembling in appearance a gigantic Equisetum. Here again there is an irreconcilable divergence between the views of the French authors and those of Prof. Williamson. The former separate Calamites from Camalodendron, believing them to have been confounded simply because the casts of the interior of the hollow stems of both accidentally present the same grooved and articulate aspect, though morphologically they completely differ. Calamites they maintain to be a Cryptogam whose thin walls presented within and without the same structure as those of Equisetum. Prof. Williamson urges that no such Calamite has ever been found, but that, however thin the walls of a specimen may be, they always show the Calamodendron structure if any is preserved, and that the points of agreement are too remarkable to be a mere case of mimicry between a cryptogam and a gymnosperm. Our authors, however, lay stress on the fact that there are two very distinct types of articulated root, belonging respectively to the two genera in question, but although Prof. Williamson recognises them both, he does not specially comment on the fact. As to matters of fact relating to the structure of the Calamodendron stem, opinion does not differ, but the Professor, as in the case of Sigillaria, views them as Cryptogams of exogenous growth, without, however, admitting the close relationship to the Equisetaceæ advocated by Mr. Carruthers.

The stems of Calamodendron were filled in solid with pith or cellular parenchyma when young, but became hollow with age, the fistular interior of the stem consisting then of a linear series of oblong chambers, making an entire internode and separated from each other by transverse medullary diaphragms. The exogenous zone consisted of numerous woody wedges separated from each other by peculiar prolongations of the pith, to which Prof. Williamson assigns the name of primary medullary rays, while secondary medullary rays separated the constituent vascular laminæ of each wedge as in recent Exogens. These extended vertically from node to node, when they underwent a change. The apex or inner face of each wedge originates in a duct or canal. Investing this woody zone was a thick cellular cortical layer without vessels. The bark is very rarely preserved and is not exogenous in character, the tripartite division of existing Coniferæ not being present. The outer surface appears to have been smooth, and not fluted longitudinally, at the same time masking the articulations. Camalodendron thus possessed exogenous wood playing exactly the same *rôle* as in Sigillaria, surrounding the pith, and closely resembling the first year's shoot of a recent conifer; but it differed in the verticellate arrangement of its appendicular organs. The structure of the root hardly differs from that of the stem, this indicating, according to the authors, a peculiarly primitive type, and the rootlets grew from the nodes and were branching. Prof. Williamson states, on the other hand, that the root is adventitious and not a prolongation of the main axis. The leaves or branchlets were distributed on the trunk at regular distances on the line of the nodes, which were pretty close together, alternating regularly from one to another, so that the appearance resulting was that of a quincuncial arrangement, the more obvious on account of the concealment of the nodes by the bark. There is no direct proof, but the authors believe that the foliage known as Archæocolamites and Bornia, consisting of repeatedly dichotomosing acicular leaves arranged in verticels around nodes on slightly striated stems, really belongs to Calamodendron, in which case the male inflorescence was born in catkins something like those of the Taxeæ. Sir J. Dawson, however, states that he has found leaves like those of Asterophyllites attached to stems of Calamodendron. The fruiting organs are still very imperfectly known, but Prof. Williamson believes them to have been a heterosporous Strobilus like those of Lepidodendron. The authors, in conclusion, remark upon the resemblance between leaves of Bornia and those of Trichopitys and Bryon, which are true Salisburieæ, for, though the one is verticellate and the other spiral in disposition, the possibility of an easy transition from one to the other is exemplified in Calamodendron, and both modes occur together in existing Cupressineæ and the young Abietineæ.

Prof. Williamson believes that Calamites and Camalodendron are one and the same plant, and this a cryptogam. Against the exogenous wood he sets the cryptogamic bark, the Strobilus with Calamite structure full of spores, the adventitious roots and the verticellate arrangement of the leaves. It seems hardly possible, however, that such observers as A. Brongniart, M. Grand'-Eury, M. Rénault, and our authors can all be mistaken. In the former volume a graphic description was given of the growth of the Equisetum-like Calamites as they occur at St. Etienne. Prof. Williamson has not come across an undoubted Calamite, and very prudently disbelieves in their existence, but his evidence seems negative rather than positive, and we have already seen in several instances that coal-plants may have flourished in great numbers in one country and yet be exceedingly rare in another. The Carboniferous lasted over an immense period of time, and there appears less reason, as their plants become more completely known, to suppose that the forests were then composed of few types universally distributed. Development was proceeding actively, and it is quite conceivable that a gigantic primæval Cryptogam might take on phanerogamous characters without greatly modifying its external appearance.

Another remarkable cryptogam with exogenous wood is described by Prof. Williamson as Astromyelon. The stem was hollow, and except that it was not articulated, resembled that of Camalodendron. It appears that the stem and branches grew together under exactly the same relation as those observable in an ordinary exogenous tree, the latter not differing materially in their outward appearance from those of an ordinary pine. He appears to have felt hesitation in classing it, as he uses the expression "I am inclined to place" it among Cryptogams. Its affinities he considers to be with Marsilea, and we have thus—perhaps—in the coal-measures arborescent representatives of the Lycopodiaceæ in Lepidodendron, of Equisetaceæ in Camalodendron, and of Marsiliaceæ in Astromyelon, all of them having possessed rudimentary exogenous trunks.

J. STARKIE GARDNER

HARBOURS AND DOCKS

Harbours and Docks. By L. F. Vernon-Harcourt, M.A. (Oxford: Clarendon Press, 1885.)

IN the author's previous work on "Rivers and Canals" the science of hydraulic engineering received a valuable addition and the subject was treated, as far as it was necessary for inland works, in a masterly manner, fully upholding the author's high standing in his profession. We have now another work by the same author, in which the sequel to "Rivers and Canals" is given. In "Harbours and Docks," sea-works and kindred engineering subjects receive full consideration, the two books containing together an excellent collection of data on hydraulic engineering generally.

Of all the many branches of the engineering profession, that of hydraulic engineering pertaining to sea works and similar constructions trusts less to theory and more by far to practice than any other. The hydraulic engineer for sea works has no convenient formulæ to guide him, but only previous experience and precedent. This is evident from the volume before us, for most of the sea works described are improvements on previous constructions.

The author commences with a description of the natural laws which govern the general movements of the sea, the causes and action of its waves, tides, currents, and consequent changes in the coast line, the knowledge of which is all important when any new works are projected; indeed, it is not too much to say that many sea-works have proved very expensive in their maintenance owing to ignorance of the above conditions when they were designed.

The author divides the various types of harbours into five classes—(1) estuary harbours; (2) harbours with back-water; (3) harbours partly sheltered by nature; (4) harbours protected solely by break-waters; (5) peculiar types of harbours with detached break-waters. After having given long and clear descriptions, with excellent illustrations of the several types, the author remarks with reference to the first three classes and their shelter from the sea:—"Some natural shelter exists in all the harbours referred to above, but it will be noticed that the amount of shelter varies considerably. Thus whilst at Cherbourg, Plymouth, Wick, Genoa, and Barcelona the entrance alone of a complete bay requires protection; at Holyhead, Table Bay, and Alexandria only a portion of the extensive bays in which the harbours are situated can be utilised, though the existence of the bay diminishes considerably the exposure; and lastly, at Dover, Newhaven, and Colombo projecting points of the coast, rather than regular bays, are taken advantage of for the site of a harbour." After discussing the last two classes of harbours, we have the conditions which govern the size and position of the entrances to harbours explained. We commend these chapters to the careful perusal of those who take an interest in the proposed harbours of refuge, for here will be found considerable information concerning the advantages of the several sites proposed.

Chapter V., and those following, until the end of Part I. of the book is reached, deal with perhaps the most important of all sea-works—viz. break-waters. The author classifies their several modes of construction into three classes—(1) mound of rubble and concrete blocks; (2) mound with superstructure; (3) upright wall. Under these heads we find all the principal break-waters, each being well described, the construction explained, and reason given for any special work.

It is interesting to follow the gradual increased use of Portland cement concrete in the place of natural stone, and, as the latest break-water, we may take the one at Newhaven now in construction. This break-water is practically one solid mass of cement concrete. It is built on the upright wall system, with concrete in bags deposited from hopper barges on the chalk bottom up to low-water, and concrete-in-mass above. The bags each contain about 104 tons of concrete, the concrete being mixed by a special machine consisting of a screw working in an inclined cylinder, the materials being added at one end, water being added during the transit, thoroughly mixed concrete coming out at the other end.

In Part I. of the volume is to be found every information with regard to sea-works generally; the descriptions and details of the construction of the Manora break-water, Madras harbour, and Alderney break-water among the many others, are extremely interesting, being as well written as they are good. Of the American break-waters described, those constructed in the large lakes, are, as may be expected, principally constructed of wood, some being bound together by means of iron ties. The form taken is generally crib-work, floated out to the site in sections, and filled with stone. Before leaving the subject of break-waters we will quote the author's opinion on floating break-waters; this is interesting at the present time on account of the late experiments at Eastbourne and other places. He says:—"Various schemes have been suggested from time to time for arresting waves by means of floating break-waters moored in position. It has been imagined that the undulation being on the surface might be stopped or reduced considerably by an obstacle at or near the surface, and thus the cost of building up a break-water from the bottom could be saved; though, in the case of large waves, the undulatory motion is not simply superficial, yet, undoubtedly, the power of the waves would greatly diminish if the upper portions could be arrested in their progress; and the gain in dispensing with a solid structure founded on the bottom of the sea would be very great." He then tells us of several forms tried which were not successful in reducing the waves, and in conclusion says:—"The force of waves is so great, as indicated by its effects in moving huge masses, that no fragile floating moored construction could possibly oppose an adequate resistance. The accumulated power of the wind, acting through the medium of the waves, cannot be evaded, but must be met; and this can only be effectually accomplished by a solid break-water." This part of the book concludes with a chapter on lighthouses, beacons, and buoys; the construction and cost of all the important lighthouses is given and admirably illustrated.

In Part II. "docks" receive very full consideration, Chapters XIX. and XX. dealing with sites, preliminary works for docks and dock walls; suffice it to say that all these are treated in such a way as to render it evident that the author is thoroughly master of his subject. In Chapters XXI. and XXII. the usual fittings pertaining to docks are discussed, their entrances and locks, dock-gates and caissons of all kinds thoroughly described, and their varied construction under different conditions explained. All the following chapters, which occupy the last 150 pages of the book, are taken up with a general, and in some cases a detailed, description of some of the more important English and foreign docks; it is needless to say that they are all thoroughly well treated, and the trade statistics are carefully given and useful comparative distinctions drawn.

As a work on hydraulic engineering we can confidently recommend it to all those who are interested in the subject, feeling convinced that it will be found a most useful book. The author has produced, and students will profit by, a book well written, sound, and most useful in forwarding the science. Both volumes do credit to the publishers, the plates are good and well executed. These volumes ought to find a place in every technical library in the country.

OUR BOOK SHELF

Lehrbuch der vergleichenden Mikroskopischen Anatomie. Von Dr. Herman Fol. Erste Lieferung. (Leipzig, 1884.)

THE present volume is the first of a work which promises to be in many respects an important addition to the literature of microscopic anatomy. It describes in clear and concise language most of the commendable methods used by the author himself for examining and preparing microscopic specimens of animal tissues.

The methods of injecting vessels and cavities, the nature and preparation of the various materials and apparatus useful for injection, the theory and practice of the microscope and practice of the auxiliary apparatus are treated thoroughly, the theory and practice of drawing microscopic objects, the methods most useful for making micro-photographs, and for showing stereoscopically small objects, are fully described and illustrated, and will be found most useful and instructive reading. Next, the methods for examining living tissues, for fixing and hardening them, then the various ways for embedding and making sections, are minutely described. The last or seventh section is one of the most important ones, giving an excellent *résumé* of micro-chemical reactions, including the osmic acid gold and silver methods, and the methods of staining tissues with carmine, hæmatoxylin, and the various aniline dyes.

To each section is added a useful bibliographical summary. On the whole the book is an excellent guide for microscopists, both teachers and original workers.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Unconscious Bias in Walking

THE results of some experiments recently made to ascertain the cause of the well-known phenomena of "unconscious bias in walking" will perhaps be of interest to your readers in connection with the various theories presented in the discussion of this subject in NATURE (vol. xxix. pp. 262, 286, 310, 356, 384, 452).

Within the past six months over 2500 anthropometric measurements have been made of students in the three higher classes of the Massachusetts Agricultural College, including the relative length and strength, muscular development, &c., of the limbs, and the bias in walking of forty-nine individuals has been carefully determined, with results as given in the following summary statement.

In making these measurements I have been assisted by Dr. F. Tuckerman, of this place, who will collate the data obtained in their relations to bilateral symmetry.

The tests to determine the bias in walking were made in the drill-hall of the College, a room with a hard smooth cement floor, well adapted to this purpose.

For convenience in recording the curves of divergence a meridian or base line was drawn through the middle of the floor lengthwise of the hall, and on each side of it lines of departure were marked 1 metre apart, while the latitude was indicated by transverse parallel lines every 2 metres.

In trials to determine the bias, the individual was placed on the meridian line 2 metres back of the first parallel, and after he had well fixed the bearings of the line, he was blindfolded and started at a rapid, but not hurried pace. If he crossed the first parallel of latitude on the meridian line, he was allowed to proceed, but if a marked divergence from this line was made he was stopped, and a new start was made in the right direction. Small sticks were laid down on each parallel of latitude at the point of crossing, by assistants conveniently placed for this purpose, and at the end of the course the line of march could be readily seen. In some cases irregularities in the curve indicated either a hesitating or constrained effort in walking, or errors in marking the precise point of transit.

In these cases the trials were repeated, until a reasonably true curve was obtained. A record was then made of the distance from the meridian line, to the right or the left of the point of crossing on each parallel of latitude.

From this record the curves made were plotted on a diagram, so that they could be readily compared and their peculiarities noted.

That the relative length and strength of the legs has no direct relation to the bias in walking will be readily seen from the following tabular statement:—

TABLE I.

No bias in 5 cases	In 2 the right leg is longest ... (One of these presented the greatest difference in length of legs, and the other more than the average of those with right leg longest)	In 1 the right leg is strongest In 1 strength of legs not tested
	In 3 the legs of equal length ...	In 1 the right leg is strongest In 2 the left leg is strongest (*a*)

Four are right-handed.

One uses right and left with equal dexterity (*a*). In pointing at a distant object with both eyes open, in three the right eye is dominant, in one the left eye is dominant, and in one both eyes are apparently used to determine the range.

TABLE II.

Bias to right in 14 cases	In 5 the right leg is longest ...	In 2 the right leg is strongest In 2 the left leg is strongest In 1 the strength of legs not tested
	In 4 the left leg is longest ...	In 3 the right leg is strongest (*a*) In 1 the left leg is strongest
	In 5 the legs are of equal length	In 2 the right leg is strongest (*a*) In 3 the left leg is strongest

All are right-handed.

In pointing at a distant object with both eyes open, in 12 the right eye is dominant, and in 2 the left eye is dominant, the latter in the groups marked (*a*).

TABLE III.

Bias to left in 30 cases	In 8 the right leg is longest ...	In 5 the right leg is strongest (*a*) (*b*) In 2 the left leg is strongest In 1 the legs of equal strength
	In 10 the left leg is longest ...	In 5 the right leg is strongest (*b*) In 4 the left leg is strongest (*b*) In 1 the legs of equal strength
	In 12 the legs of equal length ...	In 5 the right leg is strongest In 5 the left leg is strongest (*b*) In 2 the strength of legs not tested

One is left-handed (*a*). Twenty-five are right-handed. Four use right and left with nearly equal dexterity (*b*). In pointing with the finger at a distant object, with both eyes open, in 22 the right eye is dominant, in six the left eye is dominant, and in 2 both eyes are apparently used to determine the range.

The relative dexterity of the legs was tested in a number of cases, but a press of other duties prevented further experiments in this direction. From the tests made, however, it is obvious that there is no direct relation of the relative dexterity of the legs to the bias in walking.

From these experiments it is evident that the cause of the observed unconscious bias in walking is not to be found in the mechanical proportions, or relative strength, or dexterity (?) of the legs.

The application of well-established physiological principles will, however, furnish a ready explanation of the phenomena in question.

The co-ordination of the voluntary muscles is the exclusive prerogative of the nervous system and the senses are important factors in all movements involving a definite direction. The muscles of locomotion when called into action under ordinary conditions, as when walking in a straight line, are co-ordinated or brought into an orderly correlation, by impulses conveyed to the nervous centres through the afferent or sensory nerves, but when in the dark, or in a mist, or when one is blindfolded, the senses are not available as a guide to direction, the co-ordinating nervous mechanism is dormant, and a divergence from a right line is made to the right, or the left, from a lack of equilibrium in the action of the efferent or motor nerves.

In several of the trials, to determine the bias in walking, interruptions occurred before the course was completed, by the opening of the door at the side of the hall and the talking, in a low tone, of the visitors, which served as a guide in orientation, and the curve made before the interruption was suddenly corrected to a line parallel to the meridian.

In all of the trials the greatest care was taken to prevent the senses from gaining clues to the right direction.

Unconscious bias in walking is obviously the result of vital activities involving complex actions and reactions in the nervous system, which may be clearly defined in general terms, while the details of the obscure changes taking place in the nervous mechanism cannot, in the present state of our knowledge, be fully traced. Moreover, it is evident that the phenomena in question must be studied from the same stand-point of other biological processes which cannot be explained or expressed by purely physical or chemical conditions. Massachusetts Agricultural College, Amherst, Mass., April 7

The Flora of Canada

THE review by Mr. J. G. Baker in your last number (p. 242) of the second part of Prof. Macoun's "Catalogue of Canadian Plants" prompts me to send you a few notes on some of the features of the flora of Canada, which I had an unusual opportunity of observing last autumn under the guidance of Prof. Macoun in the neighbourhood of Ottawa, and again in the magnificent railway trip given to members of the British Association by the Canadian Pacific Railway Company from Lake Superior to Kicking-Horse Pass in the Rocky Mountains.

Throughout Eastern Canada and the Eastern United States the European botanist is struck with the strange intermingling, in the wayside flora, of forms new and strange with those familiar by every roadside and in every hedge-bank in England. Away from human habitations the flora is almost altogether novel, but near houses, introduced purposely or accidentally, the English weeds are rivalling and even supplanting the native. I was particularly struck with noticing the vegetation of the grass lawn by the hotel on the Catskill Mountains at an elevation of about 3000 feet. It consisted almost entirely of the same species as you would expect to find in similar situations at a lower altitude in the old country: *Achillæa Millefolium*, *Daucus Carota*, *Plantago major*, *Chenopodium album*, *Cnicus lanceolatus*, &c., most or all of them importations. Elsewhere, in the east, you find docks, milfoil, thistles, shepherd's purse, jostling *Asters*, *Asclepiases*, *Amaranthuses*, *Solidagos*, and other peculiarly American weeds. Exactly the same thing is taking place with introduced animals. I was staying at a farmhouse in Ontario, not far from Niagara, and was told that the English house-sparrow made his appearance there about three years since, and is already as abundant as in England, and a terrible nuisance. Some English plants, however, like our daisy and primrose, seem to refuse to naturalise themselves to the American soil and climate.

Everywhere the lines of the railways are marked by the advent of the foreigner. As Prof. Asa Gray said at Montreal, even English weeds now travel by express train. It is most interesting, in travelling westwards over the vast continent, to note the gradual disappearance of European and the unrivalled supremacy of American types. But it is not only westwards that the tide of floral conquest makes its way. A fellow-traveller of our party had the good fortune to gather, near Port Arthur on Lake Superior, where we were detained twenty-four hours by stress of weather, a grass, *Beckmannia erucæformis*, 300 miles east of any locality previously recorded

Although in the main the indigenous American flora is altogether different specifically from ours, yet there are exceptions. I am not now speaking of the Alpine flora of the Rocky Mountains, which agrees to a wonderful extent generically, and even specifically, with the flora of the Alps, Pyrenees, or Grampians. Covering the vast extent of ground from the eastern sea-board to the Rockies are a few species undoubtedly indigenous and absolutely identical with European and even English forms. I may mention three illustrations taken from widely-separated natural orders—*Potentilla fruticosa*, *Campanula rotundifolia*, and *Linaria vulgaris*. How to reconcile these facts with any theory accounting for the geographical distribution of species on the face of the earth it is difficult to say.

Even more interesting are those cases where American and European plants are regarded as belonging to the same species, but where there is a certain difference difficult to define, but recognisable at a glance. To take, again, three examples:—Among the most cosmopolitan of ferns are *Osmunda regalis* and *Pteris aquilina*. Abundant throughout Canada, there is yet, in both cases, a general habit by which they are at once distinguished from the English forms. Again, the American *Plantago major* is all but indistinguishable from the English wayside weed. And yet, it is said, American horses know the difference. Prof. Macoun is contemplating a visit to Europe next year, when one of his special objects will be to compile an account of these closely-allied but yet distinct eastern and western forms. It is possible that such a comparative list—and it could not be in better hands—may throw some light on some of the many still unsolved problems connected with the evolution and distribution of species. ALFRED W. BENNETT

The Fauna of the Seashore

IN addition to the instances from the Molluscan class mentioned in the interesting letter from Mr. Arthur R. Hunt (NATURE, pp. 243-4), as illustrating—after Prof. Moseley's most valuable contribution—"the variety of method exhibited by the littoral fauna in resisting wave-currents," may be mentioned one of a higher class among the fishes—viz., the common smooth blenny (*Blennius pholis*).

No one who has hunted for this pretty little fish in rock-pools, or who has kept it in an aquarium, can have failed to notice its remarkable adaptation to the ever-varying environment of the littoral zone. The angular form of the head and smooth, mucous-covered body enable it readily to burrow within the smallest crevices of the rocks, to prevent its being washed ashore when the tide is coming in, and to prevent its being carried into deep water when the tide is going out, where it would readily fall a prey to rapacious fishes, as it has apparently little power to swim freely to a distance, not needing to do so in shallow water. Its peculiarly modified ventral fins, forming almost anterior limbs, enable it to cling securely not only to weeds and rocks, but even to perpendicular surfaces, for similar purposes to those above stated, while its beautifully-marked body—of splashed dark and light greens—seems to be a case of mimicry of the sea-weeds which afford it protection from its natural enemies among its own class and those of the higher Crustacea. An allied deep-sea genus (*Anharricas*, the wolf-fish), whose ancestor was probably a littoral blenny, has the ventral fin entirely wanting, and the head is round, for the obvious reasons that it does not need to cling to surfaces nor to burrow in crevices. This fish is, however, compensated by a formidable array of sharp teeth to protect it from its natural enemies. In the aquarium no fish, in my experience, is so readily tamed as the smooth blenny, so as to allow it to be handled, or exhibits such a high degree of piscine intelligence, arising doubtless from long education, both inherited and acquired; in the varying environment which is its habitat. A specimen now in my aquarium daily avails itself of the advantage of the dry ledge of the slope-backed tank "to get a mouthful of fresh air," while at other times it usually takes refuge in an untenanted old shell of the common whelk (*Buccinum undatum*), where it is secure from the gobies and other fishes in the tank, and where it watches—as one can see its fellows do so at any time on the sea-coast in the middle of a rock-pool—expecting the return of the tide and prepared to adapt itself thereto. In "A Year at the Shore," pp. 215–16, Mr. P. H. Gosse, F.R.S., mentions, on the authority of Mr. Ross, of Topsham, the case of a blenny which for five months proved "a regular and correct tide-indicator," spending a portion of its time on the rock-work, and going back to the tank at the time of the return of the tide.

I quite agree with Mr. Arthur R. Hunt's idea that it would be a great gain if we could copy Nature a little closer, and have "working-models of the sea in some of our new aquariums."

Birmingham, July 22 W. R. HUGHES

Artificial Earthquakes

PROF. MILNE'S experiments with artificial earthquakes in Japan, noticed in NATURE of June 4 (p. 114), show that the vertical free surface-wave had the quickest rate of transit, and this was taken to account for the preliminary tremors of an earthquake. The normal wave travelled with a less velocity, and the transverse wave slowest of all. In the earthquakes which occur here from time to time there are generally, if not always, two distinct shocks felt, and it is possible that the second is the transverse wave following on after the swifter normal vibration. I have not heard that there are any seismographs in the Punjab, and in the alarm of the moment it is not easy to notice the direction of the motion without apparatus; fortunately our earthquakes do not leave any automatic record in the shape of fissures or fallen buildings. But Prof. Milne's experimental results are curiously confirmed by observations in Kashmir during the earthquakes of this month, which do not appear yet to have quite subsided. The Kashmir correspondent of the Lahore *Civil and Military Gazette* of to-day's date writes as follows:—"The more severe shocks seemed to be followed by others in a different direction, like cross waves. I noticed this in a boat which quivered all over during a severe earthquake, but rolled somewhat afterwards." T. C. LEWIS

Government College, Lahore, June 29

The Recent Earthquake in Switzerland

THE following is a table of events of the earthquake in Switzerland of June 20 last, compiled from numerous and interesting observations of the phenomenon, obligingly forwarded to me from all parts of the country.

The earthquake consisted of a series of shocks:—

1. *Preparatory Shocks.*—Very weak and ill-defined from midnight to 3 a.m.; at Neuchâtel and Chaud-de-Fonds.
2. *Great Shock*—At 5.16 on the morning of June 20; at the centre of the earthquake.
3. *Consecutive Shocks.*—At 7.26 a.m. June 22 at Neuchâtel; at 8.30 a.m. of June 22 at Yverdun, Payerne, Estavayer, Concise, Boudry, Neuchâtel; at 11 a.m. of June 23 at St. Imier; at 2.30 p.m. of June 23 at Neuchâtel; at 9.20 a.m. of June 24 at Yverdun (?)

The great shock had its centre near Yvonand and the central area may be defined by the triangle formed by Yverdun, Neuchâtel and Payerne. The shock was strong enough to alarm the inhabitants, to displace some articles of furniture and even to throw down a chimney at Payerne. I assign to the shock the strength of number 6 on the scale of intensity, of which number 10 would stand for the highest degree. The shock was felt more feebly in a vast territory extending as far at least as Geneva, Le Brassus, Le Locle, Bâle, Glaris, Thun, Saxon: that is, it traversed the whole plain of Western Switzerland from the Jura Alps. A subterranean noise was heard very distinctly in the whole central area and even a little beyond it.

The shock had very markedly the character of successive oscillations, horizontal or vertical, their direction differing according to the locality. Such is, indeed, the usual type of earthquakes, as has been shown by the study of them with registering instruments, and it is interesting to notice that the various observations of the earthquake of June 20 all perfectly concur in ascribing to it this character. F. A. FOREL

Morges

THE PITCHER PLANT

THE variety of the Pitcher Plant (*Sarracenia variolaris*) found in North America is carnivorous, being a feeder on various animal substances.

Mrs. Mary Treat, an American naturalist, made, a few years ago, several experiments upon the plants of this species to be found in Florida; and to the labours of this lady the writer has been indebted, in some measure, in the preparation of this paper.

The *Sarracenia* derives its name of "Pitcher Plant" from the fact of its possessing the following curious characteristics. The median nerve is prolonged beyond the leaves in the manner of a tendril, and terminates in a species of cup or urn. This cup is ordinarily three or four inches in depth, and one to one and a half inches in width. The orifice of the cup is covered with a lid, which opens and shuts at certain periods. At sunrise the cup is found filled with sweet, limpid water, at which time the lid is down. In the course of the day the lid opens, when nearly half the water is evaporated; but during the night this loss is made up, and the next morning the cup is again quite full, and the lid is shut.

About the middle of March the plants put forth their leaves, which are from six to twelve inches long, hollow, and shaped something like a trumpet, whilst the aperture at the apex is formed almost precisely in the same manner as those of the plants previously described. A broad wing extends along one side of the leaf, from the base to the opening at the top; this wing is bound, or edged with a purple cord, which extends likewise around the cup. This cord secretes a sweet fluid, and not only flying insects, but those also that crawl upon the ground, are attracted by it to the plants. Ants, especially, are very fond of this fluid, so that a line of aphides, extending from the base to the summit of a leaf, may frequently be observed slowly advancing towards the orifice of the cup, down which they disappear, never to return. Flying insects of every kind are equally drawn to the plant; and directly they taste the fluid they act very curiously. After feeding upon the secretions for two or three minutes they become quite stupid, unsteady on their feet, and whilst trying to pass their legs over their wings to clear them, they fall down.

It is of no use to liberate any of the smaller insects, every fly, removed from the leaf upon which it had been feeding, returned immediately it was at liberty to do so, and walked down the fatal cup as though drawn to it by a species of irresistible fascination.

It is not alone that flies and other small insects are overpowered by the fluid which exudes from the cord in question. Even large insects succumb to it, although of course not so quickly. Mrs. Treat says:—"A large cockroach was feeding on the secretion of a fresh leaf, which had caught but little or no prey. After feeding a short time the insect went down the tube so tight that I could not dislodge it, even when turning the leaf upside down and knocking it quite hard. It was late in the evening when I observed it enter; the next morning I cut the tube open; the cockroach was still alive, but it was covered with a secretion produced from the inner surface of the tube, and its legs fell off as I extricated it. From all appearance the terrible *Sarracenia* was eating its victim alive. And yet, perhaps, I should not say 'terrible,' for the plant seems to supply its victims with a Lethe-like draught before devouring them."

If only a few insects alight upon a leaf no unpleasant smell is perceptible during, or after, the process of digestion; but if a large number of them be caught, which is commonly the case, a most offensive odour emanates from the cup, although the putrid matter does not appear to injure in any manner the inner surface of the tube, food, even in this condition, being readily absorbed, and going to nourish the plant. In fact, it would seem tha the *Sarracenia*, like some animals, can feed upon carrion and thrive upon it.

In instances in which experiments have been made with fresh, raw beef or mutton, the meat has been covered in a few hours with the secretions of the leaves, and the blood extracted from it. There is, however, one difference between the digesting powers of the leaves when exercised upon insects or upon meat. Even if the bodies of insects have become putrid, the plant, as has already been stated, has no difficulty in assimilating them; but as regards meat, it is only when it is perfectly sweet that the secretions of the leaves will act upon it.

The Pitcher plant undoubtedly derives its principal nourishment from the insects it eats. It, too—unlike most other carnivorous plants, which, when the quantity of food with which they have to deal is in excess of their powers of digestion, succumb to the effort and die—appears to find it easy to devour any number of insects, small or large, the operation being with it simply a question of time. Flies, beetles, or even cockroaches, at the expiration of three or four days at most, disappear, nothing being left of them save their wings and other hard parts of their bodies.

The *Sarracenia* is, indeed, not only the most voracious of all known species of carnivorous plants, but the least fastidious as to the nature of the food upon which it feeds. W. C. M.

THE ECLIPSES OF AUGUST, 1886

IT has been before stated in NATURE that the total solar eclipse of August 28-29 next year can be most favourably observed on the west coast of Africa near Benguela. In a recent number of *Science* Mr. Skinner supplies a valuable account of the local conditions, which we here reprint:—

"Benguela is about 400 miles south of the mouth of the Kongo, and about 200 miles south of the mouth of the Koanza. The climate of the lowlands bordering the coast near Benguela is fatally unhealthy for strangers, making it compulsory, on the score of prudence, for an observing party to penetrate the interior sufficiently to attain the mountainous highlands which lie not far inland.

"The American Board of Commissioners for Foreign Missions has for some three years occupied two mission stations in this region—viz. Bailundu, about 133 miles eastward from Benguela, and Bihe, about 70 miles southeast from Bailundu. Through the courtesy of Rev. Judson Smith, D.D., secretary of the American Board, and Mr. Frederick A. Walter, secretary of this west-central African Mission, I have received definite statements of some of the precautions necessary, and some of the difficulties to be encountered by an observing party locating in this region. I will give in brief the points with which Mr. Walter favours us.

"Dangers to the person from savages are not to be apprehended. The climate of Bailundu and vicinity is exceedingly salubrious. During a residence of nearly three years, Mr. Walter and his family have experienced no illness to be ascribed directly to the climate, but in every case to overwork, over-exposure to the sun, or want of proper food.

"The difficulties in reference to transportation are considerable. Transportation is done entirely by men; waggons and animals cannot be used. The gross weight for a carrier is from 65 to 70 lbs.; commonly it does not exceed 58 lbs. Packages, either bales or boxes, should be of about the following dimensions:—14 inches by 9 inches by 30 inches, or, if more convenient, 16 inches by 10 inches by 24 inches. No single package should exceed 18 inches in width by 10 inches in depth. Pieces not exceeding 60 lbs. in weight, though 8 or 10 feet long, can be carried by a single carrier.

"As to means of subsistence, an observing party must bring *all their supplies with them*, as it is essential to the health of newcomers that they should live on food to which they are accustomed. The time required for a round trip of a caravan from Bailundu to Benguela may be stated as one month to six weeks.

"Mr. Walter states that the chances for clear sky at the time of the eclipse are very favourable.

"It may be stated that the land rises very abruptly as one leaves the coast from Benguela, and in a few miles attains a very considerable altitude, and throughout these highlands the climate is very healthful."

INTERNATIONAL INVENTIONS EXHIBITION

SELF-ACTING or automatic machinery has made wonderful strides of late years, and its progress in the special department of watch-making cannot be more advantageously studied than in the beautiful display of machine tools now exhibited by the American Waltham Watch Company at South Kensington. We think that a few remarks with reference to the functions of these tools may be of service to the readers of NATURE when viewing the collection. The machine tools are all labelled, and can readily be identified.

(1) A screw-making machine.—This machine is engaged in producing watch jewel screws; the size of the screws may be appreciated when we state that it takes more than 8500 to weigh one ounce troy. Lengths of wire are transformed into these tiny screws in the following manner. The machine is fed with the wire through a hollow mandrel, the wire is seized and rotated rapidly, a movable cutter is brought against it, and immediately the body of the screw is turned. Two dies are at hand which attach themselves, and they cut the thread; on reaching the limit of their cut, they pull out the wire a distance, the thickness of the screw head, for hitherto the wire has only projected the length of the body of the screw through the mandrel head. The dies disengage themselves, and a second cutter cuts off the screw at its junction with the mandrel head. There is an alternating arm, the most conspicuous part of the machine: this takes possession of the screw as it is cut off, and, carrying it to a different part of the machine, holds the head against a small circular mill, where the notch is cut. The screw is now finished, and is discharged into a magazine by a kind of ramrod. The machine turns out 4000 screws a day, and indeed the successive operations go on with so much rapidity, that it requires some practice to follow them. It is to be noticed that when the dies are cutting, the wire is stationary, and the machine then quickens its motion to save time. When the dies pull forwards, the chuck holding the wire opens simultaneously. Copious streams of oil are supplied to wash away the shavings, and the oil after being used once, escapes into reservoirs from whence it is automatically pumped up again. The different parts of the machine are regulated almost entirely by cams, the dies by a very elegant arrangement of opposing toothed sectors.

(2) A machine for cutting off dial feet—*i.e.* attachments. If this machine stood alone it would be interesting, but it is overshadowed by its neighbours.

(3) A machine for roughing out staves or pinions.—This is similar in some respects to the screw-making machine. Lengths of wire are fed through the mandrel, and a cutter shapes one end of the staff or pinion, giving it a male centre. It is then cut off, but the other end has to be shaped with its male centre too. Again we have an alternating arm, which carries the pinion away and places it in a very similar mandrel on the other side. So soon as it is gripped it begins to rotate; a cutter comes and shapes the unfinished end with its male centre. When done it is discharged into a magazine, as the tiny screws were.

(4) This is a machine for trueing down the staves or

pinions roughed out in (3). Like (2) this is a simpler machine, but worthy of attention. The roughed-out pinions are here turned true upon their own centres. Notice that when the tool has turned off the necessary amount it stops of itself, till started for a fresh piece.

(5) A pinion-polishing machine.—The polisher is driven to and fro by crank motion. After a sufficient number of rubs have been given the pinion turns automatically and presents a fresh face to the polisher, till all the leaves are done. The other side of the stand shows us a lathe requiring no special explanation.

(6) An automatic machine for cutting pinions.—In this is exhibited an elegant arrangement for bringing a succession of cutters into play. The principle, however, is very much better illustrated in the scape-wheel engine that follows; we therefore defer explanation.

Alongside of this machine is another for cutting the bevelled wheel teeth for keyless work.

(7) A scape wheel tooth-cutting engine. The scape wheels to the number of sixty are threaded upon a kind of split spindle, which passes through the spaces around their arms, and holds them firmly. The spindle with the wheels around it looks like a solid rod of brass, and the cutter acts transversely so as to scoop a groove through all the sixty at once. Owing to the peculiar shape of tooth and the degree of finish necessary, seven different cutters are required. The actions are as follow:—The spindle being placed in position, the first cutter operates. When it has made one groove the spindle turns; it makes another, and another, in all 15, which corresponds to the number of teeth. A sudden change now happens—the first cutter is diverted, and a second takes its place This cutter works through all the fifteen spaces, and then the next supersedes it, until all have had their turn and the wheel is finished. We understand that the whole sixty wheels are cut in about twenty minutes.

(8) Another polishing machine, of somewhat similar design to (5).

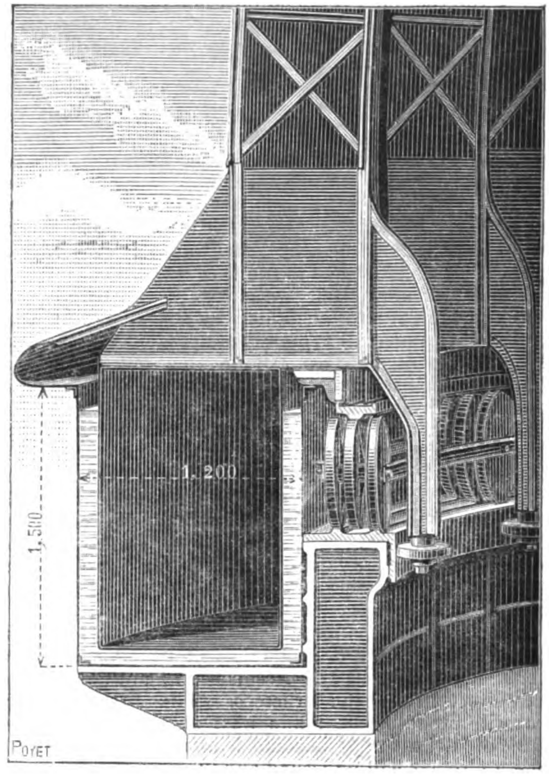
(9) On a counter opposite to the main stand is shown an interesting instrument for determining the strength of watch-balance springs. In this the differential principle is employed, the spring to be tested being measured against one of known force, and the number of degrees the latter is deflected registered. The springs are sorted into compartments corresponding to these numbers.

There are two other tools not working at present, but still of considerable interest. The first is supplementary to (9), which only gives the strength of the spring within certain limits. There is a normal balance with spring attached, and the balance and spring to be tested are mounted on an arm alongside of it. A lever sets both balances vibrating simultaneously, and it is easy to perceive in a few seconds whether their vibrations are synchronous or not. The other tool is automatic, and is for the purpose of drilling and tapping the screw-holes in compensation-balances. These holes are placed at irregular distances, as experience has suggested. By means of a divided plate the machine automatically finds these intervals. A very pretty feature will be noticed when the machine is drilling—viz. that the drill is withdrawn occasionally by the machine to free the cuttings, just as would be done by a workman.

HENRY DENT GARDNER

THE NICE FLOATING DOME

WE have already (NATURE, vol. xxxii. p. 62) referred to the floating dome for the great equatorial of the Nice Observatory of M. Bischoffsheim. We give now an illustration from *La Nature*, which shows the details of the annular floater. The entire dome is supported on the annular floater situated at its base. The floater, of hollow metal, swims in a circular caisson containing water holding saline matter in solution. When the dome is in the position of normal buoyancy, the only friction which opposes its movement of rotation is the friction inside a liquid body, and consequently is extremely feeble, notwithstanding the great weight of the moving mass. Experiments prove that one man can easily set the dome in motion with his hand. The floater of the dome is open above like an undecked boat; it has a rectangular section of 1·50 m. in height by 0·95 m. in breadth. Its walls are bound together by rivets of steel.



The annular caisson, which receives the floater and the liquid, has a rectangular transverse section; its height is 1·50 m., and breadth 1·20 m. The latter dimension thus exceeds the breadth of the floater by 0·25 m., which gives a lateral play of 0·125 m. in the inside and 0·125 m. at outside between the floater and the caisson. Finally, the caisson rests on thirty-six strong cast-iron supports, distributed at equal distances over the upper part of the mason-work of the tower.

A NEW ENDOWMENT FOR RESEARCH

IT is usually the case that private endowments for public purposes are made subject to narrowing restrictions, and then it too often ensues that with the lapse of time the very object of the gift is defeated by the restrictions—the letter kills the spirit. It must therefore be a matter of congratulation when a great public donation is left as free as compatible with the general object for which it is made. This is remarkably the case with a noble and munificent endowment established by Mrs. Elizabeth Thompson, of Stamford, Connecticut—an American lady well known for her public benefactions. Her long experience with churches and various charitable enterprises had led her to question whether the money spent in them achieves the greatest possible good. She finally reached the conviction that knowledge is the real source, the impelling power, of human progress, and it became her desire, from motives of the highest philantropy, to contribute to the promotion of science.

When the plan for the establishment of an International Scientific Association was brought forward at Montreal, and again at Philadelphia before the great National Associations, Mrs. Thompson considered that the proposed International Society would be the fittest body to assume the trust she wished to establish. Accordingly, she placed in my hands the sum of 5000 dollars (1500*l.*) as the nucleus of a fund to be controlled by the International Association when organised.

Not long since Mrs. Thompson communicated to me her desire to transfer the above-mentioned sum to a board of trustees and to add to it at once 20,000 dollars more, making a total permanent fund of 25,000 dollars. Mrs. Thompson has been as liberal in the conditions she has established as in the amount she has given. According to her letter of conveyance, "the income of the fund is to be devoted to the advancement and prosecution of scientific research in its broadest sense, it being understood that to provide for and assist in the maintenance of an International Scientific Association is a method of application which seems to me very desirable."

The trustees are left with very great discretionary powers, which are to be guided by certain general directions. It is above all expressly understood that the prime object is to contribute from the income towards defraying the cost of scientific researches. The Board of Trustees consists of five members: Chairman, Dr. Henry P. Bowditch, Professor of Physiology and Dean of the Harvard Medical School; Treasurers, Wm. Minot, jun.; Prof. Edward C. Pickering, Director of the Harvard Astronomical Observatory; General Francis A. Walker, President of the Massachusetts Institute of Technology; and the Secretary, Dr. Charles S. Minot. It was considered important to have as great a variety of interests represented as possible, and this is accomplished by the association of these gentlemen.

When the International Association is organised the income of the fund presumably will be expended under the direction of that new Association; until then, under the direction of the trustees. The first appropriation will probably be made next autumn, when several hundred dollars will become available. At the proper time a circular will be issued announcing the manner in which applications may be made. As it is desired to give the fund an international character, it is hoped that foreign journals will copy this notice.

In conclusion I wish to express my admiration for the wisdom shown by Mrs. Thompson. It is certainly very remarkable that a person not specially versed in science, nor directly interested in any of its branches of investigation should be induced by a desire to benefit her fellows, not to give for some temporary need, but, with exceptional insight, to give for the development of the very sources of progress. The same sound judgment governed her decision as to the conditions of her gift, for it is difficult to foresee any probability which will render this endowment futile. Very often a public gift has its object determined by the donor's personal interests. I believe Mrs. Thompson was governed solely by her convictions as to the application of her money which would do most good.

At their first meeting the trustees voted unanimously to call their trust "The Elizabeth Thompson Science Fund."

CHARLES SEDGWICK MINOT

Boston, Mass., U.S.A.

NOTES

WE are informed by Dr. Armstrong that arrangements have been made for two discussions in the chemical section over which he will preside at the meeting of the British Association at Aberdeen. The one will be on the Determination of the Molecular Weights of Liquid and Solid Bodies, the other on Electrolysis. It is proposed to have a series of critical papers read which shall embody, as far as possible and desirable on such an occasion our knowledge of these subjects, and also indicate the directions in which investigation is specially required and may be most usefully carried on. These subjects have been chosen as being of general interest and of special importance to the chemist, and in the hope of inducing chemists and physicians to cooperate in attacking the many problems which await solution. Capt. Abney will open the first discussion with a paper on the spectroscopic method. Profs. Guthrie, Reinold, and Dilden, Mr. S. U. Pickering, Dr. Russell and Dr. Armstrong will also contribute papers. Professor Lodge will open the discussion on Electrolysis, and Prof. Schuster, Capt. Abney, and Mr. Shelford Bidwell have already consented to contribute papers on portions of this subject. Dr. Armstrong will be glad to hear from any other gentlemen who may wish to aid in forwarding what promises to be a useful departure.

A TELEPHONE has just been brought to this country from America which is absolutely independent of electricity, so that batteries, coils, and cells are quite dispensed with. This obviously greatly simplifies the working of the instrument, and in the "mechanical telephone," which was recently subjected to a severe test, simplicity and distinctness are claimed as its chief characteristics. The instrument consists of a diaphragm, or sounding-board made of strips of willow wood, which has been found by experiment to possess a remarkable sensitiveness to sound vibrations. These strips of wood are closely woven together and varnished. In the centre of the diaphragm a small disc of metal is placed, from which the wire proceeds to any point desired up to two miles. In recent trials the instrument freely answered to all demands upon it, the ticking of a watch, musical sounds, whispering, &c., being heard with great distinctness.

WE understand the Fishery Board for Scotland, in order to learn further what has been done in other countries for increasing the fish supply, has requested Prof. Cossar Ewart, when on the Continent during the autumn, to visit some of the principal fishing stations in Norway and Sweden. It will be remembered that Prof. Ewart, by visiting at his own expense Canada and the United States last autumn, was able to present to his Board a valuable report on the "Progress of Fish Culture in America." An equally interesting report on the Norwegian fisheries may be expected.

IN accordance with previous announcements the summer meeting of the Institution of Mechanical Engineers will be held at Lincoln on Tuesday, Aug. 4, and the following days of the week. The following papers have been offered for reading and discussion after the address of the President, Mr. Jeremiah Head:—Description of Dunbar and Ruston's steam navvy, by Mr. Joseph Ruston, M.P., of Lincoln; on recent adaptations of the Robey semi-portable engine, by Mr. John Richardson, of Lincoln; description of the Tripier spherical eccentric, by M. Louis Poillon, of Paris; on private installations of electric lighting, by Mr. Ralph H. C. Nevile, of Wellingore; on the iron industry of Frodingham, by Mr. George Dove, of Frodingham; description of an autographic test-recording apparatus, by Mr. J. Hartley Wicksteed, of Leeds. A formidable programme of excursions and visits to various works has been arranged.

WE referred a short time back to a proposed excursion by the Geologists' Association to Belgium, under the direction of MM. Dupont, Gosselet, Purves, and Renard. The monthly circular, giving full details of the arrangements, is now before us, from which we learn that during the six days of the excursion (August 10 to 15) visits will be made to the typical sections of Cambrian, Devonian, and Carboniferous rocks, including the altered rocks of the Ardennes; the Devonian limestones of Roly, &c., which M. Dupont regards as true coral atolls; the grand section of Devonian and Carboniferous limestone along the Meuse; the Grotto of Han, and the Devonian limestones, &c., near Rochefort. The circular contains nine maps and cuts illustrating the geology of Southern Belgium, a table of geological formations, and a list of maps and books relating to the district. There are also full particulars as to routes, fares, &c. A pamphlet on "The Geology of Belgium and the French Ardennes," containing papers by Gosselet, Bonney, Rutot, Van den Broeck, and Topley, has also been prepared by the Association, and is published by Stanford. This gives a fuller account of the literature, and is illustrated by three maps and thirteen cuts.

ON Saturday, July 25, a whole day meeting of the Essex Field Club was held at Witham and neighbourhood. The party, about sixty-five in number, was met at Witham Station by the Vicar, Canon Snell, and after being conducted over the church, an inspection was made of the ancient earthwork surrounding the railway station. A paper on this camp, which is believed to have been constructed by Edward I., was communicated by Mr. F. C. J. Spurrel, who had prepared for distribution a number of printed copies showing the plan of the entrenchments. After lunch at the "Spread Eagle," Witham, an ordinary meeting of the Club was held for the election and proposal of new members, Prof. R. Meldola, in the absence of the President, taking the chair. At the conclusion of the meeting brakes were in attendance, and the party proceeded to Black Notley, passing *en route* through the village of Cressing, where in former times the Knight Templars had a preceptory. The remains of the Temple, now a farmhouse, were inspected by the permission of the present owner, Mr. J. H. Shoolbridge, who had had excavations made in various parts of the grounds in order to expose some of the old brickwork foundations. In the churchyard of Black Notley, by the tomb of John Ray, Prof. G. S. Boulger gave an excellent account of the "Domestic Life of John Ray at Black Notley." Mr. E. A. Fitch followed with an equally interesting account of Ray's labours as an entomologist. The Rector of Black Notley, the Rev. J. Overton, was in attendance in order to conduct the party over the church. In the neighbouring school-room the Rev. F. W. Kenworthy, Vicar of Braintree, had arranged for exhibition a fine collection of flint implements, many of which had been found in the neighbourhood, and some of the palæolithic specimens being of special interest as having been found beneath the chalky boulder clay. After leaving the school-room a visit was paid to "Dewlands," the home of John Ray at Black Notley, by the permission of Mr. Mortier, the present occupier. Proceeding to Faulkbourn, the rector, the Rev. F. Spurrel, conducted the party over the church, and, by the invitation of Capt. Talbot, Faulkbourn Hall was next visited, although the length of the day's programme prevented the club from taking advantage of the hospitality of the owner. After a short ramble through the grounds and an inspection of the hall from the exterior, the party proceeded to Terling Place, where a most hospitable reception was given by Lord and Lady Rayleigh. In the course of the evening Lord Rayleigh addressed the meeting on some mechanical questions involved in the flight of birds, and some of the party were then conducted to the laboratory, where a number of experiments bearing upon his lordship's researches on sound, hydrodynamics, &c., had been arranged for exhibition. Amongst those present at the meeting were Mr. G. J. Symons, F.R.S., Prof. S. P. Thompson, Mr. E. B. Knobel, Sec. R.A.S., Dr. T. Taylor, &c. In carrying out the local arrangements much assistance had been rendered by Mr. W. D. Cansdale.

THE British Medical Association is holding its annual meeting this week at Cardiff.

THE annual meeting of the Belgian Royal Society of Public Medicine, to be held at Antwerp on August 26-30, will this year assume a somewhat international character. The Committee issue a special invitation to its foreign corresponding members, with a view to their taking part in the discussion of the main topic to be submitted to the meeting. That topic is thus formulated:—"What are, in the present state of epidemological science, the most practical international prophylactic measures to be taken, especially in Belgium, against pestilential malaria?'

THE annual meeting of the National Fish Culture Association will take place on Thursday next under the presidency of the Marquis of Exeter, when reference will be made to the Indian and Colonial Exhibition to be held next year, at which the Association is to represent the Fisheries Department, in accordance with the request of the Royal Commissioners.

AT the last meeting of the Seismological Society of Japan (reprinted in the *Japan Gazette*) Dr. Knott read a paper on earthquake frequencies. The writer's aim was to discover, if possible, some satisfactory reason for the winter maximum of frequency. Earthquake statistics show that, wherever there is a marked winter season there is a corresponding increase in seismic action. In searching for possible causes for this periodicity Dr. Knott left out of account purely terrestrial actions, due to the earth's cooling and shrinking, or to the unequal distribution of surface matter as displayed in the arrangement of continents and oceans, for, although these no doubt produce earthquakes, they cannot cause periodicity. This restricts us to such periodic stresses as may result from the tidal actions of the sun and moon, or from the meteorological changes which accompany the sequence of the season. The writer discusses each of these possible causes in turn. Earthquake statistics do not afford us any clear evidence of fortnightly or monthly periods, and on the whole he discards the tidal action of the sun and moon as incapable of explaining the annual period in earthquake frequency. Coming to meteorological causes, the seasonal changes of temperature cannot have any direct effect, as they are inappreciable at a depth of from 20 to 30 feet; storm depressions and wind generally may be left out of account, as the earth is sluggish in responding to short-lived stresses. The attempts that have from time to time been made to connect earthquakes with the indications of the barometer *at the locality* could hardly be expected to lead to any definite result, for we have no right to assume that the earthquake is caused by an external stress applied directly at the origin of the disturbance. We must consider the stresses over a large area inclosing the locality in question. Are there, then, any meteorological phenomena of the necessary period and sufficiently long-continued in their different phases to give rise to stresses to which the earth's crust could reasonably be expected to yield? There seems, Dr. Knott says, to be such a possible cause in the annual oscillations of barometric pressure over land and sea. In cold weather this pressure is high over the land and low over the sea; in warm weather this relation is just reversed. This gives rise to steep gradients, which of course are steepest just where land and sea meet. Japan, for instance, between Siberia and the Pacific, is under one of these steep gradients. This semi-annual see-saw of pressure is very marked in all temperate regions, the steepest gradients always occurring in the winter months. Then, so far as regards the winter excess of pressure, a much more powerful cause than barometric changes is to be found in the snow-fall. If we consider the great winter accumulation of snow in the higher latitudes, especially over continental areas, such as Siberia, we see that the magnitude of the shearing stresses along the region where the snow accumulations cease—that is, along the littoral districts—must be considerable. In lower latitudes, however, this explanation fails us, and the effect of rainfall on account of its non-persistency can hardly be taken into account. Thus there seem only two possible meteorological phenomena which can be regarded as causing the annual periodicity of earthquakes—the snow-fall gradient and the barometric gradient. Of these the accumulations of winter snow over the land surfaces must be regarded as vastly the most potent. It must not be forgotten that in the case of a rigid mass like the earth a slight steady stress may be more effective than a short-lived shock.

ON Thursday the 16th inst. the first annual meeting of the Manchester and District Association of Science and Art Teachers was held in the Manchester Technical School, Mr. W. Gee, agent of the Union of the Lancashire and Cheshire Institutes, presiding. The report showed that "the Committee have endeavoured to diffuse information regarding methods of teaching and apparatus used by good teachers, and that some of the meetings have been very successful." The principal papers of the year had been "On the Science Department's List of Apparatus," "The Honours Examination in Machine Drawing and Building Construction," "Diagram Making," "The Magic Lantern as applied to Science Teaching," and "The True Purposes and Right Pursuit of Art." Visits had also been made to inspect scientific works at the Cheetham College Library and the Manchester Free Reference Library, and also to the Manchester Telephonic Exchange. The officers were appointed for the new year, including the re-election of Prof. Sir Henry Roscoe as President. The chairman drew attention to the subordinate position still occupied by science at several of the public examinations, and it was understood that this subject would be considered by the executive.

AT the half-yearly general meeting of the Scottish Meteorological Society on Monday the following business was transacted:—Report from the Council of the Society; the proposed earthquake observations on Ben Nevis, by Prof. Ewing, Dundee; methods of observing the temperature and humidity of the air (with experiments), by H. N. Dickson, Scottish Marine Station; Prof. Crum Brown exhibited an anemometer for maximum wind-pressure.

A TELEGRAM from Calcutta, July 25, states that three shocks of earthquake have occurred in Runpur, Bengal Presidency, causing serious damage. A village near Nattore has sunk completely into the earth.

A TELEGRAM from Teneriffe announces that a shock of earthquake was felt there on the morning of July 22. No details have yet been received.

MR. C. G. ROOKWOOD prints some notes on American earthquakes in the June number of the *American Journal of Science*, the earthquakes being those which occurred in the preceding year in North and South America. The list contains fifty-four items, not counting the one of Nov. 13. They may be geographically classified thus:—

Canadian Provinces	5
New England	9
Atlantic States	5
Mississippi Valley	7
Pacific Coast	21
West Indies	2
Central America and Columbia	3
Peru	2
Uruguay	1
	55
Deduct for Aug. 10, counted twice ...	1
	54

By seasons they are classified thus:—Winter, 12 (Dec., 2; Jan., 8; Feb., 2); Spring, 15 (March, 8; April, 7; May, 0); Summer, 8 (June, 4; July, 0; Aug., 4); Autumn, 19 (Sept. 4; Oct., 5; Nov., 10; Spring and Summer together, 23, Autumn and Winter together, 31. The following localities were shaken on two or more days:—Los Angeles, Cal., Jan. 4, Jan. 16, Oct. 22; San Francisco, Jan. 25, March 15, 25, July 15, Nov. 12; Oakland, Cal., March 25, April 17, 20; Eureka, Cal., Jan. 27, April 6, 8, 11; Concord, N.H., Aug. 10, Nov. 12, 23. The only shocks causing much damage were Nov. 5, Panama; Nov. 6, Colombia; Nov. 22, Lima, and Aug. 10, Middle States.

WE have received from Stonyhurst College Observatory the "Results of Meteorological and Magnetical Observations for 1884," by the Rev. S. J. Perry, F.R.S. The work done at this observatory becomes more and more valuable every year. Of the solar surface 281 drawings were made during the year and 88 complete measures of the chromosphere. The spectra of sun-spots have been measured on 30 days, and the widening of 200 lines between B and D accurately measured.

A MEETING of the Washington Philosophical Society not long ince took the form of a symposium, in which various members gave answers to the question: "What is a glacier?" The following are the various definitions given; but it should be mentioned that there are explanations and suggestions in most cases which we have not space to reproduce in full. "An ice-body, originating from the consolidation of snow in regions where the secular accumulation exceeds the loss by melting and evaporation—*i.e.* above the snow-line—and flowing to regions where the loss exceeds supply—*i.e.* below the snow-line" (*Mr. Russell*); "A river of ice, possessed, like the aqueous river, of movement and plasticity" (*Mr. Emmons*); "A mass of ice with definite lateral limits, with motion in a different direction, and originating from the compacting of snow by pressure" (*Mr. W. H. Dall*); other members did not attempt such precision of expression. Mr. Chamberlin pointed out that hard-and-fast lines of demarcation do not prevail in nature, but rather gradations of character. The terms névé and glacier were probably used by guides and travellers for convenience. "There is an area of growth and an area of waste to every glacier; superficially the area of growth coincides with the névé; the area of waste is that of the glacier proper." Mr. McGee said that as glacier ice and névé ice belonged to a graduating series, the two phases can only be arbitrarily discriminated. "Perhaps the most satisfactory line of demarcation detectable is the snow-line, above which the superficial *débris* is buried by precipitation, and below which it is exposed by ablation."

WE have to acknowledge the receipt of the third Biennial Report of the Central Station of the Java Weather Service, as well as of various quarterly reports and monthly bulletins issued by Dr. Hinrichs, the director. The appropriation for the work is very small, but there appears to be a large number of volunteer observers all over the State. In a foot-note to a list of these the director notices the death of one of his volunteers with the following epitaph:—"Died, June 10, 1882. He was a most painstaking observer, furnishing good reports in fine handwriting."

A FEW days ago a salmon weighing 28 lbs. was netted at Jomfruland, in the Christiania Fjord, which was marked under the left fin with a straight line and a Latin A. Probably the line was meant for an I, making the marking I A.

MR. JOHN WHELDON, of Great Queen Street, has sent us Part I. of his Catalogue of Botanical Works. It extends to 84 pages and contains 1306 entries.

In a paper read before the last meeting of the French Academy of Medicine M. Lagneau described his researches into the anæsthetics employed in Europe by physicians in the Middle Ages. That such were known is beyond any doubt. Abelard, speaking of the creation of Eve from a rib of Adam, speaks of the deep sleep which fell upon the latter as similar to that which physicians produce in patients upon whom they wish to operate. Pliny speaks of a stone of Memphis which, when crushed and treated with vinegar, renders any part to which it is applied insensible to pain; and many old authors speak of surgeons producing sleep in their patients before an operation by mixing with their food a decoction of the leaves or root of the mandragora, or some grains of the plant called "morion." Preparations of these two plants, as well as of other narcotics, were employed by surgeons down to the thirteenth and fourteenth centuries, but much less in subsequent times. Opium was also used for a similar purpose, while in the East the anæsthetic properties of hemp have been known from the earliest times. These were all taken into the stomach; but anæsthesia by inhalation was also known. Two different preparations were discovered in the thirteenth century: one by a Dominican of Rome, the other by a surgeon named Theodoric, who was also a preaching friar, and subsequently a bishop. Both of these were prepared from opium, henbane, mandragora, hemlock, and many other plants, and were inhaled from a sponge. It is, however, difficult to believe that preparations so little volatile could produce anæsthesia by simple inhalation. M. Perrin, who has studied ancient anæsthetics, has given the composition of a liquid which contains all the ingredients required for chloroform, and it is said that this was applied to witnesses or prisoners who were about to be tortured in the judicial tribunals of the Middle Ages. After inhaling it the unfortunate subject was plunged into a semi-comatose state, which diminished in a certain degree the pain of the torture. This liquid was always kept in a place adjoining the torture-chamber.

The additions to the Zoological Society's Gardens during the past week include a Leadbeater's Cockatoo (*Cacatua leadbeateri*) from Australia, presented by Mr. H. Grant; two Great Eagle Owls (*Bubo maximus*), European, presented by Mr. E. G. Carpenter; a Common Peafowl (*Pavo cristatus*) from India, presented by Miss Rowland; an Indian Shama (*Copsychus macrurus*) from India, deposited; an Axis Deer (*Cervus axis*), two Squirrel-like Phalangers (*Belideus sciureus*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN

Tuttle's Comet.—In No. 2674 of the *Astronomische Nachrichten*, published during the last week, are elements and an ephemeris of this comet, by Herr Johannes Rahts of Königsberg. The orbit has been deduced from the observations of 1858 and 1871–2, with perturbations by Mercury, Venus, the Earth, Mars, Jupiter, Saturn, and Uranus to July 11, 1885. Under such conditions it may be anticipated that Herr Rahts' ephemeris will closely represent the track of the comet. His elements are as follows:—

Perihelion passage, 1885, September 11·14265 G.M.T.

Longitude of perihelion	116 28 58·8	M. Eq. 1890·0
,, ascending node ...	269 42 1·5	
Inclination	54 19 45·5	
Angle of eccentricity	55 14 22·6	
Mean daily motion	257″·8648	
Log. semi-axis major	0·7590765	

Motion—direct.

Hence we have—

Eccentricity	0·8215436	Semi-axis major ...	5·7422
Perihelion distance	1·02475	,, minor ...	3·2739
Aphelion distance...	10·4596	Semi-parameter ...	1·8666

Period of revolution, 13·76 years.

Tuttle's comet was first seen by Méchain at Paris on January 9, 1790, and was observed there till February 1. Parabolic elements calculated by Méchain did not lead to any suspicion of ellipticity of orbit. On January 4, 1858, Mr. Tuttle, of Cambridge, U.S., discovered a comet, which was independently detected by the late Prof. Bruhns a week afterwards, and its orbit was found to present so close a resemblance to that of the second comet of 1790 as to immediately lead to the comets being considered identical, the identity being established by Bruhns, who found that five revolutions had been completed between 1790 and 1858. The dates of perihelion passage in this interval were thus determined by Clausen after taking into account the perturbations produced by the planet Jupiter—

	G.M.T.		G.M.T.
1790, January	30·87	1830, December... ...	6·64
1803, November ...	7·27	1844, June	28·96
1817, May	18·76	1858, February	23·52

The comet was not recognised at any one of the four intermediate returns.

From Herr Rahts's ephemeris we have the following positions during the absence of moonlight in August:—

At Greenwich Midnight

1885	R.A. h. m. s.	Decl. ° ′	Log. Dist. from earth	Intensity of light
August 6	7 13 27	+29 48·1	0·2853	0·39
7	7 16 51	29 12·7		
8	7 20 14	28 36·6	0·2816	
9	7 23 36	27 59·9		
10	7 26 56	27 22·7	0·2780	0·42
11	7 30 16	26 44·7		
12	7 33 35	26 6·3	0·2744	
13	7 36 54	25 27·3		
14	7 40 12	24 47·7	0·2708	0·46
15	7 43 28	24 7·4		
16	7 46 43	23 26·6	0·2674	
17	7 49 59	22 45·3		
18	7 53 13	22 3·5	0·2640	0·49
19	7 56 27	21 21·1		
20	7 59 40	20 38·0	0·2607	
21	8 2 53	19 54·5		
22	8 6 5	19 10·5	0·2575	0·52
23	8 9 16	18 25·9		
24	8 12 27	+17 40·8	0·2544	

The intensity of light when the comet was first observed at Marseilles at its last appearance, October 12, 1871, is taken as unity. On September 10 it will be 0·55, the comet rising two hours before the sun. It must always be faint at its present return, so much so probably as to render observation difficult.

The New Comet (Barnard, July 7).—From observations on July 9, 12, and 15 the following elements result:—

Perihelion passage, 1885, September, 20·6740 G.M.T.

Longitude of perihelion	290 10·5
,, ascending node	93 27·1
Inclination	76 6·1
Log. perihelion distance...	0·36549

Motion—direct

An orbit calculated by Dr. Holetschek, of Vienna, much resembles the above.

It would appear that the perihelion distance of this comet may prove to be greater than in the case of any other comet hitherto computed, excepting the extraordinary one of 1729, which did not approach the sun within four times the earth's mean distance.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, *AUGUST* 2–8

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on August 2

Sun rises, 4h. 27m.; souths, 12h. 5m. 58·2s.; sets, 19h. 45m.; decl. on meridian, 17° 40′ N.: Sidereal Time at Sunset, 16h. 31m.

Moon (at Last Quarter on August 3) rises, 21h. 56m.*; souths, 4h. 29m.; sets, 11h. 13m.; decl. on meridian, 5° 34′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury ...	7 6 ...	13 50 ...	20 34 ...	7 56 N.
Venus ...	6 41 ...	13 42 ...	20 44 ...	11 14 N.
Mars ...	0 59 ...	9 19 ...	17 39 ...	23 50 N.
Jupiter ...	7 5 ...	13 57 ...	20 49 ...	9 21 N.
Saturn ...	1 20 ...	9 30 ...	17 40 ...	22 30 N.

* Indicates that the rising is that of the preceding day.

Occultation of Star by the Moon

August	Star	Mag.	Disap. h. m.	Reap. h. m.	Corresponding angles from vertex to right for inverted image ° °
6 ...	B.A.C. 1526 ...	6 ...	3 32 ...	3 56 ...	129 174

August	h.	
4 ...	21 ...	Mercury in conjunction with and 2° 32′ south of Jupiter.
5 ...	17 ...	Saturn in conjunction with and 0° 4′ south of μ Geminorum.
6 ...	3 ..	Mercury at greatest elongation from the Sun, 27° East.
6 ...	7 ...	Venus in conjunction with and 0° 26′ north of Jupiter.
6 ...	20 .	Mars in conjunction with and 1° 20′ north of Saturn.
7 ...	8 ...	Mercury at greatest distance from the Sun.
7 ...	14 ...	Saturn in conjunction with and 4° 13′ north of the Moon.
7 ...	15 ...	Mars in conjunction with and 5° 33′ north of the Moon.
8 ...	17 ...	Mercury in conjunction with and 3° 42′ south of Venus.

GEOGRAPHICAL NOTES

LIEUTENANT PALAT, of the French Cavalry, has been despatched by the Ministers of Public Instruction and of Commerce on a mission to the Sahara, his point of departure being Senegal and his terminus Algeria. The advanced posts recently occupied by the French in the Senegal, and the presence of a gunboat on the Niger, are believed to render the present a favourable moment for such an expedition. At Timbuctoo Lieutenant Palat will appear as a French officer, but from this place to Algeria he will travel as a Moslem doctor. His mission, though of geographical interest, appears to be undertaken chiefly with the object of leading the trade of the Sahara to Senegal on one side and to Algeria on the other.

AT the meeting of the Paris Geographical Society on the 3rd inst. M. Lostalot, French Consul at Jeddah, described in detail the circumstances attending the murder of M. Huber; a letter was read from M. Teisserenc de Bort continuing his account of his expedition in the Sahara; M. Jules Girard discussed the changes of level on the coasts of Scandinavia, and M. Demanche read a paper on the half-breeds of Canada, with especial reference to the recent revolt.

THE Spanish Government has appointed a geological commission, of which Señor Abella y Casariego is the president, to investigate the Philippines. The commission will not confine itself to geology, but will also study the geography and topography of the archipelago; and it is instructed to prepare a map which will complete and correct existing ones.

THE last *Bulletin* of the Royal Geographical Society of Antwerp (June IX. 6th fascicule) contains a report of the proceedings at the reception of Mr. Revoil on his return from the Somali country, and an interesting reprint of the diary of a journey from Antwerp to Vienna and back in 1724, made by representatives of a commercial corporation at Ostend to obtain certain alterations in the letters patent granted by the Emperor Charles VI.

A CORRESPONDENT writes:—In your note on Mr. Grenfell's recent explorations in the Congo Basin you state that the northern bend of the Congo is found by him to be in 2° 11′ N. This had already been found by Stanley; *vide* the map in his recently-published book. You also note that the Mbangi River has been traced by him to a point in 4° 30′ N. lat., lying north-by-east (magnetic?) of its mouth in 0° 26′ to 0° 42′ S. lat. At this ultimate point its breadth is stated to be 673 yards. Now the breadth of the River Thames at Gravesend is considerably greater, and its source in a direct line from Gravesend westward is about 105 miles, the drainage area being, in round figures, 5000 square miles. Arguing from this we should conclude that the source of the Mbangi does not lie east of 20° E. long., and, applying the measurements to Stanley's map, the water parting falls just on the line thereon suggested. The distance in a direct line from the ultimate point reached by Mr. Grenfell to the last known point on the Welle is 540 miles, and to the source of the Welle some 900 miles. Judging, then, from this preliminary note, it appears to be practically impossible for this river, of less than the third of a mile in breadth, to carry off the water of the Welle Basin; and Mr. Stanley's suggestion that the Biyere (wrongly called the Aruwimi) is the outlet of the Welle is rather strengthened than otherwise by this latest, and certainly not least important, contribution to our knowledge of the mighty Congo.

A SOMEWHAT amusing quarrel has arisen between the parishes of Kjelvik and Maasö about a point of considerable geographical interest—viz. the proprietorship of the North Cape. It is caused by the establishment on the celebrated promontory of a *restaurant*, the taxes of which are claimed by both parishes. The Cape has always been considered to form the boundary between the two, without it being stipulated to whom it actually belonged.

The Deutsche Seewarte has issued a chart of the ice in the Atlantic Ocean this spring, which, as it may be remembered, penetrated very far south and east in consequence of continuous northerly and north-westerly winds. Several icebergs appear even to have been found in the Gulf Stream. It seems from experience that, first towards the end of June the ice recedes northwards, while between the banks and the east coast of Newfoundland it remains longest, even after it has disappeared south and south-east of the banks.

FROM recent observations it would appear that during the last thirty years or so the elevation of the shores around the Baltic and the Gulf of Bothnia has gone on with greater rapidity than during the previous period of observation. The shore-marks by which the fact of the elevation has been ascertained were made about the year 1750, at the time of the dispute between Celsius, the celebrated Swedish astronomer, and a German man of science as to whether the level of the Baltic was rising or sinking, Celsius maintaining the latter view. Since the shore-marks were made it has been shown that a movement of elevation of the land has been going on around the island of Bornholm, the level of which remains constant. The rate of emergence is most rapid in the north. In the neighbourhood of the frontier of Finland it amounts to two metres, while in the south it is only a foot. The increased rate of emergence in recent times is clearly shown on the rock known as Stora Reppen, not far from Piteå. That rock in 1851 had emerged 94 cm. above its former level since the commencement of the observations, while in August, 1884, it had risen 50 cm. further.

THE Geographical Society of Australasia has, it is stated, completed arrangements for the exploration of New Guinea, and a fully-equipped expedition has started under the leadership of Capt. Everill.

THE HIGHER MATHEMATICS

PROF. G. MITTAG-LEFFLER, principal editor of the *Acta Mathematica*, forwards us the following communication, which will shortly appear in that journal:—

His Majesty Oscar II., wishing to give a fresh proof of his interest in the advancement of mathematical science, an interest already manifested by his graciously encouraging the publication of the journal *Acta Mathematica*, which is placed under his august protection, has resolved to award a prize, on January 21, 1889, the sixtieth anniversary of his birthday, to an important discovery in the field of higher mathematical analysis. This prize will consist of a gold medal of the eighteenth size bearing his Majesty's image and having a value of a thousand francs, together with a sum of two thousand five hundred crowns (1 crown = about 1 franc 40 centimes).

His Majesty has been pleased to entrust the task of carrying out his intentions to a commission of three members, Mr. Carl Weierstrass in Berlin, Mr. Charles Hermite in Paris, and the chief editor of this journal, Mr. Gösta Mittag-Leffler in Stockholm. The commissioners having presented a report of their work to his Majesty, he has graciously signified his approval of the following final propositions of theirs.

Having taken into consideration the questions which from different points of view equally engage the attention of analysts, and the solution of which would be of the greatest interest for the progress of science, the commission respectfully proposes to his Majesty to award the prize to the best memoir on one of the following subjects:—

1. A system being given of a number whatever of particles attracting one another mutually according to Newton's law, it is proposed, on the assumption that there never takes place an impact of two particles, to expand the coordinates of each particle in a series proceeding according to some known functions of time and converging uniformly for any space of time.

It seems that this problem, the solution of which will considerably enlarge our knowledge with regard to the system of the universe, might be solved by means of the analytical resources at our present disposition; this may at least be fairly supposed, because shortly before his death Lejeune-Dirichlet communicated to a friend of his, a mathematician, that he had discovered a method of integrating the differential equations of mechanics, and that he had succeeded, by applying this method, to demonstrate the stability of our planetary system in an absolutely strict manner. Unfortunately we know nothing about this method except that the starting-point for its discovery seems to have been the theory of infinitely small oscillations.[1] It may, however, be supposed almost with certainty that this method was not based on long and complicated calculations, but on the development of a simple fundamental idea, which one may reasonably hope to find again by means of earnest and persevering study.

However, in case no one should succeed in solving the proposed problem within the period of the competition, the prize might be awarded to a work in which some other problem of mechanics is treated in the indicated manner and completely solved.

(2) Mr. Fuchs has demonstrated in several of his memoirs[2] that there exist uniform functions of two variables which, by their mode of generation, are connected with the ultra-elliptical functions, but are more general than these, and which would probably acquire great importance for analysis, if their theory were further developed.

It is proposed to obtain in an explicit form those functions whose existence has been proved by Mr. Fuchs, in a sufficiently general case, so as to allow of an insight into and study of their most essential properties.

(3) A study of the functions defined by a sufficiently general differential equation of the first order, the first member of which is a rational integral function with respect to the variable, the function, and its first differential coefficient.

Mr. Briot and Mr. Bouquet have opened the way for such a study by their memoir on this subject (*Journal* de l'École polytechnique, cahier 36, pp. 133-198). But mathematicians acquainted with the results attained by these authors know also that their work has not by any means exhausted the difficult and important subject which they have first treated. It seems probable that, if fresh inquiries were to be undertaken in the same direction, they might lead to theorems of high interest for analysis.

(4) It is well known how much light has been thrown on the general theory of algebraic equations by the study of the special functions to which the division of the circle into equal parts and the division of the argument of the elliptic functions by a whole number lead up. That remarkable transcendant which is obtained by expressing the module of an elliptic function by the quotient of the periods leads likewise to the modulary equations, that have been the origin of entirely new notions and highly important results, as the solution of equations of the fifth degree.

[1] See p. 35 of the Panegyric on Lejeune-Dirichlet by Kummer, "Abhandlungen der K. Akademie der Wissenschaften zu Berlin," 1860.

[2] These memoirs are to be found in—(1) "Nachrichten von der K. Gesellschaft der Wissenschaften zu Göttingen," February, 1880, p. 170; (2) Borchardt's "Journal," Bd. 89, p. 251 (a translation of this memoir is to be found in the "Bulletin" of Mr. Darboux, 2me. série, t. iv.); (3) "Nachrichten von der K. Gesellschaft der Wissenschaften zu Göttingen," June, 1880, p. 445 (translated into French in the "Bulletin" of Mr. Darboux. 2me série, t. iv.); (4) Borchardt's "Journal," Bd. 90, p. 71 (also in the "Bulletin" of Mr. Darboux, 2me série, t. iv.); (5) "Abhandlungen der K. Gesellschaft der Wissenschaften zu Gottingen," 1881 ("Bulletin" of Mr. Darboux, t. v.); (6) "Sitzungsberichte der K. Akademie der Wissenschaften zu Berlin," 1883, i. p. 507; (7) The memoir of M. Fuchs published in Borchardt's "Journal," Bd. 76, p. 177, has also some bearings on the memoirs quoted.

But this transcendant is but the first term, a particular case and that the simplest one of an infinite series of new functions introduced into science by Mr. Poincaré under the name of "fonctions fuchsiennes," and *successfully* applied by him to the integration of lineary differential equations of any order. These functions, which accordingly have a *rôle* of manifest importance in analysis, have not as yet been considered from an algebraical point of view as the transcendant of the theory of elliptic functions of which they are the generalisation.

It is proposed to fill up this gap and to arrive at new equations analogous to the modulary equations by studying, though it were only in a particular case, the formation and properties of the algebraic relations that connect two "fonctions fuchsiennes" when they have a group in common.

In case none of the memoirs tendered for competition on any of the subjects proposed above should be deemed worthy of the prize, this may be adjudged to a memoir sent in for competition that contains a complete solution of an important question of the theory of functions other than those proposed by the Commission.

The memoirs offered for competition should be furnished with an epigraph and, besides, with the author's name and place of residence in a sealed cover, and directed to the chief editor of the *Acta Mathematica* before June 1, 1888.

The memoir to which his Majesty shall be pleased to award the prize as well as that or those memoirs which may be considered by the Commission worthy of an honorary mention, will be inserted in the *Acta Mathematica*, nor can any of them be previously published.

The memoirs may be written in any language that the author chooses, but as the members of the Commission belong to three different nations the author ought to subjoin a French translation to his original memoir, in case it is not written in French. If such a translation is not subjoined the author must allow the Commission to have one made for their own use.

THE EDITORS OF THE "ACTA MATHEMATICA"

DR. PERKIN ON THE COAL-TAR COLOURS[1]

TAKING a precedent from some of those who have occupied this chair before me, I have selected for my few remarks to-day the subject in relation to Technical Chemistry, with which I have been personally connected—namely, the colouring matters produced from coal-tar products, with some of the lessons its development appears to me to teach is in connection with industrial chemistry. Sir Frederick Abel, in his address in 1883, when speaking of the history of gunpowder, said that "It is one of the most remarkable features connected with the history of gunpowder, that until the last quarter of a century no radical changes should have been introduced into the manufacture and modes of applying this, the first known practically useful explosive agent." It appears to me that this is more or less true of all the older industries, which resulted simply from experiment and observation without any other basis to work from. They have had long histories in which little progress has been made, but of late years, owing to our advanced and rapidly increasing scientific knowledge, they are undergoing great, and in many cases radical, changes.

The coal-tar colour industry stands in a very different position to our older ones. It has a sharply-defined origin, and a very short history dating back only to 1856, and it is not yet twenty-nine years since the date of the first patent. It is an industry which has been founded on scientific discovery, and has developed side by side with it, being in fact a most important handmaid to research, which in its turn has repaid it by new discoveries. At the date of its introduction very little was known of the chemistry of colouring matters; they were always found difficult bodies to investigate, and when produced in reaction were generally regarded as secondary products, and every endeavour was made to get rid of them so that the other products associated with them might be examined; but now, owing to the very extended study which has been made of these bodies, on account of this industry, and the relationships which have been found to exist between the colour of the compounds and the chemical constitution, it is possible with more or less certainty to predict the colour a compound will have before it is produced, and the means which can be used to modify it.

[1] The President's address, Institute of Chemistry.

It will be impossible for me to give you but a very brief sketch of the history of this industry in the time at my disposal; anything like a complete account would fill volumes. On account of this I shall not be able to refer except casually to the coal-tar industry itself, the development of which is nearly entirely due to the one under consideration. Nor can I give a consecutive account of the coal-tar colours themselves, because the discovery of new series of colouring matters, and the progress of old ones, necessarily produce overlapping as it were, and renders such a course difficult and confusing. I therefore propose to take them according to the groups we now know them to belong to. I will therefore commence with that which contains the first colouring matter connected with this industry—mauvein and safranine group of compounds.

As I already mentioned, the coal-tar colour industry dates from 1856, the discovery of the aniline purple or mauve dye being made during the Easter vacation of that year, and the patent for its production taken out on the 26th of the following August. From the accounts I have already given elsewhere, I have mentioned how the discovery of this colouring matter was made during the prosecution of scientific research, which had for its object the artificial production of quinine, a subject which of late has very much occupied the attention of chemists, though it has not as yet been accomplished.

When commencing this industry, which was looked upon by many with considerable doubt as to its practicability, the difficulties encountered were very numerous on account of its unique character, but few of the processes having their representatives in other industries, the products were also very valuable, so that great care had to be employed with them. The success of the product tinctorially had not been proved on the large scale, so that it was necessary to proceed tentatively and not launch out too rapidly.

Aniline, as is well known, was at this period a rare body, originally obtained from indigo by Unverdorben in 1826, but for its production from benzene we are first indebted to the discovery of nitrobenzenein 1834 by Mitcherlich, and then to Zineri, who found that this substance when submitted to certain reducing agents produced a base which was eventually identified as aniline. It was not long before the date of this industry that a method of producing this base from nitrobenzene, with greater ease than by the process of Zinin, was discovered; and it is to Beauchaump we are indebted for this, who found that the reduction might be easily accomplished by means of iron filings and acetic acid. Had this discovery not been made, aniline could not have been produced sufficiently cheap to be used for the production of colouring matters. And it is interesting to note that this process of Beauchaump, slightly modified, is the one used to-day for the production not only of this base, but its homologues and analogous compounds.

It was not long before the difficulties of producing nitrobenzene were to a great extent overcome. Messrs. Simpson, Maule & Nicholson also began to experiment on the production of nitrobenzene, and after a time were able to produce it at a sufficiently low cost to be able to supply us with part of our requirements. I mention this in passing because it was the starting point of the history of the connection of this firm with artificial production of colouring matter, which they carried on so successfully afterwards.

After the mauve was discovered it was necessary to teach dyers how to use it. Being an organic base, it is opposite in properties to the vegetable colouring matter, and therefore the ordinary methods of application were not generally useful, and much time had to be spent in dyehouses and printworks in the early days of this product in reference to this subject, and at that time the question of fastness to light soap and bleaching liquor was much insisted on. Fortunately for the future of the coal-tar colour industry, although the mauve would not resist bleaching liquor well, it proved to be a very fast colour—the fastest purple yet produced, I believe—and thus its introduction became rapid. After this the love of brilliancy of colour which it had induced caused less attention to be given to the subject of fastness. I quite think that had this, the first coal-tar colouring matter, yielded colours as fugitive as some which have since been used, this industry would probably have been, to say the least, much delayed in its progress; so that it will be seen the mauve had to bear all the burdens of the difficulties incident on the inauguration of this industry, the future products being free from these impediments. The importance of this colouring matter after its success was established was quickly recognised in France, and its manufacture commenced there. This soon resulted in its importation into this country irrespective of patent rights. As, however, the foreign manufacturer employed responsible agents in this country, the law was without difficulty put into operation successfully—unfortunately, however, only to teach Continental manufacturers the lesson not to employ responsible agents in this country any longer, but, by means of correspondence or travellers, to deal directly with the consumers, and this *modus operandi* (practically, though perhaps not theoretically) enabled them to ignore the existence of patents, and import their products freely into this country. On this point I shall have to speak again further on. The mauve was first employed in silk dyeing in London, Mr. Thomas Keith & Sons, of Bethnal Green, being the first to use it. The second application was calico printing, Messrs. James Black & Co., of Glasgow, being the first to employ it largely for this purpose. It afterwards was extended to other trades.

With reference to the chemical history of this dye, although it had been submitted to analysis very soon after its discovery, its formula, or rather the formula of its principal constituent "mauvein," was not established until some time after it had become a commercial product, and was prepared in a crystalline condition. It was then shown to have the composition $C_{27}H_{24}N_4$ (*Proc. R. S.* xiii. 170).

It was found to be a very powerful base, decomposing ammonia salts with evolution of ammonia, and combining with carbonic acid to form a carbonate. Its ordinary salts are produced by its combination with one molecule of a mono-basic acid, its hydrochloride being $C_{27}H_{24}N_4HCl$.

In concentrated sulphuric acid it dissolves with a dirty green colour, changing to blue on slight dilution, and back to purple when thoroughly diluted; this is a distinctive reaction of this class of substance. Further researches have shown (*J. Chem. Soc.* xxxv. 717-732) that in the ordinary colouring matter there are two other compounds, one which is remarkable for its solubility, and from analysis appears to have the composition $C_{24}H_{20}N_4$; and the third, which has not been fully examined, possesses a redder shade of purple than the other.

The first product, or mauvein, is evidently a derivative of paratoluidine and aniline. The third of orthotoluidine and aniline, and the second of pure aniline. This has been called pseudo-mauvein. It might perhaps be better called phenol-mauvein.

When boiled with aniline mauvein yields an indigo-blue product, difficultly soluble in alcohol. This change takes place without formation of ammonia, and shows how different mauvein is in its character to rosaniline.

Runge found that aniline, when treated with dilute chloride of lime, yielded a blue- or violet- coloured solution, which soon underwent change. Some experiments on this, made in 1868 (*J. Chem. Soc.* xxii. 25-27), showed that the product which I termed "Runge's blue," was a peculiar compound, the salt of an organic base, which itself dissolved in alcohol with a reddish brown colour, the salts being blue. It is quite different from mauvein, and of no practical value; but what is interesting is that when exposed to heat, as by boiling a solution of one of its salts, it decomposes with formation of mauvein.

A beautiful colouring matter was obtained from mauvein by treating it with ethylic iodide. It gives shades of colour of a very red purple tint, and it was therefore called dahlia. It was mostly used in calico and delaine and other kinds of printing, but being costly, the production was never very large. This substance is a mono-ethylic derivative of mauvein, and all attempts to further ethylate this compound have proved fruitless. In properties it appears to be more like an ammonium compound than a replacement product.

Safranines.—In the preparation of mauvein, a colouring matter was obtained from the liquors, from which it was precipitated, producing beautiful crimson-red shades of colour on silk. The amount produced in this way was so small, however, that we are even not able to introduce it as a dye. But it was found that it could be produced by the oxidation of the mauve dye itself, and was then manufactured under the name of "aniline pink," but afterwards "safranine." This substance is evidently closely related to mauvein, as it gives the characteristic reaction with sulphuric acid I have already referred to.

The preparation of this from the mauve dye was, however, too costly to allow of its being brought into general use. However, new processes have been since discovered, by which this or other colouring matters of its class can be produced cheaply.

The first of these processes consisted in passing nitrous acid into commercial aniline, and then heating the mixture with arsenic acid, and then extracting the colouring matter produced. Hofmann examined this, and showed that it had the formula $C_{21}H_{20}N_4$ (*Ber.* vi. 526, 1872).

The examination of the product which was obtained by oxidising the mauve dye, I found to have the composition, $C_{20}H_{18}N_4$ (*J. Chem. Soc.* xxxv. 731), results which correspond with analyses published by Dale and Schorlemmer (*J. Chem. Soc.* xxxv. 682), obtained from the examination of a similar product. This substance, I found, was associated with that examined by Hofmann in a product prepared by Messrs. Guinon & Co., of Lyons.

Methods of a more synthetical nature have since then been discovered. O. Witt found that safranine could be obtained from orthoazotoluene and hydrochloride of toluene at 150-200° (*Ber.* x., 874, 1877). He then found that by oxidising a mixture of one part of paraphenylenediamine, and two parts of aniline, on the application of heat a safranine could be obtained which has the formula, $C_{18}H_{16}N_4$, and which is called phenosafranine.

The formation of this colouring matter by this and other processes has been studied by Nietzki (*Ber.* xvi. 464). He finds that the aniline in the reaction, in which paraphenylenediamine takes part, may be substituted by other primary monamines, or a mixture of these with dimethylaniline, and thus a large number of these dyes can be obtained.

Phenosafranine is now produced very largely, and in a pure crystallised condition, and is a very useful dyeing agent.

If we assume that all the safranines are strictly homologous compounds, the formula that Nietzki gives for phenosafranine would make the formula of that examined by Hofmann, and that examined by myself and Dale and Schorlemmer, to be incorrect, and that they should contain two hydrogens more than are assigned to them. This I cannot think is possible from all the analytical results we obtained.

The constitution of mauvein has not yet been established, and I have still experiments on this subject in hand. This may also be said of safranine, I think, although Nietzki has proposed a formula for it, in which nitrogen occupies a similar position to the metharacarbon in the rosaniline series.

Triphenylmethane Derivatives.—We must now go back again to the early days of this industry to consider the next class of compounds—viz., triphenylmethane derivatives.

The industrial success of the mauve dye caused aniline to become a very favourite body to experiment with, and the result was that in 1859, the discovery of that important colouring matter first known as fuchsine or magenta took place. Hofmann had observed in his experiments on the action of carbon tetrachloride on aniline in 1858, the formation of a red colouring matter, which consisted of this substance as a secondary product of the reaction, but it was M. Verquin who first discovered a process for the transformation of aniline into a red colouring matter of tinctorial value. This discovery of the compound marks a most important fresh departure in the history of coal-tar colours. As I mentioned, the mauve had paved the way for future colouring matters, and this new substance, which could be applied to fabrics by the same methods as the mauve, was most eagerly sought after owing to the brilliancy of its colour; and probably its manufacture was one of the most successful financially of all the aniline colours.

M. Verquin's process, which consisted in treating tin tetrachloride with commercial aniline, was soon superseded by better processes. The number of patents taken out for the production of this dye was very large, and all imaginable products were claimed as capable of producing it from aniline. The two most important, however, were those in which mercury nitrate and arsenic acid were used. The first of these processes, with which I had some experience, required much care to regulate the reaction and prevent deflagration. The next process with arsenic acid, known as medlocks, was by far the best, and was used very extensively until the last few years, the use of nitrobenzene as the oxidising agent being now mostly used in the place of arsenic aicd.

The manufacture of magenta, which at this period was often called roseine, was carried on chiefly in this country by Messrs. Sampson, Maule, & Nicholson, by the arsenic acid process. Mr. E. C. Nicholson and Dr. A. P. Price, of this firm, worked out the process with great success, and were the first to produce this colouring matter in a pure state. The beautiful display of the crystallised acetate, shown at the Exhibition of 1862, illustrated this fully.

It was with products supplied by Mr. Nicholson that Dr. Hofmann made his first researches on this colouring matter. He changed its name from roseine to *rosaniline*, and found that the base, when in combination with acids, had the formula $C_{20}H_{19}N_3$.

The important observation of Nicholson, and the critical experiments of Hofmann, on the necessity of using, not pure aniline, but a mixture of aniline and toluidine for the production of this substance, was made about this period.[1]

The next important step in this industry was the use of rosaniline itself as a source of new colouring matters. For this we are indebted to the experiments of two French chemists—viz., MM. Gerard and Delaire, who discovered that rosaniline salts, when heated with aniline, gave violet and blue colouring matters, which they called Violet Imperial and Bleu de Lyon. It is, however, to Mr. Nicholson that the credit of producing these bodies, in a practically pure state, belongs. This especially refers to the blue, the product known as opal blue, used by Dr. Hofmann in his investigations on the subject, being of great purity. Dr. Hofmann showed that these products were phenylated rosanilines, as is now well known, ammonia being given off in the reaction. And I may mention in passing that the manufacture of these blues is now carried on to such a large extent that the ammonia produced in this reaction is collected for the production of its sulphate or other salt.

One of the difficulties in the way of the new blue was its insolubility in water. Mr. Nicholson, however (in 1862), probably thinking of the method used to render indigo soluble, experimented upon the action of sulphuric acid in this compound, and he found that it was possible to obtain sulphonic acids from it. One of these, the sodium salt of which is known as "Nicholson's" or "alkali blue," is the monosulphonic acid, which is itself insoluble in water, but forms soluble salts, which can be applied to the goods, and then decomposed by acids. This compound has had much to do with the successful introduction of this colouring matter. The other product known as soluble blue is the sodium salt of trisulpho acid.

In the early part of 1864 the Hofmann violets were introduced. These, as is well known, are the ethylated rosanilines produced by acting upon rosaniline with ethyliodide. These colouring matters are more brilliant, though much more fugitive than mauvein; but by this time the desire for permanency was giving way very much to that of brilliancy; and these colouring matters were quickly taken up by dyers and calico printers.

About this time some colouring matters derived from phenol were introduced, and which, curiously, are found to belong to the class of substances now under consideration. These were brought forward by Messrs. Guinon, Marnas, and Bonnet, of Lyons. The first product was aurine, prepared from phenol by means of oxalic and sulphuric acid (Kolbe and Schavtt's process). The next was polvuine, obtained by acting upon aurine with ammonia. The third was azuline, prepared by heating aurine with aniline. This last was a blue dye, which has since been shown to consist chiefly of triphenylrosaniline.

Purple and violet derivatives were also obtained from rosaniline by a process of my own, in which brominated turpentine was employed. These were known as Britannia violets, and were much used.

Other coloured derivatives were also discovered; for example, by the action of aldehyde and sulphuric acid, a blue product was obtained, which, when treated with sodium hyposulphite or sulphuretted hydrogen water, yielded the well-known aldehyde green.

On examining the action of acetylchloride on Britannia violet, I obtained a peculiar green, which was used principally by calico printers, and very considerable quantities of acetylchloride were prepared for this purpose. The process was not published. This green was of a blue shade, and was obtained in a crystallised condition in combination with picric acid. The crystals had a golden metallic reflection.

Soon after this it was noticed that a green compound was produced in the preparation of the Hofmann violets, though generally only in small quantities. It was afterwards found that by making rosaniline react with an excess of methylic iodide that it could be produced practically. It was called iodine green; but the product now manufactured is a chloride. This colouring matter gave good candle-light greens. One of

[1] In my original patent it was shown that colouring matters could be obtained, not only from aniline, but also from toluidine xylidine and cumidine.

its peculiarities is that when heated it is converted into violet methyl-rosaniline, with loss of methyl-chloride.

A new method of producing rosaniline violet was proposed by Lauth, and patented by MM. Porrier and Chappat, in June, 1866. The process consisted in taking aniline, in which hydrogen had been replaced by an alcohol radical, and oxidising this instead of first preparing rosaniline, and then replacing the hydrogen in the colouring matter by the radical. The product proposed for this purpose was methyl-aniline.

Owing to the improved method of methylating aniline, which, I believe, was first proposed by Messrs. Gerard and Delaire (*Bull. Chem. Soc.* [2] vii. 360), this process has become a very important one, and large quantities of dimethyl-aniline are now used, the oxidation being effected by copper salts. The product, according to the reseaches of Otto Fischer, consists chiefly of pentamethylpararosaniline.

The most important advance in the production of green colouring matters of the triphenyl-methane series was the discovery of the benzaldehyde, Victoria or malachite green.

In 1877, Otto Fischer, whilst investigating the condensation products of tertiary aromatic bases (*Ber.* x$_2$, 1625), obtained by the action of benzaldehyde on dimethyl-aniline in presence of chloride of zinc, a colourless base of the formula $C_{23}H_{26}N_2$, the salts of which, when exposed to the air, rapidly oxidised to a fair blue-green dyestuff, which, he thought, would prove to be of complicated constitution. A little later (*Ber.* xi$_1$, 950) he showed that by oxidising this colourless base with some of the ordinary oxidising agents, this green could be more easily produced, and that it stood to the colourless compound in the same way as rosaniline does to leucaniline. Emil and Otto Fischer afterwards say (*Ber.* xii. 796) that the first experiments for the production of this green were made by the Badische Aniline und Soda Fabrik, in March, 1878. About this time Oscar Doebner (*Ber.* xi. 950) found that a green colouring matter was produced by heating benzaldehyde with benzyl trichloride and zinc chloride. This product has been found to be identical with that of Fischer's. This green colouring matter is now largely made from benzaldehyde, as this process is found to be the best. A similar compound is also prepared from diethyl-aniline, and is known as brilliant green. It is a beautifully crystalline body. It is rather curious that this produces shades of colour somewhat yellower than the green from dimethyl-aniline, whereas, being of a higher molecular weight, we should have expected it to be blue.

The principal difficulty which had to be contended with in the production of these colouring matters was the need of a supply of benzaldehyde The usual method of obtaining it from bitter almonds, which was the only one in use, was quite out of the question, so that other sources had to be looked for. The Badisches Aniline und Soda Fabrik, however, successfully overcame this difficulty. At first they experimented with the process of Lauth and Grimaux, which consists in the oxidation of benzyl-chloride, with an aqueous solution of lead nitrate; but the product made by this process was too dear. But they found that the decomposition of benzylidene-dichloride, by means of water, as observed by Cahours (*Ann. Chem. Suppl.* 2306) and Limprecht (*Ann. Chem.* 139, 316) gave them a means of producing this compound successfully, the reaction being as follows:—

$$C_6H_5CHCl_2 + OH_2 = C_6H_5.CHO + 2HCl.$$

This process, which they have successfully employed since March, 1878, consists in the preparation of benzylidenedichloride from pure toluene, and in the subsequent treatment of this chlorinated body with milk of lime, at 100° C.

I have stated that the group of colouring matters under consideration are called triphenylmethane derivatives, and to show how this has been proved to be the case, I must now refer very briefly to some of the theoretical work which has led to this knowledge. The most important of this refers to rosaniline. I have already drawn attention to the work of Hofmann, which gave us the first knowledge of the composition of this colouring matter, and the further information that it contained hydrogen, which could be displaced by phenyl and alcohol radicals; but as to the matter of constitution, I think the experiments of Caro and Wanklyn were the first, as they showed the relation which existed between rosaniline and aurine, or rosolic acid, and, in fact, produced rosolic acid from rosaniline; but it is to the beautiful researches of Emil and Otto Fischer that we are indebted for a clear knowledge of the constitution of this class of colouring matter.

But to clear the ground before proceeding further, I must remind you that ordinary commercial rosaniline, or magenta, prepared from aniline and toluidines, is a mixture of colouring matters. This was first known by Mr. Nicholson, who found that for the production of the finest blues it was necessary to purify the base and separate one of these before phenylating; but it is only of later years that the difference between these bodies has been carefully studied and explained. The base examined by Hofmann contained C_{20}, and is the chief constituent of commercial rosaniline. The other contains C_{19}, and is now called pararosaniline, because it is produced from aniline and paratoluidine. Similarly, in commercial aurine, two compounds are found, one containing C_{20}, now called rosolic acid, and one containing C_{19}, now called aurine; and these latter can be produced from the corresponding rosanilines; and Dale and Schorlemmer have also shown that aurine can be also converted into pararosaniline, by the action of ammonia (*J. Chem. Soc.*, xxxii. 121).

Emil and Otto Fischer, however, by submitting the leuco compound of commercial rosaniline to the diazo reaction, obtained the hydrocarbon $C_{20}H_{18}$, and from rosaniline prepared from paratoluidine and aniline, the hydrocarbon $C_{19}H_{16}$.

And this latter hydrocarbon was found to be identical with Kekule's triphenylmethane—

$$\begin{matrix} C_6H_5 & & C_6H_5 \\ & C & \\ C_6H_5 & & H \end{matrix}$$

Triphenylmethane.

On nitrating this hydrocarbon they obtained a trinitro derivative, which, when reduced, gave the tri-amido body,

$$\begin{matrix} NH_2C_6H_4 & & C_6H_4NH_2 \\ & C & \\ NH_2C_6H_4 & & H \end{matrix}$$

Leucaniline.

which is paraleucaniline, and by carefully heating its hydrochloride to 150–160°, it was converted into pararosaniline.

Also they found that by oxidising trinitrotriphenylmethane they obtained trinitrotriphenylcarbinol, and this when reduced gave pararosaniline direct.

From these results the constitution of the base is evidently—

$$\begin{matrix} NH_2C_6H_4 & & C_6H_4NH_2 \\ & C & \\ NH_2C_6H_4 & & OH \end{matrix}$$

Pararosaniline.

The salts– the hydrochloride, for example—being

$$\begin{matrix} NH_2C_6H_4 & & C_6H_4NH.HCl \\ & C & \\ NH_2C_6H_4 & & \end{matrix}$$

Pararosanilinehydrochloride.

Similar results were obtained from the hydrocarbon from rosaniline; it is tolyldiphenylmethane:—

$$\begin{matrix} C_6H_4(CH_3) & & C_6H_5 \\ & C & \\ C_6H_5 & & H_6 \end{matrix}$$

The rosolic acid and aurine corresponding to the rosanilines are constituted in an analogous manner:—

$$\begin{matrix} HOC_6H_4 & & C_6H_4O \\ & C & \\ HOC_6H_4 & & \end{matrix} \quad \text{and} \quad \begin{matrix} HO \\ CH_3 \end{matrix} \Big\} C_6H_3 \begin{matrix} & & C_6H_4O \\ & C & \\ HOC_6H_4 & & \end{matrix}$$

Aurin. Rosolic Acid.

From these results we see the beautiful relationships of the various colouring matters of this series to each other, and by it obtain information which is of practical value, as well as theoretical. From the following formulæ of a few of these products their relationships are seen:—

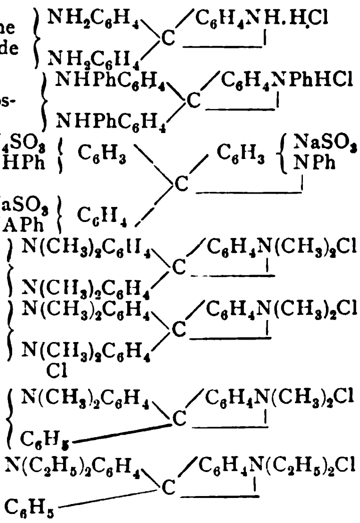
Marsh gas
$$\begin{matrix} H & & H \\ & C & \\ H & & H \end{matrix}$$

Triphenylmethane
$$\begin{matrix} C_6H_5 & & C_6H_5 \\ & C & \\ C_6H_5 & & H \end{matrix}$$

Leucopararosaniline
$$\begin{matrix} NH_2C_6H_4 & & C_6H_4NH_2 \\ & C & \\ NH_2C_6H_4 & & H \end{matrix}$$

Pararosaniline
$$\begin{matrix} NH_2C_6H_4 & & C_6H_4NH_2 \\ & C & \\ NH_2C_6H_4 & & OH \end{matrix}$$

Pararosaniline Hydrochloride
Aniline blue Triphenylpararosaniline.
Soluble blue
Methyl violet Hexamethylpararosaniline.
Methyl green Heptamethylrosaniline
Victoria, or Benzaldeyhde green.
Brilliant green



The effect of replacing hydrogen by hydrocarbon radicals in rosaniline is seen to result in the shade of colour becoming blue for each hydrogen replaced—the effects of those of high molecular weight, such as phenyl, being to produce the bluest shades; thus triphenylrosaniline is blue, whilst hexamethylrosaniline is blue-violet, notwithstanding it contains six hydrogens replaced.

After all the replacements possible have been effected, as in hexamethylrosaniline, the result of the combination of the products with halogen compounds of methyl is very interesting. The particular group to which this is attached becomes of the nature of an ammonium, and the colour changes to green—*i.e.*, methyl green—and this, like other ammonium compounds, when heated, dissociates, with loss of the halogen compound of methyl, and then hexamethylrosaniline is reproduced. Again, if this ammonium group be replaced by phenyl, we also get a green—*i.e.*, Victoria green.

The structure of some of these bodies has been proved by another most beautiful synthetical process, which has lately come into use—a process which enables us now not only to say that we employ the volatile products of the distillation of coal, but also the coke itself; as carbonic oxide, in combination with chlorine, is one of the important agents—*i.e.*, phosgene or carbonoxychloride is used. This product was discovered in 1812 by J. Davey.

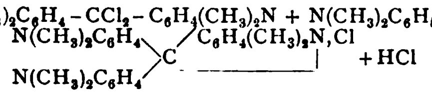
In 1876 W. Michler gave an account of his researches on the synthesis of aromatic ketones by means of phosgene (*Ber.* ix. 716), in which he showed by the action of this substance on dimethylaniline that a tetramethylised diamidobenzophenone was contained. This substance has, therefore, the constitution—

$$N(CH_3)_2C_6H_4 - CO - C_6H_4(CH_3)_2N.$$

The formation of this product takes place in two phases, but I need not enter into that now.

The first experiments to turn Michler's synthetically prepared tetramethylated diamidobenzophene to practical account were made by Dr. A. Kern, in the works of Bindschedler, at Basle. Dr. Kern proved that an agent like phosgene might be produced on a larger scale, and he invented a process to convert Michler's ketone base into methyl purple. This process was derived from the ketone synthesis of triphenylmethane from benzhydrol and benzene, and consisted in preparing the tetramethyldiamidobenzhydrol, and condensing the latter with dimethylaniline; thus the leuco base of hexamethylrosaniline was obtained, and then oxidised with lead peroxide. This process, which was too costly for practical purposes, has been superseded by one discovered by Dr. Caro, who has found that this ketone base can be made to form condensation products with dimethylaniline and other products directly, by the use of phosphorus trichloride—this substance converting it first into a chloride, which then reacts on the dimethylaniline, thus—

$$N(CH_3)_2C_6H_4 - CCl_2 - C_6H_4(CH_3)_2N + N(CH_3)_2C_6H_5 =$$



And this reaction takes place quantitatively, the body being so pure that it readily crystallises from water in prisms, like potassium permanganate, only with very much more brilliant lustre. These contain water of crystallisation. The condensation can also be effected with phosgene gas. The colouring matter obtained by this means is bluer than that obtained from dimethylaniline by oxidation, which consists chiefly of the pentamethyl compound.[1]

Diethylene can also be made into a ketone with phosgene or carbon oxychloride, and this product condensed with diethylaniline yields hexaethylpararosaniline.

Instead of dimethylaniline, dimethyl-α-naphthylamine can be used, and in this case a beautiful blue colouring matter is obtained, and if α-phenylnaphthylamine, the Victoria blue is produced, and by varying the reaction in this kind of way a great variety of colouring matter can be synthetically prepared.

With ammonias this ketone condenses to form the new yellow colouring matter, auramine, with aniline phenylauramine. With quinoline it produces a green very similar to Victoria or benzaldehyde green. I must not, however, spend any more time over this interesting part of the subject, but may say here again we have pure scientific research, conducted for its own sake, bearing fruit. The discovery of W. Michler, which remained for seven years a matter of theoretical interest, now comes forward as a matter of practical value.

(*To be continued.*)

THE DEVONIAN SYSTEM OF RUSSIA

M. P. VENUKOFF has recently given a general sketch of the Devonian rocks of Russia. As is well known, these rocks, so largely developed in Russia, contain such a peculiar fauna that geologists have been puzzled to establish a parallel between them and the different subdivisions of the Devonian system of Western Europe. Two great areas of Devonian strata are known in Russia: that of the north-west and that of the central basin. From Esthonia and Livonia the former extends north-eastwards to Lake Onega and perhaps even to the White Sea, and southwards through Pskor and Vitebsk to Moghiber. In Smolensk only traces of Devonian rocks have been found; but further south-east a great tract of these rocks runs through Tula, Orel, Voronesh, Ryazan, and Tamboff.

Prof. Grewinck, in his "Geologie von Livonia und Kurland" in 1861, and again in 1879, and Prof. Barbot de Marny, in the Russian *Mining Journal* of 1878, attempted to classify the Russian Devonian deposits; not to mention the earlier English work of Murchison, followed by those of Pander, Pacht, Helmersen, and Kutorga, and recently by those of MM. Stuckenberg, Inostrantseff, and Romanovsky. The mixed characters of the fauna have thus always presented great difficulties in the way of satisfactory correlation.

The recent monograph by M. Tschernyskev (*Mem.* Geol. Committee, i., 3) shows how rich a field remains to be explored before our knowledge of the Devonian fauna of Russia in any measure approaches completion.

M. Venukoff, in his *résumé* of the present condition of the problem, gives a brief account of all that is known as to the Russian Devonian system in each separate government, followed with an analysis of the work done by previous geologists. He then presents a detailed exposition of his own observations and conclusions in North-West and Central Russia; giving long lists of fossils which comprise the rich collections recently made by M. Antonowitsch. In the north-western basin three stratigraphical series have long been known: the lower sandstones, the middle limestones and dolomites, and the upper sandstones. The lower member contains only fishes and small *Lingulæ*, though on the Oyat the ichthyolites are accompanied with *Rhynchonella livonica*, *Streptorhynchus crenistria*, *Avicula rostrata*, *Isocardia*, and numerous *Algæ*. The fauna of the limestones is mostly that of deeper water, but even among these strata there occur occasionally—as at Lake Ilmen—beds of sandstone with shallow-water forms (the fishes *Coccosteus*, *Asterolepis*, *Osteolepis*, and the little *Lingula bicarinata*, Kut.). On the whole the middle limestones of Pskov and Novgorod may be sub-divided into four stages or zones characterised, the first, by *Rhynchonella Meyendorfii*, *Rh. livonica*, *Spirifera muralis*, *Atrypa reticularis*, *Orthis striatula*, and *Strophalosia product-*

[1] See Patents, Caro, 4428, September, 1883; 4850, March 13, 1884; and 5038, March 18, 1884.

oides; the second, by the same fossils, but without *Rh. Meyendorfii*, and with two additional species of *Spirifera* (*S. disjuncta* and *S. lenticula*); the third has yielded only these two Spirifers, and *Str. productoides*, while the fourth contains also *Atrypa reticularis* and *Orthis striatula*. Among the Devonian rocks of Central Russia, which consist only of limestones, M. Venukoff tries to establish the following four subdivisions: the Voronesh marls and limestones characterised by the presence of *Spirifera Anosoffi*, together with *Atrypa reticularis*, *Strophalosia productoides*, several Orthoceratites and Corals, the Elets beds, where *Sp. disjuncta*, and a variety of *Sp. Archiaci* replace *Sp. Aanosoffi*, the other leading fossils being: *Rhynchonella livonica*, *Athyris concentrica*, *Productus subaculeatus*, *P. membranus*, *Strophalosia productoides*, *Streptorhynchus crenistria* (*umbraculum*), *Pleurotomaria*, *Euomphalus*, &c. The intermediate beds between these two groups are especially rich in corals (*Aulopora serpens*, *Cyathophyllum ceratites*, *Syringopora abdita*, *S. tabulata*, species of *Stromatopora*, &c.). The Elets beds are covered with a series of limestones characterised by the presence of *Arca oreliana*, and these last are followed by the well-known group of Muraevuya (in Ryazan) which constitutes a passage between the Devonian and Carboniferous systems. The correlation of the subdivisions of the deposits of the Devonian groups of North-Western with those of Central Russia, and of both with those of Western Europe, is beset with difficulties. Still it appears that the limestones of Elets and Voronesh, as also those of the Duna (especially since M. Antonowitsch's researches), are comparable with the *Stringocephalus* group of the Eifel and Nassau; some resemblance may also be traced between the Elets and Voronesh limestones and the higher parts of the Middle and Lower members of the Upper Devonian system of England. They may likewise represent the "Frasnien" subdivision of the Upper Devonian series of the Boulonnais. Regarding the Lower Devonian Sandstones of Russia, Murchison's correlation of them with the [Lower] Old Red Sandstone of Caithness and Elgin remains unshaken. The break between these sandstones and the Silurian deposits which they cover seems also to be confirmed. As to the Devonian rocks of Poland, it appears from M. Mikhalsky's researches (*Izvestia* of the Geol. Committee, 1883) that the Lower, Middle, and Upper Devonian divisions of Western Europe are found there, the Upper being akin to the *Rhynchonella cuboides* group of the Eifel. Again, on the other side of the country the discovery on the eastern slope of the Ural of a *Clymenia* closely akin to the *C. annulata* and the *C. spinosa* (*Izvestia*, 1884, 4) is a fresh confirmation of the likeness of the Ural Devonian rocks to those of Western Europe. According to M. Tschernyshev the limestones of the western slope of the Middle Ural chain belong to the Lower Devonian, those of the Byelaya River (*Izvestia*, 1885, 3) belonging to its lower subdivisions.

SCIENCE IN BOHEMIA

THE Royal Bohemian Society of Sciences celebrated, on December 6 of last year, the hundredth year of its public existence. Occasion has been taken to issue some special publications, comprising a historical sketch of the Society and a *résumé* of the principal researches, a list of all papers, and another of members, since the commencement. The Society originated in a private one for study of science and history started in 1770 under the presidency of Ignaz von Born, who was not only an able scientist of the time, but an ardent freemason (as were many of his fellows). It is a curious fact, throwing light on the aims of this Society, that its publications were all in German, not in Latin, the usual scientific medium in Bohemia at that time. No one thought of using Bohemian for science. *Now* a considerable portion of papers appear in Bohemian, not always accompanied by a German *résumé*, through which some are rendered more accessible to the average linguist here.

Of the various scientific work recorded in the *Abhandlungen* and *Sitzungsberichte* for 1883–84 we may first notice that on fossil forms. The sponges of the Bohemian chalk formation, as represented in the Prague Museum, are being gone through by M. Pocta. In the new method of studying such remains, special weight is attached to inner structure, the outer form being regarded as of secondary importance; and following this course M. Pocta contributes the first two portions of a careful and finely-illustrated monograph dealing with the *Hexactinellidæ* and *Lithistidæ*, two of the seven orders of Zittel's classification. M. Pocta describes elsewhere the varieties of isolated sponge spicules met with in the chalk. Some sponge remains from the Lower Silurian strata of Bohemia resemble (according to M. Feistmantel) the species *Acanthospongia Siluriensis*, described by MacCoy in 1846, and found at Cong, near Galway. We further notice accounts of fossil flora of the anthracite formation in Central Bohemia (M. Kusta), and of remarkable stem remains of *Araucaroxylon* from the same (M. Feistmantel), &c. M. Novak shows from Bohemian trilobites how the form and markings of the hypostome offer good generic characters which may be taken as decisive where the other parts of the body agree.

Among interesting fossils brought before the Society is a scorpion from the "Moravia" coal-pit at Rakonitz. This is one of the little known order of *Pedopalpi*, and is the first fossil representative of a still living genus, *Thelyphonus*, and probably of the order. Its great similarity to present forms is noteworthy, showing persistence of type in this genus from the Carboniferous period. The same pit has yielded four new spiders, and the number of known Palæozoic arachnida is now (according to M. Kusta) 34. A fossil cockchafer was found in a mass of Tertiary quartz received from France at a millstone manufactory in Prague. The body stood nearly free in an oval hollow of the stone, doubtless corresponding to the cocoon. M. Fric has sent it to the Jardin des Plantes, Paris.

From a chemical examination of the dark colouring matter of ebony, M. Belohoubek concludes that it is to be regarded as coal, and the case is a striking one, as being that of carbonisation of plant material occurring physiologically in a living plant. The author not having sufficient young ebony could not exactly determine the mother-substance. M. Celakovosky finds in certain anamorphoses of the ovulum of *Raphanus sativus*, L., and in abnormal leaves of *Croton*, evidence in support of the foliolar theory of the ovulum. M. Palacky furnishes two instalments of his valuable, though necessarily incomplete and tentative sketch of the geographical distribution of plants. The formation of serial buds is studied by M. Velenovsky. M. Hansgirg extends the knowledge of Bohemian algæ (imperfectly studied hitherto), and there are yearly reports on the additions to Bohemian botany.

The organs of excretion of *Hirudineæ* are to be regarded (according to M. Vijdovsky) as modified "segmental organs" of the *Oligochæta*; as the former worms may be considered as Oligochæta degenerate through parasitism. The same author furnishes an account of the freshwater sponges of Bohemia; he finds five well-characterised species with some varieties belonging to the three sub-genera, *Euspongilla*, *Ephydatia*, and *Trochospongilla*. Of freshwater Bryozoa M. Kafka finds in Bohemia thirteen species, two of them new. M. Bayer shows how widely apart *Pelobates* and *Bombinator* are in the structure of their skeleton, and offers a new classification of the Anoura.

Considering the nature of steel-hardening from the electrical standpoint, in connection with the corresponding behaviour of some silver alloys, MM. Strouhal and Barus arrive at the result that neither the mechanical nor the chemical hypothesis as to steel hardening suffices alone to explain the phenomena, and, while the proportion of carbon is the principal factor for determining the behaviour of steel, this behaviour must be explained by a combination of chemical and mechanical influences. The authors offer a definition of steel on the basis of the electrical behaviour of iron with increasing proportion of carbon. M. Kolacek makes a contribution to the theory of the Gramme machine. M. Seydler investigates the application of the principle of energy to the pondero-motive and electro-motive actions of the electric current, also the theory of tension of electrostatic phenomena from the standpoint of the theory of elasticity. There are various papers in mathematics, crystallography, &c., which we must not stop to notice. Tables of rainfall at different stations of Bohemia are furnished by M. Stodnicka.

To this brief account, indicating some directions of recent Bohemian science, we will add a word about the great work of Barrande. That eminent geologist, who died on October 5, 1883, left his collections, &c., to the Bohemian Museum; he also left directions and funds for the completion of his "Système Silurien du Centre de la Bohème," of which twenty-two volumes had appeared between 1852 and 1881. Drs. Waagen and Novak now undertake, at Barrande's request, the further work required. The text and plates relating to the Gasteropods and Echinoderms were found in a nearly finished state, but the Polyps, Graptoliths, and Bryozoa have still to be worked out for the most part. Four volumes will thus be added to this remarkable work, making in all twenty-six, with 2000 plates of illustrations.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

THE Bristol Merchant Venturers' School of Science, Technology, and Commerce, erected at a cost of nearly 50,000*l.*, to replace the old Trade and Mining School, was formally dedicated by the merchants to the city on Saturday, when their handsome gift, including the complete charge of the school, estimated at 1000*l.* a year, was received by the Mayor on behalf of the citizens. After the Trade and Mining School was handed over to the Colston Trust by the Endowed Schools Commissioners, this science school, which had already won a very distinguished position in the country, made such rapid progress that the building was soon found inadequate for the 500 scholars attending it, and the Merchant Venturers, who constituted the chief part of the governing body known as the Colston Trust, determined to build a new school on the plan of the newest and best equipped English and foreign school, with the best-known methods and appliances for science and art instruction. Finding that the Colston Trust funds assigned for the purpose were inadequate to the demand of such a large building, they undertook the entire charge, so that the scholastic institution will henceforth be known as the Bristol Merchant Venturers' School. Sir Frederick Bramwell, C.E., Chairman of the Council of the City Guilds Institution for the Advancement of Technical Education, the Mayor and High Sheriff of Bristol, the Bishop of Gloucester and Bristol, Mr. Samuel Morley, M.P., Mr. Lewis Fry, M.P., Col. Donnelly, Capt. Abney, and others took part in the inaugural ceremony, which was prefaced by a luncheon given by the master of the Society, Mr. R. W. Butterworth, at the Merchant Venturers' Hall. After the luncheon the party repaired to the new schools, and the opening ceremony took place in the examination hall. The Master (Mr. Butterworth) presided, and in opening the proceedings gave a history of the growth of the old Trade School and its development into the present great establishment. The Master then called upon Sir Frederick Bramwell to declare the building open. Sir Frederick Bramwell said he thought that he might safely say that almost by universal agreement the training to be given in schools such as that was held to be a training that ought to be given, and was a national benefit and blessing. That meeting, he said, was not to initiate something new, for, as had been said, the work had gone on for thirty years; it was not to mark a birth, but to mark progress; not the full development, or anything like it, but a stage—for they would hope that not many years would elapse before an audience as numerous and as earnest as that he saw before him would meet in Bristol to celebrate some further marked step in the development of technical education in the city. What was the object in giving this technical education? The primary object was to enable men and women to earn their living better than they could otherwise do. The primary object of such education was to teach men engaged in industrial pursuits to conduct them in a manner which would redound to their happiness and material prosperity, and this would redound to the prosperity and welfare of the whole nation. A man instructed as he would be there would be enabled to carry on his industry in a totally different manner from those who had to begin the battle of life fifty years ago. At that time they had to profit by what could be taught them derived from experience, but without understanding the principle on which the things depended. They should remember the great things which for the first sixty years of this century were done by men who had not the advantage of technical education. But when a man had that advantage he was enabled to look at the experience of the past in a totally different manner, because he knew the principles on which that experience was based, and knew when it was applicable or inapplicable. Whatever his determination, the Englishman was badly weighted in his struggle with his foreign competitor if the latter had the means of applying science to his industry when the former had not. In London they were doing good work of this sort, one of the branches being technological examination, and during the past three years the number of those that came up more than doubled—from 1900 to 3900. That increase did not arise from the governing body relaxing the examination; on the contrary, they thought it right to add to he stringency of the examination. So the best judges of all, the very men whom they wished to instruct, themselves proved that they valued this instruction. It could not be said that this was a question where they were endeavouring to force on an unwilling people the advantages of education the value of which they did not recognise; and thus they had the encouragement arising from appreciation of their efforts.

MR. ARTHUR SMITHELLS, B.Sc. (London), assistant lecturer and demonstrator in chemistry at the Owens College, Manchester, has been elected to the Professorship of Chemistry at the Yorkshire College, Leeds, rendered vacant by the appointment of Dr. Thorpe to the Chair of Chemistry in the Royal School of Mines and Normal School of Science, South Kensington.

SCIENTIFIC SERIALS

Journal of Franklin Institute, No. 713, May.—Prof. C. F. Himes, actinism. A lecture delivered at the Philadelphia Electrical Exhibition, giving a succinct account of modern investigations.—F. E. Ives, isochromatic photography. Describes his blue-myrtle chlorophyll process.—C. J. Hexamer, fire hazards in textile mills. Deals with relative risks of cotton, wool, and shoddy of various qualities.—W. B. Le Van, economy in the use of high-pressure steam. Describes a new high-pressure boiler.—Prof. Pliny E. Chase, further experiments in weather forecast. Of interest to meteorologists.—Prof. E. J. Houston, glimpses of the International Electrical Exhibition, No. 7, Drawbaugh's telephonic inventions. Description and drawings of the instruments of this notorious person.

No. 714, June.—Dr. Persifor Frazer, the World's Industrial and Cotton Centennial exposition. Gossip about the New Orleans Exhibition.—Prof. J. Burkitt Webb, a simple form of draught gauge; a simple instrument for measuring the decrease of pressure in a flue directly by scales.—Dr. Werner Siemens, on the electromotive action of illuminated selenium, discovered by Mr. Fritts. In this communication, which is translated from the German, Dr. Siemens describes as being entirely new and scientifically of the most far-reaching importance, the phenomena discovered by Mr. Fritts, which were, at Philadelphia, condemned by Prof. Rowland as unworthy of being brought before the Physics section of the American Association. Dr. Siemens agrees with Mr. Fritts that in his experiments there is a direct conversion of the energy of light into electrical energy.—E. L. Corthell, the Tehuantepec Ship Railway.—Prof. E. J. Houston, facsimile telegraphy.—Appended to this number are the reports of the examiners of the Philadelphia Electrical Exhibition on electric arc lamps, and on carbons for arc lamps.

Annalen der Physik und Chemie, xxiv. No. 4, April.—Prof. F. Melde, experimental researches in acoustics. Gives account of new experiments with a phonic wheel and other electromagnetic means of exciting vibrations.—G. Tammann, on the vapour-pressure of salt solutions. Gives many hundreds of determinations of lowering of pressure of aqueous vapour by addition of some soluble salt. The author concludes that for a given salt the product of the relative pressure-reduction into the volume of the solution relatively to that of the water it contains is a constant. Exceptions are attributed to polymerisation. — Prof. W. von Bezold, on current-figures in liquids. The method consists in observing the forms which result from putting aniline dyes (such as are used for ink in hectograph) upon the liquids. The present paper deals with the internal currents set up by differences of temperature produced by surrounding with a ring of ice, &c. The figures are curious and instructive.—Prof. E. Kittler, on measurement of strength of currents. Describes the method of taking strength of currents by measuring potential when the current is passed through a known resistance.—Prof. G. Quincke, electrical researches, No. xi. This series deals with the constants of electromagnetic rotation. For sodium light, Quincke finds the constant for bisulphide of carbon to be 4·409′ at 21° C. Becquerel found 4·630′ at 0°, and Lord Rayleigh and Mrs. Sidgwick found 4·2002′ at 18°. Quincke gives tables of statistical results for other liquids, agreeing in the main with those of Perkin and of Becquerel.—A. Gockel, on the relation of the Peltier-heat to the efficiency of galvanic elements. A discussion of the work of Braun, Chaperon, Czapsky, Bouty, and others, with redeterminations.—W. Herman Schultze, on the reaction between two mutually perpendicular magnetic distributions. Very careful experiments confirm Siemens's result that longitudinal magnetism diminished by a transverse magnetisation.—A. König and Fr. Richarz, a new method of determining the constant of gravitation.—Leo Arons, interference fringes in the spectrum. Fringes are observed to intrude; which the author eventually traces to the films between the two lenses of the achromatic telescopes.—Robert Weber, the electrical siren. An interesting apparatus producing tones in a receiving telephone by interrupting the circuit by a rotating cylinder having series of electric contacts around its periphery.

xxv. May.—Prof. L. Lorenz, determination of the electric resistance of mercury columns in absolute electro-magnetic measure. The result of the author's method is that the true value of the ohm is represented by a mercury column of 1 square millimetre section and 105·93 centimetres in length.—Franz Stenger, contributions to the electric conductivity of gases.—Hans Jahn, on the validity of Joule's law for electrolytes. The careful experiments establish the validity to a very close degree.—R. Lamprecht, on flexible conductors under magnetic influence. A mathematical discussion.—J. J. Balmer, note on the spectrum lines of hydrogen. The wave-lengths of twelve observed lines are found to agree with the formula $\lambda = N(m^2/m^2 - 4)$, where N is a coefficient, and m and n whole numbers. For hydrogen, $N = 3645 \times 10^{-8}$ cm.—Dr. Fr. Vogel, change of refraction in glass and calc-spar with temperature. The author finds, with Fizeau, a diminution in the difference between the two indices of calc-spar nearly proportional to the elevation of temperature.—Prof. W. Voigt, the optical properties of very thin metal films. Rediscusses Quincke's results.—Julius Elster and Hans Geitel, note on a sensitive Doubler. This is nothing else than a Thomson's water-dropper.—Elster and Geitel, remarks on the electric processes in storm-clouds. The authors regard thunder-clouds as acting as the water-dropping doubler does, in raising at the expense of the kinetic energy of the falling drops the electric potential of the mass placed under electric influence.—Elster and Geitel, on the development of electricity during formation of rain.—Dr. H. Kayser, on lightning photographs.—Prof. G. F. Fitzgerald, on the memoir of Prof. Kundt on the electromagnetic rotation of the plane of polarisation of light by iron, cobalt, and nickel.—Hanichi Muraoka, on the magic Japanese mirror.—K. Exner, remark on the velocity of light in quartz.

Rendiconti del Reale Istituto Lombardo, June 11.—Further remarks on the functions that satisfy the differential equation $\Delta^2 u = 0$, by Prof. Giulio Ascoli.—On the resolution of certain modular equations, a complement to the author's paper on the transformation and division of the elliptical functions, by G. Morera.—Inversion of the movement of the pupil in the case of a person affected by progressive analysis, by Prof. A. Raggi.—On certain physiological functions of the lower organisms: a contribution to the morphology of the Metazooi, by Prof. Leopoldo Maggi.—Reply to the recent objections advanced against a science of penal jurisprudence, by E. A. Buccellati.—Some recent studies on the origin of the Institutions of Justinian, by Prof. C. Ferrini.

THE largest space in the *Nuovo Giornale Botanico Italiano* for July is occupied by a paper by Sig. C. Massolongo, on the Hepaticæ gathered by Dr. Spegazzini in Terra del Fuego in 1882, an important contribution to Hepaticology. Ninety-five species are described, a considerable number of them new, including, also, one new genus, *Pigafettoa*. The paper is illustrated by no less than seventeen plates. The kindred Bryology claims also a paper by Sig. Venturi, on the Italian representatives of the section *Harpidium* of *Hypnum*. Sig. Piccone gives a list of marine and freshwater Algæ observed by him on or near the Ligurian coast, many of them being new to the district. The only papers in this number not concerned with Cryptogamy are teratological—by Sig. Terracciano on a quadrilocular capsule of *Agave*; and by Prof. Caruel on Viridescence in *Verbascum*.

IN the *Journal of Botany* for July, Mr. W. H. Beeby describes and figures the recently-discovered *Sparganium neglectum* from Surrey, for which he claims the rank of a good species. With the exception of a teratological note on Peloria in *Habenaria bifolia* by Mr. H. N. Ridley, all the other papers in this number are descriptive and topographical:—New ferns from Brazil, by J. G. Baker; additions to the British lichen-flora, by Rev. J. M. Crombie; Notes on the flora of Ceylon, by Dr. Trimen; on the flora of the Philippine Islands, by R. A. Rolfe; on Dovedale plants, by Rev. W. N. Purchas.—Dr. Buchanan White records one more addition to the Flowering plants of Great Britain, *Schœnus ferrugineus*, from Perthshire.

SOCIETIES AND ACADEMIES

LONDON

Geological Society, June 24.—Prof. T. G. Bonney, F.R.S., President, in the chair.—John MacDonald Cameron, Matthew Heckels, and Robert H. Williams, were elected Fellows of the Society.—The following communications were read:—Supplementary notes on the deep boring at Richmond, Surrey, by Prof. John W. Judd, F.R.S., Sec.G.S., and Collett Homersham, F.G.S. Since the author's former communication to the Society on the subject, this boring, in spite of the strenuous efforts made by the Richmond Vestry, and the contractors, Messrs. Docwra and Co., has had to be abandoned, after reaching a total depth of 1447 feet from the surface. This depth is 145 feet greater than that of any other well in the London Basin, and, reckoning from Ordnance datum, reaches a lower level by 312 feet than any other well in the district. Before the termination of the work temperature-observations were obtained, which generally confirm those previously arrived at. The strata in which the boring terminated consisted of the red and variegated sandstones and marls previously described, which were proved to the depth of 208 feet. Although it was demonstrated that these beds have a dip of about 30°, complicated in places by much false-bedding, no conclusive evidence could be obtained concerning their geological age. They may be referred either to some part of the Poikilitic series, or to the Carboniferous (for similar strata have been found intercalated in the Carboniferous series at Gayton, near Northampton), or they may be regarded as of Old Red Sandstone age. Some interesting additional observations have been made since the reading of the former paper, on the Cretaceous rocks passed through in this well. Mr. W. Hill, F.G.S., of Hitchin, has found the exact analogue of the curious conglomerated chalk met with at a depth of 704 feet at Richmond. His observations entirely confirm the conclusion that we have at this depth the "Melbourne rock" with the zone of *Belemnites plenus* in a *remanié* condition at its base. Some new facts concerning the state of preservation of the fossils in the Chalk Marl are also recorded. With respect to the conclusions arrived at by the author concerning the distribution of the Jurassic rocks on the south side of the London Basin, an important piece of confirmatory evidence has been supplied by a deep boring made at the Dockyard-Extension Works at Chatham. This section, for the details of which the authors are indebted to the officers of the Geological Survey, shows that under the Chalk and Gault, with normal characters and thickness, there lie 41 feet of sandy strata of Neocomian age, and that these are directly underlain by blue clays of Middle Oxfordian age, as is proved by the numerous fossils which they have yielded. We have now, therefore, direct evidence of the existence and position of strata of Lower, Middle, and Upper Oolite age, respectively, beneath the Cretaceous rocks of the south-east of England.—On the igneous and associated rocks of the Breidden Hills in East Montgomeryshire and West Shropshire, by W. W. Watts, F.G.S. The author, in this paper, described the succession of rocks in the small tract near the Breidden Hills situated between Welshpool and Shrewsbury. The Cambrian rocks are: (1) Criggion shales, dark and barren, much penetrated by intrusive diabases and about 2700 feet thick. (2) Andesitic lavas and ashes, followed by conglomerates of the same materials. (3) Ashy grits and shales containing *Climacograpsus antiquus? C. bicornis? C. scharenbergi, Cryptograpsus tricornis, Diplograpsus foliaceus, Leptograpsus flaccidus? Beyrichia complicata, Trinucleus concentricus, Orthis testudinaria, Bellerophon bilobatus*, The rocks are thus of Bala age, the fossils indicating that the ashy grits and shales are on the horizon of the top of the Glenkiln or bottom of the Hartfell series. These are followed by Silurian strata. (1) *Pentamerus* beds. Soft sandstones and mudstones yielding *Pentamerus globosus? P. oblongus, P. undatus, Leptæna transversalis, Strophomena rhomboidalis, Petraia subduplicata*. (2) purple shales, unfossiliferous. (3) Lower Wenlock shale, with *Monograptus vomerinus? Cryptograpsus*, sp., *M. priodon*, var. *Flemingi*. These graduate into (4) Upper Wenlock shale, with *M. priodon, M. vomerinus? M. basilicus, M. nilssoni, M. rœmeri*. (5) Lower Ludlow shale. *M. colonus, M. nilssoni, M. salweyi, M. lintwardenensis*. The paper concluded with microscopical descriptions of the igneous rocks, of which there are two sets: (1) An older set interbedded with the Cambrian and consisting of andesites bearing a large percentage of a mineral allied to enstatite, together with augite and a small quantity of hornblende and mica. These are chiefly lavas, but some few are perhaps intrusive rocks and dykes. (2) Intrusive rocks of a diabase type, generally, however, containing a variety of enstatites identical with that in the andesites. These are intrusive in the Cambrian rocks, and from their relations appear to be most probably of post-Silurian age.—Note on the Zoological position of the genus *Microchœrus*, Wood, and its apparent identity with *Hyopsodus*, Leidy, by R. Lydekker, B.A., F.G.S.—Observations on some imperfectly known Madreporaria from the Cretaceous formation of England, by R. F. Tomes, F.G.S.—Correlations of the "Curiosity-Shop" beds, Canterbury, New Zealand, by Capt. F. W. Hutton, F.G.S. The "Curiosity Shop" is a locality on the River Rakaia in the Canterbury Plains, and has been thus named on account of the numerous fossils found in some calcareous sandstones cut through by the river. The section exposed consists of (1) river-gravels; (2) loose grey quartz sands; (3) soft calcareous sandstone with glauconite, passing downwards into tufaceous clay; (4) calcareous sandstone without glauconite; (5) loose grey or yellowish brown sands. By Mr. McKay, of the Geological Survey, No. 2 had been referred to the Pareora series (Miocene?), No. 3 to the Upper Eocene series, and Nos. 4 and 5 to the Cretaceo-Tertiary series. The author, who was inclined to class all these beds in a single series, pointed out that the only difference between the fossils found in Nos 3 and 4, the most important fossiliferous beds, consisted in the presence of a greater number of forms in No. 3, all found in No. 4 being identical with those in the overlying bed. He then gave a complete list of the species of Vertebrata, Mollusca, Brachiopoda, Echinodermata, Bryozoa, and Cœlenterata, from the locality, 48 in all, and compared them with those from the Weka Pass stone, 26 in number, and the Ototara fossils from Oamaru, to show that a large proportion were identical. He gave reasons for not agreeing with the views of Dr. Hestor and Mr. McKay, who held that unconformity exists between the beds referred by them at the Curiosity Shop, in the Weka Pass district, and north of Otago, to the Upper Eocene and Cretaceo-Tertiary series respectively, and showed, both from palæontological and stratigraphical data, that all these rocks must be included in one system, the Oamaru system of Dr. von Haast and himself.—On the fossil flora of Sagor in Carniola, by Constantin, Baron von Ettingshausen, F.C.G.S. The author in this paper gave the principal results of his examination of the fossil flora of Sagor, consisting of 170 genera and 387 species, of which a list was appended. The plants were obtained from fourteen different localities, some of the most important species from each of which were mentioned; in one of these localities the flora underlying the brown coal of the district belonged to the uppermost Eocene, whilst the remaining stations were assigned to the lowest stage of the Miocene system. The great diversity of the fossil plants showed that the Tertiary flora of this and other localities must be considered the origin of all the living floras of the globe; for in the fossil flora of Sagor are found plants representative of forms now found in Australia, North America, and Mexico, California, Chili, India and the East Indian Islands, Europe, Africa, Norfolk Island, and New Zealand. Examples of all these were cited.

Edinburgh

Royal Society, July 6.—Sheriff Forbes Irvine, Vice-President, in the chair.—Dr. R. W. Felkin, F.R.G.S., gave an account of the For tribe, one of the Negro races of Central Africa.—The Astronomer-Royal for Scotland communicated a paper, by Dr. Daniel Draper, on bisulphide of carbon prisms, and also exhibited some stereoscopic photographs.—Drs. Woodhead and Hare, in a paper on the vital relations of micro-organisms to tissue-elements, endeavoured to classify as far as possible the actions of micro-organisms on tissues. They pointed out that the reaction of the tissue-elements themselves had latterly been too much lost sight of, and that a more careful study of the normal cell-life history must in time be the means of throwing considerable light on the subject under discussion. They insisted very strongly on the digestive action of micro-organisms.—Thomas Andrews, F.C.S., submitted a paper on the resistance, during recrystallisation, of fused salts of the halogens, compared with some others and glass.—Prof. Turner gave an account of a specimen of Sowerby's whale (*Mesoplodon bidens*), recently obtained from Shetland, calling special attention to the great complexity of the stomach, the contents of which seemed to indicate that the animal fed upon fish.—Mr. W. E. Hoyle laid before the meeting the second part of the Preliminary Report on the *Challenger* Cephalopoda.

Paris

Academy of Sciences, July 20.—M. Bouley, President, in the chair.—Observations of the small planets made with the large meridian at the Observatory of Paris during the first quarter of the year 1885, communicated by M. Lœwy.—Note on the movement of rotation of the earth around its centre of gravity, by M. Tisserand.—On various propositions relating to the movement of a solid body around a fixed point, by M. G. Darboux.—A spectroscopic study of substances rendered phosphorescent by the action of light or by electric discharges, by M. Edm. Becquerel.—On the metaphosphate of thorium, by M. L. Troost. This substance, obtained by the reaction of the chloride of anhydrous thorium on an excess of metaphosphoric acid in solution, takes the form of crystals insoluble in water and easily separated from metaphosphoric acid. Its analysis yielded metaphosphoric acid 52·45; thorine 47·64.—Researches on the duration of excitability in the excito-motor regions of the brain proper after death, by M. Vulpian.—Observations on the fauna of the island of Great Comoro, to the north-west of Madagascar, by MM. Milne-Edwards and E. Oustalet. From a careful study of the mammals and birds of this island the authors conclude that it is not a geographical dependence on Madagascar, that it never was attached to that region, and that its fauna has borrowed from the surrounding lands.—Note on the intermediary orbit of the moon, by M. Hugo Gyldén.—On the vaso-motor action of suggestion on hysterial subjects in a state of somnambulism, by M. Dumontpallier. From experiments made on two women subject to hysteria in the hospital de la Pitié it appears that, under certain conditions, suggestion may produce a vaso-motor modification characterised by a considerable increase of temperature in any region determined at pleasure. This result opens the way to a series of fresh experiments of the same order, and renders possible a physiological interpretation of phenomena, the reality of which science had hitherto regarded as somewhat doubtful.—Observations of Barnard's new comet made at the Observatory of Nice (Gautier's equatorial), by M. Charlois.—On the sixteen systems of planes of the regular convex icosahedral, by M. E. Héward.—On the capillary constants of the saline solutions, by M. A. Chervet.—Note on the production of the lowest temperatures, by M. K. Olszewski.—Experiments on the regulation of the charges and discharges in electric accumulators, by MM. Crova and Garbe.—Note on the electric resistance of alcohol, by M. G. Foussereau.—Heats of formation for some phtalates, by M. Colson.—Remarks on some phenomena of oxidation and reduction produced by the microscopic organisms of the soil, by M. A. Müntz.—On the variation of the physical properties in the series of chloro-acetic derived substances, by M. L. Henry.—On the existence of glycogene in the yeast of beer, by M. Léo Errera.—On the existence of a nervous system and of an organ of sense in *Rhabdocœles acœles, Convolvula Schultzii*, and other members of the same group, by M. Yves Delage.—Note on the analytical and comparative morphology of the mandible in the hymenopteræ, by M. Joannes Chatin.—The Coregoni of the Swiss lakes (*C. dispersus, C. balleus*, &c); their marine origin, classification, reproductive processes and gradual adaptation to their changed surroundings, by M. V. Tatis.—Note on the tertiary basin of Grenada, by MM. M. Bertrand and W. Kilian.—A contribution to the study of antiseptics; action of the antiseptics on the higher organisms (continued); phenic acid and resorcine, by MM. A. Mairet, Pilatte and Combemale.—Experiments made on the body of a criminal recently guillotined at Troyes, by MM. P. Regnard and P. Loye. These experiments mainly confirm those already observed on animals, and tend to reassure those who suspect the persistence of conscious life after decapitation.—Observations on the foregoing experiments, by M. Paul Bert.—On the photographic determination of the trajectory of a point in the human body during the movements of locomotion, by M. J. L. Soret.—Note on the theory of the perception of colours, by M. Aug. Charpentier.—A formal denial of the reports regarding the appearance of cholera in Hérault was made by M. Colson on the authority of a letter from Dr. Boissier, local medical inspector.

Berlin

Physical Society, June 12.—Dr. Lummer communicated his further observations on the interference-phenomena produced by glasses parallel to the same plane. If monochromatic light fell from a luminous surface on a glass plate of moderate thickness, differences of phase arose by reflection on the anterior and posterior surface, in the beams of light falling under different angles. These differences of phase, as the speaker demonstrated by showing the course of the single bundles of rays produced on the retina of an eye focussed for parallel rays, a system of coloured and dark concentric rings, similar to Newton's rings of colour. This system of rings appeared, however, only when the plates were exactly parallel, at least to as great a degree of precision as that of the rays which enter the pupillary aperture by reflection from any point. These rings might therefore be utilised as a test of the parallelism of the glasses. Deviations of 0·2 wave-length caused no disturbance in the rings, but differences in the thickness of the glass amounting to 0·5 λ certainly gave rise to such disturbance. Bringing the glass before the eye, which was always accommodated to infinitude, considerably large spaces of the glass might be tested in reference to their parallelism. Any thinning or any thickening of the glass would be at once marked by displacements in the ring-systems and their wandering from the interior to the outside, or from the outside to the interior. The speaker compared his method of observing the interference phenomena, and testing the parallelism of the glass surfaces with that of Fizeau, and brought out the differences of the two, as also the advantages of his method.—Dr. Kayser gave a report of two works quite recently published on spectrum analysis, which seemed to make an important advance in the theory of spectral lines. It had formerly been attempted in vain to find harmonic relations, such as those existing among the upper tones of a sounding body, among the lines shown by the spectrum of a metal vapour, but the attempt to find such simple relations was abandoned after the question had been discussed by Prof. Schuster. Lately, however, Herr Balmer, in calculating the wave-lengths of the hydrogen lines, as given by Angström, had found a relation between these lines, expressed by the formula $h = \frac{m^2}{m^2 - 4} \cdot C$, when C had the value of 3645·6 millionths of a millimetre. In place of m let there be put in turn the numbers 3, 4, 5, 6, then were obtained Ångström's undulatory lengths of the four visible hydrogen lines. If the calculation were carried still further, and for m were placed the values 7, 8, &c., on to 16, then were obtained values for hydrogen lines which coincided very well with the wave-lengths of the lines which Dr. Huggins had found in the ultra-violet spectrum of the white stars, and had recognised as the invisible hydrogen lines. The longest among these ultra-violet hydrogen lines had been photographed by Prof. Vogel in the spectrum of a glowing hydrogen tube. This relation between the hydrogen lines had now received an increased significance from an investigation by Prof. Cornu, in which he had found a perfectly determinate proportionality in the lines of the ultra-violet spectrum of aluminium and of thallium to the ultra-violet hydrogen lines. Like the hydrogen lines, the pairs of lines of the two metals referred to advanced so much nearer to one another, and became so much paler the more one approached the more refrangible end of the spectrum; and if any line of the aluminium or the thallium spectrum was made to coincide with the corresponding line of the hydrogen, then did all the remaining lines coincide. This relation obtained both for the first and for the second lines of the pairs of lines in the metal spectra.—Prof. von Helmholtz drew the attention of the Society to an investigation of Dr. Wernicke, which will shortly be published, of great importance for the theory of the reflection of light. The experiments had reference to the reflection of thin plates in which each ray divided into two, one being reflected, the other refracted and again reflected by the posterior surface, in addition, still further secondary refractions and reflections came into account. The difference of phase in the reflected rays, on monochromatic light being applied, was observed through their interference phenomena. According to the theoretical development given by Dr. Wernicke, without any hypothetical assumption whatsoever, the difference of phase depended on the sine of the angle of incidence, on the cosine of the angle of refraction, and on three constants. By examining a large series of solid bodies—transparent crystals as well as metal films—Dr. Wernicke found in the case of incidences which were approximate to the angle of polarisation that, if the plane of polarisation were parallel to the plane of incidence, the three constants became zero. If, on the other hand, the plane of polarisation was perpendicular to the plane of incidence, the constants had a definite value. This experimental result was in agreement with Fresnel's theory of reflection. According to Naumann's theory the constants must become zero in the case of perpendicular polarisation planes and have a definite value in case of parallel direction. According to Ketteler's theory the constants could never become zero.

STOCKHOLM

Academy of Sciences, June 10.—The following papers were presented for insertion in the *Transactions* of the Academy: Contributions to the physiological anatomy of the algæ, by Herr N. Wille.—On Japanese cephalopoda, by Herr A. Appellöf, B.A.—On the determination of the amount of electromotive power of the voltaic arc, by Prof. E. Edlund.—Contribution to the question of the action of fluidity upon the electric conducting power of electrolytes, by Dr. S. Arrhenius.—Researches on the electric spark in fluids, by Dr. C. A. Mebius.—On the conformation of the hypostoma in some Scandinavian Asaphids, by Prof. W. Brögger.—On an Inoceramus from Queensland, by Prof. B. Lundgren.—A catalogue of the Silurian crustacea of Gothland, I. Trilobites and Merostoma, by Prof. G. Lindström.—On intermediate orbits, which at a given moment with a contact of the third order, join with the real orbits, by Prof. Gyldén.—On alcohol in beer, by Prof. Hamberg.—On marine vertebrates from the northernmost part of the province of Tromsö and West Finmark, by Dr. C. Aurivillius.—On rhodonite from Pajsberg and Langbau, by Hen. G. Flink.—On the crystallographic constituents of godolinite, by Hen. F. Eichstedt.—Crystallographic researches on the rarer metals, by Hen. C. Morton.—On some combinations derived from dicyanphenylhydracin, by Dr. J. J. A. Bladén.—On melanism and combinations of melam, by Dr. P. Claesson.—Some speculations and experiments on filtration in its bearing upon the processes of transudation in the animal body, by Drs. R. Tigerstedt and C. G. Santesson.—Prof. Smitt reported on the International Ornithological Congress in Vienna of last year.—Prof. Wittrock exhibited the first fasciculus of the fodder-herbs of Sweden, edited by Drs. Jönsson and Whalsted, and gave an account of a report on a botanical expedition to Norrland and Norway, for the purpose of studying the morphology and phylogeny of the Hierarsia, by D. S. Almquist.

A POSSIBLE WINDFALL FOR SCIENCE

IN a recent article we referred to the question of the amalgamation, so to speak, of the astronomical and civil day, in connection with the introduction of world time or prime meridian time, suggested by the Washington Conference. We pointed out that there were various opinions touching the time at which the change should be made, but that the concensus in its favour is so strong that it is certain to be made some time or another.

Our contemporary *Science* has recently called attention to a point which, if carried out, will make the work complete at an annual saving on the outlay of the present of something like 20,000*l.*

How is this to come about? In this wise. Let us suppose four nations *A*, *B*, *C*, or *D*, who each support a national observatory chiefly for the benefit of its Marine. This benefit consists in telling the mariners at what instant, according to the time shown by the clocks of *A*, *B*, *C*, or *D*, any celestial event, useful to him for determining his place at sea, will happen.

Let four ships, one of them representing each one nation, be within a cable's length of each other in the middle of the Pacific when the time comes for making an observation to determine position. Four books will be used, the production of which has been enormously costly, as each consists almost entirely of figures which depend upon elaborate calculations.

If the books are rightly calculated and the captains are skilful, of course the same position will come out in each case.

Evidently this work has been done four times over, and it is equally obvious that the result should have come out the same if the position had been determined properly on either ship from data supplied by either book. Why is this? Because our nations, though they have accepted in common the art of printing, the art of binding of printed pages together to form a book, and Arabic numerals, have not accepted a common time.

To come down from our generalities the four ships might have belonged to Germany, France, the United States, and Great Britain, and the four books might have been the *Berliner Jahrbuch*, the *Connaissance des Temps*, the *American Ephemeris*, and the *Nautical Almanac*. Sympathetically with these four books, at least three different times might have been indicated by the chronometers. And here lies the point. *Because* these chronometers show the time at Paris, or Berlin, or London therefore the computations of each celestial event, using the same data, employing the same processes, have been undertaken by each nation.

But even this is not all. We have said that at least three different times might have been indicated, and on our supposition only three times would have been indicated, because the U.S. Marine actually use Greenwich time.

Now it is clear that the general introduction of world time or prime meridian time, with the idea of which we are beginning to be familiar, will do for time what the introduction of the Arabic numeral did for numbers—it will denationalise and generalise it whenever necessary; and each observatory, sooner or later, is certain to have a clock showing the prime meridian time of the earth as it has one already of the skies, and when this comes about it will be to the general advantage for all to deal with the common time for purposes common to the planet.

Now among these what can be imagined more planetary than those with which the mariner has to do, and if this be so why shall there not be one unique planetary ephemeris.

From the abstract point of view more than one ephemeris cannot be defended, though it may be pardoned if, as *Science* suggests, the nations, to save their *amour propre*, must have ephemerides for their several meridians "much the same as all patent medicine firms and pill vendors feel the need of an almanac and calendar for the conservation of individual interests: it saves themselves and their patrons the indignity of referring to somebody else's almanac, and advertises the fact that they are enterprising enough to have one."

We cannot believe that the feeling characterised above, though it exists, would stand in the way of such a vast saving of labour and such a general improvement as might be brought about by an International Ephemeris, provided the question were well ventilated and wisely discussed by a congress summoned *ad hoc*. On this point *Science* writes:—

"It is certain that the deliberations of such a congress could not fail to advise governmental co-operation in the preparation of the nautical almanacs now existing, national pride aside, and this might be done in a multitude of ways, most prominently in the case of the preparation of the data relating to the moon. Take, for example, the hourly lunar ephemeris and the lunar distances as printed each year in the *British Nautical Almanac* and the *American Ephemeris*. These data occupy about one-third of the entire number of pages of each of these publications; they are now prepared independently by the two offices, but are, when printed, substantially identical in both; and, further, the work being done at about the same time in the two countries, the results of the one do not serve any sufficient purpose as a check upon the accuracy of the other. The cost of this part of the almanac alone to each nation amounts to several thousand dollars annually, —an amount which might be reduced one-half by the preparation of these data conjointly, to say nothing of other immediate and favourable results which might be secured by such co-operation.

"The wisest conservatism would appear to suggest the annual publication by the nations conjointly of a single volume of astronomical predictions, which, in addition to other improvements, should combine all those desirable features not dependent upon individual meridians, and which in some degree characterise all the astronomical ephemerides of the several Governments. The contents and arrangement of the articles of such an ephemeris could only be determined by an international conference. While this may be little better than mere speculation, any one who has the four principal ephemerides in constant use will readily recognise how small a portion of each is employed, and, with extended interpolation-tables, how little the inconvenience of using the ideal ephemeris solely would be."

It is sufficiently obvious that this enormous simplification and improvement must come about some time or the other, and it is to be hoped that no very long time will be allowed to elapse before some Government stirs in the matter. We have already a permanent international organisation, which, if its functions were to be extended so as to include the measurement of time as well as of space, might consider the question without any large increase of its numbers; we refer to the *Commission du Mètre*, which already largely consists of astronomers. We point this out to show that there are no real difficulties in the way of a preliminary consideration of the matter—nay more, that there are ways of reducing the difficulties by the choice of a body which already exists, and exists too in France, where the idea of a neutral meridian still lingers. We believe that a serious practical discussion would show that the idea which lies at the root of the contention for a neutral meridian is as impossible now as it has been in the past with regard to other internationalisations, such as Roman letters and Arabic numerals. If this were so, a great step would have been gained.

The writer in *Science*, however, does not propose that the Governments should be urged forward by any idea of saving their share of the sum we have already mentioned, and quite rightly. The idea is thrown out that it should be spent in an international mountain observatory, where in turns astronomers of all countries could carry out their special researches. The idea is a most admirable one, and will commend itself to all who know how years, and we may even say centuries, are being lost by heartbreaking attempts to do at a low level important work which is really only practicable at a high elevation.

PROFESSOR TAIT'S "PROPERTIES OF MATTER"

Properties of Matter. By Prof. Tait. (Edinburgh: Black, 1885.)

THE subject of this excellent little book includes the mechanical properties of matter, and much that is usually treated under the head of Chemical Physics, such as Diffusion and Capillarity. It might be difficult to give a reason why the electric and thermal conductivities of mercury, for example, should not be included among its properties as much as its density and its capillarity; but the distinction is convenient, and to some extent sanctioned by usage.

In the introductory chapters the author expounds some rather peculiar views with perhaps more insistance than is desirable in an elementary work. The word "force" is introduced apologetically, and with the explanation that "as it does not denote either matter or energy it is not a term for anything objective." No one will dispute the immense importance of the property of conservation, but the author appears to me to press his view too far. As Dr. Lodge has already pointed out, if conservation is to be the test of existence, Prof. Tait himself does not exist. I forbear from speculating what Dr. Lodge will say when he reads on p 11 that "not to have its price is conclusive against objectivity."

Chapters IV. to VII. form an elementary treatise on Mechanics, in which even the learned reader will find much that is interesting in the way of acute remark and illustration. Under the head of Gravitation are considered Kepler's laws, the experimental methods for determining the constant of gravitation ("the mean density of the earth"), and the attempts (such as Le Sage's) which have been made to explain the origin of gravitation.

The succeeding chapters on the deformation of solids and the compression of solids, liquids, and gases, are perhaps the most valuable part of the work, and will convey a much needed precision of ideas to many students of physics whose want of mathematical training deters them from consulting the rather formidable writings of the original workers in this field. The connection of Young's modulus of elasticity, applicable to a rod subject to purely longitudinal pull or push, with the more fundamental elastic constants expressing the behaviour of the body under hydrostatic pressure and pure shearing stress respectively, is demonstrated in full. Prof. Tait remarks that "Young's treatment of the subject of elasticity is one of the few really imperfect portions of his great work ('Lectures on Natural Philosophy.'). He gives the value of his modulus for water, mercury, air, &c.!" A deficiency of explanation must be admitted, but I am not sure that Young's ideas were really confused. The modulus for solids corresponds to a condition of no lateral *force*, that for liquids to no lateral *extension*. The distinction should certainly have been pointed out; but the moduli are really comparable in respect of very important effects, which Young probably had in his mind—viz. the propagation of sound along a bar of the solid in one case, and in the other through a fluid, whether unlimited or contained in an unyielding tube.

As a great admirer of Dr. Young's work, I cannot resist adding that if in some respects his treatment of elasticity is defective, in others it is in advance of many modern writings. Witness the following passage:—"There is, however, a limit beyond which the velocity of a body striking another cannot be increased without overcoming its resilience, and breaking it, however small the bulk of the first body may be, and this limit depends upon the inertia of the parts of the second body, which must not be disregarded, when they are impelled with a considerable velocity. For it is demonstrable that there is a certain velocity, dependent on the nature of a substance, with which the effect of any impulse or pressure is transmitted through it; a certain portion of time, which is shorter, according as the body is more elastic, being required for the propagation of the force through any part of it; and if the actual velocity of any impulse be in a greater proportion to the velocity than the extension or compression, of which the substance is capable, is to its whole length, it is obvious that a separation must be produced, since no parts can be extended or compressed which are not yet affected by the impulse, and the length of the portion affected at any instant is not sufficient to allow the required extension or compression."

The theory of "bending" and of "torsion" are discussed in Chapter XI. When the section of the rod deviates from the circular form, the torsional problem becomes rather complicated; but a statement is given of some of the interesting results of Saint Venant's investigations. In his treatment of the compression of solids and liquids, the author is able to make valuable contributions derived from his own experimental work.

In the chapter on "gases," a long extract is given from Boyle's "Defence of the Doctrine Touching the Spring and Weight of the Air," in order to show how completely the writer had established his case in 1662. As to this there can hardly be two opinions; and Prof. Tait is fully justified in insisting upon his objections to "Mariotte's law." In Appendix IV. a curious passage from Newton is discussed, in which the illustrious author appears to speak of Mariotte sarcastically. It is proper that these matters should be put right; but Prof. Tait is hardly impartial enough himself to succeed in enlisting the complete sympathy of foreigners. Cases of glaring injustice should be rectified; but there will always be a tendency (from which Englishmen cannot claim to be exempt) to give a full measure of credit to one's own countrymen, if only because one is better informed concerning their labours.

There is one matter, suitable to an elementary work, which I should be glad to see included in a future edition, viz., the principle of dynamical similarity, or the influence of *scale* upon dynamical and physical phenomena. It often happens that simple reasoning founded upon this principle tells us nearly all that is to be learned from even a successful mathematical investigation; and in the very numerous cases in which such an investigation is beyond our powers, the principle gives us information of the utmost importance. An example will make this clear. The pitch of a tuning-fork of homogeneous steel is dependent upon the size and shape as well as upon the elastic quality of the material; but the matter is too difficult for rigorous mathematical treatment. If, however, it be asked, How does the pitch depend upon the *size* of the fork, the shape and material being given? we need no complicated mathematics at all. The principle of dynamical similarity tells us at once that the time of vibration is proportional to the linear dimension.

Another example might be taken from a reaction which Prof. Tait describes as specially complex—viz., collision. A glass ball drops upon a marble floor from a height of one foot. How does the size of the ball affect the strains during collision and the danger of rupture? The principle teaches that if the scale of time be altered in the same proportion as the scale of length, similarity is secured, so that the strains are equal at corresponding times and at corresponding places. Hence a larger ball is not more likely to break than a smaller one, unless in consequence of the greater *duration* of the strains. I feel sure that in Prof. Tait's hands this very important and fundamental principle might be made intelligible to the great mass of physical students.

It would lead us too far to refer in detail to the various subjects treated in the later chapters under capillarity, diffusion, osmose, transpiration, viscosity, &c., but there is one point that I should like to mention. The explanation on p. 249 of the behaviour under water of drops of ink and of solution of permanganate of potash assumes the existence of a capillary tension in the surface separating the two fluids. In my own experiments on jets with this very solution, I have never seen any tendency to break up into drops (as, according to Savart and Plateau, there would be in air), and have therefore supposed that the capillary force was *nil*, or at any rate very small. Moreover, theory shows that the force depends entirely upon the suddenness of transition between two media, which suddenness must be broken down almost instantaneously when two miscible liquids come into contact. As the matter stands there seems to be here some discrepancy, which, perhaps, Prof. Tait could elucidate.

In his preface the author holds out hopes of further volumes on the same plan, dealing with dynamics, sound, and electricity. The readers of the present work will, I am sure, join in the wish that the appearance of these may be delayed no longer than is absolutely necessary.

RAYLEIGH

GRISEBACH'S "VEGETATION OF THE EARTH"

Die Vegetation der Erde nach ihrer klimatischen Anordnung. Ein Abriss der vergleichenden Geographie der Pflanzen. Von A. Grisebach. Zweite vermehrte und berichtigte Auflage. 8vo. Vol. I., pp. 567; Vol. II., pp. 693. (Leipzig: Wilhelm Engelmann, 1884.)

FROM the date, and the statement on the title-page that this is an augmented and corrected second edition of a work which was published in 1871, it might be expected that it contains the results of much more recent investigation; but an examination of the present edition is very disappointing. Indeed, it is doubtful, to say the least, whether it deserves the descriptive title given to it; for the "Quellenschriften und Erläuterungen" do not appear to contain a single additional reference, and it is not easy to discover that it has a claim to be anything more than a reprint, with some trifling alterations, of the original edition of 1871. The author died in 1879, so that one naturally looked to see who was the editor of this edition, and it was only after much seeking that a clue was found in a foot-note on p. 15 of the preface. After the appearance of the "Vegetation der Erde," A. Grisebach continued to write annual reports on the progress of geographical botany, and these, together with other scattered articles, were published in a collective form in 1880 by his eldest son, under the title, "Gesammelte Abhandlungen und kleinere Schriften zur Pflanzengeographie." From the foot-note in question it appears that this son—a gentleman in the Consular service of his country, and presumably unacquainted, or imperfectly acquainted with botanical literature—edited the new edition of the "Vegetation der Erde," "based upon the corrections and additions left by the author." Now it is perfectly certain that Grisebach regarded the annual reports referred to as so many supplements to his greater work, and the substance of which he would doubtless have incorporated therein had he himself prepared a second edition. Since his death, too, considerable additional information on geographical botany has come to light; and, what is more, it has been collected and published in German by Drude, Engler, and others; yet, as already mentioned, the additions and corrections in the present edition are merely trivial, and cannot be said to enhance materially the value of the work. In a footnote to Grisebach's preface to Tchihatcheff's admirable French edition of the original work, reproduced here, it is stated that some additions of Grisebach's thereto are here intercalated in their respective places. This is very good, but why Tchihatcheff's copious annotations and additions, recognised and sanctioned, as it were, by the author himself, should be ignored in a second German edition, is incomprehensible, saving the assumption that both with respect to his father's annual reports and other sources, the son was wholly incapable of doing his father justice. It is a pity that the task of preparing a second German edition was not entrusted to a competent botanist, because the original work, apart from the uncompromising antagonism to Evolution that pervades it, still occupies an undisputed position in modern botanical literature. As it is, the French edition is not merely an advance on the original German—it is incomparably better than the second German edition. It is only, however, fair that some justification of such assertions should be given. Taking the chapter on Oceanic Islands as an example, it may be confidently stated that no additional information is given; yet there is no branch of geographical botany that has advanced more during the last decade than insular. On the other hand Tchihatcheff embodies nearly all that was known up to date. One slight alteration observed in this chapter is—Madeira is stated to be 50 German geographical miles nearer Europe than the Azores, instead of 150, as in the original. Then certain unfounded statements in refutation of the arguments of other botanists concerning the relationships of insular floras remain uncorrected. Thus, in allusion to Sir Joseph Hooker's demonstration ("Insular Floras," p. 7) that the vegetation of St. Helena has, on the whole, its nearest affinities in South Africa, it is objected, on the authority of Roxburgh, that three out of the five genera named by Hooker were originally introduced into the island from the Cape of Good Hope, whereas an examination of Roxburgh's enumeration of the plants of St. Helena reveals the fact that the indigenous, and endemic, St. Helena species of the genera in question were unknown to him, and his remarks apply only to actually introduced species. Again, to repeat in 1884 such statements as that the vegetation of Juan Fernandez has little systematic relationship with that of the Chilian or Antarctic floras and that *Pringlea antiscorbutica* is restricted to Kerguelen Island is unpardonable, because the contrary is now historical. Defects such as those pointed out are numerous, but as they are mostly due to the state of knowledge fifteen years ago, the author of the work of that date is not to be blamed for them; rather the present editor and publisher for offering the public an old book as new.

W. BOTTING HEMSLEY

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Nomenclature in Elasticity

THE word *stress* is used, sometimes in the sense of *load*, sometimes in that of *load per unit area*. Clearness, however, requires these two ideas to be kept perfectly distinct, and therefore to be denoted by separate terms. *Load* is surely expressive enough, or, if not, there is the more comprehensive word *force*: why then use *stress* synonymously? It would be far better to reserve *stress* to signify *load per unit area*. This Prof. Kennedy (p. 269) calls *intensty of stress*; but why not *stress* simply? The word *intensity* is not in itself suggestive of anything distinctive, and is therefore useless.

Pressure and *tension* are terms used in the same loose manner, though, when intended to represent *force*, they sometimes have the word *whole* prefixed. Is it not better to say *force* when we mean *force*? We can then reserve *pressure* and *tension* as vector-synonyms of *stress* in the sense of *force per unit area*, which is indeed their usual *rôle*.

Another misused term is *resilience*, which sometimes denotes the *work* done in producing *proof* strain in a body (Rankine's definition), sometimes the *work* done *per unit volume* in producing *proof* strain, sometimes the *work* done *per unit volume* in producing *any* strain. I prefer, myself, the third definition: the second would then be the *proof resilience*, and the first might be called the *strain-energy*.

However, whatever terminology is finally agreed upon, let it be perfectly definite and consistent.

In his Fig. 1 (p. 269) Prof. Kennedy writes: "Breaking load, 18·85 tons per square inch." According to his own nomenclature, he should surely say: "*intensity of* breaking *stress* 18·85 tons per square inch," and this I should prefer to call simply the breaking stress—premising that for *tons* I should write *tons' weight*. In this case, as the diameter is ¾ inch, and therefore the section ·442 square inch, the breaking *load* is 8·33 tons' weight. Similarly in the other figures.

Christ Church, Oxford ROBERT E. BAYNES

Earthquake-Proof Buildings

MR. MUIR is quite correct as to the facts and date of the introduction of the aseismatic tables into Japan. In 1869-70 seven aseismatic tables for carrying the lighting apparatus were sent from here and erected in Japan, and Mr. Simpkins, who has recently returned from Japan, informs me that there are three in action at present. Two iron towers, 46 feet high, with this arrangement at their base, were also constructed and shipped for Japan, but the vessel was lost and no more were sent out, as the engineer in charge—Mr. Brunton—took an unfavourable view of their efficiency—his idea being that they would not work, as he considered that buildings of "great weight and solidity, thereby adding to their inertia and checking their oscillation, were best suited to meet the difficulty in Japan." Mr. Milne's experiments with aseismatic tables have borne out Mr. David Stevenson's original view as to their power of mitigating an earthquake shock. A Mechanical Telephone

HAVING observed in this week's NATURE a notice of a "mechanical telephone" said to be brought from America, I may state that so far back as 1878 I experimented on the transmission of sounds by wires, and communicated the results obtained, from a large number of experiments, to the Physical Society of London in March, 1878; the paper being afterwards published in the *Philosophical Magazine* for August, 1878. These experiments are referred to by the Count du Moncel in his book on "The Telephone," published in 1879. I found no difficulty in carrying on a conversation through wires laid in various ways from room to room of a house; and musical sounds, breathing, and whistling were also readily transmitted, and through most unlikely arrangements, such as a common wire fence. Various materials were tried for the transmitting and receiving ends—disks of cardboard set in deepish rims being found to give excellent results with a No. 16 copper wire. In one of my experiments I found that the disks were not required, the wire itself picking up and transmitting the sounds. The results obtained were most interesting; but as the range was necessarily limited, it did not seem to me that there was much scope for practical application. W. J. MILLAR

100, Wellington Street, Glasgow, July 31

Electrical Phenomenon

ABOUT ten o'clock in the evening of July 23 a party of four of us were standing at the head of the avenue leading to this house, when we saw a feebly-luminous flash appear on the ground at a distance of some thirty yards down the avenue. It rushed towards us with a wave-like motion, at a rate which I estimate at thirty miles an hour, and seemed to envelop us for an instant.

My left hand, which was hanging by my side, experienced precisely the same sensation as I have felt in receiving a shock from a weak galvanic battery. About three minutes afterwards we heard a peal of thunder, but, though we waited for some time, we neither saw nor heard anything further.

The gardener, who was one of the four, thus describes what he saw:—I thought it was a cloud of dust blowing up the avenue, and before I could think how that could be when there was not a breath of wind, I saw you three gentlemen covered for a second in a bright light, and that was all. Another of the party says that he observed what seemed to be a luminous cloud running up the avenue with a wavy motion. When it reached the party it rose off the ground and passed over the bodies of two of them, casting a sort of flash on their shoulders. The distance traversed was about twenty yards, and the time occupied between two and three seconds. (My own estimate of distance and velocity makes the time occupied almost exactly two seconds.) The day had been extremely hot and sultry, as also had the preceding day been, the thermometer readings being sometimes 80° F. in the shade.

On asking the gardener for further particulars, he tells me that the distance traversed by the luminous cloud was about forty yards, and that, when it had gone about half the distance, he saw a flash of lightning in the direction of it, but sideways; also that the top of the cloud seemed to be three or four feet from the ground, and it gradually rose higher as it came along. When the cloud reached the party he saw one of them distinctly by its light, the night being otherwise quite dark at the time; and, lastly, that the cloud went a few yards beyond the party into the open space in front of the house, and then disappeared.

Our Ancestors

DURING eight centuries—say to the time of the Norman conquest—one's direct ancestors amount to a far greater number than would at first be contemplated. Taking three generations to a century, one has father and mother (2), grandparents (4), great-grandparents (8). At the end of the second century the number of ancestors springs to 64. Following the calculation you will find that at the end of eight centuries one is descended from no less than 16,000,000 ancestors. Intermarriage of course would reduce this estimate, and there is no doubt it must have largely prevailed. But the figures are so enormous that, in spite of all, I venture to suggest that the words "All ye are brethren" are literally true.

CO-ORDINATION OF THE SCIENTIFIC BUREAUS OF THE U.S. GOVERNMENT

A MOVEMENT is on foot in the United States for rearranging the various scientific departments of the Government under one central authority, and a report on the subject has been made by a committee of the National Academy of Sciences, consisting of Gen. Meigs, and Professors Trowbridge, Pickering, Young, Walker, and Langley, appointed for the purpose. The Report is published at length in *Science*. After referring to the state of things in Europe in this respect, it gives a brief account of the method in which such bureaus are organised in other countries; discusses at some length the character of the work done by the coast and geodetic and the geological surveys, especially in those points where their provinces are similar, pointing out that two distinct and independent trigonometric surveys of the United States are now in process of execution; distinguishes between the military and meteorological work of the Signal Service, and recommends their complete separation; indicates the danger of duplication of work by the Coast Survey and Hydrographic Office, but is not prepared to recommend that the latter be detached in any way from the control of the Navy Department, nor that the hydrographic work of the Coast Survey, for over forty years conducted so satisfactorily, be separated from that organisation, but suggests the lines on which it thinks the Coast Survey should work; lays down the principle that the Government should not undertake any work which can be equally well done by the enterprise of individual investigators, and that such work should be confined to what will "promote the general welfare of the country;" urges the importance of a proper extension of the trigonometrical survey of the United States; and, finally, recommends either the establishment of a department of science, or of a mixed commission of nine members—two of them scientific civilians to be appointed by the president for six years, two scientific men from the army and navy, three heads of the principal scientific bureaus, together with the president of the National Academy, and the secretary of the Smithsonian Institution.

To the Department of Science, or to the supervision of this Commission, it would transfer the Coast Survey, the Geological Survey, and the Meteorological Bureau, and establishing a physical laboratory, add to it a Bureau of Weights and Measures, the functions of which are now performed by the Coast Survey. The province of the proposed Commission is amply defined.

In the course of the Report the Committee give an interesting sketch of the work accomplished by the Coast Survey.

The Coast Survey was originally organised for the purpose of constructing maps and charts of the coast and harbours for the benefit of commerce and navigation. Conflicting opinions respecting the proper management of the Survey led to the formation, in 1843, of a board of officers with the duty of reorganising the Survey. This board submitted a plan which was enacted by Congress into law, upon and under which law the Survey has hitherto been executed. This plan provided for the cooperation of military officers, naval officers, and civilians in the various parts of the work. Under it the work of the Coast Survey has been continued to the present time.

In recent times a great extension of the field of operations of the Survey has been made, apparently looking to a triangulation covering the entire territory of the United States. The maps published annually with the report of the Survey enable us to know the geodetic work it has executed. It appears, from the maps accompanying the report of 1882, that on June 30 of that year a chain of triangles had been extended throughout the entire length of the Atlantic and Gulf coasts, and throughout about half the Pacific coast. Besides these coast-lines, extensive regions in the interior are seen to be triangulated. In the north-east, the triangulation covers the greater part of the States of New Hampshire, Vermont, and Massachusetts, about half of Connecticut, and it also includes a considerable part of the State of New York.

The reconnaissance has extended westward from the New Jersey coast, so as to include the greater part of the State of New Jersey, and a long strip in Pennsylvania. From Pennsylvania, the extended line of primary triangulation follows the Alleghany Mountains into Northern Alabama, and is now being continued across the country to Memphis.

A triangulation of the Mississippi River was extended from its mouth nearly to Memphis, where it would meet the last-described chain of triangles. The chain connecting the Atlantic and Pacific coasts has been completed nearly across the State of Nevada, and the reconnaissance includes nearly half of Utah Territory. The line is also surveyed at various points in Colorado, Kansas, Missouri, and Illinois. Besides all this, isolated regions in Wisconsin, Indiana, Illinois, Ohio, Kentucky, and Tennessee have been reconnoitred by the Coast and Geodetic Survey, in a way indicative of a plan designed ultimately to cover the entire territory. As its appropriations for some years past have made provision for the collection of data for a general map of the United States, we may fairly regard the Coast and Geodetic Survey as having undertaken a trigonometric survey of the whole United States.

The general views of the Committee respecting the working of the departments of the Government are worthy of special attention. They conceive it to be a sound principle that Congress should not undertake any work which can be equally well done by the enterprise of individual investigators. The leading universities are constantly increasing the means of scientific research by their professors and students; and, while the Government may with propriety encourage and cooperate with them, there is no reason why it should compete with them. The scientific work of the Government ought not, therefore, to be such as can be undertaken by individuals. It should also be confined to the increase and systematisation of knowledge tending "to promote the general welfare" of the country. Within these two restrictions there is a large and increasing field, which is only partly occupied by the organisations now under consideration.

The attention of Congress should be directed to the fact that the administration of a scientific bureau or department involves greater difficulties than that of a purely business department. The connections between the work done and the results ultimately to be attained for the public are not at all obvious to the people and press, and thus the great benefit of vigilant watching and constant criticism is wanting. Again: its administration requires a combination of scientific knowledge with administrative ability, which is more difficult to command than either of these qualities separately. These difficulties are intensified by the absence of any central authority to control the work of a Government scientific organisation. Each head of a scientific organisation is now practically absolutely independent, and, in his individual judgment of what his organisation shall do, is controlled only by Congress itself, acting only through its annual appropriation bills. The Committee conceive that this state of things calls for measures of reform.

A feature of such reform will be the collection of the organisations now under consideration, together with such other scientific bureaus as Congress may see fit to include in the scheme, under one central authority, to be recognised as responsible for, and controlling generally, the scientific operations of the Government. Various forms of such an authority might be devised, the choice of which will some day be made by Congress. The best form would be, in the opinion of the Committee, perhaps, the establishment of a "department of science," the head of which should be an administrator familiar with scientific affairs, but not necessarily an investigator in any special branch.

"Your Committee," the Report concludes, "states only the general sentiment and wish of men of science, when it says that its members believe the time is near when the country will demand the institution of a branch of the executive government devoted especially to the direction and control of all the purely scientific work of the Government. In this day the pursuit of science itself is, visibly to all men of education, directly connected with the promotion of the general welfare.

"Should such a department be now impracticable, should public opinion not be now ready for it, the next best measure, in the opinion of scientific men, would be to transfer all such work or bureaus to some one executive department. Keeping in mind what has been said respecting the two classes of work under the Signal Service, we are of opinion that the functions of the several organisations under consideration could now be most advantageously divided among perhaps four bureaus, viz.:—

"1. The Coast and Interior Survey, to be concerned principally with geodesy and hydrography, and to consist of the present Coast and Geodetic Survey.

"2. The Geological Survey, to comprise the present Geological Survey with its organisation unchanged.

"3. The Meteorological Bureau, to which should be transferred so much of the present *personnel* and functions of the chief signal office as are not necessary to the military duties of that office.

"4. A physical observatory, to investigate the laws of solar and terrestrial radiation, and their application to meteorology, with such other investigations in exact science as the Government might assign to it. In this connection, attention is called to a resolution passed by the recent Electrical Conference in Philadelphia, requesting the establishment, by the Government, of a Bureau of Electrical Standards. We are of opinion that the functions of the Bureau of Weights and Measures, now performed by the Coast Survey, could be advantageously transferred to the proposed bureau, and extended so as to include electrical measures.

"The members of your committee are conscious that placing these bureaus under one department would not necessarily result in the proper co-ordination of their work, because the head of such department would probably find it impracticable to enter into the consideration of all details necessary to that purpose. It appears to us that the evils already pointed out require, in any case, the organisation of a permanent Commission to prescribe a general policy for each of these bureaus. The functions of this Commission would be:—

"1. To examine, improve, and approve the plans of work proposed by the several bureaus, and to revise their estimates in accordance with such plan. The performance of this duty would require consultation with their chiefs generally and separately respecting the character of their work, and they should be members of the Commission.

"2. To approve in detail the methods of expenditure of the appropriations.

"3. To recommend such measures as they deem necessary to the efficiency of the bureaus under their supervision. It should, however, be understood that this Commission is not charged with purely administrative responsibility. It prescribes what shall be done, and recommends any measures necessary to secure that object, but does not concern itself with administrative details.

"We submit the following as a suggestion for the formation and *personnel* of such a Commission:—

"The Commission shall consist of (1) the President of the National Academy of Sciences; (2) the Secretary of the Smithsonian Institution; (3) and (4) two civilians of high scientific reputation, not otherwise in the Government service, to be appointed by the President of the United States for the term of six years; (5) one officer of the Corps of Engineers of the army; (6) one Professor of Mathematics in the navy, skilled in astronomy—these two to be designated by the President of the United States for a term of six years—who, with (7) the Superintendent of the Coast and Geodetic Survey; (8) the Director of the Geological Survey; and (9) the officer in charge of the Meteorological Service; shall constitute the Commission of ——. The Secretary of the —— department shall be *ex officio* President of the Commission.

"The members of the Commission, for their services as such, shall each be paid by the United States compensation in the sum of —— dollars per annum. Their necessary transportation and travelling expenses shall be provided for as are those of the officers of the army and navy when travelling on public business or duty, to be paid out of the appropriations for the services under their supervision.

"The Commission shall meet in Washington, D.C., for the transaction of business, not less than four times a year; but the President of the Commission may convene it whenever in his judgment the exigencies of the service require a meeting.

"The Commission shall be attached to the office of the secretary of the department of ——, and under his superintendence shall exercise a general control over the plans of work of the Coast and Geodetic Survey, the Geological Survey, and the Meteorological Service, and shall have the charge and custody of all the archives, books, documents, drawings, models, returns, apparatus, instruments, and all other things appertaining to the Commission.

"The estimates of the heads of these bureaus or offices shall pass through the Commission for revision and approval; and, after the annual appropriations have been made, no money shall be expended under them, except after revision and approval by the Commission of projects submitted by these bureaus in compliance with such projects.

"If at any time public money is being spent by any of these bureaus not in accordance with the views of the Commission, the Commission shall notify the proper auditor of the fact."

Our readers are already aware that the Congressional Committee appointed to consider the organisation of the surveys and other scientific work of the Government made no report at the last Session of Congress. The Commission was, however, continued as a Commission of the succeeding Congress. The expired places of Messrs. Pendleton and Lyman were filled by new appointments from the members elected to the next Congress. A meeting of the reorganised body has been held, which adjourned until next November without coming to any definite conclusion respecting the measures to be finally proposed. Before adjourning, Major Powell was authorised to make public the testimony which he had laid before them on different occasions, and which covers most of the points to be acted on by the Commission.

Major Powell's statements naturally include a very detailed account of the methods, work, organisation, and expenses of the Survey over which he presides. He also submitted his views upon the best method of consolidating the geological and coast surveys with the other scientific bureaus of the Government. This is the really important question before the Commission, since upon its decision must turn the general efficiency of the Government scientific service for a long time to come. The necessity for some such consolidation is strongly felt in Congress as well as outside of it. The one danger to be avoided is that of some hasty plan being adopted which may suit the exigencies of the moment, but may not work well after those exigencies have passed.

One very strong reason for placing the scientific bureaus under one head, or in one department, is that scientific work has many features peculiar to itself, which require it to be conducted upon principles different in some respects from those which prevail in other departments. The head of an ordinary bureau or department of the government, and indeed every man in public life, is conversant only with offices and duties which there is no serious difficulty in satisfactorily filling, with the aid of that knowledge of men and of the world which he acquires through his daily intercourse with others. Such a person is accustomed to finding scores of candidates for every office, from whom a suitable selectionis always possible. The idea of an office for which there may be no applicants, or, if there are any, for which it is morally certain that the applicants are all unfitted, no matter how good their recommendations, is one which he finds it difficult to assimilate. Indeed, in the case of the purely scientific office, the ability to find the proper men must be a part of the life education of the man who is to make the selection. It is safe to say that the best officers who have served in the coast and geological surveys are men who, under the ordinary system of Government appointments, would never have been heard of in connection with the positions which they so ably fill.

The same thing is true of the administration of a scientific bureau. No uniform system can be devised which will apply to all the details of a great scientific work. When we go beyond the regular routine operations it is needful that the duties shall be accommodated to the man, and that in many cases a larger measure of liberty shall be allowed the latter than could be tolerated in the usual operations of a Government department. All this requires, on the part of the administrative head of the department, an appreciation of the subject which can only be acquired by long familiarity. If the head is not specially charged with mastering the peculiar methods of administration thus rendered necessary, the chances are that he will fall into one of two opposite errors: either he will leave the heads of the scientific bureaus to manage things in their own way, without any administrative control whatever, or he will exert his authority in such a way as to endanger the efficiency of the work. The former is undoubtedly the more natural course to take, and thus arise the friction and duplication of work which so seriously impair efficiency and discipline.

Yet another feature of Government scientific work is that it is far removed from that public criticism which is so conducive to efficiency in other branches of the service. It is difficult to conceive that such a state of things as was exhibited by the surveys of the territories ten years ago could have existed in the performance of any work with which the public were conversant. At that time we had at least two independent surveys of the territories, prosecuted by different departments of the Government and with nominally different objects, but which were practically identical in their actual work. The officers in charge were independently surveying and mapping the very same regions. At the time that Hayden's Atlas of Colorado was published, Capt. Wheeler was engaged in surveying Colorado and making maps of the territory substantially identical in their objects with those of Hayden. Both surveys were intended to cover the whole public domain.

Nothing quite so bad as this is likely to arise in the future. But there is still room for much duplication of work as well as taste through competition in getting possession of particular fields. As a general rule, the head of a department is quite ready to approve of any extension of work which any of his bureau officers may propose, and has not always time to learn that the same work is being done, or might be better done, by some other department. The annual provision which Congress has got into the habit of inserting into the appropriations for the Signal Office—"provided that hereafter the work of no other department, bureau, or commission authorised by law shall be duplicated by this bureau"—is not quite satisfactory: it leaves open the question whether any proposed work is "the work of any other department, bureau, or commission."

The report of the National Academy of Sciences proposes to remedy some of these evils by placing the general policy of the scientific bureaus under the control of a mixed commission, organised somewhat after the plan of the Lighthouse Board. If the bureaus are to remain separate, we see no better plan than this for securing the proper coordination of their work; but Major Powell points out certain difficulties in the way of its successful operation. His strongest objection is, that subordinate officers of various departments would have to practically control the work, thus reducing the heads of the departments to channels for transmitting instructions. If the proposed Commission were to assume any administrative control of the work, this objection would certainly be fatal. The official responsibility of the head of a department for the work of his bureaus should not be interfered with. But the report of the Academy expressly disclaims charging the Commission with any administrative responsibility. Its sole function was to prescribe the policy o the bureaus; that is, to decide what each one should do, and what each one should refrain from doing, the whole execution of the work decided upon being left completely in the hands of the regular authorities. We see no reason why this should be "irksome" to the heads of the departments. We also feel that Major Powell assigns undue importance to the influence of the single military officer proposed by the Academy as one of the nine members of the Commission. It is not so clear to us, as it seems to be to him, that one such officer could leaven the whole lump of the Commission with ideas of military discipline unsuitable to the conduct of a scientific bureau.

But however favourably we may view the plan of this Commission, we must hold that the consolidation of the bureaus under a single head, or in a single department, would give far more assurance of efficiency. Especially is this the case with the two national surveys. Their work now covers the same fields, and their mutual interdependence is such that they should work under a common plan. The Geological Survey requires for its proper execution certain geodetic and astronomical work, the execution of which is not within the proper province of the geologist. It is absolutelynecessary that this geodetic and astronomical work should be so planned and executed as to meet the wants of the Geological Survey, and at the same time it is the proper function of the geodetic survey. We are informed by Major Powell that he makes use of all the coast-survey results so far as they are available, but he does not indicate what fraction of his labour is thus saved; and it goes without saying that he has no authority, directly or indirectly, to require that the coast and geodetic survey shall do anything which he may want done.

Among the suggestions made by Major Powell was one that all the scientific bureaus should be placed under the general direction of the regents of the Smithsonian Institution. This does not appear to have been considered practicable, and was not further urged by the director himself. One of the possible plans is to place all these bureaus under the interior department. The principal objection to this course is that that department is already overloaded with work, so that its head could not give the proper consideration to the subject. Yet this is the simplest course, and would certainly be an improvement on the present state of things. The more effective course would be to form a separate department of science and public works. To this there seems to be no positive and serious obstacle except the difficulty of getting any measure of the sort enacted into a law. The question whether the head of the department should be a scientific expert or a public administrator is an ulterior one, which need not be discussed at present. In the latter case the question of its being regarded as a cabinet office would arise. There will be little hesitation in deciding this question in the negative.

THE LICK OBSERVATORY[1]

THE Lick Observatory, in its present condition on the summit of Mount Hamilton, California, is so nearly completed, with the exception of the great telescope, that the institution may now be sketched to advantage in its permanent form. In an early issue of *Science*, therefore, this enterprise will be traced through its various stages, from the inception onward. Astronomers have been slow to avail themselves of the great advantages of mountain elevation and isolation in the prosecution of astronomical research, partly because of the pecuniary outlay attending the necessary expeditions, but chiefly because some of the earlier expeditions to mountain summits were not attended with results of especial importance, and, on good theoretical grounds, the meteorological conditions of such stations appeared likely to be so unfavourable as to counterbalance fully the advantages to be derived from mere elevation. And besides, the evidence derived from the two most famous expeditions—that of Prof. C. Piazzi Smythe to the Peak of Teneriffe and of Mr. William Lassell to Malta—was so contradictory in character as to afford very good ground for abandoning the hope of immediate advantage to astronomy from superior elevations.

[1] From *Science*.

It is not possible to say how far Mr. James Lick was acquainted with these endeavours of scientific men; nor need the immediate circumstances or events which impelled him to his extraordinary astronomical bequest be considered here. Prof. Newcomb points out the fact that his movement followed close upon the completion of the great Washington telescope in 1873, then the largest in existence. Had Mr. Lick known the opinions of the best astronomers on the subject of mountain observatories, and the likelihood of securing, on elevated and isolated peaks, results at all commensurate with the trouble and expense of occupying such stations, he would have found very little to encourage the project. In this case, however, as very often before, a little experience has proved to be worth more than an indefinite amount of scientific theorising. It has been said that the scheme of building "a powerful telescope, superior to and more powerful than any yet made," was the nearest of all to the heart of Mr. Lick: there is abundant evidence that this is true; and it may be also true that he regarded the Observatory as an appendage of the telescope. But the course of subsequent events has proved it a matter for sincere gratulation in astronomical circles that he ever regarded either the Observatory or the telescope at all; for, had not the prospective researches with the great telescope arrested his attention, there is very little reason for believing that, in so far as he was concerned, astronomical science would ever have been in a position to reap benefit from the splendidly equipped Observatory which already exists on the summit of Mount Hamilton.

That Mr. Lick was bound, heart and soul, in the project, not only of a great telescope, but of the best possible location for it, is evident from the fact that, when nearing his eightieth year, and although oppressed with physical infirmity, he resolutely undertook a waggon journey of some forty miles or more, reclining on a mattress, all for the sake of investigating a proposed mountain site in person. His solicitous concern for the enterprise was very marked. Those who knew him best say that, if his practical knowledge of astronomy had been greater, he would have given every penny of his vast fortune for the great telescope, and the Observatory and its endowment. He would have recognised, too, the great improbability of such an institution being completed within a period of a few short years, and would thus have been led to provide for the reasonable use of the instrumental equipment as fast as it was put in place on the mountain. The failure to make such provision constitutes the chief point of unfavourable criticism on the part of astronomers, and is in many respects unfortunate; but sundry advantages also have arisen from it, which may be recognised with more profit, particularly as this condition of things must remain unalterable until the great telescope is completed, and the entire institution comes under the administration of the University of California, in full accord with the terms of Mr. Lick's bequest.

Five years ago no one could have anticipated that the year 1886 must pass with the great telescope still unfinished. It is worthy of note, however, that, while the delay in obtaining the necessary glass for the objective has proved so great an embarrassment to the work of the opticians, it has not as yet sensibly impeded the progress of the construction of the Observatory itself. To this fact we alluded at p. 377 of the current volume of *Science*, stating as well the very reasonable grounds for the belief that the plans of the Lick trustees, in so far as they pertain to the construction of the great telescope and the conjoint Observatory, will be completely executed at the close of the year 1887. With its unparalleled instrumental equipment, and an unusual endowment for the prosecution of astronomical research; located where the sky is cloudless most of the year, and at such an elevation as to be above the clouds a great part of the remainder; and situate in a region, too, where the steadiness of the air permits astronomical measurement of the highest precision to proceed uninterruptedly throughout the entire night for months at a time,—the Lick Observatory is destined, under prudent management, to take its place at once in the foremost rank; and, although it is the first established mountain observatory, it may well expect to hold its own in the emulation of similar institutions which may subsequently be inaugurated at greater elevations.

TWILIGHT[1]

THIS essay, an extract from a more comprehensive work on the problem of twilight, which the author hopes to conclude in the course of this year, and embodying a lecture recently delivered by him both in Hamburg and Leipzig, describes the phenomena of twilight in general and of the remarkable sky-glows of the winter of 1883 in particular, with clearness, fullness, and exactness, and explains the physical causes of these phenomena from a special and mature study of that universally interesting field of observation, by numerous highly pertinent and illustrative experiments, and altogether in a manner which should bring home, even to the unscientific reader, a new sense and a new intelligence of the painting offered anew every morning and evening to the study and delight of man universally.

After relating and taking measure of the stupendous outburst of Krakatoa and the brilliant glows involving nearly the whole earth for a long period after that event, and comparing these two consecutive phenomena with the analogous phenomena of the outburst of "Graham Island" in 1831, followed by brilliant twilights and peculiar blue and violet sun colours, attracting the admiration, in particular, of Italy, France, and Germany, the book addresses itself to the task of investigating the physical laws concatening these two apparently heterogeneous phenomena, and why all volcanic outbursts are not attended by the same wonderful optic displays. While each particle of dust, smoke, or fog causes a bending or diffraction of the light, a collective effect, comprehending a brilliant development of colours, is produced only when all the particles of matter are of equal size and are distributed uniformly in space—a condition not even most remotely fulfilled in the case of ordinary smoke and fog. Diffraction includes the lateral dispersion of the light, which is all the more efficient the nearer the edges lie to each other, and therefore the smaller the particles are, and also the "interference" of like-coloured rays of light. When a red light falls, for example, on a fine glass thread or a diamond stroke scratched into glass, the shadow will consist not of one thin black line, but of a whole system of parallel stripes alternately dark and brilliant, *i.e.* black and red. When, again, a white light falls on the diamond stroke, the reflection shows a system of parallel stripes glowing in all the colours of the rainbow. In the case of a single line the development of colours is indeed so small as to be scarcely perceptible, but with many thousand lines of exactly the same breadth, and situated at exactly the same distance from one another, the reflex image is such that, taken up on a white screen, it is visible at great distances. Perfectly corresponding is the case with granules of dust. The shadow of a single granule of dust in red light consists of a system of concentric rings, alternately dark and redly luminous, which are all the broader the smaller is the granule. In white light, on the other hand, the shadow of the granule consists of alternately dark and bright rainbow coloured rings. If the dust granules are all of the same size, then will the like-coloured rings pretty nearly coincide, and, in the case of a sufficiently large number of granules, the reflex image will be composed of coloured rings of great luminousness. If, on the other hand, the dust-granules are of different size, then will all the different colours coincide, and, according to a well-known optic law, the image will be colourless. The image of a dust-cloud may, therefore, be rich in colours, poor in colours, or colourless, according as the particles of dust of which it is composed are of the same or of different size.

The experiments of Coulier and Mascart, extended by Aitkin, have demonstrated that in a perfectly moist air, no formation of fog is possible, however much the temperature is lowered, so long as the air is absolutely free of dust; and that the more air, sufficiently moist, is charged with such foreign particles, the more intense is the formation of fog under a sufficient lowering of the temperature or pressure of the air. Let filtered and completely moist air in a glass ball have its pressure diminished, then will only a few particles of fog reveal themselves to the most careful inspection, even under the powerful light of an electric lamp—particles of fog which, moreover, yield not the slightest coloured image. Admit now into this filtered air a few cubic millimetres of ordinary house air, then will a very fine, silvery, transparent fog at once form itself, of such slight density that even in the case of a considerable area of it the transparency of the atmosphere would be but very little affected. At the first moment of its formation let a reflected image of the sun, or the reflected light of an electric lamp, be viewed through it: the image will be seen surrounded by an intensely luminous blue or greenish light, with a broad, reddish ring, the colouring of which may range through all stages from brilliant purple red to the most delicate pale pink.

The phenomena of colour produced and explained by experiments of the above description are made to serve as the key to the more extensive but essentially identical phenomena composing the total process of twilight, which is distributed, like a spectacular play, into three acts with a prelude, and sometimes, though comparatively seldom, an afterlude—parts which, however, are not strictly distinguished in time, but occur to some extent simultaneously and overlap each other; as also to the comparatively unimportant deviations—apart from the intensity of colouring—from the normal course, which obtained in the remarkable sky-glows that arrested universal attention throughout the fall and winter of 1883.

HENRY MILNE-EDWARDS

HENRY MILNE-EDWARDS was born at Bruges in October, 1800. Having completed his elementary studies in Belgium he attended medical lectures in Paris, where he took his diploma in medicine in 1823. While he retained an interest in medical and surgical pursuits until late in life, and was a member of the Academy of Medicine, Paris, of the Medical Societies of London, Edinburgh, &c., his earliest passion seems to have been for the study of natural history, and he soon abandoned the practice of his profession and devoted himself to scientific researches among the lower forms of animal life.

During the years 1826 and 1828, in company with his friend and fellow-labourer Audouin, the assistant to Lamarck and Latreille, he made a careful study of the various invertebrates to be met with on the coasts at Granville, around the Isles at Chansey, and as far as Cape Frehel. A member of the French Academy was, during 1828, engaged on some hydrographical work off this coast, and good-naturedly assisted the littoral zone workers, enabling them to use the dredge in somewhat deeper water than they could reach from a row-boat. The results of these investigations were laid before the Academy of Sciences in July and November, 1829, and formed the subject of an elaborate report presented to the Academy in November, 1830, by Cuvier, Dumerit, and Latreille, Baron Cuvier being the writer of the report. In this memoir, for the first time so far as we know, the idea of zones of marine life is promulgated; these were four in number. A considerable portion of the memoir is devoted to the subject of the bristles in Annelids and to a description and classification of the Annelids of the coast of France. The reporters did not hesitate to express their satisfaction with the work the two friends had done, calling the special attention of the Academy to the "efforts heureux par lesquels ces deux habiles naturalistes sont parvenus à enrichir la Faune française d'espèces si nouvelles et si curieuses, et la zoologie en général d'observations si intéressantes." These happy efforts were but the forerunners of others carried on, in the case of Milne-Edwards, throughout a lengthened life.

In 1841 Milne-Edwards was appointed to the Professorship of Natural History in the Collége Royal de Henri IV., and about the same time we find him holding the Chair of Zoology and Comparative Physiology at the Faculty of Sciences, of which Faculty he was afterwards the Dean. On his friend Audouin's death, he was made Professor of Entomology at the Museum, Jardin des Plantes.

A considerable number of original memoirs, the titles of which it is here unnecessary to detail, were published about this period by Milne-Edwards in the *Annales des Sciences Naturelles*. This famous periodical first appeared in 1824, under the editorship of Audouin, Brogniart and Dumas. In 1834 the second series, from which geology and mineralogy were excluded, commenced under the joint editorship, for the zoological portion, of Audouin and Milne-Edwards, so that for now fifty years the zoological department has been under his management.

While labours as important as they were numerous secured for H. Milne-Edwards a high position among men of science, his name was also universally well-known and made popular by his elementary works on zoology. His "Eléments de Zoologie" were published in 1834 and were reissued in 1851 as a "Cours élémentaire de Zoologie." This work had an enormous circulation in France, and has not only been translated into several other languages, but also, until almost the other day, it formed the stock-in-trade, either as to its text or its illustrations, of most of the many small elementary works on natural history published in Europe.

In 1838 Milne-Edwards was elected a member of the Academy of Sciences in the section of anatomy and zoology. He was made an officer of the Legion of Honour in 1847, and a commander of this Order in 1861. In 1862 he succeeded Isidore Geoffroy Saint-Hilaire as Professor of Zoology at the Jardin des Plantes, and in a year or two afterwards was made assistant director of the museum.

Of his more important works as distinct from his memoirs may be mentioned his "Histoire naturelle des Crustacés," 1834-40. In this he was assisted by his friend Audouin, and it long remained as a standard authority on this group.

The "Histoire naturelle des Coralliares," 1857-60, was commenced after Milne-Edwards's return, in 1834, from a collectingtour on the coast of Algeria; but in 1847, in order to satisfy the calls of his publishers, he associated Jules Haime, so well known for his memoirs on the Polyps in the Palæontographical Society of London and in the *Annales des Sciences Naturelles*, with him in this work; but the death of Haime in 1856 compelled Milne-Edwards to complete the work himself. It is in a few tender words dedicated to the memory of Jules Haime.

"Leçons sur la Physiologie et l'Anatomie comparée de l'Homme et des Animaux" were published between 1857 and 1881, in fourteen volumes. The series is dedicated to his friend, M. J. Dumas, to whom he had dedicated the first work of his early pen. These lectures will always possess an importance to the student, from the immense mass of details, accompanied with copious references to the labours of others, that are brought within a limited compass.

"Recherches anatomiques et zoologiques faites pendant un Voyage sur les Côtes de la Sicile, &c.," forms a splendid quarto volume of over 850 pages, which are illustrated with nearly 100 coloured plates. This work is, for the most part, a corrected report of a series of memoirs contributed to the *Annales des Sciences Naturelles* by Milne-Edwards, A. de Quatrefages, and Emile Blanchard.

There can be little question that the name of H. Milne-Edwards will always rank high among the naturalists of the first half of the nineteenth century, and for years he was incontestibly one of the leaders of zoology. He was among the first who, not content with the study of the dead forms of animal life, made prolonged visits to the sea-coasts to study the living forms and to investigate their habits. These were days before biological stations were thought of and when the details of geographical distribution were little known. That Milne-Edwards's study of the geographical distribution of the lower forms of Invertebrates led him to the theory of there being centres of creation was what, from a purely zoological point of view, might have been expected; and when larger and truer views burst upon the world through the genius of Darwin, Milne-Edwards's mind, already preoccupied, was never altogether able to take them in. By the student of biology Milne-Edwards will be remembered by his theory of the division of physiological labour, one which threw an interesting light on many an intricate problem.

H. Milne-Edwards was an excellent linguist. English he spoke like a native. In manner courteous, he was kindly and affable to all. His house at the Jardin des Plantes was for years the focus of attraction for all the men of science in or visiting Paris. He was the possessor of a splendid library, the treasures of which were most freely at the services of students. He was a member of most of the learned Academies of Europe and America, and the possessor of several orders of State. Full of years and service, he died in Paris on July 29 last. As Geoffroy Saint-Hilaire was on his death succeeded by his son Isidore, so, happily for zoology, Henry Milne-Edwards has, in his son Alphonse, handed down his name and place to one every way worthy of both.

RADIANT LIGHT AND HEAT

Preliminary Notions

IT has been known from time immemorial that a sufficiently hot body when left to itself gives out light and heat, and likewise grows cold. It has also been known that a body not sufficiently hot to give out light may yet be capable of giving out heat, cooling as it does so.

If the above facts be studied scientifically they at once give rise to a series of important issues, all of which we are now in a position to reply to. These may be put in the form of the following questions:

(1) Is radiant light a substance or, if not, what is it?
(2) With what velocity does it move through space?
(3) Is radiant heat physically similar to radiant light?
(4) What is meant by a hot body?
(5) In what manner is the issue of radiant light and heat related to the cooling of the body?

Of these five questions the second was the first to receive a solution, and this through the aid of astronomical observations.

Römer, a Danish astronomer, determined in 1675 the velocity of light by means of the eclipses of Jupiter's satellites. It so happens that the planes in which the earth and Jupiter move around the sun, as well as the plane in which Jupiter's satellites move around that planet, coincide very nearly with each other. As a consequence the first or nearest of Jupiter's satellites passes within the shadow of the planet at intervals of 42hr. 28m. 36s., and thus becomes obscured.

Now, if light were to travel instantaneously from Jupiter to the earth we should always see this obscuration at the moment when it took place. But even if light required time to travel, yet if the earth were always at a constant distance from Jupiter we should see the obscuration at a constant interval of time after its occurrence. Now Römer found that when the earth was furthest away from Jupiter there was a retardation in the time of the occurrence equal to 16m. 36s., as compared with that when the earth and Jupiter were nearest together.

It will be seen from the diagram (Fig. 1) that the

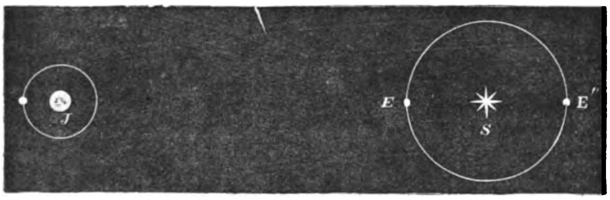

Fig. 1.

earth and Jupiter are nearest together when the earth is between Jupiter and the sun, and that the two are furthest apart when the sun is between the earth and Jupiter. Hence it follows that the difference in the distances from each other of the two planets in these two positions is equal to the diameter of the earth's orbit, or 183,000,000 of miles. If, therefore, light takes 996 seconds to cross this distance it ought to travel at the rate of 184,000 miles per second.

The velocity of light has likewise been determined by experiment. The arrangement for this purpose adopted by Fizeau is the one most easily understood. It consists of a toothed wheel, which may be made to revolve with great rapidity. Now a ray of light is made to pass through one of the intervals between the teeth, and to fall upon a reflecting mirror placed at a considerable distance off in such a manner that when the wheel is at rest the ray will be reflected back through the same interval. If, however, the wheel is in rapid motion it is possible that during the time which the ray takes to travel to the reflecting surface and back again the wheel may have moved so much that the ray is caught by the next tooth, and not allowed to pass through; while, if the motion be still more rapid, the ray may get through the next interval, and so on. Without entering more minutely into the conduct of the experiment, it will at once be seen that we have here the means of measuring the velocity of light.

By these and similar methods this velocity is now very accurately known, and is found to be about 187,000 miles, or 300,000 kilometres per second.

The evidence is very strong that all varieties of light, whether red, orange, yellow, green, blue, indigo, or violet move through vacant space with the same velocity.

Having thus briefly replied to the second of these questions, let me now return to the first, and inquire as to the nature of radiant light. We are able to conceive of two, and only two, varieties of progress in space. The one of these is the progress of actual matter, the other the progress of a form. An arrow discharged from a bow, or a bullet from a gun, represents the former of these, while the ever-widening circles which follow the plunge of a stone into a pool of water represent the latter. The progress which is visible when the wind blows along a field of corn or grass is another good illustration of a moving form. Here the corn or the grass is certainly not carried along, and if the wind is so carried, yet we cannot see the wind. What we see is an advancing form due to the oscillating motion of the various heads of corn or blades of grass. In like manner when a cannon or a gun is discharged at some distance from us the noise reaches our ear after a greater or less interval, depending upon the distance. Here it would be absurd to suppose that certain particles of air had been shot all the way from the cannon into our ear with the constant velocity of 1,100 feet per second—this velocity in the case of a gun or pistol being likewise the same as when the most powerful cannon is discharged. It is well known that in this instance a blow is given to the air, thus causing an arrangement of condensed and rarified particles which progresses with a certain definite velocity. The speed of progress of this form may either be determined by direct experiment, or by calculation founded on the well known properties of air—the two methods agreeing perfectly well together.

Now in many respects there is a strong analogy between sound and light, and these very questions which have been asked for sound are equally appropriate in the case of light. Can it be thought likely that hot bodies emit myriads of very small particles, which pass through space with the enormous velocity of 187,000 miles per second? or again, is it likely that this velocity should be precisely the same for all bodies and for all temperatures?

It is a singular circumstance that the illustrious Newton, to whom science owes so much, and one of whose achievements was a correct, or nearly correct, analysis of the conditions of undulatory motion in air, should nevertheless have become a powerful advocate of the corpuscular theory of light, thus lending his great authority to retard the progress of the rival theory, which represents light as an undulatory motion, similar in many respects to that which constitutes sound.

It is to Huyghens in the first place, and to Young and Fresnel in more recent times, that we owe the establishment of the undulatory theory of light upon so firm a basis that the older hypothesis is now entirely forgotten, or regarded only as a scientific curiosity.

There are two ways in which a theory may break down. Its various assumptions may display a great lack of living energy, or, in other words, may exhibit inability to expand themselves so as to incorporate a large volume of fact. Each new fact would thus imply the construction of a fresh assumption, so that there would be as many hypotheses as facts. A cumbrous structure of this kind, it is needless to say, would be utterly useless as a scientific instrument, and would finally fall to pieces from its own weight.

Another mode in which such a theory may break down is by the promulgation of some statement which is ultimately found to be contrary to fact. The corpuscular theory of light has broken down in both of these directions. For, in the first place, it had to be propped up by many fresh assumptions devised solely for the purpose of explaining fresh facts, and wholly useless in any other respect. In the next place one of its fundamental statements was ultimately contradicted by an appeal to experiment, carried out by M. Foucault, an eminent French observer. According to the corpuscular theory, or that of emission, the velocity of light ought to be greater in water than in air. On the other hand, according to the undulatory theory, the velocity in water is less than in air. If, therefore, it can be shown that light moves faster in air than in water then the undulatory theory is right; if the contrary, then the theory of emissions is right. Foucault succeeded in showing by an experimental method that light travels faster in air than in water, and this result has ever since been considered as decisive in favour of the undulatory theory.

We come now to our third question: Is radiant heat physically similar to radiant light? Here the difficulty is an instrumental one; the difficulty, in fact, of inventing something which shall do for dark heat what the eye can do for light.

At a comparatively early period Sir John Leslie devised his *differential thermometer*, with which he was able to obtain valuable results, to be hereafter alluded to. In this instrument we have two bulbs, A and B, filled with air, and connected together by a bent tube (Fig. 2) the lower

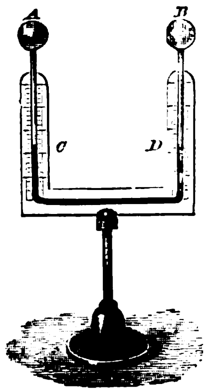

FIG. 2.

portion of which is filled with some coloured liquid, which ought not to be volatile. Let us begin by supposing that both bulbs are of the same temperature, and that under these circumstances the air is at the same pressure in both. The line between C and D, the surfaces of the liquid, in the two tubes will consequently be horizontal. Now suppose that the bulb A is heated, its air pressure is in consequence increased, and hence the liquid will be pushed down at C and up at D. In like manner if B is heated the liquid will be pushed down at D and up at C, and the change may be roughly taken as proportional to the difference in temperature between the two bulbs, this difference being supposed to be small. If, however, both bulbs are heated simultaneously, and to the same extent, there will be no motion in the liquid, inasmuch as there will be no difference in pressure of the air of the two bulbs.

In consequence of this mode of action the instrument has received the name of the differential thermometer;

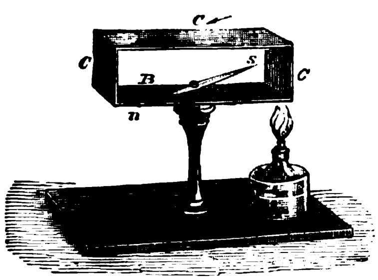

FIG. 3.

indeed, it is abundantly evident that what is measured is not the absolute temperature of A and B, but only the difference in temperature between the two.

Delicate as this instrument might at first sight appear to be, it forms but a poor substitute for the human eye, and had it not been for a new discovery, we should not have been able to make much progress in our knowledge of dark heat. The discovery alluded to is that of Seebeck, who found that in a circuit, composed of two metals soldered together, a current of electricity is produced when one of the junctions is heated, while the other is kept cool. If, however, both junctions be simultaneously heated to the same extent, no current is produced.

Here, then, we have an instrument similar in principle to that of Leslie, or, in other words, a new species of differential thermometer, and we shall now show that this arrangement is capable of being made extremely delicate as a measurer of small differences of temperature. The existence of a current of electricity is easily known by the motion of a magnetized needle, which tends to place itself at right angles to the direction of the current. Suppose now we have a circuit (Fig. 3), in which *C* denotes copper and *B* bismuth, and that we heat one of its junctions as in the Figure. We shall have, in consequence, a positive current following the direction of the arrow head, and the north pole of the needle will be pushed towards the observer as indicated in the Figure. When we make use of a magnet to measure a current we call our instrument a *galvanometer*. Our object, therefore, in this arrangement, is clearly to get as large a current as possible out of a small temperature difference, and then to measure this current by means of a galvanometer made as delicate as possible.

In order to obtain as strong a current as possible we must make use of a considerable number of junctions, as in Fig. 4, only in practice these junctions are very close

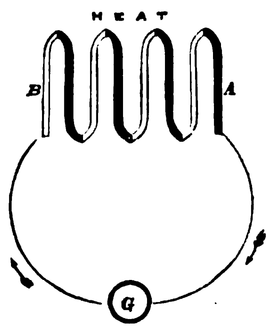

FIG. 4.

together. Here the heating influence is applied to the upper junctions, while the lower ones are kept cool. Another point is to select two suitable metals for our junctions—that is to say, metals the heating of which shall produce a powerful current. This is done by consulting a thermo-electric list of metals; in other words, a list such that the positive current shall go across the heated junction from the metal nearest the top to that nearest the bottom of the list.

The following is a series of this nature:

Bismuth.	
Nickel.	Silver.
Lead.	Zinc.
Tin.	Iron.
Copper.	Antimony.
Platinum.	Tellurium.

Now there is an important law which holds with reference to this series. If, for instance, we have a compound circuit, such as that in Fig. 5, connected with a galvanometer, we shall get the same current *in one direction* by heating through 1° C. the copper and tin junction, and also the tin and antimony junction, as we shall *in the opposite direction* by heating the antimony and copper junction. In other words, the various metals in the above list are to be regarded as being at so many different levels, and the strength of the current depends upon this difference of level, and not at all upon the exact number of halting places we make use of in going from the one level to the other. It thus appears that we shall get the greatest effect by selecting two metals near the opposite extremities of the list. Bismuth and antimony are generallly the metals chosen, and 36 or 49 junctions of these are frequently used, the metals being packed close together, but insulated from each other, and thus forming a sort of cube, each end of which contains, say, 36 junctions. These junctions are generally covered with lamp-black. If the one end of this be heated we shall have a current in the one direction; if the other end, we shall have one in the other direction; while, if both ends be heated simultaneously and to the same extent,

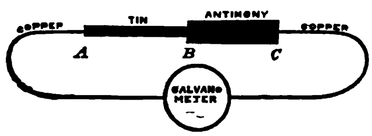

FIG. 5.

we shall have no current whatever. This arrangement forms what is termed a *thermopile,* and the cube of elements is generally encased in a brass covering presenting two terminals, in which the wires of the galvanometer are to be inserted and screwed tight. Inasmuch as this arrangement is generally used for viewing and measuring heat rays, a brass cone polished in the inside is often attached to the thermopile (Fig. 8) with the view of catching a large area of heat rays and reflecting them into the pile.

The galvanometer consists essentially of a magnet, which is delicately suspended by a very fine thread. Around it we have numerous coils of wire (but not in this case *very* numerous coils of *very* fine wire), which convey the current, each single coil counting separately in its action upon the magnet.

The various coils must, of course, be insulated from each other. A comparatively weak current will thus produce a visible effect if there be only a sufficient number of coils.

But yet the result so obtained is not the best, because we are having, after all, a strife between the influence of the current and that of the earth upon the small magnet. Assuming that the galvanometer was so placed to begin with that the magnet was in the magnetic meridian, then the current will tend to move the magnet to a position at right angles to this plane, while the earth's magnetic force will tend to keep it where it is. There is thus a strife between the two, and this will greatly interfere with the delicacy of the instrument. What we have

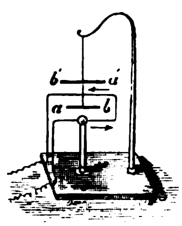

FIG. 6.

to do is so to counteract the earth's directive force that the little magnet may behave as if it was not under any external magnetic influence whatever.

A needle for which the directive effect of the earth's magnetic force is thus neutralised is said to be rendered *astatic.*

There are two ways in which this may be accomplished. We may use two needles of as nearly as possible the same strength, joined rigidly together with their poles in opposite directions, as in Fig. 6. Numerous coils of wire are wound around the lower needle, one of which we have exhibited. Here the upper current will tend to twist *b'* above the plane of the paper, while the lower current will act on *b'* in an opposite direction, this lower current, however, being further removed from the upper needle than the upper current, the latter will predominate, and the needle will, on the whole, be twisted round so as to place *b'* above the plane of the paper. Furthermore, the lower needle will be twisted round by both the upper and the under currents so as to place *a* above the plane of the paper, and hence the two needles will be twisted by the current in the same way, whilst the directive force of the earth's magnetism which opposes any motion of the needle will, by the arrangement above alluded to, be either altogether cancelled or rendered very small.

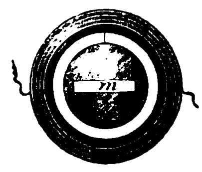

FIG. 7.

A galvanometer of this kind was employed by Melloni along with a thermopile as already described, and it was with these that he obtained the valuable results which we shall presently mention. But before dismissing this subject let us allude to some still further refinements made since the time of Melloni, which have contributed very greatly to increase the delicacy of this combination.

We have spoken about one way in which the effect of the earth's force may be neutralised, but we may likewise adopt the method of Sir W. Thomson, indicated in Fig. 8, where an external magnet, M, is so placed as to cancel the earth's action on the suspended galvanometer magnet which is supposed to be placed in the centre of G.

A still greater refinement consists in the joint use of both the methods now described. A system of two magnets

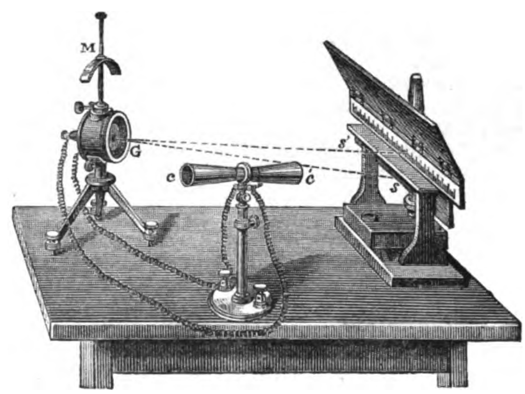

FIG. 8.

placed oppositely and united rigidly together is employed, a separate coil being made to surround each magnet. An external magnet is then so placed as to neutralize any directive force that may yet linger in the system. By this means very great delicacy almost amounting to instability may be obtained.

We shall conclude by mentioning an optical arrangement introduced by Sir W. Thomson, which greatly adds to the delicacy of the galvanometer. In this arrangement (Fig. 7) a small galvanometer magnet is attached to the back of a mirror, which mirror is suspended by a very fine thread.

Again (Fig. 8) there is a lamp behind the scale S S', and a slit, or, better still, a round aperture below the scale, with a wire in its middle, is lighted up by the lamp, and a reflected image of this lighted aperture thrown by means of the magnet-mirror, already described, upon the scale. This image may be made to move over a large space of the scale for a comparatively small motion of the mirror. If the image be that of a round circle of light, with a wire in the centre, we shall be easily able to read the position on the scale of the image of the wire, and by this means measure the motions of the mirror with very great accuracy and delicacy.

Having thus described in detail the various arrangements tending to make the thermopile and galvanometer a very delicate instrument for measuring radiant heat, let us proceed to discuss the reply which this combination gives to the question raised.

Melloni, who it must be remembered did not work with the instrument in its most perfect form, soon began to find that very many of those substances which were transparent for light, were, on the contrary, nearly opaque for dark heat. As he continued his labours he had, however, the satisfaction of finding a substance that was as nearly as possible equally transparent for both—this substance being crystallized rock salt.

He next found that just as by placing together two screens of coloured glass, one of which absorbs the redder portion of white light, while the other absorbs all but the redder portion, we may virtually stop all the radiation, so by certain combinations of screens it was equally possible to stop all the radiation from a source of low temperature heat. In the one case the result was perceived by the eye, and in the other by the thermopile. By this means he found that green glass and alum formed a peculiarly opaque combination. He next tried the same combination for the solar rays, and found that when they were first intercepted by a screen of green glass, they had a very feeble power of passing through a second screen of alum. The similarity in the behaviour of the rays from these two sources led him to imagine that heat accompanied with light and low temperature heat, are not physically dissimilar.

Again, the discovery by Melloni of the *diathermancy* or transparency for heat of rock-salt, led him to construct prisms and lenses of this material. By these means he proved that dark heat is capable of refraction, thereby exhibiting another bond of similarity between it and light. The subject was afterwards taken up by Forbes, who showed that the refrangibility of dark heat is inferior to that of the luminous rays. Forbes likewise showed that dark heat is capable of polarization and depolarization, and more recently other observers have shown that all the various properties of light may be exhibited at will in similar experiments with dark heat.

We have thus strong evidence for believing that dark heat is similar to light, the difference between them being physiological rather than physical, or, to speak more exactly, rays of dark heat may be presumed to differ from one another and from rays of light in no other respect than that in which the various rays of light differ from each other. In fine, the only difference is one of wave length or refrangibility, this being of such a nature that dark heat is less refrangible and has greater wave-length than light.

It is desirable at this stage to say a few words about the spectrum which is obtained from a luminous source by means of a prism.

Let us suppose, for the sake of simplicity, that the luminous source is a thread or slit of light, and that, by means of a lens, after the manner of a photographer, we wish to obtain an image of this slit of light and throw it upon a white screen. This image will appear as a white luminous slit of light. If, however, we interpose a prism between the source of light and the screen we shall obtain a very different result. In the first place the rays will be much bent by the prism, so that the screen will have to be placed in a very different position in order to receive the image of the slit. In the next place all the rays which go to constitute the light will not be bent to the same extent, so that the image of the slit given by one constituent ray will be thrown upon a different portion of the screen from that given by another. Thus the red rays will be least bent, then the orange, the yellow, the green, the blue, the indigo, and the violet, these last forming the most refrangible of the rays that enter into the composition of white light. What we shall really have, therefore, will be a great number of images of the slit placed side by side without any interval between them, these images being red at the one extremity and violet at the other. We shall, in other words, be presented with a long parti-coloured ribbon instead of a single white slit. This ribbon forms what is known as the *spectrum* of white light, and if before it is thrown upon the screen it be reflected from a plane mirror we may easily show, by making the mirror oscillate rapidly backwards and forwards, that this ribbon when in motion reconstitutes itself into a colourless white. The spectrum has various properties. Part of it can affect the eye—we say part of it, for there are dark rays at either extremity which the eye cannot perceive.

Part of it can perform certain chemical changes. Here again we say part of it, because there are certain chemical changes which certain rays seem at first sight incapable of producing.

All of it is, however, capable of heating a substance upon which it falls and by which it can be absorbed. We have thus three effects—the luminous, the actinic, and the heating effects; and certain portions of the spectrum are capable of exhibiting all the three.

If we take the action of the rays in blackening chloride of silver as a type of actinic influence we shall find that the maximum of the action is near, if not beyond, the most refrangible extremity of the visible spectrum.

If we take the effect upon the eye as our measure of light we shall find that the maximum is at the yellow, whilst if we take the heating effect of the spectrum under its usual circumstances of production we shall find that this has a maximum near the least refrangible extremity.

Now these considerations give rise to the following question: Is there only one thing present at one part of the spectrum, or are there three things?

At first it was imagined by some of the physicists of a past generation that there was in reality more than one thing and that the light and heating effects were produced by different agents. It was, however, afterwards found that if you operate on any portion of the spectrum by reflexion, absorption, polarisation, or in any other way, all the various qualities of that region are affected in the same proportion, so that if the light effect is reduced by one-half the actinic and heating effects are reduced by one-half likewise.

This decides the question, for we cannot imagine two or three separate agents existing at the same place and each possessing exactly the same physical qualities as the other; in other words, things which are not physically different from each other must be the same.

Thus we have now come to the conclusion that there is only one physical entity at any one part of the spectrum, and we have likewise been driven to see that in order to compare one part of the spectrum with another we must not use the eye, which has its own peculiarity, or some particular chemical substance which has likewise a partiality for certain rays.

What we have to do is to measure the amount of heat-energy possessed by the various parts of the spectrum, and this is done by allowing the rays in question to fall upon a suitable thermo-pile covered with lamp-black and then measuring the amount of heat to which they give rise by means of the indication of the galvanometer attached to the pile. A coating of lamp-black absorbs most of the rays, and if it is not absolutely perfect in this respect it is at any rate more perfect than any other substance.

We can have now a very clear conception of what takes place when we heat a body such as coal. At first it gives out a spectrum consisting of rays, all of which are less refrangible than those of the visible spectrum. Soon, however, as the coal continues to rise in temperature, it not only increases the number of such rays but takes on others of a more refrangible nature, entering into the visible spectrum when it begins to be red-hot.

Thereafter it pushes its way further and further into this spectrum, taking on successively yellow and green rays, blue, violet, and actinic rays as the temperature still rises, until at length it shines forth with the lustre of the electric light or of the sun.

Let us now proceed to reply to the fourth question, What is meant by a hot body? At first it was supposed that heat was a substance possessing mass but not weight, an imponderable, as it was termed, which insinuated itself between the particles of bodies, thus causing them to expand. This substance was further supposed to be rubbed out by friction and beaten out by percussion. It will be perceived that we have here a corpuscular theory of heat very similar to that of light, the one forming indeed the natural sequel to the other. The experiments of Davy, in which two pieces of ice both below 0° were made to melt one another by their mutual friction, and those of Rumford, made in boring cannon, sufficed, in the course of time, to convince physicists that heat cannot be a substance, inasmuch as the melting of the ice in Davy's experiments, and the heat produced in those of Rumford, would equally imply the creation in large amount of the matter of heat. It was therefore concluded by both these experimentalists that heat is not a substance but rather a species of energy. That is to say the only difference between a hot body and the same body when cold is that, in the former state the molecules of the body are in violent motion backwards and forwards, while in the last state this kind of motion is much less. This is the dynamical theory of heat at present universally held. In it heat is regarded as a kind of energy, so that when heat is produced by friction or percussion, a certain quantity of visible energy disappears from the universe, while at the same instant an equivalent quantity of heat-energy appears, or is created.

A little reflection will, however, show us that there is not here any *real* creation or annihilation, but merely the simultaneous disappearance of one kind of energy and the appearance of another; in fact, nothing more than a transmutation of energy. Joule was the first to prove the definite mechanical relation that exists between the visible energy which disappears and the heat which is generated, and according to his experiments, if a pound of water were to fall from a height of 772 feet under gravity, and if all its visible energy on reaching the earth could at once be converted into heat, the water would be found to have risen 1° Fahr. in temperature. It will at once be recognised that just as the material or corpuscular theory of heat fits into the corpuscular theory of radiant light, so does the dynamical, or energetic theory of heat fit into the undulatory or wave hypothesis. We may, in fact, imagine the little particles or molecules of heated bodies to be in a state of continual vibration resembling in this respect a bell, or the string of a musical instrument, except that their vibrations are much more rapid than those which constitute sound.

And just as the vibrations of a bell are carried off by the gaseous medium, *i.e.* the air which surrounds the bell, and ultimately affect our ear, producing the sensation of sound, so are the vibrations of molecules carried off by a medium (the ether) which surrounds them and ultimately affect our eye, producing the sensation of light. This train of thought enables us at once to reply to our fifth question, and to assert that there is a definite mechanical relation between the amount of heat which leaves a hot body as it cools, and the radiant energy which accompanies the act of cooling. And this definite mechanical relation may be stated in very simple language. If, for instance, a pound of water cools through 10° Fahr. then the radiant energy which it gives out in the process of cooling, if this should be made to impinge upon another pound of water, and be entirely absorbed by it, would heat it through 10°, so that while the one pound of water has become 10° cooler the other has been raised an equal amount in temperature.

We are now in a position to reply as follows to the questions proposed:

(1) Radiant light consists of an undulatory motion in a medium called ether.

(2) It moves with the velocity of 187,000 miles per second.

(3) Radiant heat is physically similar to radiant light, the only difference being that its wave length is greater, and its refrangibility less than those of light.

(4) A hot body is one whose molecules are in rapid motion.

(5) There is an equivalence in energy between the amount of radiant light and heat emitted by a hot body and the sensible heat which the body loses. Radiant light and heat may be termed *radiant energy.*

Without pretending to enter here into a philosophical discussion it is instructive to notice that all of these questions which were capable of being answered in two ways were answered wrongly at first.

Although this procedure of the human mind has delayed the correct solution of a very important series of questions, yet we in the present age cannot reasonably complain of what has taken place. It has given us a confidence in our present views that we could hardly have had if the question between two alternative views had not been threshed out in the past.

We can thus look to the future without dismay, and need not fear the gradual rising into strength of a school which shall call in question any of the very important conclusions at which we have now arrived.

Surely there is an advantage in being wrong first and right afterwards, especially when it was a past generation who went wrong and we ourselves who are right!

BALFOUR STEWART

(*To be continued.*)

NOTES

WE understand that Prof. Huxley, P.R.S., has agreed, at the request of the Lords of the Committee of Council on Education, to continue to act as Dean of the Normal School of Science and Royal School of Mines at South Kensington, and also to be responsible for the general direction of the biological instruction therein.

THE Senatus of the University of Edinburgh resolved at its last meeting that a lectureship of comparative embryology be instituted, and appointed Mr. George Brook, F.L.S., as lecturer, subject to the approval of the University Court. Mr. Brook has for some time been engaged in making investigations for the Fishery Board for Scotland.

THE Indian *Civil and Military Gazette* writing of the ornithological collection presented by Mr. Allan Hume of the Civil Service of India to the British Museum, says that its value and extent are only now beginning to be realised. It amounts to 62,000 skins of all kinds, and it has cost Mr. Bowdler Sharpe, of the Natural History Department of the British Museum, more than three weeks of uninterrupted labour to pack and send it away. Even now the work is not at an end, for the collection of eggs, which is no insignificant one, remains to be despatched. The gift, which represents the labour and learning of a lifetime is described by Mr. Sharpe as "the grandest collection of birds ever made."

FROM the Seventh Annual Report of Examinations in Technology, under the direction of the City and Guilds of London Institute for the Advancement of Technical Education, we notice that there is again a fair increase in the number of candidates who presented themselves, and a satisfactory proportional increase in the number of those who have passed. In 1884, 3,635 candidates were examined, of whom 1,829 passed. In 1885, 3,968 candidates were examined, of whom 2,168 have passed. Thus the increase of passes is six more than the total increase in the number of candidates. There is a slight falling off in the number of subjects in which the examinations have been held, owing to the fact that in four of the subjects, viz.:—Salt Manufacture, Oils and Fats, Silk Manufacture, and Mechanical Preparation of Ores, the number of candidates was below the minimum for which an examination is held. Applications for examination were received, however, in 46 out of the 47 subjects included in the programme. From the returns furnished in November last, it appears that 6,396 persons were receiving instruction in the registered classes of the Institute, as compared with 5,874 in the previous year. These numbers do not include the students in attendance at the technical classes of various schools and colleges at which the Professors do not accept payment on results. Two new subjects were this year added to the list, viz.:—Boot and Shoe Manufacture and Framework Knitting, in which subjects 69 candidates and 40 candidates respectively presented themselves. Nearly all these candidates received instruction in the recently-opened Technical School at Leicester. The percentage of failures on the results of the examinations in all subjects has decreased from 49·7 in 1884 to 45·3 in 1885. The proportion of failures is still large, showing the necessity of better instruction on the part of the teachers, and of more careful and sustained work on the part of the students. Of the inability of the majority of the candidates to make intelligible sketches, the examiners continue to complain; but it is hoped that this defect in the education of artizans will gradually be remedied as linear drawing comes to be more generally taught in our public elementary schools. During the past session, 263 classes have been held in different parts of the kingdom in connection with the Institute's examinations. Of the 6,396 students in attendance at these classes, 3,271 presented themselves for examination, and that of these 1,670 succeeded in satisfying the examiners. Last year, the number of candidates who passed from the registered classes of the Institute was 1,387, showing an increase of 283, which is a large proportion of the total increase, viz., 333 of successful candidates. This year, for the first time, Manchester heads the list of provincial centres from which the largest number of candidates have passed, the number being 147 as against 115 last year. A like number of candidates have passed from the Polytechnic Institution, London. Next in order of merit comes Glasgow, with 119 as against 139 last year, Bradford with 97 as against 90, Leeds with 84 as against 70 (55 from the Yorkshire College), Bolton with 75 as against 98, and Huddersfield with 72 as against 39. It is expected that about 750 of this year's successful candidates will gain a full Technological Certificate, in virtue of their having obtained from the Science and Art Department the necessary qualifying certificates in Science, in addition to their certificate in Technology. Of the 1,829 candidates who passed last year, 566 obtained the full certificate. This increase of 184 in the number of full certificates is a very satisfactory feature in this year's examinations. Compared with the total number of successful candidates, the percentage of those to whom full certificates will be awarded has increased from 31·2 to 34·5. From year to year, improvements suggest themselves in the working of these examinations, by which they are rendered more practical, and at the same time better adapted to the requirements of the students. The opening of the Central Institution, by affording new facilities for the training of technical teachers, will, it is hoped, do much towards improving the character of the instruction in the Institute's classes in connection with these examinations. Summer Courses for teachers, to be continued in subsequent years, have this year been held for the first time at the Central Institution, and the applications for admission to these courses show that the value of the instruction is likely to be fully appreciated by those for whom it is intended.

THE death is announced, at the age of fifty-five years, of Mr. Robert F. Fairlie, the well-known engineer; and also of Dr. Heinrich Wilhelm Reichardt, Professor of Botany in the University of Vienna.

AT the annual speech day at Reading School, on Tuesday, July 28, a new laboratory was opened by Dr. J. H. Gladstone, F.R.S. The Town Clerk (Mr. H. Day) read a statement to the effect that natural science had been taught in the school since the year 1872, but up to 1884 no adequate class-rooms had been fitted up or set apart for that purpose, except in a temporary way. Last year the Head Master submitted a scheme to the Trustees, and after the subject had been fairly thought over, three gentlemen, Messrs. G. W. Palmer, Alfred Palmer, and Walter Palmer, sons of the Member for Reading, volunteered to provide the accommodation recommended by Dr. Walker. The trustees gladly availed themselves of so generous an offer, and the result was that the school now possessed in that room—fitted up for chemical analysis, and in the adjacent lecture-room—excellent means of giving instruction in the usual branches of natural science. Dr. Gladstone then declared the laboratory open. Having praised its general arrangements, he congratulated the school on having obtained so magnificent a gift from the Messrs. Palmer, who were thus endeavouring to place chemistry upon an equal footing with the other studies carried on at that school. He would not go into the great controversy between things and words, but they would all agree that it was necessary that the knowledge of things should precede the knowledge of words, because the knowledge of words was only a kind of simulacrum unless the knowledge of things preceded it. A knowledge of chemistry was pre-eminently an experimental science, and they wanted that kind of training for all boys. Different studies gave a different training to the mind, and chemistry gave a training not only to the perceptive faculties, but also to the reasoning processes, and therefore chemistry had been wisely chosen to take an important part in the curriculum of that school.

THE foundation stone of the new buildings of the Sorbonne, which are to cost 22 millions, was laid on Monday by M. Goblet, French Minister of Education. The cellars and ground floor have already been built.

THE protracted season of midsummer heat throughout the United States has been broken, the *Times* correspondent states, by a series of drenching rains, accompanied by cyclones. A severe easterly storm began on Sunday, continuing throughout Monday, the wind changing to westward, and rains deluging the entire country east of the Mississippi. The heaviest rainfall, which was at Chicago, reached 5½ inches in the twelve hours ending Sunday at midnight. A universal report from all parts of the country tells of the vast damage done by the floods and cyclones. The rainfall on Monday evening at Philadelphia was nearly 3 inches. The cyclone started in Maryland about two o'clock on Monday afternoon, passing northward along the eastern border of Philadelphia at three o'clock. It wrecked houses and mills and destroyed cattle and crops in Maryland and Delaware, doing the severest injury along the Delaware river front of Philadelphia. Passing from south to north, a low, black, revolving ball of smoke moved at the rate of nearly a mile in a minute, crossing twice over the Delaware River, which is crescent-shaped. Five lives have been lost, six persons are missing, and about 100 injured. The damage done is estimated at half a million of dollars. Six hundred buildings were unroofed and the walls partly destroyed, railway cars blown from their tracks, trees uprooted, and several vessels wrecked. Two steamboats on the river had their upper works lifted off and destroyed, the pilot of one being drowned, while from the deck of another horses and a waggon were lifted by the wind and dropped into the river.

THE Government Astronomer of Hong Kong has published a notice with regard to typhoons, from which it appears that the earliest signs of these phenomena in the China seas are clouds of the cirrus type looking like fine hair, feathers, or small white tufts of wool travelling from east to north, a slight rise in the barometer, clear and dry but hot weather, and light winds. These are followed by a falling barometer, while the temperature rises still further. The air becomes oppressive from increasing dampness, and the sky presents a vaporous and threatening appearance. A swell in the sea, and also phosphorescence of the water, as well as glorious sunsets, are other signs useful to the mariner who is acquainted with the usual conditions in the locality. When the typhoon is approaching the sky becomes overcast, the temperature in consequence decreases, the dampness increases, and the barometer falls more rapidly, while the wind increases in force. Nearer the centre the wind blows so that no canvas can withstand it, and the rain pours down in torrents, but there is no thunder and lightning. Still nearer the centre there is less wind and rain, and the sky is partly clear, but the sea is tremendous. This is therefore the most dangerous position. Typhoons may be encountered in any season of the year, but are most frequent in August and September. They appear to originate south-east of the Philippine Islands. In August and September they frequently pass east of Formosa, or travel towards north-west up through the Formosa Channel, or strike the coast of China. Afterwards they usually recurve towards north-east and pass over Japan or across the sea north of Japan, but not with the violence that is characteristic of tropical storms. During the remainder of the year they most frequently cross the China Sea from east to west.

A TELEGRAM from St. Petersburg, dated August 3, states that despatches from Tashkend and Verny announce that there has been a severe earthquake at Pishpek (? Bish-uzek), damaging all the houses at that place. The shock extended to the settlements of Sukuluk and Belovodsk, which were laid in ruins. At Belovodsk a church fell in, many of the congregation assembled in it at the time being killed. Numerous fissures appeared in the ground. A later telegram from Verny reports that altogether fifty-four people were killed and sixty-four injured by the earthquake at Belovodsk and Karabolty. The shocks continue and the people are terror-stricken.

A TELEGRAM from Malaga states that a shock of earthquake occurred at Motril on the afternoon of July 30.

THE *Times* states that much uneasiness is being caused by the continued absence of tidings as to Mr. F. A. Gower, who lately carried on a series of experiments with a view to testing the adaptability of balloons to war purposes. Mr. Gower, who is well known to the scientific world as a joint patentee of the famous Gower-Bell telephone, had made Hythe the centre of his operations, and thence made several ascents. His final undertaking in this country was a successful aërial voyage across the Channel early in June. He continued his trial trips in France, and met with a misadventure while awaiting an opportunity of returning in a balloon to England. Undeterred by this, he made an ascent on July 18 from Cherbourg, and since that date nothing definite is known of his whereabouts. A pilot balloon which he had previously despatched has been found and sent on to Hythe; and a balloon has been picked up without a car some thirty miles off Dieppe. Sixteen days having now elapsed since the ascent and no message having been received from Mr. Gower, whose invariable practice it was at once to notify by wire his safety at either Cherbourg or Hythe, at both of which places he has left property, the gravest fears are entertained that he has been drowned. It may be mentioned that the experiments being carried on by Mr. Gower were within the cognisance of the Government, and have so far, it is believed, proved of a very satisfactory character.

ACCORDING to *Science* the daily papers announce that the U.S. commissioner of agriculture has established as a part of Riley's division a branch of investigation relating to economic ornithology, and has appointed Dr. C. Hart Merriam, a well-known ornithologist and secretary of the American Ornithologists' Union, a special agent to take charge of this part of the work. Dr. Merriam will make his headquarters at Sing Sing, N.Y., until Oct. 1, and after that at Washington. The scope of the investigation will cover the entire field of inter-relation of birds and agriculture, particularly from the entomologist's standpoint. The inquiry will relate primarily to the food and habits of birds, but will include also the collection of data bearing on the migration and geographical distribution of North American species. In this last inquiry the department hopes to have the co-operation of the Ornithologists' Union, Dr. Merriam being at the head of the Union's committee on migration.

DR. ELKIN, in charge of the heliometer of the Yale College observatory, has, *Science* says, been engaged for nearly a year and a half past in measuring the group of the Pleiades, his original plan being to measure with this instrument the same stars which Bessel measured with the Königsberg heliometer about fifty years ago. Dr. Elkin has taken advantage of all the improvements in the instrument and the methods of using it which have been developed in the last half-century; and, in addition to the successful carrying-out of his carefully elaborated plan of triangulation, he has also been able to extend his work to a large number of stars which Bessel did not measure. The position-angle and distance of the Bessel stars from the large star Alcyone are included in the work. The results of this very valuable work cannot be fully discussed and prepared for publication until the positions of certain stars of reference have been obtained from the work of other observatories where they are now being determined. Dr. Elkin has also obtained measures of the distances of a number of craters on the moon from neighbouring stars on thirty-six nights, near the times of first and last quarter. The positions of these craters on the moon itself had been determined; also series of measures made of the diameters of Venus, of the outer ring of Saturn, and of the satellite Titan referred to its primary. A registering micrometer has been devised, and, in the form constructed by the Repsolds, has proved a complete success, greatly increasing the amount of work which the observer can accomplish. Dr. Elkin proposes to devote the heliometer for a year and a half to come to investigations in stellar parallax. The plan of research mapped out and already commenced will, it is hoped, if carried to completion, furnish a reliable value of the relative parallax of stars of the first and eighth magnitude.

PROF. A. LANDMARK, chief director of the Norwegian Fisheries, has published some interesting particulars of his studies of the capability of salmon to jump waterfalls. He is of opinion that the jump depends as much on the height of the fall as on the currents below it. If there be a deep pool right under the fall, where the water is comparatively quiet, a salmon may jump 16 feet perpendicularly; but such jumps are rare, and he can only state with certainty that it has taken place at the Hellefos, in the Drams River, at Haugsend, where two great masts have been placed across the river for the study of the habits of the salmon, so that exact measurements may be effected. The height of the water in the river of course varies, but it is as a rule, when the salmon is running up stream, 16 feet below these masts. The distance between the two is 3½ feet, and the Professor states that he has seen salmon jump from the river below across *both* masts. As another example of high jumping, he mentions some instances of Carratunk waterfall, in Reumbec, in North America, where jumps of 12 feet have been recorded. Prof. Landmark further states that when a salmon jumps a fall nearly perpendicular in shape it is sometimes able to remain in the fall, even if the jump is a foot or two short of the actual height. This, he maintains, has been proved by an overwhelming quantity of evidence. The fish may then be seen to stand for a minute or two a foot or so below the edge of the fall in the same spot, in a trembling motion, when with a smart twitch of the tail the rest of the fall is cleared. But only fish which strike the fall straight with the snout are able to remain in the falling mass of water; if it is struck obliquely, the fish is carried back into the stream below. This Prof. Landmark believes to be the explanation of salmon passing falls with a clear descent of 16 feet. The professor believes that this is the extreme jump a salmon is capable of, and points out that, of course, not all are capable of performing this feat.

IN the new part of the *Transactions* of the Essex Field Club (vol. iv. part 1) the first and perhaps most interesting paper is Prof. Boulger's presidential address on the "Influence of Man upon the Flora of Essex."

ACCORDING to the *Chinese Recorder*, Dr. Wallace Taylor, a missionary doctor of Osaka, Japan, has made important discoveries regarding the origin of the disease *kakké*, or *beriberi*, as it is known in Ceylon. He traces it to a microscopic spore, which is often found largely developed in rice, and which he has finally detected in the earth of certain alluvial and damp localities.

WE have received from Denver the first volume of the *Proceedings* of the Colorado Scientific Society. Denver as a western mining camp, with an evil reputation, and Denver the capital of the State of Colorado, are places separated by ages of civilisation; but mining is prominent in both. The members of the Scientific Society appear from the list to be mainly civil or mining engineers, metallurgists, geologists, assayers, &c., and the papers are largely on these subjects, *e.g.* the estimation of arsenic, and of copper; the ore deposits of the Summit districts of Rio Grande county, Colorado (the principal paper in the volume), löllingite, &c. There are, however, other papers: there is the report by a commission of the society on the Artesian wells of Denver, a paper on extinct glaciers of the San Juan mountains, while one of the members, Mr. van Diest, read several papers on subjects connected with the Malay Archipelago, such as the formation of hills by mineral springs in the Island of Java, the geology of the Sumatra, and the method of mining there 250 years ago, the methods of smelting employed by the Chinese at Banka, &c. There is certainly plenty of vitality in the new society, and doubtless it will grow with the growth and strengthen with the strength of the magnificent State from which it takes its name.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus*) from India, presented by Mr. J. S. Stevens; two Turtle Doves (*Turtur communis*), European, presented by Mr. J. Hare; four Martinican Doves (*Zenaida martinicana*), a Moustache Ground Dove (*Geotrygon mystacea*), four Dominican Kestrels (*Tinnunculus domincensis*), a Green Bittern (*Butorides virescens*) from the West Indies, presented by Dr. A. Boon, M.R.C.S.; a Golden Eagle (*Aquila chrysaetas*) from Perthshire, presented by Mr. Chas. J. Wertheimer; two Larger Hill Mynahs (*Gracula intermedia*) from India, presented by Mr. Thomas Hudson; an Indian Python (*Python molurus*) from India, presented by Mr. Harrington Laing; four Proteus (*Proteus anguinus*), European, presented by Mr. Cook; a Red-headed Cardinal (*Paroaria larvata*), a Yellow Hangnest (*Cassicus persicus*) from South America, deposited; a Vulpine Phalanger (*Phalangista vulpina*), two Snow Birds (*Junco hyemalis*), a Northern Mocking-bird (*Mimus polyglottus*), bred in the Gardens.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, AUGUST 9-15

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on August 9

Sun rises, 4h. 38m.; souths, 12h. 5m. 13·6s.; sets, 19h. 32m.; decl. on meridian, 15° 45′ N.: Sidereal Time at Sunset, 16h. 46m.

Moon (New on August 10) rises, 3h. 19m.; souths, 11h. 1m.; sets, 18h. 34m.; decl. on meridian, 15° 37′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury ...	7 20 ...	13 45 ...	20 10 ...	4 13 N.
Venus ...	7 3 ...	13 47 ...	20 31 ...	7 55 N.
Mars ...	0 52 ...	9 12 ...	17 32 ...	23 48 N.
Jupiter ...	6 45 ...	13 34 ...	20 23 ...	8 48 N.
Saturn ...	0 57 ...	9 6 ...	17 15 ...	22 29 N.

August 9, 10, *and* 11.—Principal nights for observation of the August (Perseus) meteors.

August	h.	
12 ...	2 ...	Jupiter in conjunction with and 2° 30′ north of the Moon.
12 ...	9 ...	Mercury in conjunction with and 1° 55′ south of the Moon.
12 ...	12 ...	Venus in conjunction with and 2° 13′ north of the Moon.

DR. PERKIN ON THE COAL-TAR COLOURS[1]

Anthraquinone Series

I MUST now draw your attention to the important class of colouring matter compounds obtained from anthracene or anthraquinone.

Alizarin and the other colouring matters related to it form one of the most important branches of the coal-tar colouring industry, and is one of special interest, because alizarin was the first instance of the production of a natural colouring matter artificially. It will be quite unnecessary for me here to say much about the madder root, which was the original source of alizarin, and was grown in such enormous quantities, but now is nearly a thing of the past; nor will I enter into the early chemical history of alizarin, and all the laborious work which was bestowed upon it by Dr. Schunck and others. As you are probably all aware, the relationship of alizarin and its formation from the coal-tar hydrocarbon anthracene was the result of the labours of Graebe and Liebermann, the researches which culminated in this being of a purely scientific nature. The original process for obtaining it has, however, not been found of practical value, but a new one in which sulphuric acid could be used in place of bromine was afterwards discovered by Caro, Graebe, and Liebermann in Germany, and by myself in this country, apparently simultaneously. A second process was also discovered by me, which was worked nearly all the time I was engaged in this industry. In this dichloranthracene was used instead of anthraquinone, and the product thus obtained yielded colours of a brilliancy which it has been found, even to the present time, difficult to match by the anthraquinone process.

At the time of the discovery of artificial alizarin, anthracene

[1] The President's Address at the annual meeting of the Society of Chemical Industry (not the Institute of Chemistry as stated last week). Continued from p. 307.

was not prepared by the tar distillers, as it had no application, and very little was known about it. It was discovered in 1832 by Dumas and Laurent. In 1854-55, when studying under Dr. Hofmann, I worked with it for some time, but my results were never published, because, owing to the erroneous formula given for it by Dumas and Laurent, which was accepted, my results would not fit in; nevertheless the information obtained afterwards proved of great value to me, although at the time the labour spent appeared to be lost labour, showing the value of research even when not successful. The formula of this hydrocarbon was not established until 1862, when it was studied by Dr. Anderson. This was only six years before the discovery of Graebe and Liebermann, and, had not the formula of anthracene been established before these chemists commenced their work, the relationship of alizarin to it would not have been discovered, and up this day it is possible that this artificial alizarin industry would not have been in existence. Researches like that of Dr. Anderson I have often heard spoken of slightingly, because they don't bear much on their surface; but who knows what such work may lead to? Earnest workers cannot be too much encouraged.

As anthracene was not a commercial product, it was necessary to experiment on its production before alizarin could be manufactured, and not only on the best methods of getting it, but also to get a rough idea of how much could be produced, because unless the hydrocarbon could be obtained in large quantities, artificial alizarin could not compete with madder. In our works at Greenford Green we commenced by distilling pitch; but afterwards tar distillers were induced to try to separate it from the last runnings of their stills by cooling and then filtering off the crystalline products which separated out, and in fact visits were paid to most of the tar distillers of the United Kingdom, others being corresponded with on the subject, and the result was that in a short time such quantities came in that the distillation of pitch was abandoned. And although much doubt and anxiety prevailed at first as to the possibility of getting a sufficient supply of this raw material, at the present day there are about 1000 tons of commercial product (about 30 per cent.) produced in excess of the requirements, the annual production in the United Kingdom being estimated at about 6000 tons 30 per cent., or nearly 2000 tons pure anthracene.

Although the colouring matter obtained from anthraquinone or dechloranthracene was at first simply considered as alizarin more or less pure, yet on investigating the matter it was soon found that it contained other colouring matter. To this I drew attention in 1870 (*J. Chem. Soc.* xxiii. 143, footnote), and in 1872 gave the analysis of a product which I named anthrapurpurin, followed by a more extended account a year afterwards (*J. Chem Soc.* xxv. 659, and xxvi. 425). This was called anthrapurpurin; because it is an anthracene derivative having the formula of purpurin, with which it is isomeric. In the latter paper I also referred to another colouring matter dyeing alumina mordants of an orange colour (*J. Chem. Soc.* xxvi. 425). It was also shown that anthrafluoric acid when fused with alkali gave a colouring matter behaving with mordants in the same way (*J. Chem. Soc.* xxvi. 20), and which has proved to be the same body. This latter reaction was afterwards more fully studied by Schunck and Roemer, and the colouring matter produced by it was shown also to have the formula of purpurin; they therefore called it flavopurpurin (*Ber.* ix. 678), so that the colouring matters formed have proved to be three in number—alizarin, anthrapurpurin, and flavopurpurin, all of which are valuable dyes, whereas in madder root there is only alizarin and purpurin, the latter being of only secondary value. This can now also be produced from anthracene. The researches which have been reached on the subject of the conditions under which these different colouring matters are formed, have led to the discovery of methods for their separate production, so that in artificial alizarine, which name commercially embraces all these colouring matters, both mixed and separate, we have more than a simple replacer of madder root, and as these colouring matters just referred to can be applied with the same mordants, varieties of styles of work can be produced by the calico printer and dyer which before were unknown. Anthrapurpurin is, I believe, of as great importance as alizarin itself, and used with it increases its brilliancy, and alone gives very brilliant scarlet shades.

Artificial alizarin was first produced commercially in this country by my firm at Greenford Green in 1869; when one ton was produced in 1870, forty tons were made in 1871, 227 tons, and so on increasingly. It was not produced on the Continent until 1871, when, according to Graebe and Liebermann, 125-150 tons were made. These weights do not apply to dry colour, but to paste.

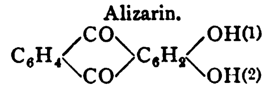
I cannot go into any lengthened account of the chemistry of this industry here; its development, however, has kept pace with theoretical investigations, in some cases it may be said to have forestalled it. For example, in the old methods of working, more anthrapurpurin than alizarin was produced; the conditions required to modify this were found out by experiment. According to all our previous knowledge as to the introduction of hydroxyl into a body by the fusion of its sulphonic acid with alkali, a monosulphonic acid should give a monohydroxyl compound, and a disulphonic acid a dihydroxyl compound. Therefore to produce alizarin, which is a dihydroxyl compound, an anthraquinone disulphonic acid was thought to be the proper thing to use. By experience this was gradually found to be incorrect, a monosulphonic acid being required to produce alizarin, a disulphonic giving anthra or flavopurpurin, the colouring matter not being due to the primary but to a secondary reaction as was afterwards shown by research—the mono and dioxyanthraquinones (the latter known as anthraflavic and isoanthraflavic acids) being the first products of the reaction, and then undergoing oxidation by the caustic alkali employed, and then yielding the corresponding colouring matter, a portion of the products, however, being at the same reduced back to anthraquinone.

A very important improvement preventing this loss by reduction was discovered by J. J. Koch, who found it might be avoided by the use of a small quantity of potassium chlorate with the alkali used in the fusion.

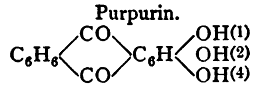
The amount of caustic soda used in this industry is very large at the Badische Aniline and Soda Fabrik—and, I believe, elsewhere—it is made on the spot; and I must say the cleanly way in which alkali is made in the above works contrasts very favourably with what I have seen in some of the alkali works in this country.

Like rosaniline, alizarin has now become a material for preparing other colouring matters. Of these there are two in use, viz., nitroalizarin, which gives orange-yellow shades with alumina mordants, and alizarin blue, a remarkable compound prepared from nitroalizarin by treating it with sulphuric acid and glycerine. This gives shades of colour like indigo. When first discovered, considerable difficulty was found in its application, on account of its insolubility; it has since been found to form a soluble compound with sodium bisulphite, and by this means its application has become much easier. The constitution of the colouring matter derived from anthracene may be represented as follows:—

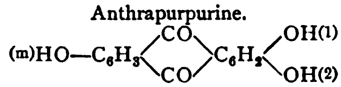
Alizarin.



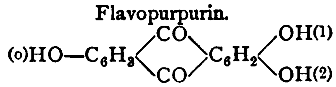
Purpurin.



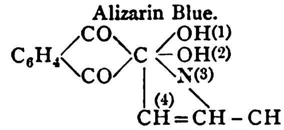
Anthrapurpurine.



Flavopurpurin.



Alizarin Blue.

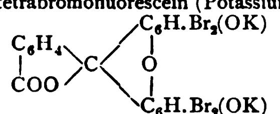


These colouring matters under the name of artificial alizarin are the most important of the coal-tar colours, their money value amounting to more than a third of the entire value of all the colours produced in the industry, and at present the price of artificial alizarin compound tinctorially is not more than one-fourth of that which madder or garancium ordinarily were before their production. There are now three works producing it in this country, but the bulk of that used still comes from Germany.

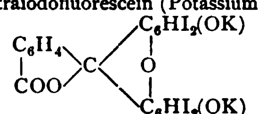
Phthalines.—The discovery of this class of bodies dates back to 1871, and was the result of the investigation of Baeyer. He found that phenols unite with a number of polybasic acids and with aldehydes, with separation of water when the mixture is heated alone, or with glycerol and sulphuric acid, the compounds formed not being ethers. Those produced when phthaiic anhydride is employed and which embrace those of practical value, are called phthalines. The first of these discovered by Baeyer was gallein (*Ber.* iv. 457), produced by heating pyrogallol with phthalic anhydride; its formula is $C_{20}H_{14}O_5$; by reduction it loses the elements of water and with hydrogen forming *cerulein.* These colouring matters, which for a long time remained unnoticed, are now being extensively used.

Later, in 1871, Baeyer discovered resophthalin, or fluorescein (*Ber.* iv. 555). This substance, which is remarkable for its yellowish green, fluorescence, dyes silk and wool yellow, but does not combine with mordants, and is not a very useful dyeing agent. But it was discovered by Caro in 1874, the subject being afterwards worked out jointly with Baeyer, that fluorescein when brominated yielded that beautiful dyestuff now called *eosine;* this was introduced into the market in July, 1874. Other substitution products were then studied, and the iodine product was found to give bluer shades of red than the bromine. One of the most beautiful colours of this series is the dichlortetraiodofluorescein, in which dichlorphthalic anhydride is used in its preparation. It is called phloxine. The methylic ether of eosine and its nitro derivative also have become commercial articles. These bodies are now manufactured in a practically firm condition. Their structure has been made out by research to be as follows:—

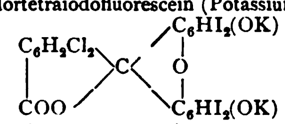
Fluorescein 
Eosinetetrabromofluorescein (Potassium Salt).



Tetraiodofluorescein (Potassium Salt).



Dichlortetraiodofluorescein (Potassium Salt).



Galliën 
The introduction of these colouring matters had a great influence on the manufacture of phthalic acid. This acid, it will be remembered, was proposed a good many years since for the production of benzoic acid, which was largely in demand for the manufacture of aniline blues, phthalic acid when carefully treated with lime yielding calcium benzoate. But as phthalic acid was required to be produced in an extensive way, new experiments had to be made on the subject. The difficulties connected with this were surmounted by the Badische Aniline Fabrik, who are now the chief manufacturers of this body and its anhydride, which is the substance required; when freshly prepared it is one of the most beautiful products one can see.

Dichlorophthalic acid is now also manufactured for the preparation of the bluish shades of fluorescein derivatives already referred to. But this is not all; it was not only necessary to produce this anhydride in quantity, but it was necessary also to produce *resorcenol.* This substance was originally prepared from galbanum by fusing it with potash, or by distilling brazilin, &c., both technically impractical processes. It was afterwards produced by fusing various halogen derivatives of phenol and benzene sulphonic acid with alkali; these also were not practical processes. It was, however, eventually found that it could be produced by fusing metabenzenedisulphonic acid with potash, the original observation being made by Carrick; and by this process this product, which was a rare compound, is now manufactured and has become a common one, being produced in very large quantities.

Indigo Series.—Indigo is too well known a substance for me to make any remarks in reference to its history as a colouring matter, and with reference to the chemical side of the question I suppose few substances have had more work bestowed upon them than this body, so that I must confine any few remarks to its artificial formation. There is one point of interest, however, connected with indigo, and that is that it was the original source of aniline, this base being discovered in the products of its destructive distillation by Unverdorben, in 1826, as already referred to.

Notwithstanding the large amount of work which has been bestowed upon this colouring matter, its constitution has only been lately arrived at, and for this, and the methods of its artificial formation, we are indebted to the beautiful and laborious researches of Baeyer. The first process for its artificial production was patented by Baeyer in March, 1880. The process consists in preparing orthonitropropiolic acid and acting upon it in presence of an alkali, with a reducing agent, such as grape sugar, xanthate of sodium, &c.

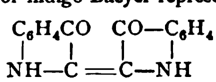
$$2[C_9H_5(NO_2)O_2] + H_4 = 2CO_2 + C_{16}H_{10}N_2O_2 + 2H_2O.$$

This process renders the application of artificial alizarin very easy to calico printing, because the products can be applied to the fabric and the reaction then completed, and thus the indigo is formed and fixed in the fibre, and this process is in use in some of the printworks of Mulhouse, where there is a continued though small demand for nitroorthopropiolic acid. Other processes have been discovered by Baeyer for the formation of Indigo; he has found that it can easily be formed from orthonitrobenzaldehyde by condensation with bodies containing CH_3CO group, such as acetone.

Hitherto this artificial formation of indigo has not met with much practical success. This does not arise from difficulties in its manufacture, but in its cost compared with natural indigo, which is a very cheap dyestuff.

So far as it has been manufactured, however, the possibility of this has been entirely dependant upon scientific research disconnected with its study. To prepare nitropropiolic acid it is necessary to begin with cinnamic acid as a raw material. This acid, until 1877, was only obtained from certain balsams, and was a very costly material. It was then discovered that it could be produced with comparative ease by the action of acetic anhydride and an acetate on benzaldehyde (*Journ. Chem. Soc.* xxxi. 428). Caro afterwards found that this process might be simplified by heating a mixture of benzylidene dichloride with sodium acetate, and it is by this process that it is now prepared.

The constitution of indigo Baeyer represents as follows:—



Several derivatives have been made which are interesting dyes, such as methyl indigo, tetrachlor indigo, etc.

Azo compounds.—The commencement of the history of the azo colours in an industrial sense has little to do with the theoretical side of the question, the early products being the offspring of empirical observations, and in no way connected with the theory of the diazo compounds, a condition of things very different from that now existing. Time will not allow me to enter into the beautiful work of Griess, much of which will be found in the *Philosophical Transactions* for 1864.

The first definite compound of this class, shown to possess dyeing powers, was a substance discovered by Prof. Church and myself, known first as nitrosonaphthalene, then as azodinaphthyldiamine, but now called amidoazonaphthalene. This substance, however, was of no practical value, because its salts, which are violet, cannot exist except in the presence of a certain amount of free acid. This substance has since been found of value in the preparation of the Magdala red.

The first substance of this class sent into the market was the phenylic analogen of amidoazonaphthalene by amidoazobenzene, which was discovered by Mène. It was introduced by Nicholson, who prepared it by a proeess which has not been published. It was afterwards patented by Dale and Caro, in 1863. This was a yellow dye, but did not demand success, because of its volatility. It has, however, since become useful for the manufacture of induline.

The first really successfull azo colour was Manchester and Bismark brown (triamidoazobenzene), which is produced by the action of nitrous acid on metadiaminobenzene.

The next important step took place in 1876, by the discovery of chrysoidine, by Caro and Witt. Independently this product is prepared by the action of diazobenzene on metadiamidobenzene.

About this time the subject began to be worked out on a scientific basis, and since then the number of diazo dyes produced is marvellous, and it will be useless for me to do more than to refer to one or two of the most important. About this period also the value of the sulpho group, began to be realised, and this has greatly added to the value of these dyes.

The first use of the sulpho group in relation to azo colours was in connection with amidoazonaphthalene, patented by myself in 1863.

During the early history of coal-tar colours, innumerable experiments were made with naphthalene derivatives to produce colouring matters, but no results of any value were obtained; the experiments were mostly made with naphthalamine. The first colouring matter that was obtained from it that was of value was Martin's yellow, a dinitronaphthol. After this came the Magdala red, which was not much used. The principal development of the coal-tar colours of late years has, however, been in connection with diazo reaction. In these reactions naphthol is much used, and this product, which a few years ago was unknown, is now manufactured by tons by fixing the naphthalene sulphonic acid with alkali, and is produced at a few pence per pound. Most of the azo colours produced from benzene derivatives are of a yellow or brown colour, but, by taking products of a higher molecular weight, colours of different shades of red are produced. The one which has commanded the greatest success is the scarlet, first known as Meister scarlet, produced by the acting of diazoxylene chloride on the disulphonic acid of β-naphthol; its constitution may be represented thus:—

$$C_6H_3(CH_3)_2 - N_2 - C_{10}H_4(OH)(HSO_3)_2.$$

And in the formation of bluer shades, diazocumene chloride is used. The cumedene used is now made from xylidene, by the beautiful reaction of Hofmann's, in which an alcohol radical associated with the nitrogen becomes that element, and enters with the hydrocarbon radical. These scarlets have had a very injurious influence on the cochineal market, and have in many cases displaced it.

If α-diazonaphthalene chloride be used instead of the xylene or cumene compounds, the colour known as Bordeaux is produced. Then, again, where derivatives of α-naphthol are used, different results are also obtained, so that great varieties of products can be produced. The preparation of these azo colours is a matter of much simplicity, and colouring matter being precipitated in bringing the products together, and, moreover, they can be produced in many theoretical quantities; hence they are remarkably cheap dyeing agents. The following are the formulæ of some of these azo dyers:—

Manchester Brown, Vesuvius or Bismarck Brown.—

$$NH_2C_6H_4 - N_2C_6H_3\overset{(m)}{(NH_2)_2}HCl.$$

$$\text{Chrysoidine } C_6H_5.N_2.C_6H_3\overset{(m)}{(NH_2)_2}HCl.$$

$$\text{Fast yellow } KSO_3.C_6H_4.N_2.C_6H_4NH_2.$$

$$\text{Metaucher yellow } \overset{(3)}{NaSO_3}.\overset{(1)}{NH_4}N_2.C_6H_4NHC_6H_5.$$

$$\text{Orange } \overset{(4)}{NaSO_3}.C_6H_4.\overset{(1)}{N_2}.C_{10}H_6\overset{B}{(OH)}.$$

$$\text{Fast red } NaSO_3.C_{10}H_6.N_2.C_{10}H_6\overset{(B)}{(OH)}.$$

$$\text{Ponceau G. } C_6H_5.N_2.C_{10}H_4OH\overset{(B)}{(NaSO_3)_2}.$$

$$\text{Ponceau 2R } (CH_3)_2C_6H_5.N_2.C_{10}H_4OH\overset{(B)}{(NaSO_3)_2}.$$

$$\text{Bordeaux } C_{10}H_7.\alpha\text{-}N_2.C_{10}H_4OH\overset{(B)}{(NaSO_3)_2}.$$

From which it will be seen that the colour changes from yellow to red and claret by the increase of the molecular weight of the radicals introduced, and also by the relative position occupied by the group, &c.

Products of the quinoline series have of late been claiming attention in relation to colouring matters. It will perhaps be remembered that, in the early days of the coal-tar colour industry, a beautiful blue colour belonging to this series, discovered by Greville Williams (*Chem. News*, Oct. 11, 1860, 219), was introduced. This substance was called cyanine. The employment as a dye for silk at first produced quite a sensation, on account of the beauty of the colour; but unfortunately it was too fugitive to be of any practical value. Recent researches have shown that chryaniline is also to be regarded as a body of the chinoline class. Alizarin blue, and also the beautiful yellow dye obtained from acetonilide by Fischer, and known as flavanilin, are found also to belong to this class of substance.

Other colouring matters which have long been prepared from quinoline direct might be referred to did time permit. The peculiar green which is produced by the condensation of tetramethyldiphenylketone with quinoline is of interest, because the introduction of this quinoline has a very different influence on the resulting colouring matter to that of other groups containing amidogen—in fact, it appears to act more like the phenyl, as the green is very analogous to benzaldehyde green.

There is a very interesting new manufacture growing out of the coal-tar colour industry, and that is, the preparation of derivatives of quinoline as substitutes for quinine. I have mentioned that much work has of late been directed to the study of quinine itself, and although the artificial formation of this substance has not yet been discovered, new bodies have been obtained during these investigations which are thought to possess valuable medical properties. This is rather a remarkable development from this industry, seeing that it was owing to experiments made on the artificial formation of quinine that it owes its foundation.

There is another peculiar colouring matter I have not yet referred to, peculiar—as it contains sulphur. I refer to methyline blue, a very valuable dye, the constitution of which has been so well worked out by Bernthsen, but I feel I must be content with this slight reference to it.

As I have shown, the coal-tar colour industry originated in this country, where for some time it was solely carried on. The second impulse was from France in the discovery of magenta and its blue and purple phenylic derivatives, which were soon brought to a state of great purity in this country. The Hofmann violets were then discovered and produced also in this country, several other colours being perfected and largely used. By this time the manufacture of coal-tar colouring matter had made some progress in Germany and Switzerland; crude products in a cheap form were first made, but improvements soon followed.

The subject of these colouring matters was taken up with great earnestness in the German laboratories, so much so that it was stated at one time that this industry was acting injuriously to science, as it had diverted an undue amount of attention from other subjects. Time has, however, proved the groundlessness of this statement. This laboratory work, as well as research work generally, fitted a number of highly-trained chemists to enter the works, when they soon improved the processes, and thus they were able to produce products of a quality to compete with those of English manufacture, which had, owing to their purity, given superior and more reliable shades of colour in the hands of the dyer; and the result of the application of this scientific labour to this industry is that Germany produces products of the highest class and at the lowest price. The fact that Germany is now the head-quarters of this industry, raises the important question, Why has England allowed this state of things to come about? All the raw materials are produced in this country, both the products from coal and the other chemicals required, and, as we have seen, the industry originated and was first carried on here, and, in addition, we are the greatest consumers of the colouring matters. This fact is well worth considering, and it is many-sided. In my opinion, the Patent Laws, and the difficulty of preventing infringements from abroad, was one cause which may have prevented this country from maintaining its first position.

When speaking of the early history of the first coal-tar colour, mauvein, I referred to this class of infringement and how it was first met by the proceedings taken against the agents employed in this country, and this course was so far successful, but only pointed out how easily the law could be evaded if foreign manufacturers gave up responsible agents and sold direct to the consumers. Having no duties on such articles, no assistance could be obtained at the Customs, and the colouring matters were generally declared under the name of vegetable dyes or extracts, so that it was impossible to stop them entering the country, and even when found, owing to the onus of proof of their being manufactured by the patentee's process laying with the patentee, an almost insurmountable difficulty was raised, as in most cases no traces of the products used in the preparation were left in the colouring matter. The only other proceedings which could be instituted were against the consumer; here again the difficulties were practically insuperable.

In most cases the consumers were using the patentee's product to some extent, and it was impossible to know to what extent, in fact, without going into the many details connected with this point, it may be assumed that in most cases proceeding against a consumer of this kind of article is detrimental and practically useless.

The result of this infringement, by importation from abroad, is that a patentee had to compete against all other manufacturers with the exception of *his own countrymen.*

There can be but little doubt that this state of things has had much to do with preventing the development of this industry, and crippling enterprise in this country, as it prevented manufacturers even from working under royalties, there being no security whatever except in name. Again, the fact that a foreigner could take a patent in this country, manufacture in his own country, and send the product here, was a great source of loss and mischief to our trade. The new patent laws may probably alter this, but still the difficulty of importation in defiance of patent right still remains.

There is another matter which tells much against this country—namely, that we are not able to export colour to foreign countries upon the same conditions as foreign manufacturers can into this, because we are met with import duties which handicap us to a prohibitive extent, whereas the foreign manufacturer, being protected in his own country, may maintain his prices there and sell at a lower price in this country; but what is still more injurious, he may dispose of surplus production in this country at or even below cost price. The injurious effect of such a course upon our market can be easily understood by business men, and I need not go into it here. These are matters our manufacturers have to contend with, and cannot help themselves; there is, however, one matter in which they are undoubtedly at fault.

We find that in Germany the manufacturer understands the value of well-trained chemists, and sympathises with them; they also realise the value of theoretical chemistry—this is a condition of things we don't find in this country.

Unless I am mistaken, the coal-tar colour industry has acted as the great stimulus to the development of general chemical industries of Germany, and these, by starting with so much scientific aid as they have called to their assistance, have made an amount of progress during the last twenty-five years which is most remarkable. Up to that time England had been the seat of most of the large chemical industries, and the success which we have had appears to me to have produced a feeling of false security, and more attention has been paid by the heads of firms to the markets than to the chemistry of their manufactures.

I believe that thirty years ago there were very few chemists employed in chemical works, either in this country or on the Continent. Now there are very few without them; but in this country they are far less numerous and much less efficient than in Germany, and for this our manufacturers are to a great extent responsible. I am told that at some of our large chemical centres, the chemists, or so-called chemists, are sometimes paid not more than could be earned by a bricklayer. If such openings are put by manufacturers before young men, their parents are not likely to give them an expensive scientific training. If they get any they are not likely to continue it longer than enough to do analysis very imperfectly, say by studying for about nine months. An ordinary tradesman would not be considered efficient unless he passed a much longer apprenticeship than this, but I know teachers complain that it is difficult to get students who are to be works chemists to stay longer than this. The result is that when really efficient men are wanted, they are not to be found, and they have to be got from abroad. In my address to the Chemical Society last year, I referred to the past neglect of research at our chemical schools, so that I need not speak further on that aspect of the subject here, though it is an important one in relation to our industries.

There is no chasm, as we have already seen, between pure and applied chemistry; they do not even stand side by side, but are linked together, so that a technical chemist needs to be a thorough chemist, and unless we employ such men we must be at a great disadvantage in relation to foreign manufacturers.

This brings me to a subject which has occupied much attention of late, but I fear is much misunderstood by the public generally. I refer to the teaching required by technical men, or technical education. The general idea is that it should be carried out in what may be called its narrow sense. That is to say, that it should be in relation to the existing manufactures and the present methods employed in them. Whereas there can be no doubt it will be of small service unless it is carried out on a very broad and scientific basis. As it is, the processes which are *publicly* known and taught, are more or less antiquated, simply because improvements are naturally kept secret as long as possible, and therefore to spend a large amount of time in studying details of old processes would manifestly be a great waste of power, and I am glad to find that this view of the matter is held by some of our leading chemical manufacturers. Our chemical industries are now undergoing such rapid and radical changes, owing to the advances in scientific discovery, that this cannot be too much borne in mind. To train a young man as a technical chemist, I consider, requires first that he should have a thorough knowledge of chemical science and know how to use it by conducting research, that he should have a general knowledge of those sciences which are connected with it, such as physics, and of those subjects required by all manufacturers, such as engineering, mechanics, &c., and also study the way chemical operations are carried out on the large scale, not in one branch of manufacture only, but in many.

With men in our works so trained, and of course possessing the suitable natural qualifications, we might expect to see our chemical industries make good progress and keep well to the front, but such a course of study could not be gone through in twelve months, nor would men so qualified be content to receive the remuneration for their services which is now given.

The proposed course for technical chemists at the Central Institute of the City and Guilds of London Institute is to occupy three years, the students having already devoted one year to elementary chemistry this makes four years of study, and this is hardly sufficient. It is to be hoped that those who are to be principals, or to take responsible positions in works will avail themselves of the opportunities afforded by this Institute or get some similar course elsewhere, so that we may have efficient men in this country to advance our chemical industries, and also that the value of such chemists may be appreciated in this country.

The employment of well-trained chemists in Germany, and the division of labour which results from this, has no doubt been one of the chief causes of the great success not only in the colour but in other chemical industries. In this country it not infrequently happens that an inventor, or the head of a firm, feels that no one can do the work he is connected with like himself, which is probably quite true; but at the same time he forgets that one person is not able to attend to the details of a number of processes adequately from sheer want of time and strength; if, however, properly qualified men can be set over them, although they may be slower and less capable than himself, yet having less divided minds and more time they are able to work out the details under his direction with much more success than he could alone, as well as see things from other points of view, and then greater perfection will be attained. I think this is a matter deserving of careful attention on the part of our manufacturers.

I have now given a very brief, and therefore a very imperfect outline of the history of the coal-tar colour industry, an industry to which none other can be compared for its rapid progress. I have drawn your attention to the fact that it is the offspring of scientific resea ch, that in return, as I before stated, it has in many cases given a fresh impulse to research by giving the chemist new products, and also by opening up new subjects of theoretical interest for consideration, and from the fruits thus resulting again reaping further benefit. This linking together of industrial and theoretical chemistry has undoubtedly been the great cause of its wonderful development. We now have not only all the colours of the rainbow, but we have also the more sombre, but often not less useful, colours, and, moreover, there are also great varieties of products of similar colours possessing different properties which fit them for special uses. This industry is also one of no mean dimensions. I have not been able to get any very recent statistical information on this subject, but notwithstanding the great reduction of prices of the products of late years, yet owing to the extended development it has undergone, the value of the annual output has probably increased, and not declined, and from what information I have on the subject, I should say it is perhaps not less than 3,500,000*l.*

In my remarks I have also been led to refer to some of the points connected with the migration of this industry from this country to Germany and the probable influence our patent laws had upon this, to the matter of technical education, and the employment of high-class chemists in chemical work. This latter subject is undoubtedly of great importance, and requires the earnest consideration of our manufacturers. It is found profitable to employ chemists of this class on the Continent, surely it should be found equally profitable to employ them here. In conclusion, I am happy to say there are signs of the coal-tar colour industry returning to our country, in part at any rate, especially in relation to alizarin, for which there are now three large works in existence, and the production of other colouring matters is also increasing.

FAUNA OF TRANS-ALAY

IN the *Izvestia* of the Russian Geographical Society (xx. 6) we find an interesting paper by M. Grum-Grzimailo, who has journeyed in the mountains north of the Alay region of the Pamir, chiefly for zoological purposes. The immense cultivated loess-fields of Osh, devoid of trees, yielded poor zoological results. Only a few uncultivated places had in the spring a rich fauna: great numbers of birds, various *Colubridæ*, the *Pseudapus pallasii*, tortoises, immense numbers of *Bufo variabilis* were met with. Here the author gathered a very rich collection of Lepidoptera; also *Zamenis kaufmanni*, *Taphrometoron lineolatum*, *Elaphis dione*, *Eryx Jaculuj*, and many others. In the middle of May all these disappeared under the burning rays of the sun. On the way to Vadil several species which were not found later on were met with, such as the *Trigonocephalus halis*, the *Anthocaris pyrothoë*, and several others. The neighbourhoods of Vadil yielded nothing interesting at that part of the season (middle of June). Of vertebrates only two *Eremids* and one *Trigonocephalus hydrus* were found. Shankh-mardan and Jordan, on the contrary, gave a rich crop of insects, and M. Grzimailo remained there for ten days. On a rich Alpine pasturage, Artcha-bash, where Kirghizes are in the habit of staying, he found very rich zoological materials. The collections were enriched with a great number of rare species, such as *Pol. tamerlana*, *Colias eogene*, *Arctia erschoffi*, *Hol. jagorum*, which are common almost exclusively to the Himalayas and the South-West Thian-Shan, as also by several new species. On the snow-covered plateaux interesting specimens were found, and among them the *Megaloperdix nigelie* and the *Arctomys caudatus*. On the upper Kok-su, extending to a height of 12,000 feet, M. Grzimailo found a number of species which he did not see either before or afterwards during his journey, especially with regard to Lepidoptera. Vertebrates are few at this height; they were represented by the *Arctomys caudatus*, the eagle (*A. fulva*), one species of *Falco*, the *Frigilis graculus*, the *Pyrrhocorax alpinus?*, *Pica*, *Caccabis huckar*, *Megaloperdix*, and *Columba*. On the pass itself the holes of the *Arctomys caudatus* are seen everywhere, as also holes of some *Arvicola*. The Lepidoptera are richly represented at that part of the summer, especially the two genera *Colias* and *Parnassius*. On the Djekaindy Pass it was the same; the *Lycænæ* were very numerous, so that on the space of 3 metres the author found fifteen species of them, of which three were unknown to him. Without mentioning localities of minor interest, the plateau between the Kara-su and the Aram is worthy of notice for the brilliant collections of Lepidoptera which were made there. One *Lacerta* was found at a height of 11,000 feet, a species of *Elaphis*, the *Canis melanotus*, the *Lepus lehmanni*, the *Ovis polii*; of birds, the Falconidæ were most usual; also the *Upupa epops*, the *Cuculus canorum*, species of *Columba*, the *Orthygion coturnix*, *Caccabis huckar*, *Corvus corax*, and many others, this last reaching the highest parts of the region. Another find of great interest must be mentioned. The late Mr. Fedchenko had already caught one female Lepidopteron, which was determined by M. Erschoff as *Colias nastes*. This species having been found formerly only in Labrador and Northern Lapland, the determination remained doubtful, the individual having been but a female. M. Grzimailo has happened to catch a number of both males and females, which really proved both to belong to *C. nastes*. It remains now to explain the strange extension of this species.

SCIENTIFIC SERIALS

Rendiconto della R. Accademia delle Scienze di Bologna, 1884-5.—On the geometrical construction of the central axis in a given system of forces, by Prof. F. P. Ruffini.—A fresh contribution to clinico-experimental studies, showing the depressing action of ipecacuanha administered in large doses in pulmonary affections, by Prof. F. Verardini.—On the velocity of the polarised rays in a body endowed with rotatory motion, by Prof. Augusto Righi.—On the physico-pathology of the suprarenal capsules, by Prof. Guido Tizzoni.—On *Perineo melus*, a new genus of parasite observed in the pig, by Prof. Cesare Taruffi.—On the antimoniates of bismuth, by Dr. Alfredo Cavazzi.—Action of gaseous phosphated hydrogen on the trichloride of gold dissolved in ether, in alcohol, and in water, by Dr. A. SOCIETIES AND ACADEMIES

BERLIN

Physiological Society, June 19.—Dr. J. Munk gave a brief sketch of the different views put forth respecting the formation of fat in the animal body, and then gave a short account of the now almost universally accepted view of Voit, who, on the basis of his very numerous experiments, laid down the doctrine that the fat in the animal body proceeded either from the alimentary fat, or, when this was not sufficient, from the albumen, which on its decomposition yielded products that by synthesis became transformed into fat, while the carbo-hydrates never yielded material towards the formation of fat in the animal body. Opposition to this doctrine was raised on the side only of agricultural chemists, who, by experiments on swine and geese produced direct demonstration that the deposition of fat was considerably increased by feeding with carbo-hydrates. In consequence of these experiments Prof. Voit admitted that omnivorous and herbivorous animals might in certain circumstances form fat out of carbo-hydrates; such, however, he maintained, was never the case with carnivorous animals and man; in them all fat was derived from the alimentary fat and the decomposition of albumen, both in his own experiments and in all hitherto published, and the fat was seen to be derivable from these two sources alone, even though only 12 per cent. of the decomposed albumen were taken for the formation of fat, and much more if, according to the theoretic calculations of Herr Henneberg, it was assumed that as much as 51 per cent. of the decomposed albumen might be utilised towards the formation of fat. Seeing now that Prof. Voit admitted that, in the case of omnivorous and herbivorous animals fat was produced from carbo-hydrates, the speaker set himself the task of establishing experimental conditions under which fat might be formed from carbo-hydrates in the case, likewise, of carnivorous animals. For these experiments he selected a dog, completely impoverished it of all fat by means of long fasting, and then gave it an aliment very rich in carbo-hydrates. The animal required to be young, or otherwise the loss of fat by fasting could not be complete, and if it were desired to obtain certainty respecting the attainment of perfect deprivation of fat, the decomposition of the albumen during the period of fasting would have to be traced by regular determinations of the quantity of azote in the urine and the excrement. Prof. Voit had (as was already known) proved that on account of its ready decomposibility, fat was a protection against the decomposition of albumen; such would necessarily be the case in the fasting organism likewise, and the corporeal fat would necessarily protect the albumen from decomposition. In point of fact Dr. Munk found in fasting animals that when they were poor in fat the decomposition of albumen slowly abated in correspondence with the ever less abatement of the weight, whereas in the case of individuals rich in fat, the nitrogenous secretions in the last period, after the corporeal fat at disposal had been decomposed, did not only not abate, but even increased somewhat. The same cause as that followed by the nitrogenous secretion was also observed in the case of the elimination of sulphur. The exact process of albuminous decomposition during fasting thus offered an indication of the attainment of complete deprivation of fat in the body. The carrying out of the experiments was, however, attended with so many difficulties, that hitherto only one experiment had succeeded. It had reference to a large dog of three to four years old, weighing about 35 kilogrammes, which had been made to fast for thirty-one days, and was then fed daily with 200 grammes of meat, 100 grammes of lime, 400 grammes of starch, and 500 grammes of sugar, made into a preparation very acceptable to the dog. The gluten was occasionally added to the aliment to restrict the decomposition of the albumen. The experiment might be continued for twenty-five days; in the two last days diarrhœa set in, and the dog was killed in order to determine precisely the contents of fat in the body. The weight of the body of the dog during the process of feeding had increased by four kilogrammes, and amounted at the end of the experiment to 27 kilogrammes. Of the albumen partaken only 800 grammes were left undecomposed in the whole body. At the outset, therefore, it could be inferred that the dog had formed and deposited a considerable quantity of fat—an inference which was confirmed by the examination of the body. The fat of the underskin tissue and of the mesentery was carefully cut out, melted, and weighed. Then the amount of fat on the muscles was determined in particular samples, and the fat on all the muscles of the animal calculated. The fat of the liver was directly ascertained, and, finally, an account was taken of the fat of the bones, the nerves, and the other organs, which was admitted to be only half the amount which other physiologists had obtained on the same parts in an individual whose skin, muscle, and liver fat corresponded with that of the dog examined in the present case. Certainly the quantity of fat thus found was considerably less than the quantity actually formed during the time of the experiment. From this sum of fat deposited by the dog there was now deducted the total amount of the alimentary fat which had been appropriated, and of the fat which might have been formed from the decomposed albumen (12 per cent.). The result was a remainder of over 900 grammes of fat formed by the dog, which was derivable neither from the alimentary fat nor from the decomposed albumen, and which had, therefore, to be attributed to the carbo-hydrates that had been copiously administered. The speaker instituted a second calculation, taking account of the assumption which had hitherto, however, never been proved or even rendered probable by a single experiment, but was purely a deduction from constitutional formulæ—the assumption, namely, that of the decomposed albumen as much as 51 per cent. might be utilised towards the formation of fat. But even under this supposition there still remained more than 400 grammes of fat formed by the dog which, contrary to the doctrine of Prof. Voit, must have been produced from the carbo-hydrates. In compliance with a suggestion thrown out in the discussion of the question the speaker had, furthermore, calculated as a fat-former the whole of the lime taken by the dog, although all experiments had demonstrated that lime in no case produced fat; and yet, after that item had been fully taken account of, there were about 60 grammes of fat left that could be derived only from the carbo-hydrates. Dr. Munk therefore deemed it indisputably demonstrated by this experiment that in the case of carnivorous as well as omnivorous and herbivorous animals carbo-hydrates might in certain circumstances contribute towards the formation of fat.—Dr. Höltzke, following up a communication recently made by him respecting the influence of narcotics on pressure in the eye, reported experiments he had made concerning the influence of the blood-pressure on the intra-ocular pressure. The view had hitherto been universally accepted that the pressure in the eye was dependent on the blood pressure, and a series of experiences and experiments had been collected by way of proving this dependence. The nerves had likewise shown that they exerted an influence on the pressure in the eye, so far as they influenced the vascular system. Of the sympathetic in particular it was asserted that its paralysis induced an augmentation, whereas stimulation of the nerve caused a diminution of the intraocular pressure, and this converse process was said to be connected with the expansion and contraction of the vessels. Seeing, however, that some investigators maintained that the effect of the sympathetic on the pressure of the eye was exactly the opposite to that just referred to, the speaker had instituted new measurements by means of a manometer, utilising the second eye in the way of control. The result at which he arrived by this means was that the cutting of the sympathetic always entailed an abatement of the pressure to an average of 6 mm. mercury, and that stimulation of the peripheral nerve ending caused an increase of the pressure amounting to 14 mm. mercury. Stimulation of the supreme ganglion of the sympathetic had the same effect. If the veins of the neck were bound on the under side and the carotid was compressed then had neither the cutting nor the stimulation of the sympathetic absolutely any effect on the pressure in the eye—a proof that the influence of the sympathetic as above stated was only mediate, that the paralysis of the sympathetic induced the lowering of the ocular pressure only in consequence of the decrease of pressure in the vascular system and that the stimulation of the nerve caused the increase of the intra-ocular pressure only because of a rise of pressure in the blood. An experiment with a view to measuring the influence of the sympathetic on an atropinised eye did not yield perfectly decisive results, a circumstance which determined the speaker to investigate once more the influence of atropine on the ocular pressure. The result was somewhat different from that recently communicated. It was now ascertained with perfect certainty that the influence of atropine by itself was a diminution of the ocular pressure and therefore the contrary of that of eserine. Only when the pupil was powerfully expanded by the atropine did the pressure in the eye rise in correspondence with the other experiences that each expansion of the pupil was accompanied by an augmentation of pressure, and each contraction of the pupil was followed by an abatement of the ocular pressure. On the expansion and contraction of the pupil, the rise or the reduction of the blood-pressure became, in turn observable, and this latter again on its side generated a rise, or, as it might be, a fall of the pressure in the eye. This parallelism of the ocular and the blood-pressure the speaker had found to hold good in all his experiments. The pressure in the vitreous body invariably showed the same changes as did the pressure in the watery chamber.

DR. LAUDER BRUNTON'S "PHARMACOLOGY"

A Text-Book of Pharmacology, Therapeutics, and Materia Medica. By T. Lauder Brunton, M.D., D.Sc., F.R.S., &c. Pp. 1139. (London: Macmillan and Co., 1885.)

IT is nearly twenty years since Dr. Brunton, then a student in the University of Edinburgh, commenced, by his researches on the physiological action of digitalis, which were followed soon after by others on nitrite of amyl, a life of laborious work which has been marked at every stage by contributions which testify to his scientific acumen and his burning love for research, and which have enriched physiology and many branches of medicine with newly-discovered facts.

Now, when the second decade of his professional life is drawing to a close, he presents us with a work which stamps him as a teacher in the highest sense of the word.

It may appear to some that an apology is needed for introducing into the columns of NATURE a review of a work dealing with departments of medicine. To any such we would reply that it falls within the scope of this journal to review the progress of all departments of natural science, and that large sections of Dr. Brunton's book are full of interest to all biologists, and almost as much to the specialised physiologist as to the practical physician.

By the term "materia medica" it has long been the custom to designate the study of the agents, whether derived from the mineral, vegetable, or animal kingdoms, which are employed in the treatment of disease. By "therapeutics" we understand the study of the application of these remedial agents to the cure of disease. Until very recently the study of therapeutics was based entirely on pure empiricism, and under conditions where empiricism (*i.e.* experiment), uncontrolled by theory and unassisted by proper methods of observation, could not but yield misleading and contradictory results. The physician employed a drug because others had prescribed it before and found it useful in certain diseases, possessing but rarely any knowledge whatever of the mode in which the drug would affect a healthy subject, or of the manner in which it affected the diseased organism. All that was taught concerning the action of drugs was based upon successive individual experiences, accumulated by individuals who were of necessity destitute of the scientific knowledge, as yet unexisting, which alone could make them "empirics" in the best sense of the word.

These observations are not intended to disparage the work of those who, sometimes possessed of marvellous intuition, worked in bygone days, nor to lead to the inference that old therapeutical experience was barren of useful results. However great the knowledge otherwise acquired of the action of a new drug, however stringent the reasoning which leads us to surmise that it is likely to exert a valuable influence in the treatment of disease, yet ultimately it is by a rational empiricism—*i.e.* by a rational and cautious series of observations on actual cases of disease—that its value will be determined; and, further, he alone will be worthy of the name of a good physician who, irrespective of theoretical considerations, bases his use of remedial agents on the results of rational empiricism. To the older therapeutic studies we owe our knowledge of the usefulness of such drugs as iron, cinchona, and digitalis, a statement which of itself is sufficient to express our obligations to the empiricism of bygone days.

There were many causes which, until lately, stood in the way of a proper study of therapeutics. It was only when the natural history of disease came to be studied by men imbued with physiological knowledge and furnished with all the appliances which physiology has borrowed from chemistry and practical physics that it became possible to lay the foundations of sound therapeutics. From such studies it appears that a morbid process is not to be looked upon as a morbid entity to be destroyed, but usually as the resultant of complex deviations in physiological processes; often, it is true, associated with structural alterations of particular organs which stand more or less closely in the relation of proximate causes of the diseased phenomena. They have shown that, in general, in the treatment of disease, the scope of the physician must be to combat particular phenomena by the use of agents affecting specially the organ and function which are the principal factors in the production of the morbid process.

In order, then, to place medicine on a proper basis, it was needed (1) that the functions of the healthy organism (*physiology*) should be studied in the full light afforded by anatomy, chemistry, and natural philosophy; (2) that the exact deviations of the several functions from the normal standard which constitute particular diseases should be ascertained with the utmost exactitude, not only so as to permit of accurate recognition (*diagnosis*) and classification, but to furnish the elements for a philosophical treatment; (3) that alterations induced in the structure of organs by disease (*pathological anatomy*) should be minutely observed, and that by the light of *experimental pathology*, the course of these alterations and, if possible, their proximate as well as their more remote causes should be ascertained; (4) that the so-called physiological action of drugs and other remedial agents should be submitted to a searching investigation: to this study the vague and misleading term of *pharmacology*, previously employed by German writers, has, unfortunately as we think, been applied; (5) that the subsequent application of drugs and other remedial agents to treatment (*therapeutics*) should be studied not only with the object of showing their influence on particular diseases, but also the way in which individual phenomena of disease have been modified.

All the above branches of inquiry are now being pursued by men imbued with the scientific spirit and furnished with all the scientific knowledge of the day. As a result, in spite of the great difficulty of the task, the physician is acquiring more and more that power of anticipating and predicting events which springs out of a knowledge of principles and distinguishes science from mere empiricism.

Until a comparatively recent period the study of the physiological action of drugs and consequently of therapeutics remained in a backward condition, which contrasted unfavourably with that of other departments of medicine. The researches of Claude Bernard on carbonic oxide and curare were the first fruits of the application of physiology to the elucidation of the action of agents capable of modifying in a definite manner the functions of the body, and opened up the path which others were to follow. Thanks to the researches of such men as Schmiedeberg, T. R. Fraser, Sidney Ringer, and our author, the representatives of a host of active and successful workers, facts have been amassed, and the prospect is daily becoming clearer of the time when the physician shall rely less and less upon mere unsupported experience, and will be guided, as by an unerring compass, in the treatment of the diseases which come under his care. We realise as we read the fine work which lies before us how much has been done in a comparatively short time; we cannot help recognising that this very work places us on a higher platform than before, and thereby gives us a wider prospect towards all points of the compass. Yet we reflect and admit that at present we have only the title-deeds of the estate. We need still to go forth to possess the land.

Dr. Brunton's book contains an enormous amount of information. It is a work which will satisfy alike the student and the expert. Clear and logical it stimulates the student by constant reference to his previous work, and compels the expert to acknowledge that the whole bibliography of the subject has been ransacked to supply the innumerable facts which are so skilfully interwoven with the results of the author's own experience.

The book is divided into six sections. The first, entitled "General Pharmacology and Therapeutics," occupies nearly half the volume. It is a successful attempt to press the most recent and often apparently most abstract conclusions of science into the service of medicine. At the very outset the reader is surprised to find himself confronted with such questions as the unity of matter, Mendeljeff's law, chemical constitution and isomorphism, all placed in more or less direct relationship to pharmacology. It is a specimen of what must be expected throughout this section. Varied scientific facts are reproduced for the sake of overburdened memories, and then in a few pregnant sentences the author connects them with his subject, and, between the lines, opens out new avenues of research.

We would draw special attention to the remark of the author on the object, value, conditions, and objections to the study of experimental pharmacology (pp. 37-41). In the ordinary administration of any drug the difficulties in the way of a correct conclusion as to its action on the system are extremely great. The conditions are so complex that the most experienced physician will often hesitate between the "post" and the "propter." We must by experiment diminish the number of coincident phenomena in order that we may link the right antecedent and consequent. This may be accomplished in various ways, as the author indicates. A simpler organism and one more open to direct investigation may be employed; an organ or tissue may be isolated from the rest of the body, *e.g.* a muscle-nerve preparation; by ligature of blood-vessels, or otherwise, the drug may be excluded from part or parts of the body, and so comparisons instituted; or the normal mechanism of a part may be modified in a definite manner, and the action of the drug examined under these circumstances, as in experiments on drugs affecting the organs of circulation, and in which the vagus is cut or stimulated. Pharmacology is based on experiments thus made, and no one who reads Dr. Brunton's book can doubt their value. The observations of the author on objections to experiments appear to us so just that we cannot avoid reproducing them :—

"*Objections to Experiment.*—Some people object entirely to experiments upon animals. They do this chiefly on two grounds. The first is that such experiments are useless, and the second, that even if they were useful, we have no right to inflict pain upon animals.

"The first objection is due to ignorance. Almost all our exact knowledge of the action of drugs on the various organs of the body, as well as the physiological functions of these organisms themselves, has been obtained by experiments on animals.

"Their second objection is one which, if pushed to its utmost limits and steadily carried out, would soon drive man off the face of the earth.

"The struggle for existence is constantly going on, not only between man and man, but between man, the lower animals and plants, and man's very being depends upon his success.

"We kill animals for food. We destroy them when they are dangerous like the tiger or cobra, or destructive like the rat or mouse. We oblige them to work for us, for no reward but their food; and we urge them on by whip and spur when they are unwilling or flag. No one would think of blaming the messenger who should apply whip and spur to bring a reprieve, and thus save the life of a human being about to die on the scaffold, even although his horse should die under him at the end of the journey. Humane people will give an extra shilling to a cabman in order that they may catch the train which will take them to soothe the dying moments of a friend without regarding the consequences to the cab-horse. Yet if one-tenth of the suffering which the horse has to endure in either of the cases just mentioned were to be inflicted by a physiologist in order to obtain the knowledge which would help to relieve the suffering and lengthen the life, not of one human being only, but of thousands, many persons would exclaim against him. Such objections as these are due either to want of knowledge or want of thought on the part of people who make them. They either do not know the benefits which medicine derives from experiment, or they thoughtlessly (sometimes, perhaps, wilfully) ignore the evidence regarding the utility of experiment."

As protoplasm is the physical basis of life and the cell its unit, Dr. Brunton commences Pharmacology with the action of drugs on amœbæ, white corpuscles, infusoria, and the various forms of specialised protoplasm found in the higher animals. A section is also devoted to microorganisms. The late extensive corroboration of the truth of the germ theory of disease throws special interest around the investigations which deal with their life-history and the manner in which they are affected by drugs. A short chapter on the pharmacology of the Invertebrata serves to reveal the comparative poverty of our knowledge in this branch, and suggests further inquiry.

We must pass over the elaborate and lengthy chapters on physiology, pharmacology, and pathology as applied to the various organs and systems of the body. It is the centrepiece of the book, and reveals the versatility, the learning and the scientific instincts of the writer.

Section II., entitled "General Pharmacy," contains a succinct account of the various classes of pharmaceutical preparations, with tables of doses of the individual members of each.

The rest of the book is chiefly taken up with an account of the preparation, characters, doses, actions, and uses of the various remedial agents. Here we find all that valuable empirical knowledge of the use of drugs which science has so far failed to analyse, but which in course of time will no doubt be incorporated with the first section. Section III. is concerned with the inorganic remedies, Section V. with those obtained from plants, and Section VI. with those derived from animals. Section IV., "Organic Materia Medica," requires special notice. It includes all the carbon compounds employed in medicine which are obtained by synthesis.

Pharmacology owes much to the enterprise of the chemist. In the first place, the extraction of definite active principles from the various vegetable structures used in the Pharmacopœia has been of inestimable value. It was formerly impossible to be sure that the preparations made year by year were of the same strength. The environment of the plant varies more or less each season, so that at one time it may manufacture more of its active principles than at another. Moreover some plants contain several powerful ingredients which are of more value apart than together. The extraction and isolation of these substances has therefore led to a correct dosage and their more definite application to the treatment of disease.

In the second place the chemist is making us by degrees independent of the plant world by producing synthetically the bodies thus isolated. Just as the manufacture of alizarine from anthracene made the dyer independent of the madder root, so the artificial production of salicylic acid has supplanted the willow. In course of time, no doubt, as Dr. Brunton suggests, this section of Materia Medica will develop greatly, whilst the number of animal and vegetable preparations will correspondingly diminish. We are not, however—thanks again to chemical research—limited merely to those principles already in the Pharmacopœia. Already we are supplied with a host of substances, the products of synthesis, amongst which many of the valuable drugs of the future will doubtless be found. Organic synthesis, apart from the valuable substances which it may yield us, as the bodies kairin and antipyrin, which have already found their use in medicine, is of extreme importance to the pharmacologist from another standpoint, for it enables him to form conjectures as to the molecular structure of compounds. So far but few definite relations have been established between chemical constitution and physiological action. Still, enough has been done to demonstrate the existence of such relations and to promise a fruitful harvest hereafter. It has been proved, for instance (Crum Brown and Fraser), that the introduction of the methyl group into the molecule of an alkaloid gives it the power of paralysing the end-organs of motor nerves. Similarly Drs. Brunton and Cash have found as a general rule that most of the compound radicals formed by the union of amidogen with the radicals of the marsh-gas series possess a paralysing action on motor nerves.

It is probable that just as in the members of homologous series we have a gradation of physical properties and a similarity of chemical reactions, so bodies having similar chemical constitution will be found to resemble each other in physiological action. Induction will then lead to deduction, and the paths in which we are to tread in order to find drugs endowed with certain properties will be indicated; in illustration of this we note that already we know where to experiment if we wish to add to the number of our anæsthetics and antipyretics.

This review could not well close without a reference to the many useful illustrations and to the elaborate indices (extending to 131 pages), which add materially to the value of the work. It will rank as the text-book on the subjects of which it treats, being at once the best exponent of existing knowledge and a powerful stimulus to further progress.

ARTHUR GAMGEE

ELEMENTARY PRACTICAL PHYSICS

Lessons in Elementary Practical Physics. By Balfour Stewart, M.A., LL.D., F.R.S., Professor of Physics Victoria University, the Owens College, Manchester, and W. W. Haldane Gee, Demonstrator and Assistant Lecturer in Physics, the Owens College. Vol. I. (London: Macmillan and Co., 1885.)

IN this the first volume of what will evidently be an elaborate work on practical physics, the authors have treated of general physical processes only, *i.e.* of the methods employed in the laboratory for the exact determination or measurement of the geometrical and mechanical properties of bodies. It is impossible to over-estimate the importance of these fundamental measures, for upon them depends the accuracy of almost all physical work. That this is the view of the authors is made evident by their having devoted nearly the whole of the first volume out of a promised three to matters purely geometrical and mechanical. Throughout the volume the most minute attention to details is apparent, so much so that it is likely to weary those who read it only; but those who use it to guide them in making the measures given will certainly benefit by the completeness with which each subject is treated.

The first chapter, on the measurement of length, may be taken as a type of the whole volume. The metre and the yard are first defined and their absolute relation stated; the actual relation of metre and yard scales—slightly differing from the absolute owing to the fact that 0° C. and 62° F. are the two temperatures of reference—is next explained. A paragraph on "end measure" and "line measure" concludes what is in effect an introduction to the first chapter. Then the "Lessons" in this chapter begin. The first lesson is on the use of scales. In this instructions are given for measuring a length with a pair of compasses and an ordinary or a diagonal scale. Results are given showing the limit of accuracy by this method. The second lesson is on the straight Vernier, the third on the barometer Vernier, the fourth on the spherometer, and the fifth on the micrometer wire gauge. Lesson 6 is a description with figures of the dividing engine of M. Perreaux, the use of which is the subject of the next lesson. The next five lessons of this chapter explain the copying of scales, the cathetometer with its adjustments, the micrometer microscope, the Whitworth measuring machine, the eyepiece and stage micrometer, while a general review of the subject of length measurement, in which other instruments and tools, including the cathetometer microscope, are described, concludes the chapter.

This brief review of the first is sufficient to show the system on which each of the eight chapters is put together.

In the second chapter on angular measurement the circular Vernier, the mirror and scale, and the spirit level of course form the subject of lessons. There is also a lesson on that simple and easily-constructed instrument of M. Cornu, the optical lever.

The chapter on the estimation of mass is very complete, for, besides an explanation of the theory and use of the balance, there is a page headed "precautions in weighing," a copy of which might well be placed on the wall above every balance in a laboratory; there is an excellent paragraph on the sensibility of the balance, with a diagram showing the observed sensibility of an Oertling, a Bunge, and another short beam balance. There is, lastly, a lesson on the errors of weights, in which instructions are given for testing a set of weights.

In the chapter on measurement of area and volume a large amount of space is given to an explanation of the Amsler planimeter. This beautiful little instrument, as is well known, gives the area of a figure round which its point is traced. In a new edition it is to be hoped that the new "precision" planimeters which in accuracy and some other respects are superior to that of Amsler, will be described.

In Chapter V., on the determination of density, are to be found full instructions for finding the specific gravity of solids and liquids by a host of methods. The corrections for buoyancy are carried to such an extent that account is taken of the latitude and the height above the sea-level in calculating the density of the air from the barometer reading; further, the effect of moisture in lightening the air is guarded against. The hydrometers of Fahrenheit, Baumé and Twaddle are described, and instructions are given for making them. The exact determination of the density of a gas, being a problem of great difficulty, is considered unsuitable for imitation in the laboratory; however, an outline of Regnault's method is given.

The chapter on elasticity, tenacity, and capillarity differs from others in the book in that the theory of the subject is given at length, as well as instructions for performing experiments in the laboratory.

The chapter on the determination of atmospheric pressure contains a full account of the method of filling and using a standard mercurial barometer. The aneroid barometer is not mentioned.

The last chapter, on time, gravitation, and moments of inertia, is purely mechanical. The difference between the sidereal, solar, and mean solar days is explained, but instructions are not given for taking a transit. Clocks, chronometers, stop-watches, the water-clock, and the chronograph of Hipp, in which a reed vibrating 1000 times a second replaces the pendulum of a clock, are briefly described.

The determination of g by Borda's and by Kater's method is given. Several forms of electro-chronograph are described—among them one in which a primary circuit is broken at the beginning and end of the interval to be measured, while the induced currents cause a spark to pass between the style of a tuning-fork and a smoked drum, so that the number of waves between the two dots produced by the sparks measures the time.

As has been already said, completeness and attention to details are apparent in every chapter of the first volume, while the names of the authors are sufficient as a guarantee of accuracy. The only cause for regret is the fact that the public has to wait for the two volumes on real physics, for those who read the first, which deals mainly with measurements of geometrical and mechanical properties, and which is therefore essentially an introduction, are likely to be impatient to see the series completed.

OUR BOOK SHELF

The History of a Lump of Gold from the Mine to the Mint. By Alexander Watt. (London: A. Johnson.)

THE author has endeavoured to treat his subject so as to interest general readers, but he might have spared them such moralisations, suggested by the word "gold," as "With what silent rapture we receive it as our own, and how different is the feeling when it comes into our hands merely to convey to another." The compilation of facts connected with the history of gold and its manufacture into coin has, however, been carefully done. Considering that the superstructure of modern chemistry was built up on the labours of the "early alchemists," we object to their being described as "those remarkable imposters," and indeed the quotations from the writings of the early chemists which are given abundantly prove their claim to more respectful treatment. The metallurgy of gold is dealt with in the most slender way, but the chapter relating to the operations of coinage is more satisfactory, and is confessedly an abstract of a series of Cantor lectures recently delivered by the chemist of the Mint.

The important question of the amount of gold actually in circulation has not been lost sight of, and the author sums it up by quoting the following passage:—"The amount of gold actually in circulation is estimated to be 100,000,000*l.*, but the coinage returns show that the amount of sovereigns and half-sovereigns issued since 1816, when their coinage began, is 247,521,429. What, then, has become of the one hundred and forty-seven millions not in circulation?" No doubt a considerable proportion has been exported never to return, but we do not think, with the author, that the operations of manufacturing goldsmiths and jewellers would account for a very large proportion of the deficiency.

There are some remarkable slips in the printing. For instance, the well-known historian of the coinage is called the Rev. Rogers Rudling, and Sir John Pettus appears as Petters; but viewed as a whole, the work may be commended as tending to disseminate information respecting the precious metal which it is desirable should be widely known.

Magnetism and Electricity. By W. G. Baker. (London: Blackie and Son.)

WITH the multitude of elementary text-books on magnetism and electricity already existing the production of a fresh one might well have seemed an unnecessary task. Nor is there anything in the little book now before us in the least degree new, either in matter or in arrangement. So far as it goes, however, it is quite satisfactory. It consists of 143 pages, and in this space the author has managed to give in a clear manner an account of so much of the subject as might reasonably be put before a school class for beginners. As it appears from his preface that this was the sole object of the author in writing the little book, he is entitled, we think, to consider that his object has been attained.

Bacillary Phthisis of the Lungs. By Germain Sée, translated by William H. Weddell. (London: Kegan Paul, Trench and Co., 1885.)

THIS is in many respects an unsatisfactory book. It is divided into seven parts. Of these the preliminaries and the first four parts comprise anatomical and histological notes, the biological study of micro-organisms generally, and the study of the bacillus tuberculosis especially, and all kinds of promiscuous notes on the causes of tuberculosis; but, owing to the dogmatic way in which these subjects are treated, the omission of details and the numerous mycological inaccuracies this portion of the book is very weak. The rest, treating of clinical, hygienic, and therapeutic subjects, is more within the author's proper domain, and will be found instructive to the medical practitioner.

Mineral Resources of the United States. By A. Williams. (Published by the U.S. Geological Survey, 1883.)

THIS book consists of a series of essays, of various degrees of importance, on the mining and metallurgic industries of the United States. The work has been mainly carried out by entrusting each subject, or a special branch of each subject, to a gentleman intimately acquainted with that branch. The thoroughness with which the subject is treated is shown by the fact that the natural history of so rare a substance as hiddenite is very fully discussed by the original discoverer, Mr. W. E. Hidden.

Naturally the most important and the most extensive essays are those on coal, iron, copper, and zinc. Silver, the position of which is at present one of the most difficult problems connected with the metals, was excluded by Act of Congress from the present investigation, and tables of the production of gold and silver in recent years are all the information given. Former publications of the U.S. Government have already made known the enormous wealth of the silver-mines, and have given fair means by which persons interested in mining may estimate the prospect of success in such undertakings.

Under iron, an account is given of the Bower-Barff process of protecting iron from rust by means of a thin film of magnetic oxide—a process which bids fair, if it stand the trial of some years' wear, to replace the process of galvanising.

To professional people who need accurate information as to the condition of the various industries, the book possesses great value. It is also full of interest to the scientific mineralogist who has mainly to depend on the opening of new mines for fresh discoveries in the mineral kingdom. One cannot help regretting, however, the space given to a history of the divining-rod, "natural magnets," and similar absurdities. The subject is as much out of place as an account of the astrological nonsense practised in the Middle Ages would be in a modern treatise on spherical astronomy.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Pitcher Plants

PERHAPS you will allow me to set "W. C. M." right with regard to *Sarracenia variolaris* and pitcher plants generally (p. 295). I am afraid the sources from whence he obtained his information were not very reliable, as will be seen from the following:—

There are six species of Sarracenia found in North America, all of them characterised by the same trumpet-shaped leaves growing in tufts, and in several of the species attaining a length of a yard. In addition to these there is the *Darlingtonia californica*, which has long twisted trumpet-shaped leaves, the top of which is curved over, forming a sort of hood, and having a rather small aperture on each side. These constitute the whole of the pitcher plants of North America. "W. C. M.," whilst professing to describe the "curious characteristics" of the Sarracenia, really describes the leaf and pitcher of Nepenthes, which, as almost everybody knows, are tropical plants, mostly natives of the Indian Archipelago, and well known in this country as ornamental stove plants. The pitchers vary much in size, some of the species producing them quite eighteen inches long and capable of holding a quart of water, whilst others have pitchers no larger than a thimble. "W. C. M." is quite wrong in saying that the lids of the pitchers of Nepenthes, or indeed of any pitcher-plant known, close again after they have once opened. When the pitcher is about full-grown, the lid pushes open, widely in some species, only slightly in others, and remains quite stationary till the pitcher dies. When the lid opens, the pitcher is found to be about one-quarter filled with a sweetish watery liquid. Under cultivation it is necessary to keep the pitchers filled with water, or they soon shrivel; and it is found that, however frequently the water is renewed, it soon acquires a slight sweetness; so that the secretion of "honey" going on in the pitcher must be somewhat copious. If the water which is in the pitcher when it first opens dries up, there is no further secretion of liquid—at least such is the case with cultivated plants. At Kew the oldest pitchers on the Nepenthes attract insects as long as they contain moisture. The Sarracenias have their pitchers formed by the folding and joining of the edges of the leaves, so as to make a long funnel which is wide at the mouth and narrowed to almost a point at the base. Over the mouth the flap-like lid is fixed and in some of the species stands erect so as to admit rain-water into the pitchers, whilst in others the lid curves over in such a manner as to hinder the rain from falling into them. In 1815 the then President of the Linnean Society, Dr. James McBride, read a communication on the fly-catching propensity of Sarracenias, from which the following is worth quoting, as it describes accurately what we have repeatedly observed in the collection of Sarracenias cultivated at Kew. He says, writing chiefly about *Sarracenia variolaris*: "If, in the months of May, June, or July, when the leaves of these plants perform their extraordinary functions in the greatest perfection, some of them should be removed to a house and fixed in an erect position, it will soon be perceived that flies are attracted by them. These insects immediately approach the fauces of the leaves, and, leaning over their edges, appear to sip with eagerness something from their internal surface. In this position they linger, but, at length allured, as it would seem by the pleasures of taste, they enter the tubes. The fly, which has thus changed its situation, will be seen to stand unsteadily, it totters for a few seconds, slips, and falls to the bottom of the tube, where it is either drowned or attempts in vain to ascend against the points of the hairs. The fly seldom takes wing in its fall and escapes. In a house much infested with flies this entrapment goes on so rapidly that a tube is filled within a few hours, and it becomes necessary to add water, the natural quantity being insufficient to drown the imprisoned insects. The leaves of other species might well be employed as fly-catchers; indeed I am credibly informed that they are in some neighbourhoods. The leaves of *Sarracenia flava*, although they are very capacious, and often grow to a height of three feet or more, are never found to contain so many insects as those of other species. The cause which attracts flies is evidently a sweet viscid substance resembling honey, secreted by, or exuding from, the internal surface of the tube. From the margin, where it commences, it does not extend lower than one-fourth of an inch. The falling of the insect as soon as it enters the tube is wholly attributable to the downward or inverted position of the hairs of the internal surface of the leaf. At the bottom of a tube, split open, the hairs are plainly discernible pointing downwards; as the eye ranges upwards they gradually become shorter and attenuated, till at, or just below, the surface covered by the bait, they are no longer perceptible to the naked eye nor to the most delicate touch. It is here that the fly cannot take a hold sufficiently strong to support itself, but falls. The inability of insects to crawl up against the points of the hairs I have often tested in the most satisfactory manner" (*Trans.* Linnean Society, vol. xii.). I have again and again released blue-bottle flies after they have been trapped, and have never yet found them act in any way that would suggest an intoxicating property in the secretion which they had fed upon—this is contrary to the information of "W. C. M.," who says:—"After feeding upon the secretion for two or three minutes they [the insects] become quite stupid, unsteady on their feet, &c." To prevent the pitchers being injured by the large number of insects which are lured into them, we find it necessary at Kew to fill the mouths of the pitchers with cotton-wool; this prevents the insects from falling in. Before this precaution was taken many of our finest pitchers were lost, owing to the decay which was caused by the rotten mass of insects which had accumulated in the bottom of the pitchers. "W. C. M." will be surprised to hear that, in spite of this cutting off of the supply of insects to the pitchers, the plants were in no way affected as regarded growth or vigour, but that the length and general health of the pitchers were more satisfactory after the insects were not allowed to enter them, than before. The concluding sentence in his remarks is rather startling, as, so far as investigations conducted by physiologists have gone hitherto, the Sarracenias are not known to be carnivorous. Mr. W. H. Gilburt, of the Quekett Microscopical Club, says:—"The pitchers contain fluid, but nothing corresponding to a digestive fluid has been detected in them; so that, if the insects which perish in the pitcher are of any value to the plant and afford any nutriment, it must be simply by maceration, and the glands can be regarded as absorbent only." Of course it may be said that Sarracenias would not have been constructed with what appears to be a view specially to catching insects, if the insects were not to serve some useful purpose in the economy of the plant. Anyhow, at present it is only safe to say of Sarracenias that they allure and ultimately destroy insects, but we do not yet know that they obtain nourishment from them. Certainly under cultivation there is abundance of evidence to prove that these, and in fact all those plants which are considered to be distinctly carnivorous, grow and thrive at least as well when insect food is not allowed them as when it is.

Kew W. WATSON

Colourless Chlorophyll

IN his elaborate "Contributions to the Chemistry of Chlorophyll" (NATURE, vol. xxxii. p. 117), Mr. E. Schunck rightly observes that the explanation given by Mr. Tschirch for the curious fact discovered by Mr. Church is not based on sufficient proof. Indeed it could hardly be admitted that the action of metallic zinc is a process of reduction, since a similar result may be arrived at when zinc oxide is used instead of the metal. (A fact that I stated in 1869).

But quite recently I have had the opportunity to convince myself that the reaction that takes place when a chlorophyll solution is *treated by metallic zinc and an organic acid* is of an utterly different nature. Through the agency of nascent hydrogen generated in the reaction, *chlorophyll is* actually *reduced, the resulting substance being* not of a green colour, but perfectly *colourless*, and presenting no traces of the characteristic chlorophyll spectrum or fluorescence. It is only on coming in contact with the air that it gradually acquires both its green colour and specific optical properties. It is highly instructive to watch the phenomenon in a test-tube placed before the slit of a spectroscope and observe the first appearance and subsequent growth of the dark bands, the colourless substance regaining in the mean while its original splendid emerald green.

The physiological importance of this fact will be obvious to all botanists interested in the subject; for my part I consider that the discovery of this colourless modification of chlorophyll brings additional proof in favour of an hypothesis that I proposed in 1875 concerning the chemical nature of chlorophyll—viz. that the green colour of this substance is due to the presence of iron in the state of a $FeOFe_2O_3$ compound. In fact, all the changes that this substance undergoes, its production, its destruction, the action of acids, of metallic zinc and zinc oxide, might be easily accounted for by admitting this simple and very plausible hypothesis.

But whatever may be the ultimate fate of this "provisional" hypothesis, the fact just stated will lose nothing of its importance. Its chief interest lies in the establishment of the existence of a colourless substance, acquiring by oxidation all the optical properties of chlorophyll. It is evident that chlorophyll is generated in this case by a process similar to that which takes place in the living plant. (The existence of such a substance has been often announced, but continues to be a subject of doubt). At the same time we may see the reason why, admitting that chlorophyll undergoes a process of reduction when CO_2 is dissociated through the agency of light (this supposition is highly probable), this transformation may not be attended by a visible change of its colour, and other optical properties—the produce of reduction being colourless and having no dark lines in the spectrum. However, the change of colour that M. Sachs observed in a great number of leaves on exposing them to direct sunlight, and which is generally attributed to a migration of the chlorophyll grains, might, partly at least, be due to this process of reduction. C. TIMIRIAZEFF

Moscow, July 15

July Meteors

BETWEEN July 8 and 14, 111 shooting stars were recorded here in 11¾ hours of observation. The paths of these, reproduced upon an 18-inch celestial globe, enabled me to fix the radiant points of 12 showers with considerable distinctness:—

No.	Epoch. July.	Radiant. ° °	Notes.
1 ...	13–14 ...	11+48	Meteors long, swift with streaks.
2 ...	8–13 ...	245+52	Slow, yellow, max. July 8.
3 ...	13–14 ...	255+37	Slow, faint, near π Herculis.
4 ...	9–13 ...	265+63	Slow, faint, near ζ Draconis.
5 ...	9–14 ...	271+21	Slow, faint. In Cerberus.
6 ...	9–13 ...	280−14	Very slow, long paths.
7 ...	13–14 ...	285+42	Very swift and short, near α Lyræ.
8 ...	9–13 ...	289+31	Swift, faint, near γ Lyræ.
9 ...	8–13 ...	290+60	Slow, bright, near ο Draconis.
10 ...	8–13 ...	303+24	Swift. In Vulpecula.
11 ...	13–14 ...	314+47	Very swift, short, bright, near α Cygni.
12 ...	9–14 ...	329+36	Swift, reddish streaks. S. of Lacerta.

Nos. 1, 7, 8, 9, 11, and 12 were well observed by Zezioli in 1867–68, and form Nos. 93, 90, 88, 89, 99, and 98 of the catalogue of radiants derived by Schiaparelli from his observations.

Generally the meteors observed here during the past month were small, but three were estimated as bright as Jupiter. The first of these appeared on July 8 at 12h. 1m., shooting rapidly along a course of 27 degrees a little west of ζ, η, θ Draconis. It left a brilliant streak, enabling the path to be very accurately noted. This meteor belonged to the radiant at 11° + 48°, and soon afterwards, at 12h. 10m., another fine one was seen pursuing a greatly foreshortened path near δ Draconis and throwing off a dense train of yellowish sparks. Its motion and appearance prove it to have been a Draconid and a member of the display from 290° + 60°. On July 9, at 13h. 50m., I recorded a fine meteor shooting upwards, just east of Altair, from a centre at 304° − 15° near α and β Capricorni; but I have not included this position in the list, as I only saw one other shooting star with a conformable direction during the period included by my observations.

On July 31 a few fine and early members of the August Perseids were seen, and on August 1, between 9h. 45m. and 9h. 50m., I noted three others, two of which were unusually brilliant, and projected vivid streaks upon their long, graceful flights through the Milky Way west of Aquila. This conspicuous and early appearance of the Perseids would seem to predicate a bright maximum on the night of August 10.

Bristol, August 2 W. F. DENNING

The August Meteors

LAST night at 9.32 a brilliant meteor crossed Cassiopeia's Chair from W. to E. parallel to the horizon. Its trail was visible for twenty-six seconds after the bursting of the meteor. During a five mile walk, lighted by many meteors, the summer lightning incessantly flashed from the northern horizon, but its brightness was never comparable to that of this meteor. It resembled most a magnesium rocket in the Crystal Palace fireworks. But even this comparison is hardly adequate.

Chatham, August 12 H. B. JUPP

A Possible Windfall for Science

IS not the better course for immediate action that the departments in England and the United States should first combine?

Let each apportion a part of the calculation, and then print it in an agreed form. The sterotype plates would be interchanged, and what a private firm does the Government can effect. In this way the English-speaking marine, including many Dutch and German captains, will be at once supplied, and part of the proposed economy and benefit be obtained without waiting for negotiations with France and Germany. HYDE CLARKE

Electrical Phenomenon in Mid-Lothian

I HAVE observed in a daily contemporary a communication quoted from your journal with reference to this occurrence on the 23rd ult.

For the information of those of your readers who are interested in such matters perhaps you will kindly allow me to observe that I also witnessed a similar, or the same, phenomenon that evening.

When driving home from a professional visit in the country, and a mile south of this town, about ten o'clock I was suddenly startled by a peculiar sensation or slight shock, and immediately perceived, ten yards in front, on the road, a bright opalescent luminosity which travelled deliberately away in a northerly direction. This cloud or wave of light covered the whole breadth of the road, and was distinctly visible for some seconds. It seemed to rest entirely on the ground, and in character reminded one somewhat of the illumination resulting from the electric light. I should imagine it was travelling at the rate of twenty miles an hour, as it was going much in the same direction I was, but of course much faster. The part of the road where it showed itself is lined by high trees on both sides in full foliage. I heard no thunder and saw no lightning or meteor to account for the strange and weird-looking light.

The interesting question then arises, What was the nature of this phenomenon?

It will be remembered that the thermometer was for several days at that time above 80° F. in the shade. Might it not be possible, therefore, for a certain volume of air to become electrified, and then, perfectly insulated by the dry surrounding atmosphere, show its existence in this manner as a luminous cloud rushing along the ground?

I may mention in conclusion that my groom, who was driving me at the time, also witnessed the occurrence.

Dalkeith, N.B., August 10, 1885 ROBERT LUCAS

On a Radiant Energy Recorder

A FEW weeks ago I wrote a short article for NATURE under the above title, describing an instrument for the measurement of radiation in heat units which was based upon the principle of the integration of temperature by the distillation of water in vacuo. Since then Mr. Edward Vivian, M.A., has kindly written me a very interesting letter, in which he says that he had several forms of an instrument based upon essentially the same principles, made for him by Messrs. Negretti and Zambra many years ago, and that some of them are still in use in his garden at Torquay. Mr. Vivian's instruments were shown at the British Association (*B. A. Report*, 1856, p. 48) and at the Royal Institution of Great Britain (*Journal R. I.*, 1857, p. 438), but no description of them appears to have been printed, which probably accounts for their not being more generally known.

University College, Liverpool J. W. CLARK

Our Ancestors

THE number of "Our Ancestors" since "the time of the Norman Conquest," mentioned in your last issue by $\left(\frac{1}{2}\right)^n$, and the consequences to be deduced therefrom, have been very interestingly discussed already by Mr. Grove in his presidential address to the British Association at Nottingham, 1866.

Freiburg, Badenia, August 8 N.

THE INSTITUTION OF MECHANICAL ENGINEERS

THE Institution of Mechanical Engineers held their summer meeting at Lincoln last week, under the presidency of Mr. Jeremiah Head, who, in his inaugural address, treated of the relative advantages of iron and steel for the various purposes for which these metals are employed. The reasons why steel *rails* are now used almost to the exclusion of iron are that they can be produced more cheaply, can be manufactured of equally good quality by either the Bessemer or Siemens process with either acid or basic-lined vessels and of almost any iron ore, and they can better withstand abrasion, disintegration, or crushing under heavy rolling loads; for the same reasons steel tires are now almost universally employed. For *ship-building* steel is superior to iron, as, owing to its greater ductility, ships built of the former metal are able to outlive collisions and minor accidents that would be fatal to iron ships. As is well known, owing to the superior tensile strength of steel, Lloyd's Committee agreed in 1877 to allow a reduction of 20 per cent. in weight of scantlings over iron, and in the thickness of plates; Mr. Head argues that, considering a ship's plate is a broad girder, its strength diminishes as the square of the thickness, and that, therefore, although a steel ship would be superior to an iron one of equal weight, an iron ship is likely to retain its form better than a steel one built 20 per cent. lighter. As regards *bridges and roofs*, the employment of iron or steel depends mainly upon the size of the structure; for light edifices, owing to its greater cheapness, iron has hitherto been used, whilst for large spans, where the weight of the structure itself is an important function, steel has been employed in the erection of bridges of spans which could not have been attempted if the engineer had been dependent on iron alone. For *boilers*, except in the matter of corrosion, in which authorities seem to differ as to the resisting power of iron and steel, but appear to be rather favourable to the former, steel is much more advantageous than iron, both on account of its being as cheap, and on account of a steam boiler of the same weight being able to withstand much higher pressures if made of steel than if made of iron; hence boilers, and marine boilers particularly, are now scarcely ever built of iron. The President recommended the application of metal in the construction of the frames of rolling stock and for railway-sleepers. As regards the continued use of wooden sleepers, there can be no question that "it is a form of waste that should be reprehended in the public interest, just as should the use of coal for ballasting or other obviously wasteful purpose. The same timber which would become useless for sleepers in, say, nine years, would last at least a century in the roof or flooring of a house." Another argument advanced, and a most important one, is that the substitution of iron and steel for timber railway-sleepers would not only give an enormous impetus to these industries while the substitution was being effected, but would permanently maintain a population of 100,000, or 3 per cent. of the whole population of the country, for renewals.

Leaving special branches of industry, to refer to special forms in which iron and steel are supplied, the President drew attention to *bar-iron* still maintaining its position, because wherever implements are *made* they come sooner or later to the village blacksmith to be *repaired*, and these find steel harder to work, more difficult to weld, and requiring more care to smith; and therefore the original manufacturer has to adopt a material and construction within the compass of the ideas and resources of the rural repairer.

As regards *castings*, an urgent need has long existed for a material which could be cast in a mould, and which should yet have the toughness and tenacity of wrought iron; and steel, exactly supplying this want, has come very generally into use, more particularly as the cost of steel castings has been greatly cheapened latterly by the employment of the Bessemer and Open Hearth processes; still, steel castings are much dearer than iron ones, because the molten metal is dearer, and the higher melting point of steel compared with iron necessitates more costly moulds. But in a majority of cases in which cast iron has hitherto been used, mass and stiffness due thereto, are required, rather than great tenacity and ductility, and there is, therefore, likely to be a simultaneous demand for castings of both steel and iron. Concurrently with steel castings, steel *forgings* have gradually been coming more and more into general use for fine and delicate work, where cost is no consideration, and homogeneity and capacity to harden of the very greatest importance.

Steel has practically no grain, and is as strong in one direction as another; thus it is eminently suitable for such work, and is naturally superseding iron completely. The conclusion of the President on the subject of the employment of iron and steel in the arts is one in which upon full consideration all must agree—viz. that the laws of gradual change, and of the survival of the fittest, apply equally in the arts as in nature, and that in the long run the fittest material will prevail according to the peculiarities and necessities of each particular case.

The first paper read at the meeting was by Mr. J. Ruston, M.P., descriptive of Dunbar and Ruston's steam navvy.

This machine may be described generally as consisting of a strong rectangular wrought-iron frame mounted on wheels. On the back end is placed the engine; at the front end rises a wrought-iron tower carrying the top pivot of a crane jib, the lower pivot resting on girders fixed to the main frame. The jib is of twin construction, being composed of two sides united only at the post and at the outer end or point; between them is a long slot, in which swings an arm of adjustable length, depending from a fulcrum fixed on the upper member of the jib; and at the base of the post is a circular platform, on which a man stands to regulate by means of a hand-wheel the "reach," or length of radius of the arm. The scoop or bucket is fixed at the lower end of the arm, and is raised or lowered by the main chain passing over the extremity of the jib. The whole of the movements are controlled by two men, called the "driver" and the "wheelman." The driver raises the scoop while making its cut, swings it round into position for discharging, and back again afterwards, and lowers it down. The wheelman regulates the depth of the cut, releases the scoop from the face of the bank, and opens the door or bottom for discharging its contents.

Supposing the navvy to be in position, the mode of working is as follows:—The bucket having been lowered till its arm is vertical, the wheelman regulates the length of the arm by means of his hand-wheel, so that the cutting edge of the bucket shall get its proper grip of the soil. The driver throws the main chain-drum into gear, and the scoop is dragged forwards and upwards by the chain, describing a circular arc of about 80 degrees. By the time it reaches the top it is fully loaded, and the driver, throwing the drum out of gear, holds it with a footbrake; at the same instant the wheelman by easing his footbrake allows the bucket to fall back so as to clear itself from the face of the bank. The driver next swings the jib round till the bucket is over the waggon, when the wheelman releases the latch by means of a cord, and the door falling open, the contents instantly drop through. The driver then swings the jib back again, and at the same time lets go the footbrake of the chain drum, thus causing the bucket to descend through a sort of spiral course, until he brings it up sharply by the brake again. The wheelman at the same moment adjusts the fall by means of his brake, so as to lower the bucket to its first position with just the right reach of arm for the next cut. During the fall the door of the bucket closes and latches itself automatically by its own weight; and all is then ready for repeating the operation.

Upwards of a hundred of these machines are now in use, the majority in Great Britain, and the remainder in various parts of the world.

In the discussion of this paper the various speakers testified to the success with which the navvy did its work when excavating materials of various degrees of hardness and toughness.

Mr. John Richardson's paper on recent adaptations of the Robey semi-portable engine was an extension of a paper read in 1873. The engine is erected on a massive wrought-iron foundation plate, to which all the working parts are fixed, together with one of the drum-shaft bearings, and the brackets for carrying the brake-straps and levers. The whole of the strains due to the working of the machinery are contained within the base plate, and are brought, as they should be, near to the position of greatest stability—namely, the ground line; while the boiler is set free from all mechanical strain, and is left to its legitimate purpose of making steam. A specially light engine has been designed for use in countries where there is little facility for transport, wrought iron and steel have been substituted as far as possible for cast iron, with the result of a large saving in dead weight and consequent saving in cost of transport.

A paper on private installations of electric lighting, by Mr. Ralph Neville, is interesting as descriptive of an application in which existing engine power was utilised and modifications made in the governing of the engine to suit the purpose of driving a dynamo machine, in which, as is well known, the action on the engine has to be prompt, the electric lamps acting as visible instantaneous galvanometers. The dynamo employed was a Siemens S 9, the lamps being mostly 100 volt 20 candle-power of Edison and Swan make. The current generated is led from the dynamo to a set of switches, by which it can be distributed into five separate circuits, the first exciting the field magnets of the dynamo itself and the others furnishing current for lights in various parts. Certain points are taken as lighting centres, and the electromotive force between them is kept constant; for this purpose small wires are connected with the mains at the required points, and the current to actuate the governor is taken off there, instead of direct from the terminals of the dynamo. The original governor attached to the engine was found to have so great an inertia that its position would remain the same for a very considerable variation of speed, so the author set up an electrical governor.

The regulating part of this governor consists of a double solenoid magnet, placed vertically and wound with insulated copper wire, within which works a double core; and to the cross-piece at the bottom of the cores is linked the long arm of a lever, the short arm of which presses upon the spindle of a double-beat Cornish valve that controls the admission of the steam to the steam-chest. For incandescent lighting in parallel, the wire on bobbins is placed in shunt circuit between the main leads; and the size of wire used is adjusted according to the electromotive force which it is desired to maintain between the mains, so that when the electromotive force is at the right point the cores are suspended within the solenoids by their attraction. Inasmuch as the resistance of the solenoids is fixed, any increase in electromotive force causes an increased current to flow through them, whereby the cores are immediately attracted with an increased force, and are caused to move upwards, thereby acting through the lever to close the valve until the electromotive force has been brought down again to its normal amount. The required movement of the valve is exceedingly small; and this method appears to be the best suited for electric lighting. An automatic expansion-gear, on which the governor might be caused to act, has the disadvantage that, when but few lights are burning, the steam is cut off at so early a period of the stroke that, unless the fly-wheel is exceedingly heavy, a fluctuation occurs in the the light during the revolution of the fly-wheel. In an engine where economy of coal has to be considered probably the best way would be to have an expansion-gear actuated by hand, which can be set approximately to the expansion required leaving the throttle-value to regulate the speed finally. But where perfect steadiness is desired it is probably better not to cut off much before half stroke, especially if a single-cylinder engine is used. The use of accumulators as regulators would of course prevent a great deal of the fluctuation, and would permit of the steam being cut off much earlier without causing any apparent unsteadiness in the light.

The electric governor was fixed on the engine and worked for the first time on January 13 last. The improvement was remarkable, the lights remaining steady, without the sudden alternations of brightness and dulness which had occurred before. But it was still found that with any considerable variation of boiler pressure or of load the electromotive force in the mains varied more than was thought conducive to long life in the lamps. As however it was found that, by augmenting or diminishing the weight suspended from the core bars, the electromotive force could be brought back to its normal amount, it occurred to the author to fix an upright cylinder in direct communication with the boiler, and to make its piston-rod press upwards on the core-bars: the diameter of the cylinder being experimentally determined by observing the weight necessary to be added or removed for certain variations in boiler pressure. This arrangement caused a very great improvement; and when the load was approximately the same it maintained the electromotive force constant under very considerable variation of steam pressure. When, however, the load was varied very considerably, say from one lamp to a hundred, it was found that more variation took place in the electromotive force than was desirable.

The arrangement was accordingly modified by causing the piston-rod to act upon a lever, and by introducing a second cylinder supplied with steam from the steam-chest, the second piston-rod acting not upon the same lever but upon the other side of the fulcrum. The end of the lever was furnished with a steel knife-edge, bearing against another knife-edge set at right angles to it upon the prolongation of the core-bars. The cylinders were also both of them made larger, and were placed so that they could either of them be moved nearer to or further from the fulcrum of the lever, whereby the resultant effect of their differential power could be easily adjusted. This arrangement answered very well indeed, and it was found that the lights could be varied from 1 to 100 and the boiler pressure from 30 lbs. to 60 lbs. with but very slight variation of electromotive force in the mains: provided of course there was sufficient steam to do the work required. It is also quite easy to cause the electromotive force to rise as the load on the engine increases—or in other words as more current passes through the main—by simply giving greater leverage to the piston connected with the steam-chest. In fact with this arrangement the electromotive force can be maintained practically constant, or can be made to vary in any desired manner with variations of steam pressure or of load.

Several experiments were made by Mr. Richardson and the author on the action of this regulator, the results of which were as follows:—When the load on the engine was allowed to remain constant, with only one lamp alight, it was found that while the steam pressure was allowed to vary between 31 lbs. and 55 lbs., the electromotive force remained constant at 90 volts. Afterwards, with the same extent of variation in steam pressure, and with the load also varying from 1 lamp to 91 lamps, the electromotive force varied only 2 volts—from 91 volts to 93 volts. The introduction of this governor has, in the author's opinion, contributed very largely to the duration of the lamps also. The discussion of this paper, which was very full, was mainly upon the governor described and the governing of engines for electric work, the necessity of an electric governor being maintained on the one side, whilst on the other it was held that all that was required was an ordinary mechanical governor of great sensibility.

The Rev. E. Venables, at the conclusion of the discussion, invited electrical engineers to advise the Cathedral authorities, as they should like to see, as a practical result of the visit of the Institution of Mechanical Engineers to Lincoln, the lighting of Lincoln Cathedral by electricity.

A VOLTAIC CELL WITH A SOLID ELECTROLYTE

I BELIEVE that there has never hitherto been made a voltaic cell with a solid electrolyte which was capable of generating the smallest sensible current—at least at ordinary temperatures. Sir William Thomson found that when warm glass was placed between plates of zinc and copper, the existence of an electromotive force was indicated by an electrometer in connection with the metals, and Profs. Ayrton and Perry extended the observation to the cases of paraffin-wax, gutta-percha, indiarubber, and shellac. But it is needless to say that with electrolytes of such enormous resistance no current could be generated of sufficient strength to be detected by any galvanometer, however delicate.

On June 27 I exhibited to the Physical Society a little cell consisting of plates of silver and copper, between which was contained a mixture of 1 part of copper-sulphide with 5 of sulphur. When this cell was connected with a reflecting galvanometer it produced a current by which the spot of light was at once deflected off the scale, copper being the positive pole. The electromotive force was found to be ·07 volt, and the internal resistance 6537 ohms. The current, therefore, though far more than merely sensible, was small. Attempts were made to reduce the internal resistance by diminishing the proportion of sulphur contained in the mixture, but it appeared that as the sulphur was diminished the electromotive force was also diminished, until, when there was no free sulphur at all, the cell failed to produce the smallest measurable current.

It occurred to me that the sulphur owed its efficacy to the fact that it formed a film of silver sulphide upon the surface of the silver plate by direct combination. I therefore made a cell thus:—A thin layer of copper sulphide was spread upon a copper plate and compressed into a compact mass against a surface of polished steel. A layer of silver sulphide was then spread upon the copper sulphide, and the cell was completed by pressing a silver plate upon the silver sulphide. The current which this cell produced through the shunted galvanometer was considerably stronger than that generated by the cell first described; but still the result was not quite satisfactory, and there seemed to be indications of short-circuiting, which I thought might possibly be due to the penetration of particles of copper sulphide through the layer of silver sulphide. The silver plate was therefore removed from the cell, and, having been brushed over with a weak solution of sulphur in bisulphide of carbon, it was heated over a gas flame, and soon became covered with a uniform and continuous coating of sulphide. The heating was continued until all the free sulphur was evaporated. When the cell was reconstructed with this prepared plate it produced a current of 6800 micro-amperes through an external resistance of ·2 ohm, and was able to deflect the pivoted needle of an ordinary coarse galvanometer.

The dimensions of the cell are as follows:—The copper and silver plates measure 2½ inches by 2 inches; the thickness of the two layers of sulphide (strongly compressed) is about 1-20th inch; the E.M.F. is ·053 volt, and the internal resistance is therefore about 7 ohms.

This cell seems to be exactly analogous in its action to a Daniell cell in which plates of copper and zinc are immersed in solutions of copper sulphate and zinc sulphate. Silver is probably the best (or only) possible metal for the positive plate, but some other metal might perhaps be substituted for the copper with advantage.

SHELFORD BIDWELL

FORMOSAN ETHNOLOGY

RECENT political events in the East have directed public attention in Europe, more especially in France, to the large and important island of Formosa. They have shown how scanty our knowledge really is of everything relating to an island which has been known to Europeans for about three centuries, which has been actually held by an European power for twenty years, and in which for about a quarter of a century there have been three ports opened to the trade of the world. Such knowledge as we possess is derived from the works of Dutch writers of the commencement of the seventeenth century, and from fugitive papers published by one or two learned societies in Europe and the East, and especially by journals and magazines in various parts of the Far East, the names of which are hardly known beyond a limited circle of special students, some of them being extinct for years. This paucity of information regarding one of the most important islands in the world, which, moreover, lies in the fair way of a considerable portion of the trade of the world, is not due to lack of inquirers or of zeal, but to physical and ethnological obstacles in the way of research which will appear presently. Such information as could be obtained from the sources here indicated with regard to the ethnology of Formosa has been collected by M. Girard de Rialle, and arranged in two articles contributed to the latest numbers of the *Revue d'Anthropologie* (January and April, 1885). The value of these articles, besides collecting and sifting much scattered information not readily accessible, or accessible at all except in the most comprehensive national libraries, is that they contain a sound working theory on one of the perplexing problems of modern ethnology, viz. the origin of certain little-known tribes inhabiting for the most part the recesses of the chain of mountains running from north to south, but nearer to the east than the west coast of Formosa, and generally known as the Formosan aborigines.

Broadly, the population of Formosa may be divided into three classes—the immigrants from China, aborigines who have submitted to Chinese rule, and the independent tribes. It would be useless to attempt to decide which of the estimates of the number of the population is most likely to be correct, for they vary between ten millions and 300,000 souls. The Chinese immigrants may soon be dismissed. They come mostly from Canton and from the neighbouring province of Fokhien. They include amongst them large numbers of Hakkas, a people who are themselves the subject of an interesting ethnological question, which, however, we cannot discuss here beyond saying that by some students they are regarded as the representatives of pure-blooded Chinese who inhabited portions of the valley of the Yellow River before the dawn of history, while others speak of them as of Malay origin. The division of the aborigines into subjugated and free is obviously of no value for ethnological purposes, although it is convenient in certain cases. Two points which may perplex the discussion of the question can be cleared away at once. The aborigines have undoubtedly been head-hunters, like the Dyaks of Borneo and the Igorrotos of Luzon, but there is no modern authority in support of the charge of cannibalism made against them by Chinese writers, especially by Ma-twan-lin in his "Encyclopædia." M. de Rialle thinks that the allegation might have been correct at an earlier period, inasmuch as the practice is known among the Battaks of Sumatra, as well as in Borneo and the Celebes. But no traces of it have appeared recently in Formosa. Another difficulty has been raised by the statement of the early Dutch writers that there is a pure black race in Formosa, of great stature, inhabiting the mountains and speaking a different language to the rest of the inhabitants. This would apparently refer to Papuans, and M. de Rialle asks whether perhaps here, as in the Philippines, we may not perceive the existence of an old autochtonous race, or at any rate one so ancient that it may well be considered such. There would be nothing surprising in this, for in the Indian Archipelago an ethnic substratum of Papuans and Negritos has been discovered. But the statement has not been confirmed by modern explorers, some of whom have travelled through the island in order to settle the question. Neither the Chinese nor the natives have ever heard of this black race, and it is possible that a very dark tribe in the south were so called by the Dutch. But M. Paul Ibis, in his "Promenades Ethnographiques," thinks that when the Malays invaded Formosa it is not impossible they found a black race there, which they exterminated or absorbed, and other ethnologists have a theory that there was once an epoch of pure Negritos in the island. However this may be, there is now no trace of the tall black race of the Dutch writers of two hundred years ago.

The Chinese divide the aborigines of Formosa into three classes—the *Pepo-hoan*, or "barbarians of the plains," the *Sek-hoan*, or "ripe barbarians," and the *Chin-hoan*, or "green barbarians." The island, as already noticed, is divided into two unequal parts by a lofty range of mountains. On the western side, which is the nearer to China, and consequently that peopled by Chinese immigrants, the country consists for the most part of large and fertile plains. The aborigines were gradually driven back from the coast by the immigration from the mainland, and pressed towards the mountains. In course of time a considerable number submitted peacefully to the Chinese authorities and became civilised, or rather sinicised. These are the Pepo-hoan of the Chinese. They live on the plains and smaller hills bordering on the mountains. Here they form large villages surrounded by rich sub-tropical vegetation. In some places near the Chinese settlements they have adopted the language and habits of the conquerors, but they have preserved their ancient culture. They are fetish-worshippers. One traveller found in one of their houses a stake on which was placed the skull of a deer adorned with garlands of flowers and herbs. This he was told was the female fetish; the male, which was by its side, was simply composed of bamboos interlaced like a cradle. A jar of pure water below appeared to be the only offering made to the divine group at the moment. The women have charge of the fetishes. Dancing appears to be associated amongst them with religious ideas and rites, and from the description of their dances they appear similar to those of the Polynesians and Micronesians. M. Paul Ibis, who was present at one of these *fêtes*, states that young women, when dressed for it, presented the closest resemblance to Tagal women. In spite of the name "barbarians" given them by the Chinese, they are no less civilised than the peasants of the Celestial Empire; they are for the most part devoted to agriculture. In some places they act as intermediaries between the independent tribes and the Chinese, conveying the forest products of the former to the coast and obtaining Chinese goods in exchange. Their great stature has been noticed by all Europeans who have seen them. The hair is dressed amongst the men by being oiled and rolled around the head, and then covered with a large turban of coloured stuff. The women twist their hair into a large mat, interlaced spirally with a red ribbon. This is wound round the head, and appears above the forehead like a kind of natural diadem. The Pepo-Hoan, who have been least influenced by the Chinese, and who have preserved their ancient customs and dress, inhabit districts in the centre of the southern half of Formosa, especially in the valley of the Lakoli River, which, flowing almost due south, enters the sea at the harbour of Tan-Kiang. The Sek-hoan, the second of the Chinese divisions of the aborigines, inhabit part of the centre of the northern half of the island, as the

Pepo-hoan do the southern half. The Sek-hoan settlements are mainly in the neighbourhood of Chang-hua, slightly to the north of the 24th parallel, and in the hilly districts dividing the mountains from the plains in the west. They appear to have fully accepted the Chinese yoke, and even the village headmen are appointed by the Chinese authorities. These tribes are absolutely sedentary, and devote themselves wholly to the cultivation of rice, sugar-cane, and indigo, which they have learnt from the Chinese. They have adopted the dress and habits of their masters; they shave the top of the head and wear long queues. The women also dress like the Chinese, but they do not deform the feet. The type of these Sek-hoan appeared quite distinct from that of other Formosans to two travellers, Mr. Bullock and M. Ibis. The former describes them as tall, but feeble, with a comparatively clear skin, large bright eyes, the mouth extremely large, with thick lips, a projecting upper jaw, and teeth long and prominent. The lower part of the face is as ugly as the upper part is prepossessing. But although they bear little resemblance to the aborigines, they have still less to the Chinese and Loochooans, the only peoples amongst whom we should seek for their origin, if they are of different blood from the other Formosans. M. Ibis states that the Sek-hoan present a contrast to the Malay type in the case of the males, although a resemblance may be found among the females. He attributes their anthropological peculiarities to mixture with the Dutch two and a half centuries ago. He states that there are still old Dutch books and documents amongst them, and that the method of cultivating tobacco (which they call *tamako*, and not by a Chinese name) is similar to that of the Batavian colonies. In the extreme north, around Tamsui and Keelung, there are also groups of Sek-hoan. Driven from the coast by the Chinese, and prevented by the savage tribes in the mountains from penetrating into the interior, these have been almost exterminated. The remnants live in scattered communities among the sandy downs or in the rocky islets off the coast. M. Ibis visited one of their villages on a small island in Keelung Bay, where he found them in great destitution, but bearing evident resemblances to the Sek-hoan further south. He also noticed the Caucasian features, which they got from the connection between their ancestors and the Dutch and Spaniards of the seventeenth century. Around Tamsui the Sek-hoan are rapidly becoming extinct; absorption into the Chinese, and opium, alcohol, and small-pox will soon do their work. Many of their most prominent features are Malay, but the form of the skull is quite different, if we may rely on two specimens brought to Europe in 1868. Dr. Schetelig found the cephalic index of the living males to average 77, of the females 76; but, on the other hand, there were the Malay physiognomy and the language of these Sek-hoan to render difficult their ethnological classification. On his return to London, however, Dr. Schetelig saw the collection of Polynesian and New Zealand skulls in the Museum of the College of Surgeons, and he found amongst these remarkable analogies with the skulls collected by him in the north of Formosa. On the north-east coast, at Suwo Bay and the neighbourhood, there are other subjugated tribes called Kabaran, Sui-hoan, and the like. They are all of the Malay type, and appear to be rapidly disappearing through contact with the Chinese.

The whole mountainous region from the north to the extreme south, forming nearly the eastern half of Formosa, is inhabited by aborigines who have accepted neither the yoke nor civilisation of the Chinese. These are called the *Chin-hoan*, or "green, unripe barbarians," in contradistinction to the *Sek-hoan*, or "ripe barbarians." These live in a state of perpetual war with the Chinese, and it is alleged that the latter brought tigers to Formosa and set them loose in order that they should prey on their enemies; the latter, however, succeeded in exterminating them. They are determined head-hunters, the young warrior commencing his career by securing a certain number of Chinese heads. Under these circumstances it is not surprising that our knowledge of these tribes should be exceedingly limited. A Spanish priest visited some of them in 1875-6, and they have been occasionally visited by Europeans who have touched on the east coast. They are represented as like the Malays, but much fairer in colour than even the Chinese. More, however, is known of the tribes in the extreme south than of those on the east coast or in the mountains. They have been heard of in Europe chiefly by their various murders of shipwrecked seamen.

The various tribes are known as Kalis, Bhotans, Koaluts, &c., and their districts have been frequently visited by European officials desirous of obtaining from them some assurance of better treatment for mariners thrown on their coast. The late Mr. Swinhoe, who visited them for this purpose, states that some of them approached the Mongol type, while in others there was an enormous development of the lower jaw. After new observations he described them as resembling the Tagals of Luzon. In 1874 the massacre of the crew of a Loochooan junk by the tribes led to a powerful Japanese expedition being despatched for their chastisement. The Kalis and Bhotans suffered so severely that their subsequent subjugation by the Chinese was rendered easy, and the Chinese Customs established a station and lighthouse on the south cape. An account of the expedition despatched to arrange this latter enterprise was read before the Royal Geographical Society in January last by Mr. Beazeley, the engineer employed in the work. Soon after the Japanese expedition M. Paul Ibis visited the south of Formosa, and has described nine separate tribes differing in linguistic and anthropological details. He thinks their dialects are connected with the Tagal language; seven of the nine had little physical resemblance to the members of the other two. Several other tribes have been described by other travellers, and in most cases they are marked by important peculiarities. It would be impossible, even if it were likely to serve any useful purpose, to go into details of the habits of each of these. All that is necessary for our present purpose is to note that there certainly are numerous distinct tribes amongst these independent aborigines, and that in describing them various travellers refer constantly to their resemblance to Malays, Igorrotos, Tagals, Soolooans, Dyaks, and other peoples of the Malay Archipelago. The reader will therefore be prepared for M. de Rialle's conclusion that these aborigines belong to the great ethnic family known as Malayo-Polynesian. MM. Quatrefages and Hamy speak of them in the "Crania Ethnica" as "analogous to the Acheenese, Lampongs, and Eastern Sundanis. They are Indonesians, closely allied to Polynesians." But there are ancient mixtures with other anthropological elements. Whether these took place in regions from which the ancient immigrants came, or in Formosa itself, will probably never be known positively. The peopling of Formosa is probably due to successive invasions, doubtless far removed from each other in point of time, by Malayo-Polynesians, and this, M. de Rialle believes, is sufficiently proved by the great differences which, notwithstanding their common anthropological origin, have been observed by travellers amongst the various mountain tribes in the island. Whether a comparative study of the Formosan dialects with those of the Philippines, Borneo, the Celebes and other parts of the Malay Archipelago, will carry the solution of the problem any farther than this remains to be seen; but there appears no immediate prospect of any student being able to study the independent tribes of Formosa. They are as remote from us, for any purpose of accurate investigation, as ever they were, and far more remote than they were from the Dutch and Spaniards nearly three centuries ago.

THE AURORA[1]

II.

We next come to the 11-year period. On this the following pertinent remarks are made:—

"It will be perfectly clear that it is chiefly observations from the Temperate Zone which have constituted the material for demonstrating the eleven-year period But as regards the Polar regions, it has been assumed that either the Aurora Borealis also follows the same laws in these parts, or that it appears with the same force and same manner all the year round. Neither of these alternatives seem, however, to be right, as a series of observations prosecuted with great care during fifteen years at Godthaab, in Greenland, have brought me to the somewhat remarkable conclusion that, as regards the varying frequency of the Aurora Borealis at Godthaab, *the law seems to be the reverse of that ruling in southern latitudes.*

"These researches, which were effected by Mr. S. Kleinschmidt, extend over a period from August 1865 to May 1880. The number of days with auroræ in the year, reckoned from August to May, were:—

1865-66	66-67	67-68	68-69	69-70	70-71	71-72	72-73	73-74
97	112	65	84	45	61	32	47	73

1874-75	75-76	76-77	77-78	78-79	79-80
97	97	104	69	100	75

"This series cannot, however, be accepted as giving the *exact* view of the relation between the varying frequency of the auroræ, because the state of the clouds would exercise a great influence on the visibility of auroræ. If thus the clouds vary greatly from one year to another, this circumstance would greatly reduce the number of auroræ. A closer study of the nebulous conditions at Godthaab, compared with the frequency of the auroræ, has caused me to consider that the number of auroræ decrease in proportion as the clouds increase in quantity. The above-recorded auroral totals must, therefore, be reduced to the same cloud unit, *i.e.* it must be calculated how great the number would have been had the nebulosity been the same every year. By this we obtain the values given under N. Under S. is given the relation between the sun-spots in the same year (July to June).

	1865-66	66-67	67-68	68-69	69-70	70-71	71-72	72-73
N.	86·2	91·3	67·4	80·9	51·7	56·5	32·0	46·0
S.	23·5	6·1	18·3	60·1	107·0	133·5	98·6	89·4

	1873-74	74-75	75-76	76-77	77-78	78-79	79-80
N.	78·4	97·0	95·0	102·0	73·0	85·2	83·3
S.	51·7	32·1	11·6	13·5	6·8	2·2	16·3

"If the two series be compared it will be found that *the law of relation between the frequency of sun-spots and auroræ is reversed.* This fact will be still more apparent from Fig. 4, where both series of auroræ and sun-spots are shown graphically.

"The few series of observations which we possess from other Polar regions, and which I have been able to analyse, indicate, though incomplete, similar conditions.

"As the greater part of the Godthaab observations were made in the morning, I have not only used the auroral days for my researches—reckoned from noon to noon—but also examined evening and morning auroræ separately. The evening and morning auroræ lead, as regards the eleven-year period, to the same conclusion as the auroral days, *i.e.* that *the Aurora Borealis is scarcest under sun-spot maxima.*" . . .

"If we consider the relation between zenith and southern auroræ in the various years of the Godthaab researches, we obtain the interesting result that the percentages of zenith auroræ in the main follow those of the auroral frequencies, *i.e., that at the periods of maxima at Godthaab, the auroræ which fall in the zenith of this place or further north, are not only absolutely, but also relatively, more frequent than at the periods of minima.* And what deduction may be drawn from this? The deduction *that the auroral zone in the course of the eleven-year period makes a movement too, of such a nature that it lies further north when the sun-spots are in their minimum than in their maximum period.*

"If this result be compared with what I have already propounded as to the eleven-year period in the Arctic regions, the interesting explanation will be obtained of the phenomenon, that this period in Greenland and similarly-situated places shows a reverse course to that in more southern regions. *The auroral maximum, occurring in the temperate regions simultaneously with the sun-spot maximum, is due to the auroral zone being then in its southernmost position, which again causes an auroral minimum in the polar regions, and, in a reverse manner, the auroral zone has its northernmost position when the sun-spots are in the minimum, which then causes an auroral minimum in the temperate regions and a maximum one in those around the Pole.*"

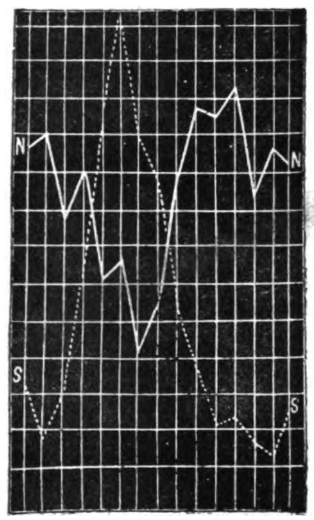

FIG. 4.—Comparison of auroral frequencies at Godthaab with sun-spots. N = Northern light frequencies; S = Spot frequencies.

These very beautiful results will show that there can be very little doubt about the movement of the auroral zone as a whole.

The next point on which much light is thrown by Mr. Tromholt's work is that the various appearances are in the main due to movements bringing auroral striæ in different relation to the spectator:—

"In one respect in particular my sojourn at Koutokæino was very instructive—viz. with regard to the understanding of the true shape and position, and the changes to which the aurora is apparently subjected when altering its elevation above the horizon. Partly through the frequency of the aurora, and partly by its appearance now in the north, now in the south, and now in the zenith, there were excellent opportunities of studying the modifications which the form suffered as it changed its position in relation to the observer.

"From this I came to the conclusion that the great many different forms referred to might certainly be reduced to a few fundamental ones. In most instances the aurora forms belts or zones, which stretch across the earth in the direction of the magnetic east-west, which zones are formed by a conglomeration of thin sheets of luminous matter ranged one behind the other, their direction being

[1] "Under the Rays of the Aurora Borealis." By S. Tromholt. Edited by Carl Siewers. (London: Sampson Low and Co., 1885.) Continued from p. 276.

parallel with the inclination needle. The luminous matter in these sheets is either even, diffuse, or divided into streamers.

"Everything now depends on the position of the observer in relation to such a zone in order that it may appear in one form or the other. If he be very far from the aurora he will see an arc, diffuse or radiating, according to the nature of the luminous matter. If he approaches he will most probably see several distinct arcs, the phenomenon gathering more force and the colours more life; and when still nearer, the aurora will appear as a band, and, if the luminous matter be radiating and passes the magnetic zenith of the observer, he will behold the auroral corona."

He thus holds that a "band" is a near arc occupying a higher position in the sky:—

"The auroral band is oftenest seen in those parts of the globe which are considered to be the true home of the Aurora Borealis, but seldom, or hardly ever, in southern latitudes. What is chiefly characteristic of the band in opposition to the arc, although no sharp line of distinction can be drawn here either, is its great height above the horizon, but at what elevation it ceases to be band and becomes arc is naturally an arbitrary determination. The band, as well as the arc, may consist of equi-luminous matter, of streamers, and of so-called luminous clouds, and it is, to a higher degree than is the case with the arc, subject to the most violent changes of position, form, and motion. Particularly when the band consists of streamers it displays the richest variations and greatest beauty, the folds of the streaming drapery, the prismatic play of colour, and the light-waves, which with marvellous rapidity course through the graceful undulating rays, forming a spectacle of light, colour, and form which makes this variety of the Aurora Borealis the most charming of all.

FIG. 5.—Phases of an auroral arc, December 1, 1878.

"The perspective fundamental form of the arc, and also the band, may, in my opinion, be explained by the aurora forming one or several rings, or fragments of such, which, with the magnetic pole as centre, or, more correctly, with a point in the magnetic axis of the earth—viz. the straight line between the two magnetic poles—lie at a certain height above the earth's surface. On account of the great circumference of the earth, in proportion to the height of the aurora, only a small portion of such a ring would be visible at one time, and each observer only see his own portion, the situation of which in relation to *his* horizon and the zenith will depend on *his* position in relation to the auroral ring."

The auroral streamers are closely associated both with arcs and bands, an arc or band composed of streamers often forming the basis for a colonnade of streamers.

Before we proceed to the consideration of the corona, the following extracts concerning streamers and their apparent motions will be read with interest:—

"The streamers embrace a number of varieties, which have only one peculiarity in common—viz. that the direction is very nearly vertical, and that the length is always greater than the width. The length differs greatly, from 2° and 3° to 30° and 40° or more. The width is very difficult to estimate, on account of the constant motion; a single streamer thus may form only a slender thread of light, while others may have a width of from 10′ to 1°, or more. Short streamers form often, as I have mentioned above, bands or arcs. The long streamers gather generally in bunches, which may either remain isolated, or particularly when the aurora has previously formed an arc, stand parallel, in such a manner that the lower, intensest, ends nearly follow the track of the former arc. Bunches of streamers, standing high in the sky, are often fan-shaped, the broadest part pointing downwards. The intensest streamers have very clearly defined edges, but from these there are all sorts of variations down to the streak of light hardly visible. At the side of, and between very intense and defined streamers, the sky seems, by the contrast, unusually dark, and this may, perhaps, explain the *black* streamers which some observers claim to have seen.

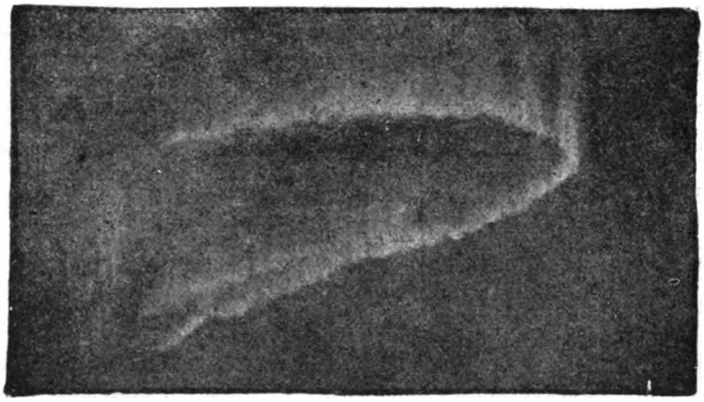

FIG. 6.—Aurora (Koutokæino).

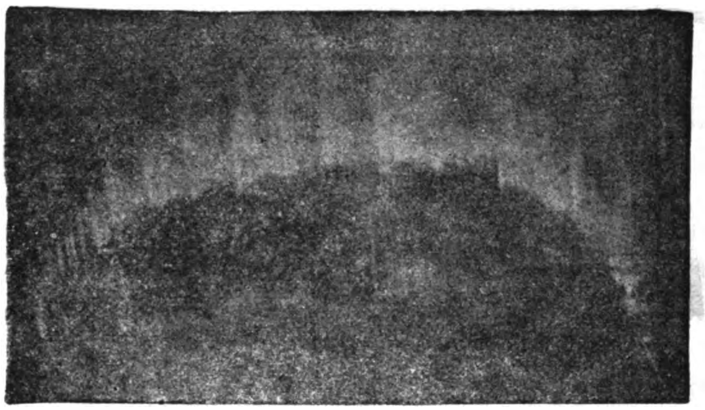

FIG. 7.—Streamers (Koutokæino).

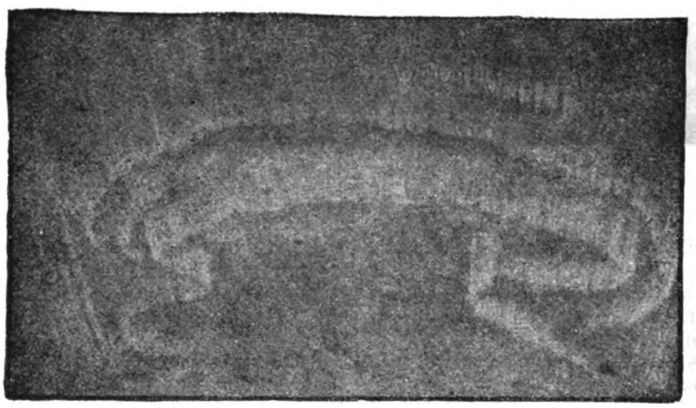

FIG. 8.—Bands and streamers (Koutokæino).

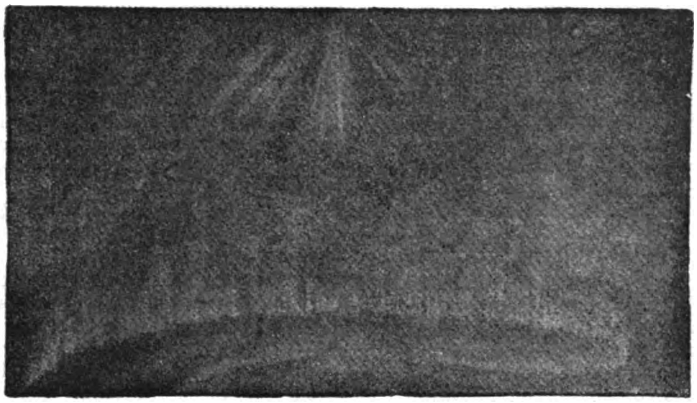
"The points of the streamers are usually faint and with no sharp line of demarcation. The stars shine through the streamers as through all other forms of the aurora, and it may, indeed, be a matter of doubt whether the strength of light of the aurora is ever great enough to outshine a bright star." . . .

"The motion of the streamers is twofold. First, longitudinally, as they strike upwards or downwards; and secondly, laterally, as they travel parallel either to the left or right. Sometimes this motion is slow, sometimes very quick, and particularly in the latter case the observer obtains the impression that the colonnade of streamers is furrowed transversely by waves of energy following in rapid succession, under the influence of which the streamers momentarily flare up. If this be the case, or the streamers really move, it is impossible to tell.

"The longitudinal course of the streamers is not apparently only, but in reality, very nearly vertical, as several facts prove that they point in the same direction as the magnetic inclination needle." . . . "In regions near the magnetic pole, where the magnetic inclination is greater, the streamers stand more perpendicularly than in more southern latitudes, where they form a smaller angle with the surface of the earth.

"Some students, as, for instance, Baron Nordenskjöld, have advanced the theory that the streamers do not occupy this position, but lie more parallel with the earth; and, indeed, when observing an apparently perpendicular streamer in the north, it may in reality form any angle with the horizon, and still seem to the eye to stand perpendicular. But from various circumstances it is clear that the direction of the streamers is, as I have stated above—viz. parallel with the inclination needle. This is, in fact, demonstrated not only by the streamers high in the sky, which form the upper part of the corona, but also by those which, under intense auroræ, stand either in the east or west, and which are then seen '*from the side*,' so to speak, *i.e.* they stand very nearly perpendicularly, as indicated to all appearances by the streamers seen to the north '*in front*.'"

The auroral *corona*, the grandest sight of all, is found at the instant a band or broken band forming a colonnade



A

B

Fig. 9.—Coronas (Koutokæino).

of streamers reaches the magnetic zenith in its progress from the north:—

"Quick as lightning streamers break forth at the same moment on the southern side of the magnetic zenith, and as the aurora travels further and further southwards, the corona becomes more and more complete. In northern regions, where the aurora frequently appears high in the sky, in a northerly or southerly direction, there is often an opportunity of seeing this form of the phenomenon, when a band of streamers passes the magnetic zenith in its course north or southwards. It is, however, not always that the aurora's passing of the zenith has the effect of producing the corona; it is seldom the case when a band constituted of diffuse luminous matter passes this point. It is, in fact, the streamers which create the corona." . . .

"If it be borne in mind that the course of the auroral streamers is identical with that of the magnetic inclination needle, it is easy to perceive the origin of the ordinary radiating aurora as well as the corona." . . .

"This form of the Aurora Borealis, which generally indicates, at all events in southern latitudes, the culmination of the aurora as regards splendour, colour, and development, is produced by the streamers shooting from every part of the sky towards a common point—viz. the magnetic zenith. With this point as centre they seem to radiate in every direction; some are very long, others short, while some form rays or bands one above the other. The heaven thereby assumes the appearance of a huge cupola, or tent of fire. In reality the streamers are all parallel; their appearance of radiating in all directions from a central point with various angles being due to perspective causes—viz. by the points of the streamers being further distant than the bases. It is the same perspective peculiarity which causes the lamps in a street or the trees in an avenue to appear to meet in the distance.

"The centre of the corona is sometimes dark—that is to say, the sky is seen between the streamers, at other times the central part is filled with luminous matter.

"It is not only the streamers which contribute to form the corona; on the contrary, all the forms of the aurora lend their beauty to produce this magnificent display. If to this is added that the Aurora Borealis in such moments develops its greatest strength, richest colour, and most intense light, it will be understood that the corona is that form of the phenomenon which possesses the greatest magnificence and most striking beauty."

With regard to the height of the aurora, a preliminary examination of the observations made in the plane Koutokæino-Bossekop gives from 50 to 100 miles, an average of 18 measurements giving 70·2 miles or 113 kilometres.

From this long article on auroræ, the reader must not think that our author is exclusively occupied with them. His two volumes are admirable examples of what books of travel should be, and it falls to the lot of few travellers to have such an interesting region to explore, or to have such an important piece of scientific work to accomplish.

THE BRITISH ASSOCIATION

OUR readers are aware that at the approaching meeting of the British Association it has been arranged to have discussions in Section A on kinetic theories of gases and on standards of white light. Prof. Crum Brown has consented to open the discussion on the kinetic theories, and has drawn up the following short abstract of points to which he proposes to allude. It would be convenient if persons desiring to take part in the discussion would forward their names, with, if possible, a short abstract, to the recorder, Prof. W. M. Hicks, Firth College, Sheffield.

Difficulties connected with the Dynamical Theory of Gases.—Prof. Crum Brown.

The Dynamical Theory of Gases appears at first sight to furnish a very complete explanation of all the properties of gases, both physical and chemical. When, however, we come to details, difficulties and apparent contradictions make their appearance. These difficulties have been pointed out from time to time, and some attempts have been made to show that they are not really fatal to the theory as usually stated; but it may be useful that some of them should be brought at this time before the section and regularly discussed.

I shall here merely mention some of these difficulties, as the explanations which have been given of them will be better supplied by others in the discussion.

1. *The difficulties connected with the doctrine, that energy communicated from without to a gas is equally shared among the whole of the degrees of freedom of the molecules.* This leads to a relation between the numbers of degrees of freedom and the ratio of the specific heat at constant pressure to that at constant volume. This ratio is for mercury gas almost exactly 5:3, from which it would appear that the molecules of mercury gas have not more than three degrees of freedom—in other words, that the whole energy of mercury gas is kinetic energy of translation of the molecules. But even if we assume that the molecules of mercury are spheres, perfectly smooth and perfectly rigid, the fact that mercury vapour has a spectrum points to some form of energy of a vibratory kind. Again, the gases, the molecules of which are supposed to consist of two atoms, have the ratio of the specific heats nearly equal to 7:5 (it seems always to be a little greater than this, which increases the difficulty). This points to five degrees of freedom of the molecule, which would be consistent with the hypothesis that these molecules consist of two smooth, undeformable spheres at a constant distance from each other, the five degrees of freedom being three of translation and two of rotation about two axes, any two at right angles to each other and at right angles to the axis of the molecule, that is, the line joining the centres of the two atoms. But here also we have spectra, and in addition the phenomena of dissociation lead to a belief that the firmness of the union of the two atoms diminishes as temperature rises, and it is difficult to reconcile this with a constant distance of the two atoms from one another in the molecule. Any variation in this distance would be a new degree of freedom in addition to the five allowed by the theory.

All attempts to reconcile chemical action and chemical equilibrium with dynamical conceptions seem to require the assumption of vibrations of the atoms in the molecule, under the influence of forces depending on the distances of the atoms from each other, and perhaps in addition to these, vibrations of the atoms as parts of the molecule, vibrations of the atoms themselves. In molecules, even of a comparatively simple kind, such considerations imply many degrees of freedom, certainly far more than the dynamical theory of gases as usually understood will admit.

2. *Difficulties connected with the doctrine that energy of each kind is distributed among the molecules according to some form of the law of probability.*

This implies that in a gas at any temperature there are molecules in the condition as to energy which is the average condition of the gas at any other temperature. That, for instance, at the ordinary atmospheric temperature there are molecules in the condition which is the average condition at a red heat.

This seems inconsistent with what is usually regarded as true, viz., that there are limiting conditions of temperature and pressures, on the one side of which certain chemical changes occur, while they do not occur at all on the other side. Thus at ordinary atmospheric temperatures and pressures, hydrogen and oxygen show no tendency to combine. At a red heat they combine almost completely. At ordinary temperatures phosphorus combines slowly with oxygen if the pressure of the oxygen is below a certain limit (dependent on the temperature), but apparently not at all if the pressure of the oxygen is above that limit. Many other cases might be mentioned, but these may suffice as instances. It is difficult to understand the existence of such definite sharp limits, if the energy is distributed among the molecules according to any asymptolic law. In such a case the rate of chemical action might be expected to diminish, but not to become zero.

I have brought forward these instances of apparent contradiction between the conclusions of the dynamical theory as usually stated, and observed facts in the hope that they may be cleared up. This may conceivably be done in two ways—either by showing that the facts have not been accurately observed, or that the conclusions have not been legitimately drawn from the theory.

NOTES

THE Iron and Steel Institute holds its summer meeting in Glasgow on September 1-5. The programme includes excursions down the Clyde and a visit to the Forth Bridge Works. The following is the list of papers down for reading:—On the iron trade of Scotland, by Mr. F. J. Rowan, Glasgow; on the rise and progress of the Scotch steel trade, by Mr. James Riley, Glasgow, Member of Council; on the present position and prospects of processes for the recovery of tar and ammonia from blast furnaces, by Mr. Wm. Jones, Langloan Ironworks, N.B.; on the structural features and working of the South Chicago blast furnaces, by Mr, F. W. Gordon, Philadelphia, and Mr.

E. C. Potter, Chicago, U.S.A.; on certain accessory products of the blast furnace, by Mr. T. Blair, Wingerworth Ironworks, Derbyshire; on a new form of cupola furnace, by Mr. James Riley, Glasgow; on a new form of pyrometer, by Mr. A. von Bergen, Middleton Ironworks, Darlington; on the ancient and modern methods of manufacturing tin-plates, by Mr. Philip W. Flower, Melyn Tinworks, Neath; on the manufacture of basic steel on the open hearth, by M. Pourcei, Bilbao, Spain; on the Forth Bridge, by Mr. Benjamin Baker, M.I.C.F., London.

THE International Telegraph Conference was opened at Berlin on Monday by Dr. Stephan, German Postmaster-General. No fewer than 33 States and 17 telegraph companies are represented, and about 72 delegates had already assembled to day. Dr. Stephan opened the sitting with an address, in which, in the name of the German Emperor, he bade the delegates welcome, and made some general observations on the rapid development of telegraphic science and communication, as well as on the desirability of placing the advantages of this science still more within the reach of all classes. On the motion of the English delegate, Mr. Patey, Dr. Stephan was elected President of the Conference, which then proceeded to appoint two committees—one for the consideration of tariff questions, the other for matters of technical administration. Dr. Stephan then thanked the Swiss Government for presiding so successfully over the International Telegraph Bureau (of Berne), and the British Government for duties it had undertaken since the last Conference at London (1875). He also adverted to the memory of several deceased members of that Conference, including Sir William Siemens.

AMONG those on whom the degree of LL.D. was conferred at the recent Graduation ceremonial of Edinburgh University are Prof. John Anderson, M.D., F.R.S., Superintendent of the Imperial Indian Museum of Calcutta, Professor of Comparative Anatomy in the Medical College of Calcutta, Fellow of Calcutta University; Dr. Johann Georg Bühler, Ph.D., C.I.E., Professor of Sanskrit in Vienna University; and M. Antoine d'Abbadie, Member of the Institute of France, well known for his writings in geology, astronomy, and Oriental matters.

ON any Tuesday, Thursday, or Saturday, until the end of September, persons of archæological tastes may visit the rooms of the Royal Archæological Institute, Oxford Mansions, near Regent Circus, to see the large and most interesting collection of antiquities which Mr. W. M. Flinders Petrie, working under the auspices of the Egypt Exploration Fund, has discovered at the Nebireh Mound, which is now established to be the site of the famous Greek City of Naucratis, and the cradle of Greek art. The thorough exploration has resulted in laying bare what was the earliest Greek settlement in Egypt, and in bringing to light archæological treasures beyond price. Innumerable objects of purely Greek art, statuettes, terra-cotta figures, painted vases, votive offerings, bronzes, sculptures have been found, together with an immense quantity of pottery in considerable variety. Naucratis was a city of potters, and Athenæus states that her ceramic productions were in great vogue around the shores of the Mediterranean. In the mound which covered the city potsherds were found in well-defined layers of different centuries, susceptible of exact classification, and as such forming an interesting chapter in the history of Greek art. The collection is particularly rich in the archaic variety of white faïence pottery, of which, prior to Mr. Petrie's labours, only three or four pieces were known to exist. He found bowls by the hundred. The connection of Greek pottery with that of Egypt is shown at every step, showing how the one descended by gradual steps from the other. The scarabœi, amulets, pictorial ornaments, deities, tiles, and other articles found in early Greek tombs all around the Mediterranean have been found amid the ruins of Naucratis in the very workshops where they were produced. The sites of several factories were brought to light, each containing many samples of their products. One of these was a Greek manufactory of scarabs for exportation, full of such blunders as foreigners would make in the hieroglyphs. In another part of the city what had evidently been a flourishing iron manufactory was unearthed, where every stage of production was carried on by Greek workmen, for ore, slag, and finished tools have all been found. The tools are principally chisels for working in wood, but there were also an axe, a hoe, a sickle, knives of various kinds, bodkins, and, what is a total novelty in archæological discoveries of this kind, fishhooks. There is satisfactory proof forthcoming that this scene of early Greek iron-working was in full vigour in the sixth century before Christ.

AT the monthly meeting of the Entomological Society of London, held on August 5, J. W. Dunning announced that a Royal Charter of Incorporation had been granted to the Society. It bears date July 20, 1885. The Ethnological Society was founded in 1833.

WE are glad to know that there is now a chance that the teaching of geography, which has been one of the blots of our ordinary English education from the many colleges downwards, will be put upon a proper scientific basis. At present it is usually made a task for the memory rather than an instrument of education. Messrs. Macmillan, in announcing a new series of Geographical Text Books, have the courage to state that "the first principles of geography, however, cannot be effectively taught from books. They must be enforced practically from familiar local illustrations." In a preliminary volume, therefore, the teacher is taught how to lay a solid geographical basis, founded upon the pupil's own personal experience. Throughout the series the fundamental idea will be to present the essential facts in such a way as will show their relationship to each other. The physical features will be connected with the climatology of a country, and both will be shown to affect the distribution of life, while the bearing of all these influences upon human history and commercial progress will be constantly kept in view. The boundaries of parishes and countries, the positions of towns and the diffusion of population, will be linked with their geographical explanation. A knowledge of the topography of a country, and of the local names by which it is expressed, will be shown to be the necessary accompaniment of an adequate knowledge of the history of the inhabitants. In short, it should be a constant aim to represent geography not as a series of numerical tables or a string of disconnected facts, but as a luminous description of the earth and its inhabitants, and of the causes that regulate the contrasts of scenery, climate, and life. Messrs. Macmillan have placed the editorship of the series in the hands of Mr. Archibald Geikie, F.R.S., Director-General of the Geological Survey of the United Kingdom, and have already secured the co-operation of Mr. H. W. Bates, F.R.S., Mr. Clements R. Markham, C.B., F.R.S., Mr. John Murray, Ph.D., F.R.S.E., Mr. E. B. Tylor, D.C.L., F.R.S., Mr. A. R. Wallace, LL.D., F.R.G.S., Rev. Edmond Warre, D.D., Head Master of Eton, Rev. J. E. C. Welldon, M.A., Head Master of Harrow, and others.

IT has been decided to withhold from publication the Report of Drs. Klein and Gibbes upon Dr. Koch's discoveries in relation to the germ theory of cholera, until the conclusions of a committee appointed by the Secretary of State for India with reference to that Report are also ready.

WE have received from Mr. Lawton, of Hull, a communication with regard to preventing collisions with icebergs. He has had frequent opportunity of noting the phenomena of echoes by means of steam-whistles, guns, fireworks, &c., and has received distinct echoes from various surfaces, some of which were not very promising. The sails of vessels and an approaching tug-boat, referred to by Prof. Graham Bell, are additional sources of sound-reflection, but Mr. Lawton thinks that the echo in the case of the latter must have come from some other surface than the bows of the boat, which, unless very bluff or square, would have a tendency to reflect the sound at right angles. If it be true that in Atlantic voyages the sound of the steam-whistle is echoed back by the fog itself, then, Mr. Lawton thinks, the echo from an iceberg enveloped in the fog would be much sharper, more abrupt, and easily distinguished from that returned by the fog, which, from its varying density and elasticity, would more resemble a prolonged rumble. The importance of this subject, the number of lives and amount of property at stake would point to the importance of having every reasonable theory tested by those most interested—viz. shipping companies, captains of steamers and sailing vessels crossing the Atlantic and those going to Australian and New Zealand by the Cape. In the present case this can be very easily done by means of the steam-whistle, ship's bell, guns, &c., in broad daylight near an iceberg; the circumstances, such as its size, bearing, and distance, the direction and force of the wind; and then it should be noted whether an echo is perceptible or not. Mr. Lawton appears to have gone to some trouble in bringing the subject to the notice of shipping companies concerned, and of describing the method of carrying out the few simple experiments needed to demonstrate the value of his theory, but adequate attention does not appear to have been given to his suggestions. We give them in a brief form here, in the hope that they may be fairly tested in the presence of an iceberg in daylight in such a manner as to enable shipmasters to estimate the practicability of the theory. He found that, during artillery practice near Hull, the opposite Lincolnshire coast, two miles off, returned echoes. There are no objects of greater height than a few cottages there, and it occurred to him the phenomenon of echoes might be utilised by vessels in iceberg regions with more safety than the temperature test, especially if the wind and current be from the ship towards the berg. Most icebergs will present numerous reflecting surfaces at right angles to any passing ship, and it is anticipated that these surfaces would echo a short but full blast of the steam-whistle at a sufficient distance, say one or two miles, for the ship's course to be slightly altered in case the berg was right ahead. If such a blast is blown in daylight in the presence of a berg for purposes of experiment, the distance and bearing of the berg, and the force and direction of the wind should be noted. If at the time a high sea or swell prevailed, the whistle should be blown when the ship is on the crest of the wave. As fog is a better conductor of sound than dry air, it is when an iceberg is enveloped in fog, as is often the case on the banks of Newfoundland, that Mr. Lawton's theory, if true, would be of any value, as it could not only indicate the distance of the berg approximately, but also its bearing from the ship.

THE Sadlers' Company have established four studentships, each of the annual value of 30*l*., and tenable for two years, at the Finsbury Technical College of the City and Guilds of London Institute. The studentships will be competed for at the entrance examination, to be held at the college on October 1, and are open to pupils above fourteen years of age who are attending or who have attended any public elementary school in the United Kingdom. The Court of the Salters' Company has agreed to raise their annual subscription to the Technical Institute from 525*l*. to 1000*l*.

DR. TRIMEN, director of the Royal Botanical Gardens of Ceylon, has just published a systematic catalogue of the flowering plants and ferns indigenous to or growing in Ceylon. The list gives the botanical, Singhalese, and Tamil names, and is a complete index to Thwaites's "Enumeratio Plantarum Zeylaniæ," but it differs from the latter work in the sequence of the families or natural orders. In addition to the flowering plants and ferns, Dr. Trimen has added five natural orders—viz. Rhizocarpeæ, Lycopodiaceæ, Isoeteæ, Selaginellaceæ, and Characeæ. The catalogue includes 156 natural orders, 1071 genera, and 3249 regular species, with 408 varieties, some of which may prove to be distinct species. The catalogue is issued as a number of the *Journal* of the Ceylon Branch of the Royal Asiatic Society.

THE weather in Southern Norway in June has been very remarkable, and we must go back to the year 1869 to find anything similar. The weather, early in the month, was very cold, the average being only 56°·5 F., while on the 11th the temperature fell to 35°·8 F., a temperature which has not before been registered in Christiania in June, at all events not since 1867. Towards the end of the month the temperature in Christiania was abnormally high, reaching, on the 28th, 79°·3 F. in the shade. The rainfall was only half of the normal quantity. As well in May as June, the weather was below the average for the whole country. At Röraas the temperature fell on June 2 to 26°·6. The information received of the weather in the north of Norway to the middle of July shows that the weather had till then been very cold, the highest temperature being only 44°·6 to 46°·8 F. in the day and below freezing-point at night. It is popularly supposed that this is due to the enormous ice masses which have this summer descended from the Polar regions on the American side right into the Gulf Stream, which has thereby become greatly cooled, a circumstance immensely influencing the weather in Norway. Seal-hunters returning to Tromsö from the White Sea and adjacent waters report that large masses of drift-ice are in motion towards the Norwegian shores; but there are as yet no reliable news from the Spitzbergen seas. On the other hand, we learn from captains who have returned from seal hunting on the east coast of Greenland and the sea north of Iceland that hardly any were caught, owing to the enormous ice-masses which are descending along the east coast of Greenland this summer, greatly in excess of previous years. It may be remembered that last year the reverse was the case here. Lieutenant Holm, who has been wintering on the east coast, reported that the sea was very free from ice even at the troublesome glacial promontory of Tuisortok, which has only once before been passed by Europeans, viz., Graah. It seems indeed that abnormal conditions prevail this summer throughout the Polar seas, and it will be of interest to learn what the state of the ice actually is north and north-east of Spitzbergen.

A VERY interesting exhibit at the Inventions Exhibition is that of "Brin Frères" for the illustration of their method of extracting oxygen and nitrogen from atmospheric air by the agency of barium oxide and peroxide. A description of the process is given in a small pamphlet, but the English requires a little correction in places to be clearly understandable. The process of oxygen extraction by means of baryta is now very old, but has never yet been made real practical use of, the baryta becoming inactive after some time. This is no doubt due to the absorption of carbonic acid by the baryta from the air. In this process air freed from carbonic acid and water by caustic soda is passed over barium oxide heated in iron retorts to a temperature not exceeding 600° C. The temperature is regulated by a pyrometer which regulates at the same time the supply of gas to the furnace. Under these conditions the oxygen of the air is absorbed by the baryta, peroxide of barium being formed. The nitrogen, which appears to be very pure, is collected separately for use in the production of ammonia. On heating the peroxide of barium to full redness pure oxygen is given off. At this stage of the process the retorts are evacuated by a powerful pump, so that the operation takes place in a vacuum or nearly so. The operations are continuous, and as long as the baryta is kept anhydrous and free from carbonic acid the same quantity will apparently last an indefinite time. The most interesting and perhaps the most useful part of this invention, or application, is the production of ammonia by a very direct process. The nitrogen obtained as above is passed over a mixture of baryta with carbon—charcoal—heated to some unknown temperature, about 300° C., certainly not higher. It is necessary, however, that the nitrogen be moist, a condition which is attained by passing it through water before it comes in contact with the mixture of baryta and charcoal. The product is really a carbonate of ammonia and not free ammonia, the water becoming decomposed under the conditions named, its hydrogen combining with the nitrogen and its oxygen forming carbonic acid. The ammonium compound seems to be formed in considerable amount, and the process should, when carried out on a large scale, be a valuable one.

A USEFUL summary of anthropological work accomplished during the year 1884 has just been issued by Prof. O. T. Mason, curator of the ethnological department, National Museum, Washington. Besides a copious bibliography of the subject, special notices and even extracts are given of the more important papers on ethnology, archæology, and other branches of anthropology that have appeared in the scientific periodicals of Europe and America. Thus detailed reference is made to the work of the British Association Anthropometrical Committee; to Prof. W. H. Flower's paper in the *Journal* of the Anthropological Institute on the size of the teeth as a racial characteristic; to Prof. A. H. Keane's ethnology of Egyptian Sudan, contributed to NATURE; to E. F. im Thurn's articles in *Timheri* on the natives of British Guiana; to Dr. Charles Rau's paper on "Prehistoric Fishing," in vol. xxv. of the Smithsonian Contributions to Knowledge; and to A. Chavero's great work on "Mexico à traves los Siglos," the first volume of which is completed, bringing the subject down to the arrival of the Spaniards. It is satisfactory to notice that the Philadelphia Academy of Sciences has created a chair of ethnology and archæology, to which Dr. Daniel G. Brinton has been appointed. The field of anthropology is now so extensively cultivated in the Old and New World that annual summaries of this sort have become indispensable.

THE Swedish Professor Warming has proceeded to Finmarken in order to study the Arctic flora on the Norwegian coast.

ON July 20 and 21 two terrible cyclones passed over the central part of Sweden, followed by rain and lightning. In several places hundreds of old trees were uprooted, and a clear road made in forests upwards of fifty yards wide. In one place a large wooden snowplough lying by the road was smashed to atoms. Fortunately no one was injured.

AT the University examination just concluded in Copenhagen there were seven lady candidates, all of whom passed, four gaining *precæteris*, two *laudabilis*, and one *haud illaudabilis*. Five of these ladies took the mathematics and natural science degrees, and only two the philological.

DURING the last two years several Celtic tumuli in the district of Geinberg, in Upper Austria, have been opened and found to contain valuable relics of prehistoric times. A few days ago a similar tumulus was discovered near Mattighofen, in the same neighbourhood, and among its contents was found a diadem of pure gold, richly carved in the well-known style of old Celtic art.

MR. DAVID DOUGLAS, of Edinburgh, has issued a new edition of the late Charles St. John's "Tour in Sutherlandshire," a fitting companion to the author's well-known "Wild Sports and Natural History of the Highlands." There is an interesting sketch of the author's life by his son, and a long appendix on the fauna of Sutherlandshire, by Mr. J. A. Harvie-Brown and Mr. S. E. Buckley.

MESSRS. CASSELL & CO. have issued the second part of vol. iv. of their "Encyclopædic Dictionary," extending from "Interlink" to "Melyris." As there is no editor's name on the title-page, we presume that Mr. Robert Hunter, who devised the work, and edited the early parts, is not now connected with it. A work of such minuteness as this ought to have had "Laramie" as a well-known geological term.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Mr. S. G. Coles; a Persian Gazelle (*Gazella subgutterosa* ♂) from Persia, presented by Mr. John Stanley Cater; two Madagascar Porphyrios (*Porphyrio madagascariensis*) from the Gold Coast, West Africa, presented by Mr. E. North Newenham; a Cockateel (*Calopsitta novæ-hollandiæ*) from Australia, presented by Mr. J. Ward; four Martinican Doves (*Zenaida martinicana*), a Moustache Ground Dove (*Geotrygon mystacea*), five Dominican Kestrels (*Tinnunculus dominicensis*), a Violaceus Night Heron (*Nycticorax violaceus*), two —— Colins (*Ortyx* —— ♂ ♂) from St. Kitt's, West Indies, presented by Dr. A. Boon, M.R.C.S.; a Common Viper (*Vipera berus*), British, presented by Mr. C. Smallman; a Ring-tailed Coati (*Nasua rufa*) from South America, a Golden-crowned Conure (*Conurus aureus*) from South-East Brazil, a Greater Sulphur-crested Cockatoo (*Cacatua galerita*) from Australia, deposited.

OUR ASTRONOMICAL COLUMN

OCCULTATIONS OF VESTA.—The minor planet Vesta will be twice occulted by the moon during the next autumn, and though observation of such a phenomenon is more a matter of curiosity than of astronomical utility, we may note the circumstances of each case. The first occultation will take place on October 27; the planet disappears before the moon is above the horizon at Greenwich and reappears at 7h. 50m. at 204°, less than ten minutes after the moon has risen. The second occultation occurs on November 23, the disappearance at 9h. 25m. on an angle of 28°, the reappearance at 9h. 46m. at 347° from north point, reckoning the angles as in the *Nautical Almanac*. At this time Vesta is near aphelion, and therefore will not be brighter than a star of the seventh magnitude.

ANTHELM'S NOVA OF 1670.—Mr. G. Knott has lately had under observation the small star situated close to the position of the star in Vulpecula discovered by Anthelm in June 1670; the star is No. 1814 of the Greenwich Catalogue for 1872. From comparisons made between July 10 and 20, Mr. Knott found it about 10¾ or 11 mag., and equal to a star following it 12 seconds, and 4'·5 to the north. It was estimated of the same brightness in August 1872, but a magnitude brighter in April 1852. In 1861, when it was 12m., Mr. Baxendell remarked that "no adjustment of the focus would bring the star up to a sharp point on the night of June 1," and a week earlier Mr. Hind had noticed "a hazy ill-defined appearance about it, which is not perceptible in other stars in the same field of view."

A rigorous reduction of Picard's observations of Anthelm's star, which are printed in Lemonnier's "Histoire Céleste," gives its place for 1670·0—

R.A. 19h. 34m. 5·33s. ... Decl. + 26° 31' 41"·5,

the right ascension being the more uncertain element and liable to an error of quite two seconds. Bringing this place up to the beginning of 1872·0 we have—

R.A. 19h. 42m. 21·60s. ... Decl. + 26° 59' 45"·4,

which differs − 3·81s. in right ascension and − 33"·1 in declination from the Greenwich catalogued position.

In the *Journal des Savans*, 1671, the new star is said to have followed β Cygni on the meridian by 16m. 44s., which would give its right ascension in precise agreement with the Greenwich observations of the small star No. 1814.

THE CINCINNATI OBSERVATORY.—The eighth part of the publications of this Observatory has been circulated, and contains the observations of comets made in the year 1883. It is noteworthy as presenting a pretty complete report on the phenomena of Pons' periodical comet of 1812 at its reappearance: the features of the tail were particularly studied, and the discussion of the observations, based upon the theory of Dr. Bredichin, has been found to add confirmation to that theory; they are best satisfied with a value of $1 - \mu$, a little less than 2·5, corresponding to his second type; and this value nearly accords with that inferred by Dr. Bredichin himself in his memoir, "Les syndynames et les synchrones de la comète Pons-Brooks (1883-84)," from a large number of observations by different observers. Thirteen plates form part of this publication, affording highly interesting details on the physical aspect of the comet from October 30, 1883, to January 26, 1884. The drawings were partly made with the 11-inch refractor, and partly with the finder of 2½ inches aperture, and an opera glass. On January 13 the comet was equal in brightness to α Pegasi.

The Cincinnati Observatory is now under the direction of Mr. J. G. Porter. The observations contained in the publication last issued were made by Mr. H. C. Wilson while in temporary charge.

TEMPEL'S COMET, 1867 II.—Dr. Schur searched for this comet unsuccessfully with the great refractor at Strassburg on many evenings in March and April: M. Gautier's calculations showed that the chance of observing the comet at this return to perihelion was but small. The next return, in the spring of 1892, will take place under much more advantageous conditions.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, *AUGUST* 16–22

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on August 16

Sun rises, 4h. 49m.; souths, 12h. 4m. 1·0s.; sets, 19h. 19m.; decl. on meridian, 13° 37′ N.: Sidereal Time at Sunset, 17h. 1m.

Moon (at First Quarter on August 17) rises, 12h. 3m.; souths, 17h. 10m.; sets, 22h. 10m.; decl. on meridian, 12° 21′ S.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′

GEOGRAPHICAL NOTES

THE Dutch journals contain an account of the Dutch scientific expedition, in March and April last, to examine the upper course of the Surinam River. The members are well satisfied with the result. Their success was due in great part to the rainy season not setting in till towards the end of the journey. They were thus enabled to examine the rocks along the course, which in periods of high water are hidden from view. Their first station was Phaedra on the left bank of the Surinam; the next the Tafra Rocks which lie in the middle of the stream. Here they were forced to leave their steamer and continue in a fishing-boat. At Bergendal they took the height of the neighbouring Blue Mountain, which they ascended, and from which they had a view of the various mountain chains of Surinam. In general the mountains of this region are covered with trees, but the Blue Mountain is quite bare. Near the mouth of the Sara creek the travellers first met some villages of the bush negroes. At Toledo, a negro village, they came to the end of their forward journey. On the return they visited gold fields near Broko Pondo, where they made themselves acquainted with the native methods of washing the gold. From a geological point of view the expedition was fortunate; but the rapid travelling and short stoppages prevented much being done by the zoologist. Professor Martin has made a collection of the rocks in various parts of the Surinam.

WRITING from Ciudad-Bolivar in May, M. Chaffanjon continues his report to the Paris Grographical Society (the first party which we have already referred to) on his exploration of the Orinoco. Since the date of his last letter he made a journey with two Indians of the Arigua tribe up the Caura River to its source. He passed freely through the territory of various tribes, such as the Arebatos, Panares, and others who are notorious for their cruelty, and he obtained from their chiefs a mass of curious information respecting their manners and religious beliefs. In an endeavour to obtained a complete skeleton, he was surprised by a band of Indians, who attacked himself and his followers. He escaped with great difficulty, and accompanied only by one of his guides reached the Caura, and continued his journey, in which he was much impeded by the rains. He was also able to visit and study the Yaruros and Mapayes tribes.

THE last *Bulletin* of the Royal Geographical Society of Belgium (1885, No. 3) contains a paper by the secretary on the Congo question, describing the explorations made in the basin between 1485 and 1877, the formation of the International Association, the creation of the Free State, and finally a description of the basin. M. Lancaster continues his notes on four months' journeyings in Texas, and M. Fontaine contributes a general paper on the geography, productions, trade, &c., of Dutch Guiana.

DR. HAACKE and Dr. Bernays are zoologist and surgeon respectively to the Australian expedition to New Guinea, to which we have already referred. The main objects of the expedition are stated to be to ascertain and fix the geographical features of New Guinea, and the nature of its fauna, flora, geology, and climate. It has been decided to make if possible the Aird river the base of operations.

AT a late meeting of the Geographical Society of Rio de Janeiro M. Alcenar Œraripe read a paper on geographical neology and neography. He referred to the necessity of introducing into geography reforms consisting mainly of the creation of new names and of uniform orthography. His remarks, though of universal application, had especial reference to Brazil. He concluded by suggesting the appointment of a commission to examine the following questions:—(1) Should there be a geographical neology for Brazil—that is to say, a nomenclature for places in the empire in which the repetition of the same name for different places would be avoided by substituting other names? (2) Should there be a geographical neography, or correction of the orthography of geographical names in such a way that the spelling would in all cases be uniform? (3) Assuming these two questions to be answered in the affirmative, how would these reforms be best carried out? The questions were referred to a commission for its report.

THE current number of *Petermann's Mittheilungen* contains a project for a new political map of Africa, with some observations on the principles of political geography, by Prof. Ratzel. This is accompanied by a double map of Africa. In one part the continent is coloured according to the prevailing occupations of the population—agriculture, agriculture with cattle-breeding, pastoral, and the chase; in the second it is coloured according to the people who form states—*e.g.* Arabs, independent Negroes, Zulus, &c. Dr. Stange writes on the orometry of the Thüringer Wald. The most important paper in the number is that by Dr. Radde, entitled "A Physico-Geographical Sketch of Talysch in the North-Western Elburz," which was originally written for an entomological work being brought out by the Grand Duke Nicholas.

THE last number of the *Mittheilungen* of the Geographical Society of Vienna contains a statement by Dr. Le Monnier with regard to the arrangements for the Austrian Expedition to the Congo; a sketch of the results of Danish explorations in Greenland by A. Rink; the conclusion of Dr. Breitenstein's paper on Borneo, and the recent letters of Colonel Prjevalsky. Dr. Breitenstein's account of Borneo is of great interest. He points out that in this great island may be studied in succession almost every stage of human development from the lowest to the highest. It is not sixty miles, for example, from Pengaron, where European machinery is employed in the coal mines, to Punun or Olo Ott, where the people are almost quite naked, and where their only protection from the weather is a grass hut here and there. It is hardly a hundred miles between Banjermassin, where Eurpean war-vessels and Krupp guns keep the Dyaks in check, and the kampong of the Prince of Murong which is protected by a thin palisade, from the top of which the heads of those captured in raids look down on the traveller. In this narrow district we have a kaleidoscopic picture of all the steps of human civilization.

AT the last meeting of the Geographical Society of Paris, M. du Caillaud read a note on the fortress of Camlo in Annam, to which the attack on the French at Hué has just given some importance; M. de Lesseps referred to soundings recently made at Gabes with a view to establishing a fort there; M. Rouire, who has recently returned from a scientific mission to Tunis, recounted his explorations in the regions between Kairwan, Susa, Hammanet, and Lake Felbiah. M. Delaplanch also read an account of a journey which he made through the centre of Persia, from Resch on the Caspian to Teheran.

DR. P. L. SCLATER suggests "Torresia" as an appropriate name for British New Guinea.

IN the *Bollettino* of the Italian Geographical Society for July, Sig. Buonfanti publishes a reply to the doubts of Herr G. A. Krause on his journey from Tripoli across the Sahara and Western Sudan to the coast of Guinea. The writer, whose letter is dated May 6, on board the *Corisco* at Banana, states that documentary proofs of the trip cannot be given till his arrival in Brussels, where the papers lie under lock and key in charge of Prof. du Fief. They include, he says, correspondence already forwarded to two American journals from Tripoli, Murzuk, &c., besides translations of safe-conducts and firmans received from the Sultans of Bornu and Socoto, and of a letter from the Sheikh [*sic*] of Timbuktu, the originals of which will be forthcoming. There are also accounts, invoices, &c., of Maltese dealers, certificates of sea-captains, certificates of missionaries, and so forth. He explains that Herr Krause heard nothing of his movements at Lagos, because he reached the coast not at that place, but at Portonuovo, some 45 miles further west. For the same reason nothing was known of him in the Yoruba country, which lies 200 miles to the east of Dagomba, Bagouza, Dahomeh, and the other districts through which he travelled.

THE Vienna Geographical Society has received good news of Dr. Oscar Lenz's African exploring expedition, which, on July 17, had reached Monrovia, the capital of Liberia. The next news will be from the Cameroons.

THE death is announced from Sydney of Thomas Boyd, the first white man to cross the Murray river, and the last surviving member of Hume and Hovell's exploring party. He was eighty-eight years of age, and had lived in great poverty for some years prior to his death.

MEASUREMENT OF EVAPORATION

I SEND a brief sketch of an instrument which I have just made for the measuring of evaporation from a water surface. The figures and letters refer to the accompanying drawings:—

Fig. 1, A.—Tank-mine, 20 in. × 10 in., standing in a large tank 60 in. × 40 in. The sides are double, a space one-tenth of an inch being between the walls and opening all around inner wall (*a*) with an outflow-pipe (Figs. 3, 4, G) let into bottom. Tank filled as Fig. 4, and refilled every three or four hours, the amount poured in being carefully measured.

Fig. 1, A, B, C.—Complete instrument. A, evaporating-tank; B, reservoir filled with water to (*n*); (*h*) a graduated glass coil, by which water pouring out through tap (*l*) is registered. Pressure upon tap regulated by (*i*) a tube and funnel buoyed up by (*k*). Water flows from B to A through a perforated, semicircular chamber (*e*), which makes water spread over the entire surface of tank. Overplus flows over at (*f*) down (*c*, *d'*) into reservoir C, similar to B in fittings. Then loss from B − gain in C = the evaporation from A. This arrangement intended chiefly for experimentation upon running water, removes the necessity for refilling the tank, although good results can be attained even then.

Fig. 2.—Tank from above. (*a*) space between walls; (*b*) inflow-pipe from B; (*e*) perforated chamber or rose; (*d*) outflow-pipe.

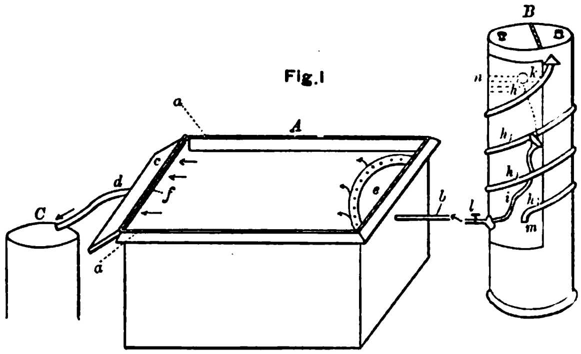

Fig. 3.—End of tank; letters as before. The outer wall in part cut away to show chamber (*a*) with emptying-pipe (*g*).

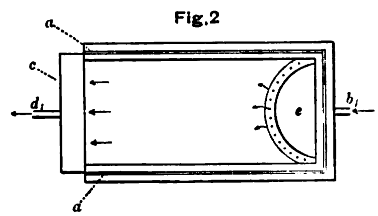
Fig. 4.—Transverse section: (*o o*), walls; (*a*), space; *g*, pipe; *p*, strengtheners. Height of water also represented.

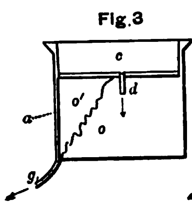
The following points are worthy of notice:—

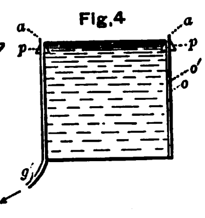


(1) The level of the water can be kept constant by regulating the flow from the tap *l* (Fig. 1, B).

(2) Error arising from splashing out of water, when heavy wind blowing, removed, the displaced water flows down (as Fig. 2), and through pipe *g* (Fig. 3), and is collected in a small measured vessel.

(3) Error arising from rainfall similarly corrected; rain falling into tank A, for greater part flows off at *f*, and is collected in C; when very heavy, flows also into *a*, and is collected as mentioned above. Then, the amount of rainfall being known from the rain-gauge, the following simple process gives the evaporation:—x = rainfall in cubic cents.; y = water in reservoirs; $x - y$ = evaporation in cubic cents.





GEORGE HASLAM
Trinity College, Toronto

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

THE following candidates have been successful in the competition for the Whitworth Scholarships, 1885, in the Science and Art Department, South Kensington:—Thomas Clarkson, age 20, engineer, Manchester, 200*l*.; Hugh O. Bennie, 20, engineer, Glasgow, 150*l*.; Robert H. Unsworth, 20, engineer, Pendleton, near Manchester, 150*l*.; Harold M. Martin, 21, engineer, Gateshead, 150*l.*; William T. Calderwood, 25, mechanical draughtsman, Glasgow, and John Richards, 22, blacksmith, Cardiff, equal, 150*l.* each; Ernest R. Dolby, 23, engineer, Leeds, 150*l.*; James Rorison, 21, engine fitter, Paisley, 150*l.*; Arthur J. Moulton, 20, engineer apprentice, Preston, 150*l.*; William McNeill, 22, mechanic, Birmingham, 100*l.*; George W. Moreton, 24, fitter, Crewe, 100*l.*; Stephen E. Mallinson, 24, assistant analyst, London, 100*l.*; Henry C. Jenkins, 23, engineer and millwright, London, 100*l.*; Robert Smith, 24, engineer, Glasgow, 100*l.*; Thomas W. Nash, 21, engineer, London, 100*l.*; Henry F. W. Burstall, 19, engineer apprentice, London, 100*l.*; Arthur J. Stopher, 22, mechanical engineer, Nottingham, 100*l.*; Sidney H. Wells, 19, marine engineer apprentice, London, 100*l.*; George Milnes, 24, fitter, Charlton, Kent, 100*l.*; Henry Begbey, 22, engineer, Old Charlton, Kent, 100*l.*; John Goodman, 23, engineer, Brighton, 100*l.*; Mark H. Crummie, 21, mechanical engineer, Hull, 100*l.*; Oliver Marsh, 22, fitter and turner, Crewe, 100*l.*; Thomas Galbraith, 23, pattern maker, Manchester, 100*l.*; Joseph H. Bowles, 23, engine fitter, Stratford, 100*l.*

SCIENTIFIC SERIALS

American Journal of Science, June.—Notes on American earthquakes, with a summary of the seismic disturbances recorded in North and South America and adjacent waters during the year 1884, by C. G. Rockwood, jun.—Taconic rocks and stratigraphy (continued): V. metamorphism and mineral constitution in the Taconic region, gradational from west to east and from north to south, by James D. Dana.—Notes on the possible age of some of the Mesozoic rocks of the Queen Charlotte Islands and British Columbia, by J. F. Whiteaves.—Crystallised Tiemannite and metacinnabarite, by Samuel L. Penfield. To the paper is appended a note by Prof. J. E. Clayton on the occurrence of Tiemannite in a mine 200 miles south of Salt Lake City.—On the gahnite occurring in the Davis Mines of Rowe, Massachusetts.—The genealogy and age of the species in the southern Old Tertiaries, by Dr. Otto Meyer.—On some specimens of meteoric iron from Trinity County, California, by Charles Upham Shepard. The analysis yielded: iron, 88·810; nickel, 7·278; cobalt, 0·172; phosphorus, 0·120.—The Potsdam group east of the Blue Ridge at Balcony Falls, Virginia, by H. D. Campbell.—Geology of the sea-bottom in the approaches to New York Bay, by A. Lindenkohl.—Additional notes on the Kettle-Holes of the Wood's Holl region, Massachusetts, by B. F. Koons.—Cause of the apparently perfect cleavage in American sphene (titanite), by G. H. Williams.

American Journal of Science, July.—Contributions to meteorology. Twenty-first paper: direction and velocity of movement of areas of low pressure, by Prof. Elias Loomis. The paper is accompanied by numerous tables showing the average direction of storm tracts, the comparative tracts of storm and atmospheric currents over the Atlantic and United States, the progress of storm centres in Europe.—Note on some Palæozoic Pteropods, by Charles D. Walcott. With some hesitation the writer includes in the Pteropod group such organisms as Conularia, Hyolithes, Coleolus, Salterella, Pterotheca, as well as Matthevia, which is here chiefly dealt with. This peculiar shell, which he so names in honour of Mr. G. F. Matthew, is, however, so distinct from all described forms of Pteropoda that a new family Matthevidæ, is proposed to receive the one genus now known.—A determination of the B.A. unit in terms of the mechanical equivalent of heat, by Lawrence B. Fletcher. The experimental work here described was completed in 1881, and forms the subject of a thesis submitted to the Johns Hopkins University in that year. In the present paper a more accurate method of calculating the currents from the deflection-curves is used, and some of the other calculations have been revised. But in other respects the results of the two papers are substantially the same. The experiment consists of simultaneous thermal and electrical measurements of the energy expended by a current in a coil of wire immersed in a calorimeter. The result depends upon the values of the mechanical equivalent and the unit of resistance, and gives a determination of either in terms of an assumed value of the other.—Cause of irregularities in the action of galvanic batteries, by Hammond V. Hayes and John Trowbridge. Here is investigated the phenomenon known as "endosmose," that is, the action by which the electric current carries whatever comes in its way from the positive to the negative electrode.—On the sensitiveness of the eye to colours of a low degree of saturation, by Dr. Edward L. Nichols.—A study of thermometers intended to measure temperatures from 100° to 300° C., by O. T. Sherman.—Notice of a new Limuloid crustacean from the Devonian formations of Erie County, Pennsylvania, by Henry Shaler Williams. This specimen, provisionally identified with Prestwichia, would appear to throw back the range of that group to an earlier period than hitherto reported. The earliest previously-discovered Prestwichia occurs in the Carboniferous formations.—Gerhardtite and artificial basic cupric nitrates, by H. L. Wells and S. L. Penfield. The mineral here described under the name of Gerhardtite was first identified as a new species by Prof. Geo. J. Brush, who found it among a lot of copper minerals from the United Verde Copper Mines, Jerome, Arizona. Its specific gravity is 3·426; hardness, 2; colour, dark green; streak, light green; transparent; crystals, orthorhombic.—On the occurrence of fayalite in the lithophyses of obsidian and rhyolite in the Yellowstone National Park, by Joseph P. Iddings.—The genealogy and age of the species in the Southern Old Tertiary. Part 2. The age of the Vicksburg and Jackson Beds, by Dr. Otto Meyer.—On the probable occurrence of the great Welsh Paradoxides (*P. davidis*) in America, by Geo. F. Matthew. This largest and most remarkable species of Paradoxides occurring in the primordial fauna of Europe was first discovered about twenty years ago by Dr. Henry Hicks near St. David's, Wales, and subsequently (1869) in Sweden. But its presence has only recently been suspected in America, where specimens of large species appear to occur both in the Cambrian slate at Saint John, New Brunswick, and in a hard silico-calcareous shale at Highland's Cove, Trinity Bay, Newfoundland.

Bulletin of the Philosophical Society of Washington, vol. vii.—Besides the usual reports of the officers of the Society, this volume contains a learned address by the President (Mr. James C. Welling) on the atomic philosophy, physical and metaphysical; abstracts, among other, of papers by Mr. W. H. Dale, on recent advances in our knowledge of limpets; by Mr. Russell, on the existing glaciers of the High Sierra of California; by Prof. Kerr, on the mica mines of North Carolina; by Mr. Riley, on recent advances in economic entomology, in which the part which insects play in the economy of nature, and particularly their influence in American agriculture, were discussed. Mr. Burnett explained why the eyes of animals shine in the dark. It is not due, he says, to phosphorescence, as has been commonly supposed, but to light reflected from the bottom of the eye, which light is diffused on account of the hypermetropic condition that is the rule in the lower animals. Mr. Johnson writes on some eccentricities of ocean currents, compiled from the records of the Lighthouse Board; Mr. Clarke on the periodic law of chemical elements; Mr. Hazen, on the recent sun-glows; Mr. Russell, on deposits of volcanic dust in the great basin; Mr. Gilbert, on the diversion of water-courses by the rotation of the earth; Mr. Doolittle, on music and the chemical elements; Mr. Bates, on the physical basis of phenomena (which is printed in full). Mr. Gilbert presented a plan for the subject, bibliography of North American geological literature; Mr. Matthews, in a paper bearing the title of natural naturalists, combated the notion that savages are versed only in the knowledge of animals and plants which contribute to their wants. The writer found that Indians have a comprehensive knowledge of animals and plants; as a class the Indians "are incomparably superior to the average white man, or to the white man who has not made zoology or botany a subject of study." The Indian also is as good a generaliser and classifier as his Caucasian brother. Several speakers who followed agreed in this conclusion.—Mr. Dutton has a paper on the volcanoes and lava fields of New Mexico.—The following are among the principal papers in the Mathematical Section: Mr. Gilbert, on the problem of the Knight's tour; Mr. Farquhar, on empirical formulæ for the diminution of amplitude of a freely oscillating pendulum; Mr. Hall, on the formulæ for computing the position of a satellite (which is printed in full); Mr. Kummel, on the quadric transformation of elliptic integrals, combined with the algorithm of the arithmetico-geometric mean.

Bulletin de l'Académie Royale de Belgique, May.—M. Ch. Fievez, on the influence of magnetism on the characters of the spectral rays. The increase of the luminous intensity of the spark and its spectrum is attributed to the action of magnetism on the luminous rays themselves. To elucidate this question the author limits his attention to the effect of magnetism in presence of the luminous and caloric movement apart from the electric spark and through the medium of the ponderable matter alone. For this purpose he studies the effect of magnetism on the spectra of the flames of sodium, potassium, lithium, and thallium raised successively to increased temperatures by the introduction of oxygen. From the results of his experiments he concludes that magnetism acts directly on the luminous rays, but abstains from any theory to explain the identity of the effects of magnetism and heat on the rays.—M. A. Swaen, on the development of the first blood corpuscles in the blastoderm of *Torpedo ocellata*. The results are given of studies made last year at the zoological station of Naples on the evolution of the folicules and the formation of the blood-vessels of this organism.—Note on the geology of the Tristan da Cunha islands, by A. F. Renard. A summary description is given of the typical rocks collected by the naturalists of the *Challenger* expedition.—State of the vegetation at Spa and Liége on April 20, and at Longchamps (Waremme) on April 21, 1885, with comparative tables, by G. Dewalque and Baron E. de Salys Longchamps.—Essay on the mechanical theory of the surface-tension of the evaporation and ebullition of liquids, by G. Van der Mensbrugghe. In this first communication on the subject the author restricts his remarks to the question of the probable cause of surface-tension.—On the movements of the brain in the dog, by Léon Fredericq. Three distinct pulsations, corresponding respectively to the beating of the heart, to the respiratory action, and to the vaso-motor periods, are determined and illustrated with numerous tracings and diagrams.—Note on the carboniferous formations of Morvan, by A. Julien. The carboniferous schists, in contact with the older quartzose and azoic schists, run mainly north and south with a thickness ranging from 150 to 300 metres. Fossiliferous beds are rare, and the fossils, a list of which is given, generally in a very imperfect state.—A Royal Library in Assyria in the seventh century B.C., by M. Lamy. A detailed account of the explorations at Nineveh since the discoveries of Layard and Botta, including a description of the Royal Library, concludes with a history of the successful efforts made by Assyriologists to interpret the cuneiform writings.

Rendiconti del Reale Istituto Lombardo, June 25.—The conflict between Julius Cæsar and the Senate (B.C. 51-49), by Prof. J. Gentile.—The Italian Criminal Code: preventive justice and offences against the police, by Dr. Raffaele Nulli.—On the conditions of resistance of elastic bodies, by Prof. E. Beltrami.—On the floral dimorphism of *Jasminum revolutum*, Sims, by Prof. R. Pirotta.—Integration of the differential equation $\Delta^2 u = o$ in any of Riemann's areas, by Prof. Giulio Ascoli.—Meterological observations made at the Brera Observatory, Milan, during the month of June.

Gazetta Chimica Italiana, Palermo, 1885.—Note on diamidoximethyltriphenilmethan, by G. Mazzara and G. Possetto.—On the relations existing between the refrangent power and chemical constitution of organic compounds, by B. Nasini and O. Bernheimer.—Synthesis of phenilcinnamenilacrilic acid and of diphenildiethylene, by O. Rebuffet.—Relation between the atomic weight and physiological functions of the chemical elements, by Fausto Sestini.—On the monobromo- and bibromopyromucic acids, by H. B. Hill.—Reply to the foregoing, by F. Canzoneri and V. Oliveri.

Rivista Scientifico-Industriale, June 15-30.—The total eclipse of the moon, October 4-5, 1884, by Prof. Carlo Marangoni.—Experiments on the extraction of the juice of tobacco and of other plants, by A. Pezzolato.—On the fossil land Articulata of the Palæozoic formations, by P. Bargagli.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, July 27.—M. Daubrée in the chair.—Discussion on the great gyratory movements of the atmosphere (continued), by M. H. Faye. The question whether these atmospheric movements are ascending or descending was compared by the author to the old astronomical argument regarding diurnal motion. Attribute it to the earth, and all becomes clear; attribute it to the stars, and you become involved in the contradictions by which the progress of science was retarded for twenty centuries.—A reply to M. Faye's communication, by M. Mascart. To the objection that the hypothesis of an ascending volume of air fails to explain the rotation of cyclones and tornadoes the author replies that if the wind in the northern hemisphere converges towards a centre of attraction it must turn to the right in consequence of the known influence of the earth's motion; hence the mass of air brought into play must revolve to the left. Thus the direction of the phenomenon is easily explained, and it follows that for a descending column of air the rotation must be reversed.—On isomery in the aromatic series: the oxybenzoic acids, their heat of formation and transformation, by MM. Berthelot and Werner.—Note on the anatomy and nomenclature of Dental, by M. de Lacaze-Duthiers. For the meaningless terms "Scaphopod" and "Cirribranch" the author proposes to substitute that of "Solenoconch" for this group of mollusks.—Observations of Barnard's comet made at the 14-inch equatorial of the Bordeaux Observatory, by MM. G. Rayet.—Elements and ephemerides of Barnard's comet deduced from the observations of July 12, 16, and 20, made at the Observatory of Nice, by M. Charlois. On presenting this paper M. Faye drew attention to the fact that the axis of the planet's orbit lies nearly in a line with the ecliptic, consequently with the planes of the orbits of the large planets. Hence, notwithstanding its inclination of 80° this planet may still be periodicaly like most of those offering the same peculiarity.—Summary of the solar observations made during the second quarter of the year 1885, by M. P. Tacchini. From these observations it appears that the solar spots and protuberances were more numerous in the second than in the first quarter of the year. In June protuberances were observed eight times which attained or reached a height of two minutes.—Observations regarding M. E. Hénard's note on the sixteen systems of the planes of the regular convex icasohedral, by M. Em. Berbier.—Note on Riemann's function $\zeta(s)$, by M. Bourguet.—On the equilibrium of a fluid mass animated by a rotatory movement, by M. H. Poincaré.—Note on the differentials of the functions of several independent variables, by M. E. Goursat.—New condensing hygrometer; its use in regulating capillary hygrometers, by M. G. Sire.—Note on the reciprocal transformation of the two varieties (prismatic and octahedric) of sulphur, by M. D. Gernez.—On a new method of volumetric analysis applicable for testing the bioxides of manganese, by M. Paul Charpentier. This method is based on the use of the alkaline sulphocyanides, and avoids certain tedious processes and sources of error presented by the methods of analysis hitherto employed. Its chief advantage is the extreme sensibility of the reaction, which enables the analyst to detect the presence of 1-3,000,000th part of iron.—Heat of formation of the alkaline alcoholates, by M. de Forcrand.—Note on the peptonate of iron, by M. Maurice Robin.—On three new compounds of rhodium, by M. Camille Vincent. These substances are:—(1) chlororhodate of mono-methylammonium, which takes the form of long, slender prisms grouped around a common centre; (2) chlororhodate of dimethylammonium deposited in the form of large efflorescent prisms of a deep garnet-red colour; (3) chlororhodate of trimethylammonium precipitated by slow evaporation in the form of long garnet-red prisms very soluble in water.—Origin and mode of formation of certain ores of manganese; their fundamental relations to the baryta associated with them, by M. Dieulafait.—On a new phase in the evolution of the reticular rhizopods, by M. de Folin. In this new state these organisms assume the appearance of small, hard pebbles, from which it is often difficult to distinguish them. The circumstance suggests the creation of a new genus, Lithozoa, of which there would appear to be several species.—Note on Megaloscopy, by M. Larrey. The author explains the optical principle by which he has been guided in the construction of a series of instruments for the inspection of the stomach, vessica, and other internal parts of the system.—Observations of the solar corona made on Mount Etna early in the month of July; reappearance of the crepuscular lights, by M. P. Tacchini. The author observed in a deep blue sky the sun encircled by a white aureole concentric with a magnificent copper-coloured corona, which near the horizon was transformed to a larger but less clearly defined arc. Since July 2 he noticed the reappearance of the red crepuscular phenomena and of the great arc at sunset and sunrise. Although less intense than those of 1883-84, he considers that their reappearance after such a long interruption shows they cannot be referred to the Krakatoa explosion.—On the cosmic origin of the crepuscular lights, by M. José L. Landerer. The author argues that these effects are due more probably to the Biela-Gambart comet than to Krakatoa. The longitude (246°) of the ascending nucleus nearly coincided with that of the earth on June 1, when the afterglows again began to acquire great intensity.

August 3.—M. Bouley, President, in the chair.—The death of M. Henri Milne-Edwards, who died on July 29, was announced by the President, who remarked that a great loss was sustained by the Academy in the person of the illustrious Member of the Section for Anatomy and Zoology, one of the greatest *savants* who had shed lustre on French science.—Discourses pronounced at the obsequies of M. Milne-Edwards, by M. A. De Quatrefages, in the name of the Academy of Sciences, by M. Fremy, Director of the Museum of Natural History, by M. de Lacaze-Duthiers, in the name of the Paris Faculty of Sciences.—On the oxalic acid present in vegetation; methods of analysis, by MM. Berthelot and André.—Researches on the effects of direct electric excitation on the glands, by M. Vulpian.—Frictionless reflection, on a plane, of the elastic displacements in a body of any form and contexture, by M. X. Kretz.—Letter addressed to the Perpetual Secretary on the subject of vaccination against cholera, by Dr. J. Ferran. In reference to this letter M. Vulpian expressed his regret on the part of the Commission that the writer had misunderstood the meaning of the note inserted in the last issue of the *Comptes Rendus*. What was asked was not Dr. Ferran's statistics now promised, but the official returns of the Spanish authorities. In a question of this sort, affecting as it did all humanity, it was hoped that the Spanish Government would consider it a point of honour to give forthwith all possible information regarding the value of Dr. Ferran's method of preventive vaccination.—Note on an asymptotic law in the theory of numbers, by M. Stieltjes.—On the "herpolhodie" in the case of any surface of the second degree, by M. de Sparre.—On the employment of alternative electric currents for the measurements of the resistance of fluids, by MM. Bouty and Foussereau.—Note on the formation of the crystallised hydrate of zinc, by M. J. Ville.—On the hexabromide of benzine, by M. J. Meunier.—Heat of formation of the picrates. From the tables accompanying the paper the author shows that the anhydrous picrates of magnesium and copper are formed with an insignificant loss of energy in the components, while the picrate of zinc even absorbs a little heat. Hence the latter will yield more useful results than the former under the influence of the same oxydant.—Note on the essence of citron, by MM. G. Bouchardat and J. Lafont.—On the form of the larva of *Dorocidaris papillata*, by M. Henri Prouho.—On the digestive tubes, the corpus Bojani, reproductive organs, and eggs of Fissurella (*F. gibba* and *F. reticulata*), by M. L. Boutan.—On the hydrocarbonated reserves of mushrooms, by M. Léo Errera. The author's researches show an unexpected parallelism, from the standpoint of physiological chemistry, between the germination of mushrooms and that of the higher order of plants.—On the comparative evolution of sexuality in the individual and the species, by M. F. Laulanié.—Influence of sunshine on the vitality of various species of Micrococcus, by M. E. Duclaux.—Comparative studies of leprosy; its pathological anatomy, by M. Henri Leloir.—Researches on poisoning by sulphuretted hydrogen, by MM. P. Brouardel and Paul Loye.—Note on a Cetacean (*Hyperoodon rostratus*) stranded at Rosendael, near Dunkirk, on July 24, by MM. Pouchet and Beauregard.—Remarks on some electric lights constructed by M. G. Trouvé for the purposes of naturalists, chemists, microscopists, &c. (one illustration), by M. de Lacaze-Duthiers.

Berlin

Physical Society, June 26.—Dr. König produced a new apparatus for the measurement of the modulus of elasticity, which was constructed according to the suggestions of Herr von Helmholtz, and was utilised in the Institute for measurements of elasticity. The modulus of elasticity was determined by loading in the middle a bar of the substance to be examined, resting both ends on firm supports. The flexion which set in was measured by means of the cathetometer, and, its value being introduced into the formula of the elasticity theory, furnished the modulus of elasticity. A source of error in these measurements arose from the circumstance that the bar resting on edges was in part pressed in and sank, as a whole. This depression was the greater as the loading was greater, and it added to the magnitude of the flexion. To avoid this disturbance in the account Prof. Kirchhoff, in 1859, placed horizontal mirrors on the two ends of the bar, and, by means of telescope and scale, observed at each side the change in situation of each mirror, a change which occurred in consequence of the flexion under the loading in the middle, and which produced on both sides an opposite displacement of the scale. The sinking of the bar on account of the pressure on the edges, and even a slanting position on the part of the whole bar exercised no influence in these measurements. The apparatus suggested by Prof. von Helmholtz developed this principle still further. It had two perpendicular mirrors with the reflecting surface directed inwards at the two ends of the bar; on one side stood a scale, on the other a telescope. The image of the scale fell on the opposite mirror, then on the second mirror, and thence into the telescope. If now the bar were loaded so that flexion occurred, then the image in the telescope became displaced to the extent corresponding with the angular changes of the two mirrors. By glancing therefore into the telescope the whole amount of flexion might be very rapidly and conveniently measured and the loading altered at pleasure; the commencement of the elastic after-effect might likewise be directly observed with great facility. In the Institute a series of measurements with this apparatus had been executed by two experimenters, measurements which yielded values agreeing with a fair degree of precision. In the case of cylindrical bars differences presented themselves according as the bar was examined in one direction or in the direction perpendicular thereto. In the case of rolled brass the difference amounted to as high as from 2 to 2½ per cent.; in the case of cast brass the difference was inappreciable. Bars of cast iron likewise showed differences of only ½ per mill. Dr. König followed this up with a proposal to measure Poisson's constants—that is, the relation of the longitudinal increase to the decrease of the transverse section. The measurement should be carried out as in the experiments of Prof. Kirchhoff, only, instead of the horizontal mirrors and two telescopes, two parallel mirrors inclined at an angle of 45° should be used at the two ends of the bar with one telescope, thus enabling the moduli of elasticity and of torsion to be measured, the relation of which furnished Poisson's constants.

PROFESSOR STOKES ON LIGHT

Burnett Lectures, Second Course. On Light as a Means of Investigation. By G. G. Stokes. (London: Macmillan and Co., 1885.)

THE interest raised by the first series of these lectures is fully sustained by this second instalment, though the subject-matter is of a very different order. *Then*, the main question was the nature of light itself; *now*, we are led to deal chiefly with the uses of light as an instrument for indirect exploration. It is one of the most amazing results of modern science that the nature of mechanisms, too minute or too distant to be studied directly with the help of the microscope or the telescope, can be thus, in part at least, revealed to reason. This depends on the fact that a ray of light, like a human being, bears about with it indications alike of its origin and of its history; and can be made to tell whence it sprang and through what vicissitudes it has passed.

The lecturer begins by pointing out that this indirect use of light already forms an extensive subject; and he then specially selects for discussion half-a-dozen important branches of it. Many readers will, we fear, be disappointed when they find that *Dispersion* (whether ordinary or anomalous) is not included in this list. It is tantalising to feel that we are not (for the present at least) to have the opinion of the author on the classical researches of Cauchy, or on the more recent speculations of Sellmeier, Helmholtz, and W. Thomson. It would, however, be unjustifiable to construe this omission into an indirect assertion that we do not yet know for certain *what* Dispersion tells us:—though the parts of his wide subject which Prof. Stokes has selected for discussion are, each and all, such as give indications of a definitely interpretable character.

The first of these is Absorption. Here we have the explanation of the colours of bodies; the testing ray having gone in, and come out "shorn." This leads to the application of the prism in the immediate discrimination of various solutions which, to the unaided eye, appear to have the same colour. It is shown how, by a mere glance, the chemist may often be saved from fruitless toil, occasionally from grave error.

From the study of what rays are absorbed, the transition is an easy and natural one to the study of *what becomes of them* when they are absorbed. Here we have heating, chemical changes, phosphorescence, &c. The remainder of the lecture is devoted to an exceedingly interesting treatment of the beautiful subject of fluorescence.

The second lecture begins with Rotation of the Plane of Polarisation of light by various liquids, with its important application to saccharimetry. Then we have Faraday's discovery of the corresponding phenomenon produced in the magnetic field, with its application in the discrimination of various classes of isomeric compounds. But the author, true to his system of mentioning practical applications only, omits all reference to quartz under the first of these heads and to gases under the second. And he does not even allude to the interesting questions recently raised as to the form of the general wave-surface in these curious circumstances.

Then comes the "still vexed" question of the history of Spectrum Analysis. The present view of it must, of course, be carefully read:—it is much too long to be here extracted in full, and to condense would be to mutilate it. Of course the claims of the author himself are the only ones to which scant justice is done. But the President of the *British Association* of 1871 fortunately gave, in his opening address, the means of filling this *lacuna*. Just as the Gravitation-theory of an early Lucasian Professor was publicly taught in Edinburgh University before it became familiar among scientific men, so the present Lucasian Professor's suggestions for the analysis of the solar atmosphere, by means of the dark lines in the spectrum, were publicly explained in the University of Glasgow for *eight successive years* before the subject became generally known through the prompt and wide-spread publicity given to the papers of Bunsen and Kirchhoff! The following are Sir William Thomson's words of 1871:—"It is much to be regretted that this great generalisation was not published to the world twenty years ago . . . because we might now be [*sic*] in possession of the inconceivable riches of astronomical results which we expect from the next ten years' investigation by spectrum analysis, had Stokes given his theory to the world when it first occurred to him."

The third lecture is devoted to the information which spectrum analysis affords as to the chemical composition of the sun's atmosphere, and its physical condition; the classification of stars, the constitution of nebulæ, and the nature of comets. Those who still maintain that the temperature of the sun's body is comparatively moderate are very summarily dealt with. Then follows a passage describing, in homely language fitted to be understanded of all, the state of the sun's atmosphere. This is specially noteworthy, as showing how efficiently a Master can impress on his readers the most vivid ideas without requiring to use any but the simplest of language.

The remarks on the nebulæ and on comets will be read with great avidity; and, by the majority of readers, with some surprise. For it is stated that the planetary nebulæ, "making abstraction of the stellar points, consist of glowing gas." And of comets we find:—"There can no longer be any doubt that the nucleus consists, in its inner portions at least, of vapour of some kind, and we must add incandescent vapour . . ." An ingenious suggestion as to the source of this incandescence is introduced as the "green-house theory." The nucleus is supposed to be surrounded by an envelope of some kind, transparent to the higher but opaque to the lower forms of radiation. Thus solar heat can get freely at the nucleus, but cannot escape until it has raised the nucleus (in part at least) to incandescence. The coma and tail are formed by the condensation of small quantities of this vapour, so that they are mere mists of excessive tenuity. Herschel's suggestion, that the development of the tail is due to electric repulsion exerted by a charge on the sun, is spoken of with approval; and the production of the requisite charge of the mist-particles is regarded as a concomitant of condensation. Nothing, however, is said as to the opposite charge which the comet itself must receive, nor of the peculiar effects which would arise from this cause:—whether in the form of a modification of the shape of the comet's head, or of a modification of its orbit and period due to a constantly increasing attraction exerted by the sun upon a constantly diminishing mass.

Of course, if this novel theory can stand the test of a full comparison with facts, it will have established its claim to become part of science. But it is hard to take leave of the simple old ideal comet:—the swarm of cosmical brickbats:—something imposing because formidable; and to see it replaced by what is, in comparison, a mere phantom, owing its singular appearance to the complexity of the physical properties it possesses and the recondite transformations perpetually taking place in its interior. The old idea of a comet's constitution was not only formidable, but was capable of explaining so much, and of effecting this by means so simple and so natural, that one almost felt it deserved to be well-founded! The new idea makes it resemble the huge but barely palpable 'Efreet of the *Arabian Nights*, who could condense himself so as to enter the bottle of brass with the seal of Suleymán the son of Dáood!

It is much to be desired that more detail had been bestowed on the nebulæ. As nothing is said about the origin of their incandescence, we must take for granted that it is supposed to be due to gravitation. A few rough numerical assumptions as to dimensions, total mass, &c., and the consequent thermal condition at each stage of condensation, would have formed materials for a most instructive explanatory note.

The last lecture deals with solar protuberances; the (so-called) Döppler's principle, and the results of its application; and, finally, with the body of the sun. The explanation given of the peculiar and rapidly changing structure of the sun's apparent disc, which is so well shown in Janssen's splendid photographs, reminds us of a suggestion made several years ago:—viz. that a succession of instantaneous photographs should be taken, at short intervals, of so homely an object as a basin of very hot "beef-tea," which has been agitated so as to bring the flocculent matter fully into suspension, and is then left to itself as nearly as possible free from rotation.

The passages in the present volume which, taken by themselves, would indicate the ulterior object of the lectures are not numerous, and nowhere bear the appearance of having been inserted for a purpose, so naturally do they arise as comments on what has just been discussed.

We wish the Author as high a measure of success in his final effort, the most arduous of the three, as he has already attained in the others:—it would be preposterous to wish him a higher. The series will then form an exceedingly valuable contribution to a class of literature in which marked success is scarcely attained once per generation, and is justly valued in proportion to its rarity.

P. G. TAIT

AGRICULTURAL EXPERIMENTS

Review of Agricultural Experiments by the Right Hon. Sir Thomas Dyke Acland. (London: Clowes and Co., 1885.)

THIS purports to be a critical review with suggestions, and is actually an attack upon the objects, aims, and results of the Sussex Association for the Improvement of Agriculture. The writer brings a long experience and a good business faculty to bear upon the working of a scientific organisation, and with some success so far as these instruments may be used as tests of the value of a delicate task requiring very special knowledge. The attitude of mind of the reviewer of these experimental results is one of scepticism. This he does not scruple to express in such terms as "we all felt rather sceptical," and "we suspected," and "I have made in all four visits to Sussex to endeavour to get at the truth." Again, "Well, thought I, this must be a queer kind of farming, perhaps I shall enlarge my experience. I think I have made out since that the local experience, however practical, may be the better of a little expansion." With such introductory remarks we can hardly look for the cold judicial criticism that commands attention and carries conviction.

The inquiries of the Sussex Association have been directed to very practical questions, viz.:—

What do roots (turnips, mangolds, &c.) require?

What do wheat and other cereals require?

What does grass or pasture require?

These objects Sir Thomas Acland appears to view in two opposite and irreconcilable ways. First, he seems to doubt the possibility of these questions being solved by experimental processes. Secondly, he appears to consider that they have all been answered long since. He thus discounts the value of the Sussex results from two points of view, each of which is destructive of the other. It is true that the leading facts constituting the answers to the above important questions have now been firmly established for many years, and that these answers were known almost a generation ago to such leading men as the late Philip Pusey, and all more recent scientific agriculturists. The value of such stations as that known as the Sussex Association consists in its power of impressing and verifying such facts, as well as in discovering new ones, and we think, under Mr. Jamieson's able guidance both of these objects are being accomplished. Among new ideas promulgated by the Sussex Association is that which is paragraphed by Sir Thomas Acland under the heading, "Battle of the Phosphates." Mr. Jamieson's contributions upon this important subject are passed over with something akin to contempt, and yet (however distasteful his conclusions may be to manufacturers of "superphosphates") his results remain unrefuted, and the most recent experiments at Woburn point, on the whole, to similar conclusions. The establishment of the value of "insoluble" phosphatic minerals reduced to a fine state of division is due in a great measure to Mr. Jamieson, and he has incurred no little unfriendly criticism on account of this new doctrine, which touches the pockets of certain strong interests. This is altogether the leading truth brought out and fought for by Mr. Jamieson, and yet it is dismissed by Sir Thomas Dyke Acland in a manner which appears to the present writer as simple superciliousness.

One could scarcely expect to read sixty-four pages of printed matter from the pen of Sir Thomas Dyke Acland without finding grain as well as "chaff." We therefore wish to set forth the useful criticisms which the Sussex Association would do well to notice. First, then, there is the fallacious method adopted in endeavouring to translate field results into money values. Not content with leaving the number of bushels per plot and pounds of straw increase to the judgment of the reader, an effort has been made to put a value upon these increased quantities. In valuing wheat at 5*s.* per bushel and straw at 2*l.* per ton the compilers of the report made a great mistake, of which their critic has not been slow to avail himself. Here he "shells" them unmercifully and effectually, especially as the straw at 2*l.* per ton turns out to be the chief item for turning loss into profit.

This is, however, entirely an artificial value, the result of restricted supply, and Sir Thomas is perfectly justified in dismissing the item entirely by compounding it with the cost of the farmyard manure, letting straw and manure mutually discharge each other's claims.

Another point successfully urged is the smallness of the plots. What possible reliance can be placed upon plots 112th of an acre in which pounds per plot are at once alleged to represent hundredweights per acre. The multiplication of unavoidable errors, and the exaggerations of extremely local differences in the soil itself, are simply fearful to think of. The larger the area the better. If acre-plots could be used so much the better, and 10-acre plots would be better still—the only limit in size being, to our mind, convenience. But 112th parts of acres must induce a feeling of distrust in the breasts of those who are practically acquainted with land. The sources of error may be enumerated as follows:—imperfect distribution, unavoidable waste in distribution, minute differences in the soil, irregular germination of the seed, partial insect attacks, direct accidental injuries or the reverse (as, for example, an animal trespassing upon a plot, or a horse dropping his dung upon it), errors in weighing, errors in severance from the ground, and other unavoidable difficulties which belong to the carrying out of field experiments,—all of these errors are magnified in the case of small plots, and minimised by the use of large ones. In these directions the criticisms made by Sir Thomas Acland are valuable: but we should like to have seen a greater sympathy with an honest effort, and less anxiety to hold up any results of value as stale, antiquated, and unnecessary.

Any one who has lived as long as Sir Thomas Dyke Acland must know that the proclamation of things old as things new is not confined to agricultural chemists, and he should be more ready to accept as inevitable the *dictum* of the wise man, that "the thing that hath been, it is that which shall be; and that which is done is that which shall be done."

THE NEW EDITION OF "YARRELL'S BRITISH BIRDS"

A History of British Birds. By the late William Yarrell, V.P.L.S., F.Z.S. Fourth Edition, Revised to the End of the Second Volume by Alfred Newton, M.A., F.R.S., continued by Howard Saunders, F.L.S., F.Z.S. Parts xx.-xxx. (London: Van Voorst.)

THE students of British birds have at last received the two final numbers of the new edition of Yarrell's celebrated work on their favourite subject, which was commenced as long ago as 1871. Fourteen years, it must be acknowledged, is a long time to wait, but on the other hand the subscribers to the new "Yarrell" have in compensation of the delay not what would be called in ordinary parlance a new edition, but what is, in fact, a complete and exhaustive summary of the present state of our knowledge of this subject, prepared by two of the greatest living authorities on British ornithology.

The two first volumes of the fourth edition of "Yarrell's British Birds," which were brought to a conclusion by Prof. Newton in 1882, were devoted to the birds of prey, the passerine birds, and the picarians. In June of that year Mr. Saunders undertook to finish the work, "not willingly nor with a light heart," but, as he tells us, "after considerable pressure and at much personal sacrifice." Forewarned by what had previously occurred, Mr. Van Voorst insisted that time must be part of the "essence of the contract," and stipulated with the new editor for the completion of the third and fourth volumes by June 1885, which, after allowing for six months' leave of absence, gave Mr. Saunders only two years and a half to prepare his account of nearly two hundred species. It cannot be denied that this was somewhat severe upon the new editor, and that, considering the pressure brought to bear upon him, the mode in which he has completed his task within the time assigned to him, deserves our highest compliments.

As has been already pointed out the so-called new "Yarrell" is, in fact, a new work. The vast amount of knowledge of British birds and their distribution acquired during the forty-two years which have elapsed since Yarrell's original work first appeared, rendered it absolutely necessary that such should be the case. It would have been much better, in our opinion, to have discarded the name of Yarrell altogether, and to have employed the leading ornithologist of the period to write a new work on British birds. But as Mr. Van Voorst, doubtless for sufficient reasons, preferred to retain the time-honoured name of Yarrell on the title-page, the new "editors" as they call themselves have, we think, surmounted the difficulties of their position with singular success. Where practicable, we are told, the original phraseology has been followed with due modifications, the opening words of the sentences have been preserved, and extracts from the authors and correspondents quoted by Yarrell have been retained. "This work of selection and adaptation has," we can well believe, "entailed severe labour." It is obvious, in fact, that it would have been a much simpler task to write most of the articles new from the beginning than to adapt those prepared by the original author fifty years ago to present use. The former plan would also, we think, have been more satisfactory to the reader, who between the "author" and the two "editors" and the friends and correspondents of each of them, is in many cases likely to be misled as to the real authority quoted for a particular statement.

While, as we have already said, the general execution of the "new Yarrell" merits our entire commendation, the systematic arrangement—an unsuccessful effort at a compromise between the old fashion and the new—does not seem to deserve equal praise. No doubt the order adopted by first editor for the three groups treated of in the first two volumes placed the second editor in a difficulty. But we cannot think that Mr. Saunders was thereby justified in relegating the Steganopodes, Herodiones and Anseres to the end of the series. With these groups he should have begun the second volume, not finished the third. At the same time it must be borne in mind that the primary object was not a strictly orthodox classification, but a good and readable "History of British Birds," and this object has, we think, been attained.

OUR BOOK SHELF

Melting and Boiling-Point Data. By T. Carnelley, D.Sc., F.C.S. Vol. I. (London: Harrison and Sons, 1885.)

THIS is a very large and important work, and one which cannot fail to be useful to the scientific chemist. It is divided into several parts, and contains, or rather consists of, tables of the elements, inorganic and organic compounds, their constitutional and empiric formulæ, melting- and boiling-points, and the authority and references to the journals, &c., in which the data are given.

The compilation of a work of this nature necessitates an enormous amount of labour and care, which in this case seems to have been expended, for misprints or misquotations appear to be absent.

It is the only one of the kind in English, although there are several German works of the same class, notably one by Richter, but of carbon compounds only. The only fault possible to find with a book like this, designed for use in the laboratory more than anywhere else, is its large size.

The present volume, the author tells us, contains 19,000 data, melting- and boiling-points, and with the second volume there is to be a total of about 50,000 data of this kind.

American Journal of Mathematics, Pure and Applied. Published under the auspices of the Johns Hopkins University. Vol. vii. Parts 2, 3, 4. (Baltimore: Isaac Friedenwald, January to July, 1885.)

THE first sixty-seven pages of Part 2 carry on Prof. Cayley's lectures on the abelian and theta functions, before the Johns Hopkins University (see NATURE, vol. xxxi. p. 189) to "the end of Chapter VII." Other papers in this part are "Solution of Solvable Irreducible Quintic Equations, without the Aid of a Resolvent Sextic," by G. P. Young (the same writer furnishes to Part III. "Solvable Irreducible Equations of Prime Degrees"), and "Notes on the Quintic," by J. C. Glashan. Mr. C. S. Peirce commences an article "On the Algebra of Logic," which runs into Part III.; it is in part concerned with a discussion of De Morgan's logic of relatives. M. Poincaré contributes a paper of fifty-six pages, "Sur les Equations linéaires aux Différentielles Ordinaires et aux Différences Finies." Capt Macmahon adds a short "Second Paper on Perpetuants." The Associate-editor, Dr. Craig, likewise briefly writes "On a Certain Class of Linear Differential Equations." Other short items in this part are: "Prüfung grösserer Zahlen auf ihre Eigenschaft als Primzahlen," by P. Seelhoff; and "Sur les Nombres de Bernoulli" (following up a paper entitled "Some Notes on the Numbers of Bernoulli and Euler," by G. S. Ely, in vol. v.), by Prof. Teixeira, of Coimbra.

The first thirty-four pages of Part IV. are taken up with a paper by Mr. A. Buchheim entitled "A Memoir on Biquaternions," in which the author carries on his investigations in a field first opened up by Clifford. In it he aims at giving "a tolerably complete development of Clifford's calculus." Mr. J. Hammond carries on his labours on the lines of some recent papers by Cayley and Sylvester, by contributing a memoir "On the Syzygies of the Binary Sextic and their Relations." Prof. W. Woolsey Johnson writes "On a Formula of Reduction for Alternants of the Third Order," and "On the Calculation of the Operators of Alternants of the Fourth Order." Short notes are communicated by F. Franklin "On the Theorem $e^{ix} = \cos x + i \sin x$," and a "Proof of a Theorem of Tchebycheff's on Definite Integrals;" and W. E. Story supplies a paper on "The Addition Theorem for Elliptic Functions." The remaining article is an additional Bibliography of the kind of which the *Journal* has now published some three or four most useful specimens. On this occasion Messrs. Nixon and Fields have compiled eleven pages of "Bibliography of Linear Differential Equations." All such lists, if fairly complete, are bound to be most useful. The authors solicit corrections of and addenda to the list for future publication.

A Guide to the Universal Gallery of the British Museum (Natural History). By L. Fletcher. (Printed by order of the Trustees.)

THIS excellent little guidebook is worthy of the highest praise. It is a good deal more than a book which tells you the primary facts respecting the objects in the cases, inasmuch as it contains a simple and elementary introduction to the study of minerals. For such a purpose the principal crystallographic, physical, and chemical characters should be explained, and the way in which these characters serve as a means of classification should be shown. Mr. Fletcher has done this excellently. He shows how the science of crystallography grew by the discoveries of Steno, Romé de l'Isle, Haüy, and others to its present state, in which it serves as a most, if not the most, important element in the discrimination of minerals. The way in which Brewster's discoveries in crystal-optics confirmed the results of crystallographic investigation is pointed out; and a brief sketch of the progress of chemistry from the days of alchemy is also given.

This all leads up naturally to the ultimate purpose—that of classification, which is so essential in the proper display of a mineral collection. Finally, in the detailed account of the minerals in the Museum attention is specially directed to the more unique specimens.

Die Spaltpilze. Von Dr. W. Zopf. 3rd Edition. (Breslau, 1885.)

THIS, the third edition, differs in no essential respect from its predecessors. Zopf still adheres to the original proposition of Von Nägeli, that the various forms of schyzomycetes are not permanent species (Cohn), but various stages in the development of the same organism. This proposition is derived from observations of the morphological characters only, and is not based on sufficiently exact methods of *pure cultivation.*

The sections treating of the physiology and chemistry of the bacteria will be found very valuable. A complete and alphabetically-arranged bibliography at the end of the work is the best as yet published. E. KLEIN

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Evolution of Phanerogams

MUCH as I dislike controversy occasions arise when it must be faced; and Mr. Starkie Gardner's notice of the two new volumes by MM. Marion and Saporta (p. 289) calls for a reply. Personally I am obliged by Mr. Gardner's obvious desire to do justice to my views; but he must excuse me if I say that some of the "main facts" on which he relies are, like similar ones employed by the two French writers, charmingly independent of anything that I can find existing in nature.

Through the kindness of my accomplished friend, the Marquis of Saporta, I received copies of his two volumes as soon as they were published. On perusing his descriptions of the carboniferous plants I found numerous statements with which I could not agree. Some of these statements refer to questions of facts; others to inferences drawn from real or imaginary facts. Having long enjoyed the valued privilege of a correspondence with my distinguished friend I sent to him a lengthy criticism of parts of his new volume which I thought to be seriously misleading; either because matters of fact were so exhibited as to convey erroneous impressions, and hence, practically, to become not facts—or because they were made to justify conclusions which the facts themselves, rightly stated, would not do. At the same time I gave my correspondent warning that I might have to correct what I regarded as his erroneous or misleading statements.

Mr. Gardner's article leads me to fulfil this announcement sooner than I intended, since he, in turn, has so far countenanced some of what I regard as the errors of the two French palæontologists as to make them his own. Like Mr. Gardner, M. Saporta had previously pointed out to me that the aim and object of his volumes did not necessarily involve interference with matters that have so long been in dispute between M. Rénault, M. Grand'-Eury, and myself. To this I could only reply that in his new work he had repeatedly shown his acceptance of views of these two palæontologists involving both facts and inferences, which I believe to be seriously erroneous. The space which NATURE can afford me will not suffice fully to review all of what I regard as the objectionable parts of the two volumes under consideration, but I may be allowed to make some comments, including some extracts from my letter to M. Saporta, indicating the nature of my objections both to his conclusions and to the comments made upon them by Mr. Gardner.

The latter gentleman makes one statement which I cannot endorse. Because MM. Rénault, Grand'-Eury, and Saporta all adopt the views of M. Brongniart he thinks it hardly possible that they can all be mistaken. This argument cuts both ways—Mr. Gardner applies it to the subject of Calamites *versus* Calamadendron. On this subject I may retort that when such men as Schimper, Weiss, Stur, and perhaps my prolonged investigation of the subject justifies my adding myself, take an opposite view of the matter in debate, it may possibly be equally impossible that we, with our vast array of specimens in our cabinets, should all be mistaken! This *argumentum ad hominem* therefore falls to the ground. I may be allowed to wonder that it should ever have been advanced.

The first point to which I would call attention shows that such men as those quoted may blunder and have blundered. I now refer to the subject of the relations of Lepidodendron and Sigillaria to each other and to the rest of the plant world. That I have for many years insisted upon the cryptogamic character of, and the close affinity existing between, both these genera is well known; and equally so, that many of the French palæontologists have followed M. A. Brongniart in regarding the Lepidodendra as Lycopodiaceous plants whose stems contain no exogenous vascular cylinder, whilst all those plants that possessed such a cylinder (a product of a Cambium layer) which they believed to be the case with Sigillariæ must, *de facto*, be Gymnosperms. That this dispute has now been settled in my favour by an important recent discovery does not seem to be known to Mr. Gardner. M. Zeiller has obtained strobili of Sigillaria which have settled the matter even in the opinion of most of the Parisian botanists. Those strobili contain spores, not seeds. This discovery demonstrates the cryptogamic character of Sigillaria, and deals a final blow at the Gymnospermous hypothesis held by the four observers in whose combined infallibility Mr. Gardner expresses such confidence.

My first friendly complaint against the authors of the "Evolution of the Phanerogams" is that they disregard proven facts when such facts inconveniently oppose their theories. *Imprimis*, they became aware of M. Zeiller's important discovery whilst their volumes were passing through the Press. Though this is a sufficient reason for only noticing it in a footnote, it does not justify their very slight recognition of its bearing upon so many pages of their arguments, of which it effectually disposes. It absolutely establishes the fact that *some* Sigillariæ, at least, are *not* Gymnosperms but Cryptogams; which fact, superadded to the many identities of structure in Sigillaria and Lepidodendron, which I have repeatedly shown to exist, renders it increasingly probable that the above statement is applicable to *all* Sigillariæ. At least, it now throws upon the opponents of that statement the onus of proving the contrary to be true, which they have not done.

Several years ago the late Mr. Binney described what he believed to be two plants—the *Lepidodendron vasculare* and the *Sigillaria vascularis*. That the only difference between these two was the possession, by the latter, of an exogenous zone, not seen in the former, was recognised by Mr. Binney. I have shown in a way, which I claim to be unanswerable, that these are one and the same plant which the external and internal characteristics alike demonstrate to be a Lepidodendron. Hence I complain to M. Saporta, "You continue to speak of *Sigillaria* vascularis. I reply that there is no such plant; and to speak of the *Lepidodendron* under that name, after all that I have done in illustration of its organisation, is unfair to me, besides seeming to support M. Rénault's absurd conclusion that an exogenous or centrifugal zone is incompatible with the possibility of a plant possessing such a zone being a Lepidodendron." I then state "further, after enumerating M. Rénault's three supposed types of Lepidodendron, from which he excludes all possibility of the existence of an exogenous zone, you say, 'ce sont les traits *essentiels* des types caulinaires Lepidodendroides.'

"I reply in language as strong as I can possibly use that this is not true. The development of an exogenous zone in the more advanced stages of a Lepidodendron's life is the rule rather than the exception."

After citing numerous proofs of this statement I say in reference to Sigillaria: "It is further a mistake to say that 'ces tiges nous sont principalement connues par les Sigillaria elegans et spinulosa.' We possess the vascular axis of the Sigillaria figured in my Memoir II., Fig. 39. This axis is identical in the minutest details of its organisation with those of the Diploxyloid Lepidodendra, and I have sections of Sigillaria reniformis which are, in structure, equally Lepidodendroid, I ask, therefore, what are the 'diversités appréciables' to what you refer on p. 23, and what ground have you for saying that this double fibro-ligneous region is 'sans analogie avec ce qui existe dans les tiges connues des Lepidodendrées'?"

On this part of the disputed questions I must object to a statement made by Mr. Gardner, in which he says that the structure of Lepidodendron "presents nothing unusual to Cryptogams." Surely a thick *exogenously developed* cylinder of scalariform vessels, arranged in radiating laminæ, separated by true medullary rays, the entire structure being produced by a Cambium zone, is very unusual in Cryptogams. Mr. Gardner then proceeds, as M. Saporta would do, to describe a contrast which has no real existence. "But in Sigillaria, a plant strongly resembling it in nearly every other respect, we find a radiating vascular or woody zone in the cellular stem with unmistakable exogenous growth. It is richly supplied with medullary rays, and, Prof. Williamson allows, presents clear evidence of interruptions to growth succeeded by periods of renewed vital activity." I allow, and never have allowed anything of the kind,[1] if this means my admission that something exists in Sigillaria that does not exist in most Lepidodendra. Mr. Gardner further represents me as believing that "the typical Lepidodendron never produced a ligneous zone." I believe the reverse of this; viz. that a development of such a zone sooner or later was characteristic of most Lepidodendra. True there are some Lepidodendra in which I have not yet discovered such a zone; but I am far from supposing that even in them such a zone will not ultimately be discovered. Anyhow the *typical* Lepidodendron can no longer be regarded as one from which this zone is absent. Mr. Gardner, after the passages quoted above, says: "In Diploxylon there is a further development, the woody zone being made up of an inner or medullary vascular cylinder either interrupted or continuous, composed of large scalariform vessels without definite order, and an outer cylinder of scalariform vessels of smaller size arranged in radiating fasciculi." What does this "further development" mean? This description is simply that of *every* exogenous Lycopodiaceous axis found in the coal measures, whether of Lepidodendron or of Sigillaria. Diploxylon, *as a genus*, has no longer any existence. The term is now useful only as an adjective descriptive of a condition of growth common alike to Lepidodendron and to Sigillaria, as well as to several other genera of Carboniferous plants. Unless I misunderstand Mr.

[1] I may here observe that conspicuous or even visible interruptions to growth are very rare amongst these coal plants. They are only very *conspicuous* in my genus Amyelon; but we also find traces of them in Stigmarian roots and in Lygenodendron. Generally these Carboniferous stems suggest the reverse of changing seasons or periodic interruptions of growth.

Gardner, he here employs words designed to suggest distinctions of organisation between Sigillaria and Lepidodendron, the existence of which I altogether deny.

M. Saporta appears to accept, without demur, statements made by M. Renault respecting Stigmaria ficoides which I emphatically reject. These statements are reactionary in the highest degree. If true they would compel us to cast overboard much of the work done during the last half century by Logan, Binney, Sir William Dawson, and a host of other observers; work, the reality of which, along with the conclusions drawn from it, was unhesitatingly accepted even by Brongniart himself. Such statements, if proven to be true, would involve a rejection of all modern views respecting the origin of coal and a return to the worthless hypotheses that were believed in half a century ago. On this subject I will at present only say that such views are absolutely irreconcilable with well-known facts. Should these views be allowed to pass unrefuted, as Sir William Dawson has properly observed, "some one will be required to rescue from total ruin the results of our labours."[1] I will at present say no more respecting these Stigmarian heresies, since I shall have to deal with them more seriously in a work now in hand for the Palæontographical Society.

Mr. Gardner makes one more statement respecting these Lycopodiaceæ that is unsupported by any evidence which my rich cabinet can supply. He say that "during growth the woody or exogenous zone increased for a certain period, but that this was quickly arrested by the absorption or destruction in some way of the Cambium layer. The *subsequent* increase in diameter took place mainly in the cortical system, and to it the growth and solidity of the stem was principally due. The exogenous element in the oldest known trees is thus seen to have been transitory and subordinate, for had it persisted indefinitely the continued generation of fresh layers or new rings of growth would have produced true Dicotyledonous stems." In the first place we have no evidence whatever of the correctness of Mr. Gardner's statement. That the vascular axis of each of these Lycopodiaceous stems was small in proportion to the diameter of its bark is undoubtedly true, and it was equally probable that the growth in the thickness of that axis was slow; but I know no facts indicating that such growth ever ceased. The diameter of each vascular axis bears about the same proportion to that of the bark, whether the stems are large or small, young or old. Hence we may fairly infer that the cortex and vascular cylinders alike continued to grow *pari passu* so long as each plant continued to live. Anyhow, I know of no facts suggesting a different conclusion.

Respecting the relation of Calamite to Calamodendron, Mr. Gardner says my evidence as to their identity is negative rather than positive. If he will honour me with a visit I think I can soon convince him that this is a mistake, and would only add that there is little possibility and no probability of Mr. Gardner's suggestions being true, viz., that I have "*not come across an undoubted Calamite*," and that such may be common in France though absent from our British deposits. We have them by thousands. What I insist upon is that they differ in no respect from the so-called Calamodendra, the supposed differences being merely due to conditions of preservation. That as soon as we get Calamites with any portion of their internal organisation preserved, they all prove themselves to be Calamodendra. And that even when their internal organisation is not preserved the marking on the surface of their thin carbonaceous covering itself demonstrates that identity. The volumes of MM. Marion and Saporta contain other statements to which, as I have informed my friend, I cannot give my assent; but what I now put on record suffices to show the general nature of the points on which we disagree. M. Zeiller's discovery has settled the questions of the existence of exogenous Cryptogams in the minds of most men—even of several of those who hitherto believed in the accuracy of Brongniart's hypothesis. Patient and persevering investigation will, in time, demonstrate which of us is right in reference to other debated questions. Meanwhile the continuance of co-operation and mutual kindly feeling, notwithstanding our differences of opinion, must be important factors in the attainment of certainty.

Manchester, July 31 W. C. WILLIAMSON

Grisebach's "Vegetation of the Earth"

IN No. 823 of your valued paper is an article by Mr. W. Botting Hemsley on the new edition of Grisebach's "Vegetation der Erde," closing with a reproof to editor and publisher for offering the public an old book as new. For my part I have to say that it was my strong desire to have a really new edition of Grisebach's classical work, which was no longer to be had in the booksellers, by one of our geographical botanists of the first rank. This, however, proved unattainable. Seeing I was bound by contract to the family of Grisebach, and the son of the deceased, Dr. Edward Grisebach, German Consul in Milan, insisted on bringing out the "new" edition himself, all entreaties, representations, and explanations were of no avail. He declared he would never trust the work of his father to other hands and that he felt himself called upon to prepare a new and improved edition. I had therefore but the alternative of seeing the work completely disappear or committing the task of a new edition to the hands of Dr. E. Grisebach, and I think no one will reproach me for choosing the first. At the worst I could only look forward to the new edition being a nearly unchanged copy of the old work (what in point of fact it is), and this seemed to me a far less evil than the complete disappearance of the work, an opinion which friendly and competent judges shared with me. W. ENGELMANN

Leipzig, August 10

[1] Address to the American Association for the Advancement of Science, p. 22, 1883.

A Singular Case of Mimicry

HAVING often read in the pages of NATURE of several cases of protection by simulation (or mimicry), I beg to mention one which has recently come under my own observation, and which, I think, ought to be registered.

I refer to a small insect which I found in a state of larva, and of a white colour, whose back (only) was covered with a layer of moss, and whose movements in this condition were so natural and rapid, that one could immediately perceive that it was the natural *modus vivendi* of the insect. The layer of moss was firmly attached to the body, and completely covered it. I made the experiment several times of placing it on its back, feet uppermost, on a sheet of paper placed on a table. After a few movements the insect, without disturbing the moss, returned to its normal position by making certain movements which resembled those of an acrobat, who, lying on his back, makes use of his hands, and, by a backward somersault, returns to his feet. The little creature is so completely disguised by this layer of moss that, on placing it on the trunk of a tree covered by the same moss, its movements are with difficulty perceived, as the moss in movement may easily be confounded with the moss of the tree. An insect or larva under these conditions could, only with great difficulty, be recognised by its natural enemies (those animals which prey on it).

I send you the specimen to which I refer, the only one I have met with, and which may, during the voyage (of thirty days more or less), die on the way, or pass through some transformation. At all events, you will be able to see the protecting cape, and determine the species, larva or insect, which it protects.

Porto-Alegre, Brazil GRACIANO A. DE AZAMBUJA

[The larva has apparently passed into the pupa stage during the voyage, and has closed the lower side of its protective covering with a silken web. If the perfect insect should emerge, we will endeavour to ascertain its name.—ED.]

Solid Electrolytes

HAVING been for some months occupied with the electrical behaviour of the compounds of copper, silver, and lead with tellurium, selenium, and sulphur, I can confirm the observation communicated to your pages by Mr. Bidwell as to the behaviour of sulphide of copper. He has constructed a primary cell with solid sulphides for the electrolytes. The smallness of the electromotive force which he has obtained is entirely due to the close proximity of copper and silver in the thermochemical series in respect to their heats of combination with sulphur. The theoretical electromotive force should be only ·05 volt.

Let me add to Mr. Bidwell's observation one of my own. If a piece of sulphide of copper is placed between platinum electrodes, a current of electricity from a battery can be passed freely through it, as it is a good conductor. But if after a time the battery is removed and the platinum electrodes are connected with a galvanometer, a current is observed. The solid sulphide between two platinum plates constitutes, therefore, a secondary cell or accumulator capable of being charged and discharged.

Finsbury Technical College, August 17

Preventing Collisions with Icebergs

ALTHOUGH it is, I believe, ascertained that fogs are often higbly athermanous, I would, at the same time, like to ask whether a thermal radiation method might not serve to show the presence of a large mass of ice in the neighbourhood of a ship. I venture to make the suggestion, as I know of no experiments on the degree of athermancy possessed by fogs, as tested by such an instrument as the bolometer of Prof. Langley. The use of this instrument, or even of the thermopile, in conjunction with a large reflector and an alarm circuit closed by galvanometer deflection, might be worth trial by any one possessing the opportunity. Engineering School, Trinity College, Dublin, August

Monkeys and Water

Is it a usual thing for monkeys, either in captivity or in their native condition, to take freely to the water? Some relations of mine have a small monkey that was brought to them from Java, and which is a great pet. One day it was thought that he should be bathed, and he was put on the edge of the bath. In a little while he hung down from the edge by a foot and hand, and drank the water, and then, plunging in, he swam backwards and forwards under the water, with his eyes open, with great enjoyment.

After the first time he was frequently bathed, and a day or two ago I saw him go through the performance. It was very pretty to see how he enjoyed it, swimming under the water and diving away from a hand put down to take him; then going head over heels at the bottom and lying on his back to bite playfully at a finger; then he would run about on all-fours with his head held out of the water, and then go under again: and after it all, when he was taken out and dried with a towel, he lay wrapped up in a shawl, sleeping comfortable and happy. I should like to know whether he is an exception to the rule in his love of the water. JERRY BARRETT

15, Avenue Road, Regent's Park, August 6

A Correction

I HAVE very stupidly made it appear in my note on pitcher plants, printed in last week's NATURE (p. 341), that Dr. McBride was President of the Linnean Society in 1815. I ought to have written, "In 1815 the then President of the Linnean Society read a communication from Dr. James McBride," &c. I suppose Sir James Edward Smith was at that time President of the Linnean Society, and that Dr. McBride never was. W. WATSON

August 15

A MODEL UNIVERSITY

THE following information for applicants for admission to the Johns Hopkins University, printed in the University Circulars in response to letters, we are sure will be read with interest and profit:—

How was the University Founded?—The Johns Hopkins University was instituted by the munificence of a citizen of Baltimore, Johns Hopkins, who bequeathed the most of his large estate for the establishment of a University and a Hospital. The foundation of the University is a capital, in land and stocks, estimated in value at more than 3,000,000 dollars; the capital of the Hospital is not less in amount. The University was incorporated under the laws of the State of Maryland, August 24, 1867, and it was opened for instruction in September, 1876. The Philosophical Faculty (of Letters and Science) is now organised. A medical department will soon be instituted.

In what is Instruction Given?—Systematic instruction is offered in English, Anglo-Saxon, German, French, Italian, Spanish, Latin, Greek, Sanskrit, Hebrew, Arabic, and in other languages and literatures; in pure and applied mathematics; in chemistry (inorganic and organic) with laboratory work; in physics (including mechanics, light, heat, sound, electricity, magnetism, &c.), with laboratory work; in biology (including physiology and morphology) with laboratory work; in mineralogy and geology; in ancient and modern history; in physical geography; in political economy and in the elements of international law; in logic, ethics, psychology, pedagogics, &c. Occasional courses of lectures are also given upon special themes in literature, science, history, archæology, art, &c.

To whom is this Instruction offered?—To all young men who are prepared to profit by it and who will conform to the simple regulations which are established by the authorities. Graduate, Undergraduate, and Special Students are received.

Those who have not already received an academic degree, should aim to secure one by pursuing a liberal and prolonged course of study, at the close of which the degree of Bachelor of Arts will be conferred. Those who may be prevented from seeking this degree will nevertheless be welcomed to the University, provided that they are in earnest and are mature enough in years, attainments, and character to profit by the advantages which are here afforded. Others who have already taken their first degree are encouraged to go forward in advanced lines of work, and for them unusual facilities are provided. Young men who are to pursue the study of law, medicine, or theology, or who have entered upon professional lives, and others who expect to become teachers, if they desire to become proficient in literature and science, have easy access to the class-rooms and laboratories. The degree of Doctor of Philosophy may be obtained, after three years of advanced study, by those who have met the required conditions.

How is this Instruction given?—By all the methods which experience has shown to be useful—varying according to the preferences of the teachers, the subjects taught, and the number of scholars. There are recitations, lectures, conferences, prolonged courses in laboratories, exercises in special libraries, personal counsel, study of nature out of doors. The usual four-year classes are not maintained, but in all the principal subjects taught there are beginners, intermediate students, and advanced workers; so that every scholar is assigned to that position in each section of the University which will yield him the greatest advantages. He may be far advanced in one subject and only a beginner in another. This result is only secured by the engagement of a large staff of teachers.

What are the Laboratory and Library Facilities?—The scientific laboratories are three in number. They are open throughout the day and are fully equipped. For chemistry there is a special building arranged for about ninety workers, and well adapted to all kinds of chemical and mineralogical work. A large building has been recently constructed for a biological laboratory, with complete arrangements for physiological and morphological work. The physical department is furnished with apparatus selected both for demonstration and investigation, and especially valuable for researches in electricity, magnetism, light, and heat. The construction of a new building for a physical laboratory is now under way.

The library includes over 26,000 bound volumes, and 650 serials are regularly received. It is open thirteen hours daily. The library of the Peabody Institute, with 80,000 volumes, and the other Baltimore libraries, are of easy access. Washington is so near that the Library of Congress, the National Museum, and the other libraries and museums of the capital may be readily visited.

What are the Necessary Expenses of a Student?—The charge for tuition in all departments (including the use of the library, and without any extra charges except for materials consumed in the laboratories), is 100 dollars per annum, payable one-half October 1, and the other half February 1.

Young men living in any part of Baltimore, or in the immediate vicinity, can lodge at home, as the first lessons are given at 9 a.m. daily, and there is rarely any required exercise as late as 5 p.m. Young men from a distance can readily find rooms and good board either in private dwellings or in boarding houses. It is possible to secure accommodations (room and board) for 5 or 6 dollars per week, and for a sum between 6 and 10 dollars per week it is still easier to be suited. The other necessary expenses of life are moderate.

Are there any Scholarships?—In accordance with the request of the founder of the University, twenty Hopkins scholarships, giving free tuition, are annually conferred upon matriculated undergraduate students from Maryland, Virginia, and North Carolina. In addition to these scholarships, eighteen honorary Hopkins scholarships, yielding 250 dollars and free tuition, are offered to those collegiate students from the three States above-named who pass the matriculation examinations with the most credit. Two scholarships giving free tuition are also open to matriculated students from the district of Columbia. Twenty scholarships yielding 200 dollars, and twenty fellowships yielding 500 dollars are annually open to graduate students.

What Special Opportunities are offered to University Students?—Advanced and graduate students are received with or without reference to their being candidates for a degree, and they are permitted to attend such lectures and exercises as they may select. They are not examined for admission to the University, but each instructor satisfies himself of the attainments of all who wish to follow his guidance before admitting them to his classes.

Systematic courses of instruction, varying every year, are announced in the annual programme. The professors are free to give personal counsel and instruction to those who seek it; books and instruments adapted to investigation and advanced work have been liberally provided; the system of Fellowships secures the presence of twenty special students imbued with the University spirit, most of them looking forward to academic careers; seminaries limited to a few advanced students under the guidance of a director have been organised in various subjects; societies devoted to philology, to mathematical, physical, and natural science, to metaphysics, to history and political science, and to archæology, afford opportunities for the presentation of memoirs and original communications, and there are also clubs for the reading and discussion of biological, physical, and chemical papers; during the year courses of lectures are given by resident and non-resident professors on topics to which they have given special attention; the libraries of the Peabody Institute and Maryland Historical Society, founded for the advantage of scholars, are easily accessible; the issuing, under the auspices of the trustees, of publications devoted to mathematics, chemistry, philology, biology, and history brings the University into advantageous connection with other foundations; special libraries connected with the seminaries bring the most important works within easy reach of the student, and the University reading-room, which is constantly open, is liberally supplied with new and with standard books and with the literary and scientific journals of this and other lands.

On what Conditions is the Degree of Doctor of Philosophy Conferred?—The degree of Doctor of Philosophy and Master of Arts is conferred upon candidates who (after having taken their first degree) have pursued University studies, for three years, under approved conditions, have passed the required examinations and presented a satisfactory thesis. At least the last year of study must be spent in this University.

How are the Fellowships Awarded?—Twenty fellowships are annually open to competition, each yielding five hundred dollars and exempting the holder from all charges for tuition. A statement of the rules governing the awards will be sent if requested. Applications for the next year must reach the University before May 1, 1886.

Is there what is commonly known as a College Course? There are seven parallel courses, by following any one of which a matriculated student may attain the degree of Bachelor of Arts. This plan combines the advantages of choice and restriction. From the variety of courses laid down, the scholar elects that which he prefers; having made his choice he finds a definite sequence of studies provided for him. The University marks out for those who elect a classical course, such a plan for the reading of Latin and Greek authors, sometimes with a teacher and sometimes privately, as will enable all who follow it to excel in these studies, while it requires that they should also learn to read French and German, and pursue during one year a course in science. It likewise provides a training which is mainly scientific, enabling the student to concentrate his attention chiefly on chemistry, or biology, or mathematics, or physics; but with these studies he must combine the study of languages, history, and philosophy.

Every matriculated student is expected to follow, under the guidance of an adviser to whom he is specially assigned, one of these prescribed courses which are fully described in the Register. Some elect the classical course. Others may concentrate their main attention upon the higher branches of mathematics. Courses are arranged also for those who wish to devote themselves chiefly to chemistry and physics. For those who expect at a later day to take up the study of medicine, there is a special course marked out, in which biology is the dominant subject. Arrangements are also made in other courses for the study of history and political science and of the modern languages and literatures.

What is required for Admission to the College Courses? —Undergraduates who wish to enter, either as matriculates, candidates for matriculation, students in the preliminary medical course, or as special students, must begin by satisfying the University that they have been thoroughly taught the English studies which are usual in good high schools, academies, and private schools, including a knowledge of arithmetic (with the metric system); geography, physical and political; the outlines of the history of the United States; English grammar and composition. The candidate for matriculation must also pass an examination in—

(1) Latin; (2) Greek (or French and German); (3) mathematics (algebra, geometry, trigonometry, analytical geometry); (4) English; (5) history; (6) natural science. Those who do not intend to follow the classical course may offer French and German instead of Greek. A student may be admitted, under certain circumstances, without matriculation.

Can a Student be aided in Completing his Studies for Matriculation?—If a student at his admission passes in a considerable part of the matriculation requirements he may postpone the remainder for a time. If he is well up in algebra and geometry he may join the University classes in trigonometry and analytical geometry; if he is a good scholar in Latin and Greek, but has not read all the authors requisite for matriculation, he may receive instruction in these authors from the University; if he has not already acquired the elements of French and German he will be aided in doing so, in order that he may enter the courses here provided.

THE HARVARD PHOTOMETRY[1]

WE have waited for the second part of this very remarkable volume completing the Harvard Photometry, rather than examine the separate portions piecemeal. There can be no doubt that its appearance is associated with an epoch in the general progress of astronomical science, coincident nearly with the other

[1] Constituting Parts 1 and 2 of vol. xiv. of the *Annals* of the Astronomica Observatory of Harvard College. (1885.)

corresponding advances in connection with the spectroscope and sidereal photography. The three combined constitute a distinct feature in the more modern methods, by which we are gradually becoming better acquainted with the infinite remote. So soon as molecular physics shall have made, as is promised, a like advance, then the infinite minute also will be brought more distinctly within the human ken.

With regard to the Harvard volume on Sidereal Photometry, without unreservedly conceding to it all the accuracy to which it lays claim, it must be gratefully acknowledged that it provides astronomers with a consistent and valuable catalogue of stellar lustre which, in a complete form, had not hitherto existed. It dispenses with the too often unreliable and discordant estimates of the past, and replaces them by scientific measures possessing, to say the least, considerable precision.

The two parts of the volume contain together no less than 512 closely-printed pages, many of them abounding with models of condensation, and constituting in themselves a remarkable instance of sustained and successful scientific labour. They embrace not only the general history of the subject to which the volume refers, but they at the same time combine elaborate criticism and valuable comparisons of the results of preceding labourers in the same field.

In the first part there is given a description of the meridian photometer, with which the measures of comparative lustre of the stars are obtained. In it are most ingeniously combined the more valuable and least dangerous devices which are found in the instruments devised by Sir John Herschel, Steinheil, and Zöllner. Taken as a whole, the instrument may be properly regarded not only as ingenious but as original. Roughly speaking, it consists of two contiguous telescopes placed horizontally nearly in the meridian, each of the object-glasses being armed with a reflecting prism, so that the light from Polaris and any other star may be brought into the same field of view, after having passed through a double-image prism. The images are then viewed through a Nicol prism, and, by means well known to physicists, the light of the one star is reduced by a measurable amount until it is adjudged to be equal to that of the other star.

We trust we may be pardoned if we suggest that this construction of the instrument may possibly be too complicated to admit of that amount of precision in the measures which could be desired, and which might be obtained by simpler means. In fact, it appears from the volume itself, that at the commencement of operations, it was necessary to abandon the results of several months' work with it; and although an improvement in the use of it was subsequently adopted, we think there still remain traces of the possibly inherent difficulty of precise adjustment. The rapidity also with which the equalisation of brightness of each star with that of Polaris is made, seems hardly consistent with the requisite precision. It is to be inferred from the volume itself that as many as forty-eight final determinations, each consisting of four equalisations of the light of a star with that of Polaris, are frequently completed within the hour, in addition to the consumption of time required for finding and identifying the successive stars and adjusting them in the field of view. But, we cannot doubt, this point has been well considered by the Harvard astronomers themselves.

In the determination of the magnitude of a star, it is the usual practice to rest content, generally, with the mean of three determinations. Each determination is made on a different night, and consists of the mean of four equalisations of the lustre of the particular star compared with that of Polaris in the field of the photometer. We venture to think that the general limitation to three only is too restricted for the purposes of accuracy. The reason for this opinion is derived from the fact that on examining the numerous cases in which as many as fifteen determinations of magnitude are made on as many nights, it is very frequently, and in fact generally, possible to find three consecutive determinations which would of themselves, in the mean, lead to a magnitude widely different from that ultimately assigned. Yet these three consecutive sets furnish no circumstance of inter-discordance among themselves which could lead to suspicion, and which might, consistently with the usual practice, have finally settled the magnitude of the star in question. We regard this not as hypercriticism, but as being the only sufficient means at hand for the examination of accuracy furnished by the volume itself.

Independently of the several catalogues containing the results of three years' unremitting labour and persevering skill, the volume abounds with the intercomparison and reduction to one scale of the work achieved in a similar direction by many preceding astronomers. The result is that astronomers who are desirous of information on the subject of stellar brightness, will probably not be disappointed if they turn to the pages of the Harvard Photometry. Combined with a memoir by Prof. Pritchard, contained in vol. xlvii. of the *Memoirs* of the Royal Astronomical Society, it is perhaps not too much to say that all that is known upon the subject up to the present date will be found easily accessible to the student.

Towards the conclusion of the volume Prof. Pickering has drawn up a very important table, which, though short, must have given him very considerable labour to compute. It contains in one summary a critical comparison of the average results of all the principal catalogues of stellar magnitude hitherto published. The Harvard Photometry is taken as the basis of the comparison, and the difference between the mean or total results of each catalogue and that of the Harvard volume is given. From the inspection of Table lxxxiii. it appears that, taken as a whole, the Harvard measures indicate in the mean a brightness of the stars compared greater than that indicated by the estimates in the *Durchmusterung* of ·14 mag., brighter than the mean of the Uranometria Nova of Argelander by ·10 mag.; of Heis by ·12 mag.; and of Houzeau by ·11 mag. These differences, it will be observed, are all in one direction, and might appear to indicate that there is a generic difference between estimates of star magnitude by the unaided eye, and measures carefully made with a photometer such as is the meridian photometer at Harvard College, because all the estimates are apparently fainter than the measures. But this can scarcely be the true explanation, since the photometric measures also of Seidel, Zöllner, and Peirce indicate, like the eye estimates, a brightness less than that of the American determinations. Moreover, the photometric measures made by Prof. Pritchard at Oxford agree in the mean of the whole, very closely with the eye estimates in the *Durchmusterung* and the other catalogues. But, whatever the significance of this fact may be, it cannot be doubted that the Harvard volume will ever remain a most valuable addition to our knowledge in an important branch of astronomical science.

U.S. INDUSTRIAL STATISTICS[1]

TO all who study anxiously social science, this is a very promising publication; its indirect testimony to the advantages of Republican institutions will be weightier to any reflective man than the eloquent tirades that are so usually bestowed upon them. It defines its object to be the stimulation and assistance of the wage-worker in his endeavour to reach a higher position. Its information respecting working men is all taken from their own contributions, a dozen pages of small print being filled with verbatim quotations from the replies of workpeople in every trade in the State, who give such

[1] "Sixth Annual Report of the Bureau of Statistics of Labour and Industries of New Jersey," 1883." Trenton: New Jersey, 1883.

varied accounts of themselves that the independence of the testimony cannot be doubted. That its work is popular is indicated by the wish expressed by one of them that "there should be a National Bureau." Factory legislation is printed in it (even 1884 legislation, although the printer's date is 1883!); the factory inspector has become a popular institution, and much testimony is borne to the smaller hardship of factory laws uniformly than loosely enforced. The more educated and more prosperous workmen are, the more ambitious and aspiring they become, and we seem on the eve of their blending with their masters when complaints are made, as here, that many of their fellow-workmen are satisfied with *only* 66 shillings a week wages; and a caution is held forth to such not to spend their money in foolishly aping the rich.

Yet, though the teacher here is no longer one of the fatherly governments of the old world using his paternal authority for the good of a rather refractory son, yet the teaching is most satisfactorily similar. Drunkenness could not be set forth as the prevailing cause of pauperism among the men or the evil of a lack of artistic taste among the masters in more vivid or unqualified terms than they are here. The sad combination of progress and poverty is bewailed, but we fear that co-operation urged here as its remedy too much overlooks the control of fashion and its effect upon supply and demand. A most practical power put in the hands of this Bureau is that of examining the accounts of co-operative companies. Any five members of a company may require such an examination.

The principal industries of New Jersey are taken, and, after full statistics of their amount, prosperity and prospects, with the wages earned by each class of workers, an interesting account is given, commencing with a short history of the methods, improvements, and general position of the trade in the United States and in other countries, and their experience compared. Any one casting about for an occupation in which he could take a satisfactory part would find in this "Book of Trades" much to supply the information first required, and much to encourage him. Among them we find a review of the silk trade, which, under the ægis of 60 per cent. duty, has made the wealthy city of Paterson; of glass-making, which at present does not extend much beyond window glass and bottles; of the cultivation of sorghum, still in its infancy in New Jersey; and of the pottery trade—after its account of which it performs the very useful function of a publication like this of appealing to such a trade to take the steps necessary for raising their standard of art. An appeal is made, not from a Government department, or from an interfering *clique* as South Kensington is occasionally regarded as being, but by the organ of his late fellow-workers, that the maker of one of those large fortunes so common in America will, for his country's glory and their help, found a technical school; while hands are led to feel that intellectual training and not mechanical energy alone is wanted. The idea is shown here also to be making its way that the school should be made the basis of technical as well as of mental training; that the dextrous use of the body should form part of the school, as well as of the playground, teaching. More than this, it is felt that they should not be two so distinct branches of education as in past days, and that the members and muscles of the body, as well as the brain, should receive elementary instruction at the school, and that the former should be placed more deliberately under the control of the latter. It is felt in America that

"The cultured mind
The skilful hand"

ought naturally to go together, and not that one should be the usual mark of the absence of the other; that, therefore, a mechanic should not mean little more than a machine, but a mechanician, able to understand, make or repair the giant body that is using its limbs to save his exertions, and therefore a man more on a level with other men whose time has been given to the cultivation of their minds only, and more justified in insisting upon their equality with the latter. It is urged in this Report that elementary technical knowledge valuable to all the New Jersey trades may be given in ordinary schools; that technical learning is popular, frequently most so to boys who are slow at books; and that successful manual occupation improves the morality of the worst of such boys.

A very favourable notice of the Reformatory school at Coldwater; a sad tale of jail arrangements, and of methods of keeping the poor, all lead to discussions of economical difficulties felt long ago in England, not by any means avoided in America, and showing how little forms of government can modify human nature. A more hopeful view of that is afforded by the account, illustrated with three engravings and three plans, of a working-man's Institute at Millville. At this one establishment, which seems to have cost little more than 4000*l*., are combined, besides large grounds used for field sports, bicycling, &c., a gymnasium and baths in charge of a barber in the basement, while on the ground floor are a conversation room hung round with maps and supplied with musical instruments on which performances are given, where also lectures are delivered, discussions held, and games of skill played. Side by side with it is a library and reading-room. Up stairs are four class-rooms and a large hall seating 500 persons, besides a gallery over the rear half of it. At the other end of it is a stage with two dressing-rooms and other necessary adjuncts. This room is used on Sundays as well as on weekdays by various societies—a choral class among others—and is a convenient source of revenue.

It is impossible to lay down our Report without feeling that if each department of its work is by itself of little importance, it will doubtless be a useful agent in making every inhabitant of New Jersey and of the United States a more intelligent worker at his trade or surveyor of the economies around him.

PIERCING THE ISTHMUS OF PANAMA[1]

THREE years ago the work of cutting through the Panama isthmus had barely commenced. The equatorial forests on the neck of land, 73 kilometres long, which marked the axis of the future interoceanic canal, had hardly been laid bare. The traveller who followed the primitive road met here and there some groups of cabins, with roofs of branches on poles, marking the site of a sounding or the improvised dwellings of a portion of the operators. Culebra, Emperador, Corosita, and Gamboa, which are now full of activity, were then almost desert, and on the coast of Colon alone the excavator traced in the marshy plains of Gatun his great track. The contrast to-day is great: a long file of workshops covers the space between the Atlantic and the Pacific. Twenty thousand workmen toil on the Cordillera, making the deep cutting for the canal. Side by side with this army, another more powerful army of colossal machines, excavators, dredges, locomotives, waggons, all the materials for transport, thousands of pairs of wheels, hundreds of kilometres of rails, mountains of coal, and shiploads of dynamite. Among the twenty-five workshops of the peninsula the attention is chiefly attracted to two points: the great rocky cutting at Culebra, which is to penetrate to a depth of 120 metres into the Cordillera, and the dam of the Chagres at Gamboa. At Culebra the previsions of M. de Lesseps have been realised: the mountainous mass which the canal will traverse is, for the most part, composed of rocks which are not very hard; repeated soundings by means of diamond perforators have shown that down to a

[1] Abstract from *La Nature*.

considerable depth the rock takes the form of schists in horizontal strata. There is no doubt that it can be cut through with rapidity; it is a matter of perforation, either by mining and ordinary explosives, or by shafts with larger quantities of some explosive to displace great masses. Here 30,000 cubic metres of rock have been displaced by an explosion of dynamite; and unquestionably this colossal channel connecting two seas may be executed by simple methods and with economy.

At the end of the great cutting of Culebra, 6 kilometres from Emperador, is the great workshop for the dam across the Chagres. This gigantic basin, containing about 1,000,000,000 cubic metres of water, the surface of which is 60 metres above the water of the canal, has a bank, the content of which is 7,000,000 cubic metres. The volume of water kept in by this exceeds a hundredfold that of any reservoir in the world. By means of this work inundations in the river are prevented, currents impeding navigation and introducing rough water into the canal are avoided, and there is no fear of the accumulation of alluvion in the bed. By regulating the flow of the Chagres and of the neighbouring streams, the dam at Gamboa assures the regular service of the canal. The method of constructing this work of proportions without precedent in the annals of public works is a very simple one. From the great cutting at Culebra, near Gamboa, and the neighbouring cuttings, about 50,000,000 cubic metres of rock are removed, while only about 7,000,000 are required for the Chagres dam, and therefore the work is one of transport only—a colossal one, it is true. Even the site of the dam is formed naturally by the disposition of the bed of the torrent, which is contracted at this place between the hills of Obispo and Santa. Cruz, which are distant about 150 metres from each other, and on which will rest the front wall of the great reservoir. Behind this first barrier will be thrown, as they are taken from the Cordillera, the 7,000,000 metres of rock, and the dam will be complete. The originality of the project is that, strictly speaking, there is no masonry at all in this enormous mass of rock of all sizes and shapes; the accumulation alone gives the mass firmness. The plan given here enables us to follow the sinuous course of the Chagres River. Like all torrents, and especially all torrents in equatorial regions, it is subject to considerable variations in its flow, and to enormous and violent floods. In winter its flow is 1600 cubic metres per second, while in spring it is barely 13 metres. Its tributaries, or *rios*, are of the same character—the rio Trinidad and the rio Gatuncillo have a flow in winter of 400 cubic metres. It would be impossible to divert these impetuous masses of water into the canal without producing currents and deposits and impeding the navigation. The overflow of exceptional floods will be conducted to the sea by secondary water courses. These latter, which vary in breadth from 8 to 12, and even to 40 metres near the Atlantic, are easily made by utilising the portions of the bed of the river situated on the same bank, and connecting them by appropriate trenches. The enormous reserve behind the dam will flow regularly in this new bed. Of course, the bed of the canal will be completely protected from these deviating waters, in the trenches by the slopes of the latter, and in the lower parts by banks which will soon be covered by a vigorous and indestructible tropical vegetation. With the construction of this reservoir, assured by the clearings from the cutting, and the water regulated and controlled by these courses, the work, like that of the cutting at Culebra, is only one of time. One objection which was raised when the public became acquainted with the almost incredible magnitude of the work, in which a reservoir becomes a great lake, was that this latter might itself be filled up with the alluvial deposits, which it was constructed to keep out of the canal. It is true that in its tropical floods the Chagres carries along a large quantity of alluvion; but this, which would be an insuperable obstacle in the canal, becomes a secondary consideration in the reservoir. It has been calculated by the chief engineer to the work that the Chagres can bring into the lake in *a thousand years* 30,000,000 cubic metres of alluvion, while the cubic content of the lake is 1,000,000,000 cubic metres.

Culebra and the dam at Gamboa have always been the two principal points, the main obstacles to the canal. But there are thirty-five other principal working stations, all connected with the railway between Colon and Panama. As the illustration shows, they are sufficiently near to each other to be considered uninterrupted. Fifty excavators and ten dredges work at the canal. Up to the twenty-fifth kilometre we meet with dredges, at first at Colon for the port, then at Gatun. As far as the Panama Plain there are more than sixty excavators. In the three workshops at Culebra are now installed the contractors who cut the canal from Amsterdam to the North Sea. At Corosal, at the sixtieth kilometre, the great port for access to the canal from the Pacific is to be placed, and there the great American dredges work in the swampy ground. It has been calculated that the work done up to the present is half that required to complete the undertaking, and that this new maritime route to the East will be opened in 1888.

The work stands at present in this position: it involves in all the movement of about 100,000,000 cubic metres of rocks of varying consistency. Of this, 70,000,000 are to be raised, according to the contracts, in successive instalments in 1885, 1886, and 1887. The remaining 30,000,000, which form the actual canal, will be raised at the expiration of this time either by the same contractors or by new ones. Knowing the amount already raised, the contract periods for raising a certain other quantity and the amount remaining to be done at the end of the present contracts, we can, by a sum in simple proportion, calculate when the whole should be completed. In 1888 it should be ready for traffic. This simple programme could only be applied to a work so colossal after a long and laborious period of minute study and preparation. The period of installation is always the most important in all these vast enterprises: the study and command of the appropriate material, the reception, testing, arrangement of the machines, the construction of the workshops, accommodation for the workmen, &c.; it is only when all these have been completed, when all have been made ready for work and tested, that the real work can commence, and that progress becomes sensible. This period of installation lasted, for example, in the case of the St. Gothard tunnel, for fifteen months; but the Panama canal calls for ten times more capital than the tunnel, it is executed in a country which has first to be cleared of a luxuriant tropical jungle, thousands of miles away from all industrial centres. The preparation for this gigantic work under these circumstances was a most important fraction of the work, and it is the opinion of competent men that what has actually been done during the installation period now brought to a close is equivalent to half of the work necessary to achieve the canal. In the case of the Suez Canal, 70,000,000 cubic metres had to be raised; of these, 50,000,000 were raised in two years after the apparatus had been put in working order. Seventy million cubic metres must be raised by the drags and excavators of the twenty-one principal contractors; 18,000,000 are to be raised by August 1 of the current year. These 21 contracts represent an outlay of about 240,000,000 francs, of which 65,000,000 have been tendered by French contractors; 55,000,000 by Americans; 20,000,000 by Italian, Swiss, Swedish, and natives, and 90,000,000 by an Anglo-Dutch Company. All nations are working therefore at the task. The French contractors are at work at the cutting at Emperador; the Anglo-Dutch Company has to remove 13,000,000 cubic metres in the great cutting at Culebra. Practically the whole isthmus is being attacked simultaneously. Fig. 4 represents the work at the station of Emperador. It is connected by rails, on which locomotives run with other stations, and with the Colon-Panama Railway. The material taken out is conveyed to the great dam, which is to keep in the water of the Chagres River. The cutting at Emperador is 200 metres wide in certain places. Next to this comes the great station of Culebra. These two stations are represented in the accompanying sketches. While all this work of dredging and excavating, making cuttings and embankments is going on at the canal, the two ports of entry on the Atlantic and the Pacific are being constructed. At Colon, powerful dredging works are opened. A pier, protected on the western side by a mole, has been built, on which a new town, Christopher Columbus, is growing. On it are placed the workshops, stores, railway stations, &c. All the constructions are connected with the rail-

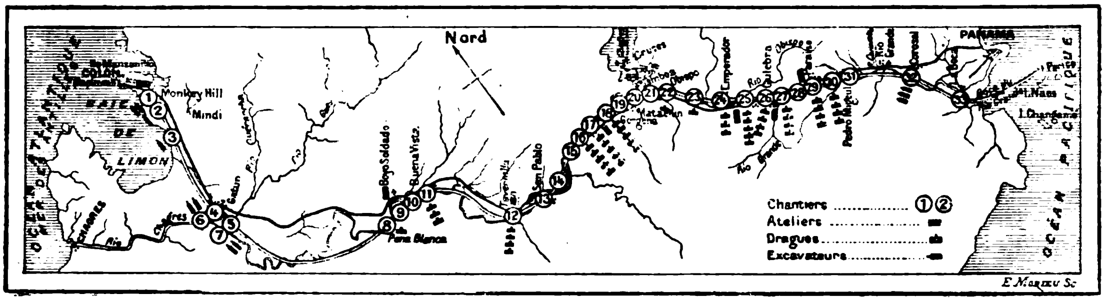

FIG. 1.—Line of Canal and works in course of execution. 1, 2, dredgings of the Port of Colon; 3, 4, 5, dredgings between Colon and Gatun; 6, 7, deviation of Rio Trinidad at Gatun; 8, dockyard of Pena Blanca; 9, 10, embankment of Bohio Saldado; 11, Buena Vista; 12, Tavernilla; 13, 14, San Pablo; 15, 16, 17, Gorgona; 18, 19, Matachin; 20, Gamboa embankment—the great dam; 21, Cerosita; 22, Upper Obispo; 23, the Obispo; 24, Emperador; 25, El Lirio; 26, 27, 28 La Culebra; 29, 30, Paraiso; 31, Pedro Miguel; 32, Corosal; 33, Boca Grande.

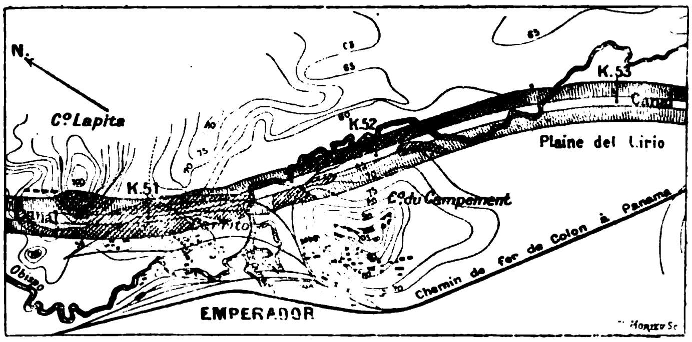

FIG. 2.—Emperador Docks.

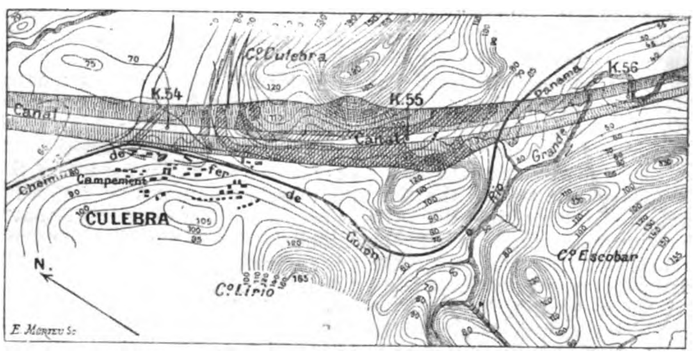

FIG. 3.—Culebra Docks.

way across the isthmus by a series of branches. Vessels drawing any amount of water can discharge at the wharf projecting into the sea, and completely protected from the wind. On the Pacific coast, the creation of a port at the mouth of the Rio Grande presents no technical difficulties, and six dredges are now at work making a channel 100 metres in width to the sea. A special organisation has been created to deal with the vast material, its employment, and repair. The isthmus has been divided into three sections, with a centre at Matachin, at the foot of the great embankment and the cutting. Here all the material is concentrated, all the repairs executed, and all the machinery put in working order. The railway of the isthmus is now the property of the Canal Company, and facilitates greatly this movement of the machinery on which the regular working of the various sections depends. By its means each working station is in communication with the central one and with every other.

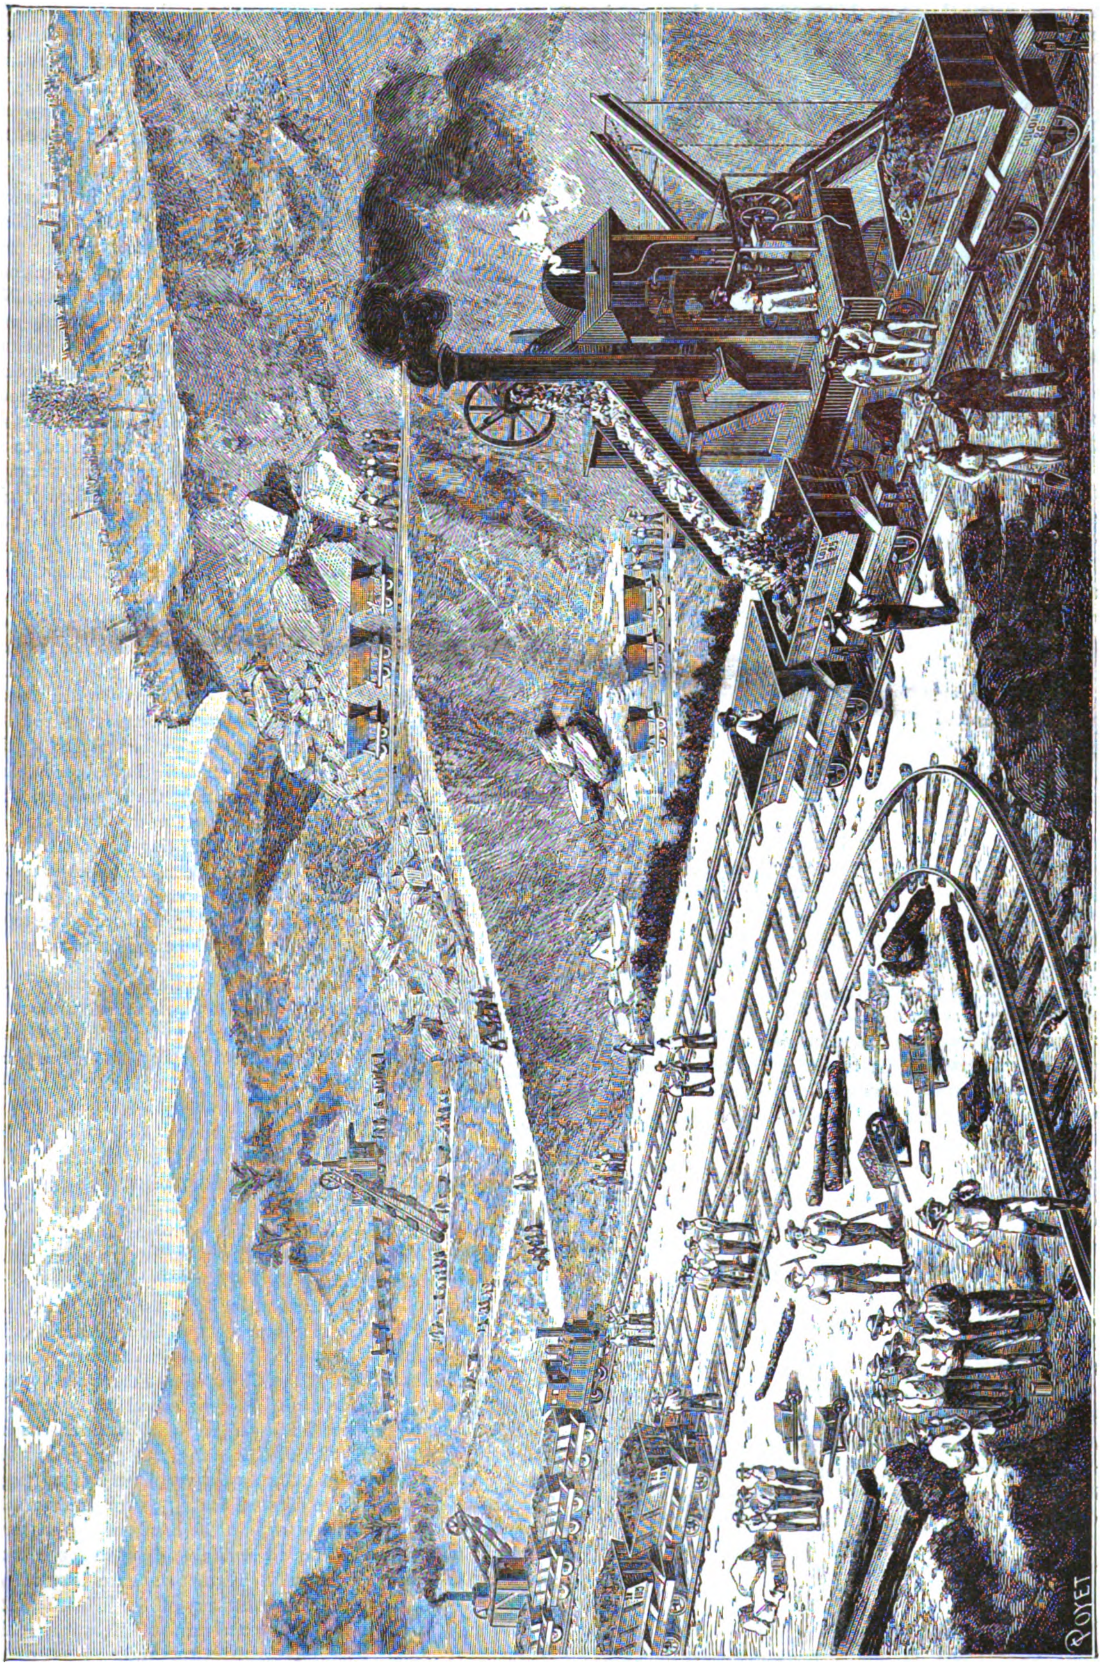

FIG. 4.—Excavations at Emperador Docks

To sum up, more than two-thirds of the work of making the canal is now in execution, under formal engagements with contractors. The problem of the canal has been solved in principle. The period of installation or preparation has been succeeded by one of execution, based on a definitive programme, accepted by those who must carry it out, the Company itself maintaining an attitude of rigorous surveillance.

NOTES

THE fifty-eighth meeting of the German Association of Naturalists and Physicians will this year meet at Strassburg. Notices of communications and abstracts of papers should be sent to Herr J. Stilling. The meeting will commence on Thursday, September 17, and terminate on September 23.

THE local committee of the American Association has issued its second circular containing the general programme of the meeting at Ann Arbor. The meeting will be called to order on Wednesday, August 26, at 10 a.m., when Prof. Lesley will resign the chair to President-elect Prof. Newton of New Haven, and the usual addresses of welcome will be delivered. In the evening Prof. Lesley will give his presidential address. On Thursday evening the citizens of Ann Arbor will tender a reception at the Court House, and on Friday it is probable that a lawn party will be given on the University grounds. On Saturday a long excursion, as previously announced, will take place; on Monday a short excursion for the members of the Botanical Club has been planned, probably to the Tamarack swamp, one of the detached spots common in Southern Michigan where a northern flora has lingered under favourable conditions through the various climatic changes of later geologic times. It is probable that similar trips to points of local interest may be arranged for some of the sections. The chairman of Section C announces that the following subjects have been chosen for discussion: first, what is the best initiatory course of work for students entering upon laboratory practice? second, to what extent is a knowledge of molecular physics necessary for one who would teach theoretical chemistry? In the discussion in Section D, mechanical science, of the best method of teaching mechanical engineering, in order that what is read and said may be to the point, the following classification should be observed: (*a*) schools of mechanical engineering; (*b*) mechanic art schools for the education of superintendents, foremen, &c.; (*c*) manual training-schools. The distinction between "mechanical laboratory practice" and "shop practice" should also be made and appreciated.

THERE seems to be no doubt that Sir Nathaniel Barnaby is about to close his connection with the Admiralty as Director of Naval Construction. We shall be interested to see in what manner the new Government fills up the vacancy, and what treatment they give Sir Nathaniel's successor, who, it is rumoured, may be Mr. W. H. White. As is known, Mr. White some time ago resigned his connection with the Admiralty for a far more lucrative post in Sir W. Armstrong's works. "But there is a difficulty in the way," as the *Pall Mall Gazette* puts it. "Private firms can pay, and do pay, their chief constructors twice, three, and four times as much as the Admiralty. Perhaps Mr. White may consent to sacrifice some thousands a year for the honour and glory of serving his country, but the time will come when scientific skill, like other commodities, will have to be purchased at the Admiralty at its market rate." Perhaps a Conservative Government will show itself more alive to this aspect of the post than its Liberal predecessor.

DR. PAGENSTECHER, of Hamburg, has just described a new form of Frugivorous Bats from a specimen transmitted to the Natural History Museum of that city by Herr H. Soyaux, of Gaboon. *Megaloglossus woermanni*, as this new mammal is proposed to be called, is remarkable as belonging to the long-tongued division of the Pteropine Bats, which was not previously known to occur anywhere within the Æthiopian region. *Megaloglossus* is closely allied to *Macroglossus* and *Melonycteris*, and in some characters is intermediate between these two genera. In its dentition it also exactly resembles them.

WE are informed by Dr. G. A. Guldberg, of the University of Christiania, that the fishery of rorquals or fin-whales (*Balænoptera*) established at Vadö in East Finmarken, for commercial purposes, continues to be turned to good account for scientific investigation. This year Dr. R. Collett, the well-known Norwegian naturalist, is visiting the place, and has already made many interesting observations upon the structure and habits of Rudolphi's whale (*Balænoptera borealis*), which has been captured in considerable numbers during the latter part of July, although the great blue whale (*B. sibbaldii*), generally so numerous, has not yet been seen upon the coast. This is attributed to the absence of the *Thyssanopoda inermis*, a small crustacean on which the blue whale feeds. Rudolphi's whale is called "seje" or "cod" whale by the Norwegians, as it appears on the coast at the same time as that fish, but its food is also a crustacean of a still smaller species than that which is the chief nourishment of its gigantic relative. It usually visits the coasts of Finmark between the months of May and August, and has lately been taken several times on the east coast of Great Britain (Firth of Forth, 1872; River Crouch, Essex, November 1883; mouth of the Humber, September 1884). Dr. Guldberg gives its average length as 40 feet, but says it sometimes attains 50 feet. Its shape is more elegant than that of the commoner species, *B. musculus*, which it otherwise resembles. Its colour is black, and does not show the bluish tint seen in the latter species and in *B. sibbaldii*. The sides are spotted with white, and the under parts are white with a faint reddish tinge. A new use to which the whales killed at Vadö have been lately put is tinning their flesh, which is said to be wholesome, and to find great favour in Catholic countries, where, being fish according to the zoology of the Church, it is allowed to be eaten on fast days.

WE have received the annual report for the past year of Prof. Spencer Baird, Secretary of the Smithsonian Institution. It includes an account of the work performed by the Institution itself, as well as that of the branches of the public service placed by Congress under its charge, namely, the National Museum and the Bureau of Ethnology. A sketch of the work of the United States Fish Commission and of the Geological Survey is added. We observe that the additions to the Museum are described as unexampled in extent, consequent partly upon the labours of the Geological Survey, of the Ethnological Bureau, of the first Commission, and of numerous miscellaneous explorations, both public and private. These various explorations are briefly described. Amongst the forthcoming publications is one on the Botany of North America, by Prof. Asa Gray, part II. of which is in the press. It comprises the Gamopetalous orders from *Caprifoliaceæ* to *Compositæ* inclusive. An enumeration by the author indicates that of the *Caprifoliaceæ* there are 8 genera and 47 species; of *Rubiaceæ*, 26 genera and 86 species; of *Valerianaceæ*, 2 genera and 22 species; of *Dipsacaceæ*, 1 genus and 2 species (naturalised); of *Compositæ*, 237 genera and 1610 species. It will form an octavo volume of nearly 500 pages. The geological map of the United States, commenced in 1883, has been completed and placed in the hands of the engraver. It was found, after collating all available data, that the knowledge acquired is not sufficient to warrant the extension of geological colours over the entire territory of the United States. Accordingly, California, Oregon, and parts of Montana, Idaho, Nevada, Arizona, Utah, New Mexico, and Texas remain uncoloured. This map will be issued in two editions within a few months. The first edition will be coloured in accordance with the scheme previously adopted and published by the Survey. It will form one of the plates of the Fifth Annual Report of the Survey, and a brief explanatory statement will accompany it. A second edition, with complete explanatory text, will be issued as a bulletin. In this edition the map will be printed in duplicate, one copy coloured in accordance with the published scheme, the other with a scheme now under consideration.

IT is reported from America that Cotopaxi in Ecuador began a serious eruption before daylight on July 23. Streams of lava, with ashes and stones, overwhelmed part of Chimbo, situated near Cotopaxi, and one hundred houses were destroyed. Reports from Guayaquil state that the eruption began at 1 a.m., sounding like incessant discharges of heavy artillery, shaking the earth and rattling windows and doors. At times there was a continuous roar. Guayaquil is 130 miles from Cotopaxi.

ACCORDING to a telegram from St. Petersburg to Scandinavian journals, dated August 4, severe earthquakes have taken place at Tashkend and Wernoje in Russia. In Pishek every house suffered, and the new settlements Sukuluk and Belowodsk were destroyed. In the latter place the church fell in. It is stated that fifty-four persons were killed and sixty injured. The shocks continued to be felt several days, and there are great fissures in the earth.

ACCORDING to a telegram from Simla, shocks of earthquake are again being felt in Cashmere.

THE Anthropological Congress which is shortly to be held at Rome will have a curious feature in a collection of seven hundred skulls of criminals, numbered and classified. To these will be added the photographs of 3000 and the brains of more than 150 convicts, thousands of autographs, poems, sketches, and special instruments, the work of criminals, an album containing a record of 700 observations, physical and moral, on 500 criminals and on 300 ordinary men. There will also be graphic maps of crime in Europe with reference to meteorology, food, institutions, suicide, &c.; tables of the stature of criminals in relation to the length of the arms, and of crime in towns compared to that in the country. M. Bertillon will exhibit the graphic curves of 23,000 *recidivistes* examined in twelve parts of the body and the practical results obtained. Photographs of Russian political and other criminals, especially of those from Moscow, and wax masks of a large number of celebrated criminals, will also be exhibited. All the notabilities in the science of criminal anthropology will take part in the Congress.

THE death is announced from Copenhagen of the eminent Danish archæologist, Prof. Worsaae.

A SUPPLEMENT to the *London Gazette* of August 12 gives a list of Jury Awards to the exhibitors at the International Inventions Exhibition.

THERE are now to be seen at the Inventions Exhibition Aquarium some specimens of the black bass, indigenous to the principal rivers and lakes of Canada and the United States of America, where they are found in abundance. This species is very difficult to rear in the waters of our country, and the manner in which they have become naturalised to their sphere of existence at the aquarium referred to is certainly remarkable. Their introduction to the waters of this country is extremely undesirable on account of their voracity, but they provide excellent sport to the angler.

IN regard to the introduction of the catfish to English waters by the National Fish Culture Association, which is discouraged on account of the voracity of this species, Prof. Baird, the United States Commissioner of Fish and Fisheries, writes to state that the catfish is an unmolesting animal and does not exclusively prefer live food to other kinds. The professor considers much advantage would accrue from their acclimatisation in our waters. The Association referred to has carefully noted their proclivities in the ponds where they are now located and experimented upon their food and at present cannot disprove Prof. Baird's assertion.

PROF. S. NEWCOMB, of Washington, is at present visiting Stockholm, as the guest of Prof. Hugo Gyldén, Astronomer Royal of Sweden. Prof. Newcomb proceeds to Pulkowa in order to visit the Imperial Observatory.

AT about midnight on July 29 a remarkable phenomenon was seen at Jönköping (Sweden), over lake Wettern. A strong luminosity was suddenly seen in the north, where some very peculiar clouds—looking like icebergs—were seen almost to touch the water. From these clouds electrical discharges continually proceeded, imparting to them a bluish, phosphorescent light, somewhat ruddy near the water and intensely yellow at their sides. It seemed like a constant discharge of fireworks from the lake. It was remarkable that the light—as is generally the case with an electrical discharge in the atmosphere—did not assume the form of bunches of streamers, but at one time flared up intensely and at others formed narrow bands across the clouds. Above the latter there was a faint bluish reflection. The lake lay as calm as a mirror, and though an optical illusion was uncommon in these parts, the western shore seemed close to the town, while the eastern disappeared in the clouds. Except the electricity-laden clouds in the north the sky was clear, stars shone, and the full moon was bright. Below the latter the sky seemed faintly red, compared with the intense electric light. At Katrineholm the same phenomenon was seen in the north-east. Here an intense glare was seen above a cloud, assuming the appearance of two gigantic lustrous trees, which remained thus for half an hour, when it changed into a variety of forms. There was no noise accompanying the phenomenon, which lasted in both places for about one hour. It is not probable that the phenomenon could have been of auroral nature on account of the brightness under a full moon.

M. CAMBRELENT, Inspector of Public Works, has made a report to the Agricultural Society of France on the subject of the dunes in the *landes* of Gascony. These sand-hills cover a surface of more than 85,000 hectares; they are more than 80 metres high and 5 to 6 kilometres wide. Before a method of arresting these was discovered they were being constantly pushed inland by the winds, invading and covering fields, villages, and even burying churches up to their towers. In 1780 Brémontier sought to render them immovable by planting them, after many experiments designed to develop a primary vegetation. His work has been continued with perseverance, and it is only recently that it has been completed, and these 85,000 hectares, which menaced all the country adjoining, have become covered with a rich forest vegetation which has fixed the dunes in one place. A great public danger has been converted into a large forest. But this work, which renders permanent, dunes already existing, has not prevented the sea from throwing up on the coast new sand day by day, which forms dunes, which in their turn invade the permanent dunes. After having fixed the old sand-hills, the problem was to prevent the formation of new ones. To solve this it was decided to construct a dune above high water, in which all the conditions of the movable dunes would be reversed. The form given to the latter by the wind is such that on the side of the sea they present a gentle slope, which the sand can mount easily as on an inclined plane, in order to fall down a steep decline. It is by the gentle slopes forming a series of inclined planes that the sand moves forward. The formation of the new dune was encouraged, but it was directed in such a manner that it had a steep slope on the side of the sea. To secure this a wooden palisade was erected about 120 metres away from the sea, all along the shore. The sand first struck against this in its progress, and fell at its foot, a portion of it escaping through the interstices left between the planks. The latter was carried some distance by the force of the wind, and fell, forming slight slopes, while the sand which fell at the foot of the palisade on the side near the sea formed a steep incline. Soon this reached the top of the palisade, and then the planks were drawn up by means of a special implement to the needed height, and the formation continued as before, the slope on the side of the sea growing steeper, while the other got more and more gentle. Ultimately the dune reaches such a height (generally 10 to 12 metres) that the sand can no longer get over it, and it is definitely arrested between the barrier and the sea. It falls back on the shore, unable to advance, until contrary winds come and blow it out to sea again. To fix the sand on the other side of the barrier, the *Arundo arenaria* is planted. The roots penetrate to a depth of 4 or 5 metres, and the plant always keeps its head above the increasing sand. The results obtained by this new dune (says M. Chambrelent) have been complete. The most violent storms have not been able to carry the sand over it; the latter has fallen back on the shore innocuous, and the advance of the inexhaustible sand coming from the sea has been absolutely arrested.

THE additions to the Zoological Society's Gardens during the past week include a Common Camel (*Camelus dromedarius* ♂) from Egypt, presented by Major Frank Graves; a Shag (*Phalacrocorax graculus*), from Ireland, presented by Capt. F. H. Salvin; a Common Stoat (*Mustela erminea*), British, presented by Mr. H. Hanauer; a Common Chameleon (*Chamæleon vulgaris*), from North Africa, deposited; a Spotted-tailed Dasyure (*Dasyure maculata* ♂), two Yellow-footed Rock Kangaroos (*Petrogale xanthopus* ♂ ♀), from South Australia, received in exchange; a Coquerel's Lemur (*Cheirogaleus coquereli*), an Elliot's Pheasant (*Phasianus ellioti*), a Bar-tailed Pheasant (*Phasianus reevesi*), four Long-fronted Gerbilles (*Gerbillus longifrons*), bred in the Menagerie.

GEOGRAPHICAL NOTES

M. VIOLET D'AOUEST read a note at a late meeting of the Geographical Society of Paris on aërial formations on the soil. Referring to Richthofen's discovery of a vast aërial formation of loess in China, M. d'Aouest described "meteoric formations" which he had himself examined in Mexico. In 1857 he made a communication on this subject to the Society; he found in the flanks of the most elevated mountains argillaceous deposits, which could not be attributed to decomposition of the rocks there, or to the alluvion deposited by rivers, or by the rain. He referred them after investigation to atmospheric currents. In the day the winds raised the particles from the plains and carried them at night to the hills, depositing them there. In course of time these deposits had reached a thickness of thirty to fifty and in places a hundred metres. The upper part, which was generally finer, stopped at the limit of herbaceous vegetation, for beyond this there was nothing to retain the particles, which were carried down by rains, glaciers, snow, or winds to the lower part. Fifteen years later he heard of Richthofen's publication on the subject, and Col. Prjevalsky during his late journeys in Thibet states that analogous aërial deposits are now being formed under the influence of powerful winds which prevail at these altitudes. Subsequently M. d'Aouest met Baron Richthofen and discussed the subject with him, when the latter stated that these formations exist in Europe, adding that it was singular how men, unknown to and far removed from each other, could be led to make the same discoveries in wholly different regions. M. d'Aouest now intends publishing a translation of Richthofen's monograph on the subject, with a supplement of his own containing a number of important documents which he has collected on these deposits. He thinks he will be able to explain loess and argillaceous deposits, the origin of which has hitherto been regarded as problematical, by this theory.

THE *Bollettino* of the Italian Geographical Society for July prints two inedited letters of early Italian adventurers in South America, recently brought to light in the Archives of Florence and Modena. The longer and more important, dated Dec. 24, 1534, is addressed from Valenzuela (Venezuela) by a certain Tomaso Fiaschi to his brother in Florence. After mentioning the preparatory arrangements made for an expedition of 800 men organised for the purpose of seeking gold in the Orinoco basin, the writer—one of the party—describes the country, the appearance and customs of its inhabitants, the nature of the soil, its climate, animal and vegetable productions. The success of the enterprise, which, nevertheless is known to have ended in failure, is anticipated, because the natives "are so bestial and have so little understanding that they think man and horse one and the same thing, and have so much dread of said horses that they die of fear, and one horseman is worth a thousand Indians, and they also greatly dread the blunderbusses, as to them a strange thing it seems to see men dying and not not know from what; so that if they were a hundred and saw four or six of them die, all would take to flight like beasts. And so we shall go to said conquest in the name of God." Further on the men are said to take "one or two wives as best seems to them, and when they don't like them they leave them and take others, and the brother the sister, though true it is mother does not take son, but there are places where they heed nothing and are like the beasts, and worship the sun and moon. And they have a kind of cotton with which they make beautiful things to their fancy, as cloths, which the women wear in front and certain *camach* (hammocks), in which they sleep, which are the length of a man, and are attached to two stakes in their houses. Here no *grano* (wheat?) nor wine is made, but instead of grano they have a certain thing which they call *maize*, which they sow the whole year, and which springs up and grows high in two months; and likewise they sow certain *ceca*, which they call *patatta*, and it has a very large *barba* (root), and said barba is cooked in the ashes, and it has the same taste as the chestnut, &c."

A PROJECT for the compilation of a detailed topography of Italy during the Roman domination will engage the attention of the Italian Historical Congress which meets at Turin next month.

A REUTER telegram from Brussels, dated August 12, says that, according to a message from Madeira in the *Indépendance Belge*, the Marquis Buonfanti, the celebrated explorer, and M. Casman, chief of the Equator station, have died on the Upper Congo.

THE current number (Band xii. Nos. 5 and 6) of the *Verhandlungen der Gesellschaft für Erdkunde zu Berlin* contains a paper by Herr Bandelier on the border lands of the United States and Mexico, in which he describes the territories of New Mexico and Arizona and the Mexican States of Sonora and Chihuahua, their climate, hydrography, topography, flora, fauna, ethnography, antiquities, &c. These subjects are touched rapidly and somewhat superficially, as Herr Bandelier delivered a lecture rather than read a paper. Dr. Hettner referred to his travels in the United States of Columbia. Our geographical knowledge of this region, he said, depends almost wholly on the surveys and description of the Italian Codazzi and the travels of Dr. Reiss and Dr. Stübel, who visited Columbia in 1867 and 1868 with the special purpose of studying the volcanoes. They visited the southern portion, and therefore Dr. Hettner decided, after having investigated the neighbourhood of Bogotá, crossed the Central Cordilleras, and visited the Cauca valley, to direct his journeys to the Eastern Cordilleras, and to study the States of Cundinamarca, Boyacá, and Santander. He had intended originally to include Western Venezuela as far as Carácas in the undertaking, but this had to be ultimately abandoned. The paper gives a brief description of the country and its people, based on these journeys. Dr. Boas describes his journey in Baffin Land in 1883-84. This paper is accompanied by a map showing the outline of the coast of Cumberland Sound and the west coast of Davis Straits according to the English Admiralty charts and to the new survey of Dr. Boas. The discrepancies are very numerous and in some cases very considerable. Herr Wagner contributes a brief sketch of the life and geographical work of the late Prof. Zöppritz.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, *AUGUST* 23-29

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on August 23

Sun rises, 5h. 0m.; souths, 12h. 2m. 22·7s.; sets, 19h. 5m.; decl. on meridian, 11° 19′ N.: Sidereal Time at Sunset, 17h. 14m.

Moon (Full on August 25) rises, 17h. 49m.; souths, 22h. 40m.; sets, 3h. 38m.*; decl. on meridian, 13° 55′ S.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′

THE MOTOR CENTRES OF THE BRAIN AND THE MECHANISM OF THE WILL[1]

Feeling deeply as I do the responsibility I have incurred in undertaking to address you to-night, I desire to express my regret that I cannot instead share with you the pleasure of listening to the distinguished man who has been prevented by a most painful bereavement from addressing you to-night.

My subject being the mechanism of the will, it might be asked, "What has a surgeon to do with psychology?" To which I would answer, "Everything." For without sheltering myself behind Mr. Jonathan Hutchinson's trite saying that "a surgeon should be a physician who knows how to use his hands," I would remind you that pure science has proved so good a foster-mother to surgery, that diseases of the brain which were formerly considered to be hopeless, are now brought within a measurable distance of the knife, and therefore a step nearer towards cure. Again, I would remind you that surgeons rather than physicians see the experiments which so-called Nature is always providing for us,—experiments which, though horribly clumsy, do on rare occasions, as I shall presently show you to-night, lend us powerful aid in attempting to solve the most obscure problems ever presented to the scientist.

The title I have chosen may possibly be objected to as too comprehensive; but until we are ready to admit a new terminology we must employ the old in order to convey our meaning intelligibly, although there may be coupled therewith the risk of expressing more than we desire. Thus when I speak of the mechanism of the will and the motor centres of the brain, I do not intend (as indeed must be obvious) to discuss the existence of the so-called freedom of the will, or the source of our consciousness of voluntary power.

I shall rather describe to you first the general plan of the mechanism which conveys information to our brain, the thinking organ; next the arrangement of those parts in it which are concerned with voluntary phenomena; and finally I shall seek to show by means of experiment that the consciousness of our existing as single beings, the consciousness of our possessing but one will as people say, while at the same time we know that we possess a double nervous system, is due to the fact that pure volition is dependent entirely on the exercise of the attention which connotes the idea of singleness. Consequently that it is impossible to carry out two totally distinct ideas at one and the same moment of time, when the attention must of course be fully engaged upon each.

[1] Lecture at the Royal Institution of Great Britain by Victor Horsley, F.R.C.S.

I fear that in making my argument consecutive, I shall have to pass over very well-beaten paths, and so I must ask your patience for a few moments while I make good my premisses.

The nervous system, which in man is composed of brain, spinal cord, nerves, and nerve-endings, is arranged upon the simplest plan, although the details of the same become highly complex when we arrive at the top of the brain.

At the same time, while we have this simple plan of structure, we find that there is also a fundamental mode of action of the same—a mode which is a simple exposition of the principle, no effect without a cause—a mode of action which is known as the phenomenon of simple reflex action.

The general plan of the whole nervous system is illustrated by this model. Imbedded in the tissues all over the body, or highly specialised and grouped together in separate organs, such as the eye or ear, we find large numbers of nerve-endings,—that is, small lumps of protoplasm from which a nerve-fibre leads away to the spinal cord and so up to the brain.

These nerve-endings are designed for the reception of the different kinds of vibration by which energy presents itself to us. As the largest example of these nerve-endings, let me here show you one of the so-called Pacinian bodies, or more correctly, Marshall's corpuscles, for Mr. John Marshall discovered these bodies in England before Pacini published his observations in Italy. Here you see one of these small oval bodies arranged on the ends of one of the nerves of the fingers, and here you see the nerve-fibre ending in the little protoplasmic bulb which is protected by a number of concentric sheaths.

Pressure or any form of irritation of this body at the end of the nerve-fibre causes a stream of nerve-energy to travel through the spinal cord to the brain, and so we become conscious that something is happening to the finger.

Here in this section of the sensitive membrane of the back of the eye, the retina, you see a similar arrangement, only more complicated,—namely, nerve-fibres leading away from small protoplasmic masses which possess the property of absorbing light and transforming it into nerve-energy. It is this transformation of nerve-energy into heat, light, pressure, &c., which it seems to me should alone be called a sensation, irrespective of consciousness. And in fact we habitually say we *feel* a sensation. The terms "feeling" and "sensation," however, are frequently used as interchangeable expressions, although, as I shall show you directly, "feeling" is the conscious disturbance of a sensory centre in the surface of the brain, and in fact feeling is the conscious perception of sensations. This distinction between feeling and sensation, if dogmatic, will save us from dispute as to the meaning of the word "sensation"; and further, the distinction is one, as I have just shown, which is justified by custom.

Now the nerve fibre which conveys the energy of the sensation is a round thread of protoplasm which in all probability connects the nerve-ending with a sensory corpuscle in the spinal cord. These nerve-fibres running in nerves are white, whereas, as you know, protoplasm is gray. They are white because each is insulated from its fellow by a white sheath of fatty substance, just as we protect telegraph wires with coatings. It is not stretching analogy too far to say that nerve-force may probably escape unless properly insulated.

In consequence of the fibres being covered with these white sheaths, they form what is called the white matter of the brain; while the nerve centres are grayish, and therefore form what is called the grey matter of the brain, so that the grey matter receives and records the messages conveyed to it by the white insulated fibres.

From the sensory corpuscle, which is a small mass of protoplasm provided with branches connecting it to neighbouring corpuscles, the nerve energy, if adequate, passes along a junction thread of protoplasm to a much larger corpuscle, which is called a motor corpuscle, and the energy of which, when liberated by the nerve impulse from the sensory corpuscle, is capable of exciting muscles into active contraction. These two corpuscles form what is called a nerve centre.

Not only are the motor corpuscles fewer as well as much larger than the sensory ones, but also the nerve fibres which go out from them are larger too. In fact it would seem as if we had another close analogy to electrical phenomena; for here, where we want a sudden discharge of a considerable intensity of nerve force, we find to hand a large accumulator mechanism and a large conductor, the resistance of which may justly be supposed to be low. Finally, the motor nerve-fibre terminates in a protoplasmic mass which is firmly united to a muscle fibre, and which enables the muscle fibre to contract and so cause movement of one or more muscles. Now, with this idea of the general plan on which the whole nervous system is constructed, you will understand that muscular action, *i.e.* movement, will occur in proportion to (1) the intensity of the stimulation of the sensory corpuscle; and (2) the resistance in the different channels. When a simple flow through the whole apparatus occurs, it is called a simple reflex action, and this was discovered in England by Dr. Marshall Hall.

To recapitulate: a nerve centre, theoretically speaking, we find to consist of a sensory corpuscle on the one hand and a motor corpuscle on the other, both these being united by junction threads or commissures. To such a centre come sensations or impressions from the nerve-endings, and from such a centre go out impulses which set the muscles in action.

I have dwelt thus at length on this most elementary point, because it appears to me that, in consequence of the rapidity with which function is being demonstrated to be definitely localised in various portions of the cerebral hemispheres, we are in danger of losing sight of Dr. Hughlings Jackson's grand generalisations on nerve function, and that we are gradually inclining to the belief that the function of each part is very distinct, and therefore can most readily act without disturbing another part.

In fact, we are perhaps drifting towards the quicksands of spontaneity, and disregarding entirely the facts of every-day life which show that every cycle of nerve action includes a disturbance of the sensory side as well as the active motor agency. Did we in fact admit the possibility of the motor corpuscle acting *per se*, and in the absence of any sensory stimulation we should again be placed in the position of believing that an effect could be produced in the absence of a cause.

For these reasons such a centre has been termed kinæsthetic or sensori motor, and such centres exist in large quantities in the spinal cord, and they perform for us the lower functions of our lives without arousing our consciousness or only the substrata of the same.

But now, turning to the brain, although I am extremely anxious to maintain the idea just enunciated that, when discussing the abstract side of its functions we should remember the sensori motor arrangement of the ideal centre, I shall have to show you directly that the two sides—namely, the sensory and motor—in the brain are separated by a wide interval, and that in consequence we have got into the habit of referring to the groups of sensory and motor corpuscles in the brain as distinct centres. I trust you will not confuse these expressions, this unfortunately feeble terminology, and that you will understand, although parts may be anatomically separated and only connected by commissural threads, that functionally they are closely correlated.

In consequence of the bilateral symmetry of our bodies we possess a double brain—a practically symmetrical arrangement of two intimately connected halves or hemispheres which, as you know, are concerned with opposite sides of the body, for the right hemisphere moves the left limbs, and *vice versâ*.

For my purpose it will be sufficient if we regard the brain as composed of two great collections of gray matter or nerve corpuscles which are connected with sensory nerve-endings, with muscles, and intimately with one another.

In this transverse section of a monkey's brain, which is stained dark blue to show up its component parts, you will see all over the surface a quantity of dark gray matter, which is simply the richly convoluted surface of the brain cut across. Observe it is about a quarter of an inch deep, and from it lead downwards numerous white fibres down towards the spinal cord. The surface of the brain, the highest and most complicated part of the thinking organ, is called the cortex, bark, or rind, and in it are arranged the motor centres I am about to describe. These white fibres coming away from it to the cord, not only are channels conveying messages down to the muscles, but also carrying messages from the innumerable sense corpuscles all over the body.

So much for one grey mass of centres. Now down here at the base of the brain you see two lumps or masses of the same nature, and these are called, therefore, the basal ganglia or grey masses. Since they are placed at the side of the paths from the cortex, and undoubtedly do not interfere with the passage of impulses along those paths, we may put them aside, remembering that they probably are concerned with low actions of the nervous system, such as eating, &c., which are popularly termed automatic functions.

In this photograph of a model made by Prof. Aeby, of Berne, you see represented from the front the two cerebral hemispheres with the centres in the cortex as little masses on the surface, and the basal ganglia as darker ones at the bottom, while leading from them down into the spinal cord are wires to indicate the channels of communication.

Note, in passing, that both hemispheres are connected by a thick band of fibres called the "corpus callosum." It is, I believe, the close union thus produced between the two halves that leads in a great measure (though not wholly) to consonance of ideas.

The arrangement of the fibres will be rendered still clearer by this scheme, in which the cortex is represented by this concave mass, and the fibres issuing from the same by these threads.

The basal ganglia would occupy this position, and they have their own system of fibres.

I will now leave these generalisations, and explain at once the great advance in our knowledge of the brain that has been made during the last decade. The remarkable discovery that the cortex or surface of the brain contained centres which governed definite groups of muscles, was first made by the German observers Hitzig and Fritsch; their results were, however, very incomplete, and it was reserved for Prof. Ferrier to produce a masterly demonstration of the existence and exact position of these centres, and to found an entirely new scheme of cerebral physiology.

The cortex of the brain, although it is convoluted in this exceedingly complex manner, fortunately shows great constancy in the arrangement of its convolutions, and we may therefore readily grasp the main features of the same without much trouble.

From this photograph of the left side of an adult human brain you will see that its outer surface or cortex is deeply fissured by a groove running backward just below its middle, which groove is called the "fissure of Sylvius," after a distinguished mediæval anatomist. This fissure, if carried upwards, would almost divide the brain into a motor half in front and a sensory half behind.

Of equal practical importance is another deep fissure which runs at an open angle to the last, and which is called the "fissure of Rolando," Rolando being another pioneer of cerebral topography. Now it is around this fissure of Rolando that the motor side of the centres for voluntary movement is situated; and when this portion of the cortex is irritated by gentle electric currents, a constant movement follows according to the part stimulated.

Because of their upward direction, the convolutions bounding the fissure of Rolando are called respectively the "ascending frontal" and "ascending parietal" convolutions.

Now here, at the lowest end of the fissure of Rolando, we find motor areas for the movement of both sides of the face: that is to say that, as regards this particular piece of the cortex, it has the power of moving not only its regular side of the face, the right, but also the left—that, in fact, both sides of the face move by impulse from it.

Higher up we find an area for movement of the opposite side of the face only. I reserve for a moment the description of this portion of the brain, and pass on to say that above these centres for the face we find the next is for the upper limb, and most especially the common movement of the upper limb—viz. grasping, indeed the only forward movement which the elbow is capable of, namely, flexion. The grasping and bringing of an object near to us is the commonest movement by far, and we find here that this centre is mainly concerned in it. Behind the fissure of Rolando Dr. Ferrier placed the centres for the fingers.

Next above the arm area is a portion of the cortex which moves the lower limb only, and in front of this again is an area for consonant action of the opposite arm and leg.

Let me here remind you that this being the left hemisphere, these are the centres for movement of the opposite, that is, the right limbs, and that in the other hemisphere there are corresponding areas for the left limbs.

Thus here we have mapped out those portions of the cortex which regulate the voluntary movement of the limbs. So far I have omitted mention of the muscles of the trunk, namely, those which move the shoulders, the hips, and bend and straighten the back. Dr. Ferrier had shown that there existed on the outer surface of the cortex, here, a small area for the movement of the head from side to side.

Prof. Schäfer and myself have found that the large trunk muscles have special areas for their movement, ranged along the margin of the hemisphere, and dipping over into the longitudinal fissure. Thus all the muscles of the body are now accounted for, and I will first draw special attention to the fact that they are arranged in the order, from below upwards, of face, arm, leg, and trunk.

The consideration of this very definite arrangement led Dr. Lauder Brunton to make the ingenious suggestion that it followed as a necessary result of the progressive evolution of our faculties. For premising, in the first place, from well-ascertained broad generalisations that the highest centre, physically speaking, is also the highest functionally and most recent in acquirement, we find that the lowest is the face, and then we remember that the lowest animals simply grasp their food with their mouth. I imagine it is scarcely necessary for me to repeat the notorious confession that our faculties are arranged for the purpose of obtaining food as the primary object of what is called bare existence.

Proceeding upwards in the scale of evolution we next find animals which can grasp their prey and convey it to the mouth, and so we find next to the face area evolved that for the arm.

And so on, the next step would be the development of the legs to run after the prey, and here is the leg centre; while, finally, the trunk muscles are dragged in to help the limbs more effectually.

To my mind this idea receives overwhelming support from the consideration of the fact that, the higher our centres are the more they require education; the infant, for instance, in a few days shapes its face quite correctly to produce the food-inspiring yell, yet takes months or years to educate its upper limbs to aid it in the same laudable enterprise. Finally, what terrible probation some people pass through at the hands of dancing-masters before their trunk muscles will bend into the bow of politeness.

Now to return to the lower end of the fissure of Rolando, to the areas for movements of the face; it was long ago pointed out by the two Dax's and Prof. Broca that when this portion of the brain immediately in front of the face area was destroyed, that the person lost the power of articulate speech, or was only capable of uttering interjections and customary "strange oaths."

In fact this small portion of the left side of our brains (about 1¼ square inches) is the only apparatus for expressing our thoughts by articulating sounds, and note particularly that it is on the left side. The corresponding piece on the right side cannot talk as it were. This remarkable state of things is reversed in left-handed people. In these the right hemisphere predominates; and so we find that when this portion was diseased, there followed aphasia, as it is called. While, however, the right side customarily says nothing, it can be taught to do so in young people, though not in the aged.

Before leaving these motor areas, let me repeat, by way of recapitulation, that the only truly bilaterally acting areas are those for the lower facial and throat muscles. This is a most important fact, for the idea has recently been propounded that both sides of the body are represented in each motor region of each hemisphere. That is to say, each motor area has to do with the movements of both upper limbs, for example. In support of my contention that this is not in accordance with clinical facts, let me here show you photographs of the brain of a man who was unfortunate enough to suffer destruction of the fibres leading from one motor area. Here you see a puncture in the brain which has caused hæmorrhage beneath the fissure of Rolando and the motor convolutions in front and behind it.

In this transverse section of the same spot you see that the hæmorrhage has ploughed up the interior of the brain. Here is the cortical grey matter, but its fibres leading down to the muscles are all destroyed.

Now in examining this patient I asked him to move his left arm or leg; he was perfectly conscious, and, understanding the question, made the effort as we say, but no movement occurred.

Now if both sides of the body are represented in each hemisphere, it seems to me that such a case would be impossible, or at least that a little practice would enable the other hemisphere to do the work; but all clinical facts say that, once destroyed, the loss is never recovered.

If we examine this motor region of the cortex with the microscope we of course find these large corpuscles, which we have learnt are those which alone give energy to the muscles.

But you must not imagine that the motor region consists solely of these corpuscles. On the contrary, as you see in this diagram, we have several layers of corpuscles. I shall return to this arrangement of the corpuscles directly.

Looking back at the surface of the brain you notice that I have only accounted for but a small portion of the cortex. Dr. Ferrier was the first to show that the portion of cortex which perceived (and I use the word in its strictest sense) the sensation of light was this part, and it is therefore called the "visual centre or area." From recent researches it would appear that we must give it the limits drawn on this diagram. Below it we find the centre for hearing.

Thus we know where two sense perceptive centres are situated.

Microscopical investigation shows that this sensorial portion of the cortex is very deficient in large corpuscles, and is correspondingly rich in small cells. Here in this diagram you see these two kinds of structure in the cortex cerebri. Note the greater number and complication of the small corpuscles in the sensory part of the cortex, and the comparatively fewer though much larger corpuscles in the motor region.

It seems to me that several beliefs are justified by these facts.

In the first place the movements produced by the action of these motor centres are always the same for the same centre; consequently it has only one thing to do, one idea as it were. Thus, for instance, bending of the arm: this action can only vary in degree, for the elbow will not permit of other movements. Hence we may look upon it as one idea. Now observe that where one idea is involved, we have but few corpuscles.

Next consider the multitude of ideas that crowd into our mind when we receive a sensation. One idea then rapidly calls up another, and so we find anatomically that there are a corresponding much greater number and complication of nerve-corpuscles.

To sum up, I believe we are justified in asserting that where in the nervous system a considerable intensity of nerve-energy is required—(*e.g.*, for the contraction of muscles)—you find a few large corpuscles and fibres provided, and that where numerous ideas have to be functionalised there numerous small corpuscles are arranged for the purpose.

But now the special interest attaching to the sensory perceptive areas is that they, unlike the motor areas, tend to be related to both sides of the body. With our habit of constantly focussing the two eyes on one object, it will strike you at once that habitually we can only be attentively conscious of one object at a time, since both eyes are engaged in looking at it, and, as you know, we cannot as a matter of fact look at two things at once.

Hence I take it, both sensory perceptive centres are always fully occupied with the same object at the same moment, and that therefore we have complete bilateral representation of both sides of the body in each hemisphere. As a further consequence, each sensory perceptive area will register the idea that engaged it; in other words, both centres will remember the same thing. Thus it happens that each sensory area can perform the duty of the other, and therefore it is a matter of comparative indifference whether one is destroyed or not, and as a matter of fact when this happens we find that the person or animal recognises objects as they actually are, and in fact has no doubt as to their nature. Here you see anatomically the reason of this peculiarity is found to be that the optic or seeing nerves cross one another incompletely in going to each hemisphere, and thus each sensory centre represents half of each eyeball.

I must pass rapidly to the description of the rest of the surface of the brain—the hinder and front ends. At the outset I must admit that all our knowledge concerning them is very hypothetical in the absence of positive experimental results.

This much we can say, that they are probably the seats of intellectual thought, for many reasons which I have not time to detail. Further, we know that these intellectual areas are dependent for their activity entirely on the sensory perceptive centres, for the dictum that there is no consciousness in the absence of sensory stimulation is very well established, as I shall now show you, however astounding it may appear. In the first place, you will remember that when we wish to encourage that natural loss of consciousness which we call sleep, we do all we can to deprive our sense-organs and areas of stimulation; thus we keep ourselves at a constant temperature, we shut off the light, and abolish all noises if we can. But a most valuable observation was made a few years ago by Dr. Strümpell, of Leipzig, who had under his care a youth, the subject of a disease of the brain, &c., which, while destroying the function of one eye and ear, besides the sensibility to touch over the whole body, still left him when awake quite conscious and able to understand, &c., using his remaining eye and ear for social intercourse. Now when these were carefully closed he became unconscious immediately, in fact slept, and slept until he was aroused again, or awoke naturally as we say after some hours.

Hence the higher functions of the brain exercised when that organ is energising the reasoning of the mind, are absolutely dependent upon the reception of energy from the sense perceptive areas.

But my only point with reference to this part of the brain is to attempt to determine how far they are connected with the motor centres in the performance of a voluntary act. With the mechanism of choice and deliberate action I have nothing to do, but there can be no doubt that the part of the brain concerned in that process of the mind is directly connected with the motor region, as indicated on this diagram, to which I would now return. From what I have here written you read, arranged schematically, the psychical processes which for the sake of argument we may assume are carried on by the mind in these portions of the cortex.

I wish to point out that we have structurally and physiologically demonstrated with great probability the paths and centres of these psychical actions. There is no break: the mere sight of an object causes a stream of energy to travel through our sense areas, expanding as it goes by following the widening sensory paths here represented, and at the same time we feel our intellect learns that new ideas are rising up and finally expand into the process of deliberate thought, concerning which all we know is from that treacherous support, namely introspection.

Then comes impulses to action, and these follow a converse path to the receptive one just described; the nerve energy is concentrated more and more until it culminates in the discharge of the motor corpuscles. We might represent the whole process of the voluntary act by two fans side by side, and the illimitable space above their arcs would serve very well to signify the darkness in which we sit concerning the process of intellectual thought.

What I have hastily sketched is the outline of the process of an attentive or voluntary act. I say attentive advisedly, for I wish now to put forward the view that the proper criterion of the voluntary nature of an act is not the mere effort that is required to perform it, but is the *degree to which the attention is involved*. The popular view of the volitional character of an act being decided by the effort to keep the action sustained is surely incomplete, for in the first place we are not seeking to explain our consciousness of an effort, we endeavour to discover the causation of the effort. Our sense of effort only comes when the will has acted, and that same sense is no doubt largely due to the information which the struggling muscle sends to the brain, and possibly is a conscious appreciation of how much energy this motor corpuscle is giving out.

Now to give you an example. I see this tambour, and decide to squeeze it, and do so. Now this was a distinctly voluntary act; but the volitionary part of it was not the effort made, it was the deliberate decision to cause the movement.

I may now point out that in this whole process we say, and say rightly, that our attention is involved so long as we are deliberating over the object, that as soon as another object is brought to us our attention is distracted, that is to say, turned aside.

All writers are agreed that the attention cannot be divided, that we really only attend to one thing at once.

It seems to me that this is so obvious as not to require experimental demonstration, but I have led up to this point because I now wish to refer to the third part of my subject, namely, the question as to whether we have a really double nervous system or not; but by way of preface let me repeat that although we may have a subconsciousness of objects and acts, that that subconscious state is true automatism, and that such automatic acts are in no sense voluntary until the attention has been concentrated upon them. For example, again I press this tambour because I desire to raise the flag, and I keep that raised while I attend to what I am saying to you. My action of keeping the flag raised is only present to my consciousness in a slight or subordinate degree, and does not require my attention, deliberate thought or choice, and therefore, I repeat, is not a voluntary action, in fact it could be carried on perfectly well by this lower sensori motor centre, which only now and then sends up a message to say it is doing its duty, in the same way as a sentry calls out "All well" at intervals.

But to return. In consequence of the obvious fact that we have two nerve organs, each more or less complete, some writers have imagined that we have two minds; and to the Rev. Mr. Barlow, a former secretary of this Institution, is due the credit of recognising the circumstances which seem to favour that view. It was keenly taken up, and the furore culminated in a German writer (whose name I am ashamed to say has escaped me) postulating that we possess two souls.

Now the evidence upon which this notion rests, that the two halves of the brain might occasionally work independently of one another at the same moment, was of two kinds. In the first place it was asserted that we could do two different things at once, and in the second place evidence was produced of people acting and thinking as if they had two minds.

Now, while of course admitting that habitually one motor centre usually acts at one moment by itself, I am prepared to deny *in toto* that two voluntary acts can be performed at the same time, and I have already shown what is necessary for the fulfilment of all the conditions of volition, and that these conditions are summed up in the word attention.

Further, I have already shown that when an idea comes into the mind owing to some object catching the eye, that both sensory areas are engaged in considering it. It seems to me I might stop here, and say that here was an *à priori* reason why two simultaneous voluntary acts are impossible; but as my statements have met with some opposition, I prefer to demonstrate the fact by some experiments.

The problem, stated in physiological terms, is as follows:—

Can this right motor region act in the process of volition, while at the same time this other motor area is also engaged in a different act of volition?

Some say this is possible; but in all cases quoted I have found that subconscious or automatic actions are confused with truly voluntary acts. I mean that such automatic acts as playing bass and treble are not instances of pure volition, as the attention is not engaged on both notes at once.

Consider for a moment the passage of the nerve impulses through the brain that would have to occur. At the outset we find that the sensory perceptive centres would have to be engaged with two different ideas at once; but Lewes showed long ago that introspection tells us this is impossible, that "consciousness is a seriated change of feelings," he might equally well have said ideas. And again, we know that when two streams of energy of like character meet one another, they mutually arrest each other's progress by reason of interfering with the vibration waves.

I will show directly that this is actually the case in the action of the cortex when the above-mentioned dilemma is presented to it.

The experiment I have devised for this purpose is extremely simple.

A person who is more or less ambidextrous, and who has been accustomed for a long time to draw with both hands, attempts to describe on a flat surface a triangle and circle at the same moment. I chose these figures, after numerous trials, as being the most opposite, seeing that in a triangle there are only three changes of movement, while in a circle the movement is changing direction every moment. To ensure the attempt to draw these figures simultaneously succeeding, it is absolutely necessary that the experimenter should be started by a signal.

When the effort is made there is a very definite sensation in the mind of the conflict that is going on in the cortex of the brain. The idea of the circle alternates with that of the triangle, and the result of this confusion in the intellectual and sensorial portions of the brain is that both motor areas, though remembering, as it were, the determination of the experimenter to draw distinct figures, produce a like confused effect, namely, a circular triangle and a triangular circle. If the drawing is commenced immediately at the sound of the signal it will be found that the triangle predominates; thus, if I determine to draw a triangle with my left hand and a circle with my right, the triangle (though with all its angles rounded off) will be fairly drawn, while the circle will be relatively more altered, of course made triangular. On the other hand, if the two figures are not commenced simultaneously, it will be found that usually the one begun last will appear most distinct in the fused result, in fact will very markedly predominate.

Now the course of events in such an experiment appears to be clear.

The idea of a triangle and circle having been presented to the intellect by the sensory centres, the voluntary effort to reproduce these is determined upon. Now, if we had a dual mind, and if each hemisphere was capable of acting *per se*, then we should have each intellectual area sending a message to its own motor area, with the result that the two figures would be *distinct* and *correct*, not fused.

The other evidence that I referred to above, which is adduced in favour of the synchronously independent action of the two hemispheres, is from the account of such cases as the following. Prof. Ball, of Paris, records the instance of a young man who one morning heard himself addressed by name, and yet he could not see his interlocutor. He replied, however, and a conversation followed, in the course of which his ghostly visitant informed him that his name was M. Gabbage.

After this occurrence he frequently heard M. Gabbage speaking to him. Unfortunately M. Gabbage was always recommending him to perform very outrageous acts, such as to give an overdose of chlorodyne to a friend's child, and to jump out of a second-floor window. This led to the patient being kept under observation, and it was found that he was suffering from a one-sided hallucination.

Similar cases have been recorded in which disease of one sensory perceptive area has produced unilateral hallucination.

I cannot see that these cases in any way support the notion of the duality of the mind. On the contrary, they go to show that while as a rule the sensory perceptive areas are simultaneously engaged upon one object, it is still possible for one only to be stimulated, and for the mind to conclude that the information it receives in this unusual way must be supernatural, and at any rate proceeding from one side of the body.

To conclude, I have endeavoured to show that as a rule both cerebral hemispheres are engaged at once in the receiving and considering one idea. That under no circumstances can two ideas either be considered or acted upon attentively at the same moment. That therefore the brain is a single instrument.

It now appears to me that one is justified in suggesting that our ideas of our being single individuals is due entirely to this single action of the brain.

Laycock showed that the Ego was the sum of our experience, and every writer since confirms him. But our experience means (1) our perception of ideas transmitted and elaborated by the sensory paths of the brain; and (2) our consciousness of the acts we perform. If now these things are always single, the idea of the Ego surely must also be single.

THE FRENCH ASSOCIATION

THE fourteenth meeting of this Association has been held this year in Grenoble, one of the most intelligent and active French provincial cities, although it has not quite 25,000 inhabitants. It is situated on the banks of the Isère, one of the principal affluents of the Rhone, and is the head city of the Isère department.

The presidential address was delivered by M. Verneuil in the municipal gymnasium in the very hall where girls and boys are daily using horizontal and vertical bars. The actual President, M. Verneuil, is a surgeon in large practice, who delivered a long address on his profession under the title of "Confessions of a Surgeon of the Nineteenth Century." After having tried with much wit and force of expression to dispell prejudices current against practitioners, he went so far as to argue that operations are less frequent in France than in other lands, in spite of animal vivisection being free.

M. Napias, the general secretary, read a long paper on the scientific men who have died during the year, which has been singularly fatal to French science, and he announced the creation of a section of public hygiene and medicine. This section was inaugurated by an address of M. Chauveau, the Director of the Lyons Veterinary School, on the choleraic vaccination by Ferran. Not having been able to witness the operations conducted by Dr. Ferran, the referee was not in a position to give a definite opinion on this all-important matter; but he is satisfied that Dr. Ferran has adhered faithfully to the principles established by M. Pasteur. Although he may be assailed as lacking correct information on the biological part of the question, none of his assumptions can be considered as being in contradiction with well-stated and observed facts. It is probable that his method may be rendered les cumbrous and painful for the patients, but credit must be given to him for his daring experiments.

M. Galande, the treasurer, showed that the Association is possessed now of 20,000*l.*, invested in public funds. The amount of the annual subscriptions is 2250*l.*, so it leaves a large surplus for the publishing of the transactions and encouragement given to science.

It was announced that the present meeting should have to vote on the fusion with the Association Française, which was created by Leverrier, and presided over by Milne-Edwards since the great astronomer died. No successor will be given to Milne-Edwards, as the two scientific bodies will unite.

The public lectures at the Sorbonne will continue, and a scientific paper will be started, issuing in fortnightly numbers.

M. Rey, the Maire of Grenoble, delivered a complimentary speech to the members of the Association, reminding them that Grenoble was the site of the first Marcel Deprez experiments after their short inauguration at Munich. The results of these important experiments now continuing between Creil and Paris are satisfactory.

In the section of anthropology M. de Mortillet discussed the question of Tertiary man. He said the question was not to know if man as he exists at the present day already existed in the Tertiary epoch. Animals certainly varied from one geological stratum to another, and these variations increased as the strata were geologically distant. The higher the animals the greater the variation. It was to be inferred then that man would vary more rapidly than the other mammals. The problem was not to discover existing man in the Tertiary period, but only to find there an ancestral form of man a predecessor of the man of historical times. The question was, Do there exist in the Tertiary strata objects which imply the existence of an intelligent being? M. de Mortillet has no hesitation in saying there do. These objects have, in fact, been found at two different stages of the Tertiary epoch—in the Lower Tertiary at Thenay, and in the Upper Tertiary, at Otta; in Portugal, and at Puy Courny, in Cantal. These objects proved that at these two epochs there existed in Europe animals acquainted with the use of fire, and able more or less to cut stone. During the Tertiary period there existed, then, animals less intelligent than existing man, but much more intelligent than existing apes. This animal, to which M. de Mortillet gives the name of *anthropithique*, or ape man, was, he maintains, an ancestral form of historic man, whose skeleton has not yet been discovered, but who has made himself known to us in the clearest manner by his works. A number of flints were exhibited from the strata in question, which had been intentionally chipped and exposed to fire. After a long discussion, the almost unanimous opinion was expressed "that after this meeting and discussion at Grenoble there can no longer be a doubt of the existence in the Tertiary period of an ancestral form of man!"

The sitting of the Sections took place in the Palace of the University (Faculties).

NORTH AMERICAN MUSEUMS

A REPORT has just been issued on a visit to the Museums of America and Canada, by V. Ball, M.A., F.R.S., Director of the Science and Art Museum, Dublin. Prof. Ball visited a large number of institutions in various parts of North America, and in his introduction says that he was impressed especially with the system, thoroughness, and good order which appeared to pervade the arrangements in the majority of these institutions. Many of them are of late growth, but already possess an astonishing degree of vigour, while their supporters and officers look forward in a spirit of great hopefulness to what must be described as gigantic extensions of their spheres of usefulness in the future. Largely dependent for their existence on the liberality of private individuals, they take what aid they can get from the Government, and it amounts, in the majority of cases, merely to State recognition. Those of them which possess directly educational functions claim an abundant harvest of good results, and there can be no doubt that the facilities which now exist for instruction in science and art are largely availed of in the principal cities of America.

Mr. Ball did not happen to come across, if such institutions exist, any which were in a condition of decadence from the apathy and indifference of those for whose benefit they had been established. On the contrary, several are unable, owing to their means or room being limited, to receive all the pupils who present themselves.

"That an interest in museums is largely felt in America is not only evidenced by the number of them which are scientifically conducted and the large number of persons who visit them, but it is also proved by the existence of commercially-conducted museums, which are mere collections of curiosities; these are brought before the public in the true showman style, and there is reason for believing are often very profitable as speculations. The only one of these which I visited is the well-known "Museum" at Niagara Falls, which contains a varied collection of natural history and art objects. In a conversation with its manager, I learnt many amusing particulars as to its history. When I suggested to him getting casts of certain objects, he replied that it would not do for him to exhibit anything but the genuine articles to Americans."

The Smithsonian Institution was of course visited, and Mr. Ball sums up its functions thus:—

"The policy of the Smithsonian Institution is to initiate original plans for abstruse research, especially on lines not occupied by other organisations. It freely gives its publications and specimens without requiring an equivalent in return, and places its books, apparatus, and collections at the disposal of investigators and students in any part of the world. It has been the chief promoter of scientific exploration and investigation of the climate, products, and antiquities of the continent by the United States and State Governments, societies, and individuals."

Of the National Museum, Washington, we are told it is the authorised place of deposit for all objects of natural history, mineralogy, geology, archæology, ethnology, &c., belonging to the United States, or collected by the coast and interior surveys, or by any other parties for the Government of the United States, when no longer needed for investigations in progress.

The contents of the Museum as they now stand have been made up from the following sources:—

"I. The natural history and anthropological collections accumulated since 1850 by the efforts of the officers and correspondents of the Smithsonian Institution.

"II. The collections of the Wilkes' exploring expedition, Perry expedition to Japan, and other naval expeditions.

"III. The collections of the scientific officers of the Pacific Railroad Survey, the Mexican Boundary Survey, and of the surveys carried on by the engineer corps of the Army.

"IV. The collections of the United States Geological Surveys under the direction of the United States geologists, Messrs. Hayden, King, and Powell.

"V. The collections of the United States Fish Commission.

"VI. The gifts by foreign Governments to the Museum or to the President and public officers, who are forbidden to receive them personally.

"VII. The collections made by the United States to illustrate the animal and mineral resources, the fisheries, and the ethnology of the native races of the country on the occasion of the International Exhibition at Philadelphia in 1876, and the fishery collections displayed by the United States in the International Fishery Exhibition at Berlin in 1880.

"VIII. The collections given by the Governments of the several foreign nations, thirty in number, which participated in the Exhibition at Philadelphia.

"IX. The industrial collections given by numerous manufacturing and commercial houses of Europe and America at the time of the Philadelphia Exhibition and subsequently.

"X. The material received in exchange for duplicate specimens from the museums of Europe, Asia, and Australasia, and from numerous institutions in North and South America.

"The United States Geological Survey, under the direction of Major Powell, at present has its offices in the Museum, but they will shortly be removed to spacious quarters which are being provided for them in the city."

Of the Museum, &c., of the Academy of Natural Sciences, Philadelphia, Mr. Ball gives the following interesting account:—

"In a 'Summary History of the Academy,' by Dr. W. S. W. Ruschenberger, dated 1877, we are afforded a full insight into the origin and development of this, which is one of the oldest, if not the premier, society of the kind established in America.

"Its foundation originated in meetings held by a few Philadelphian gentlemen in the years 1811 and 1812. Its opening meeting took place on March 21, 1812, and its objects, as then defined were the pursuit and cultivation of science to the exclusion of everything of a political or sectarian character. It was apparently because of this last declaration that a considerable amount of hostility was excited in religious and other portions of the Philadelphian community. The small band, consisting of fourteen members and thirty-three correspondents, although they were men engaged in business avocations, diligently pursued the aims they had in view in spite of all opposition. Their library and museum steadily augmented, and meetings were held and lectures delivered for the discussion and dissemination of scientific knowledge.

"After various vicissitudes during the troubled years which followed, several removals to more commodious quarters took place, and in 1826 the Academy moved to a building which had been specially prepared for its reception, where two years later it was enabled to throw open its museum, entrance to which, from that time, for forty-two years, or up to 1870, was free to the public for two days in each week. In 1840 the museum and library had again been removed to a building which had been specially constructed for their reception at the cost of several liberal friends of the Academy. Yet again in 1876 a further migration took place to the present building, which is built of brick, faced with green serpentine, as are also many other public buildings in Philadelphia; the style of the architecture is Collegiate Gothic. The museum building and the valuable collections which it contains owe their existence at the present day exclusively to the generous gifts and gratuitous labour of private individuals.

"The functions of the Academy are varied, owing to the different directions in which it operates. Its leading characteristics have been thus summed up: 'It is scientific because it encourages original investigations to the extent of its ability, and publishes whatever investigators may discover for the information of men of science. Its publications are made up entirely of the reported results of original research.

"'It is educational because it gives gratuitous instruction to the beneficiares of the Jessup fund, and opens its library freely to students.

"'It is popular because it seeks to increase the taste for natural science, and spread knowledge by opening its Museum to the public.'"

Recently the byelaws of the Academy have been modified in such a manner as to authorise the establishment of Professorships whenever endowments adequate to their support shall be made. Thirteen proposed Professorships are enumerated, and donations towards an endowment fund are invited which may yield from 1500 to 3000 dollars a year for each year.

"The library consists mainly of works on zoology and botany, but there is also a valuable collection of volumes on Roman, Greek, and French antiquities, and the collections of scientific periodicals of learned societies, which have been largely obtained in exchange for those of the Academy itself, is very rich. In 1876 the library included about 25,000 volumes, since which time it may be presumed that considerable additions have been made.

"Under the direction of the Council of the Academy, the Museum is at present administered by Dr. Leidy, who is assisted by several other Curators. The internal arrangements, owing to overcrowding and the old-fashioned form of the cases, which have not been replaced from want of necessary funds, does not at first sight commend itself as affording any useful hints with reference to the subject of general Museum arrangement; but the contents of many of these cases, as is well known to many men of science, are of great value, as they consist largely of types from which species have been originally described. Here, for instance, are to be found a portion of Gould's famous collection of humming birds, many of Dr. Lea's types of unios, and Dr. Leidy and Prof. Cope's fossil vertebrates. Among these last, most notable is the *Hadrosaurus*, an ideal restoration of which rears its lofty frame in a prominent position in the main gallery. More is now known as to the characteristics of those kangaroo-like reptiles (*Deinosaurs*) than was the case when Dr. Leidy named this one after its discoverer, Mr. Foulke. The ornithological collection, which is one of the largest in the world, contains, in addition to the humming-birds already mentioned, numerous rare specimens, one of them being the now extinct Great Awk, of which there is another example in the New York Museum of Natural History. The collection of shells which is under the custody of Mr. Tyron is renowned for its extent and value.

"The Herbarium is considered by good authorities to be one of the richest, if not the richest, in the United States. In 1876 it contained upwards of 46,000 species of plants. It was commenced in 1812, since which time it has absorbed many private collections, either given or bequeathed to it by their owners or purchased out of funds provided by friends of the Academy. Besides a general collection of minerals there is a special one which was bequeathed by the late Mr. Vaux, who also left a sum of money to provide an endowment fund for the payment of the salary of a curator and for the acquisition of new specimens. This collection, so liberally provided for, includes many noble examples of rare minerals.

"The University of Pennsylvania possesses also a mineral cabinet which is administered by Dr. Genth, whose private collection is probably in some respects unique, especially as regards pseudomorphs and minerals which have been derived from others by alteration. Here it may be mentioned that in Philadelphia there are several important private collections of minerals which have been acquired at great expense by their owners—among them those of Dr. Lea and Mr. Bemment are especially noteworthy. However scientific institutions may have progressed in other parts of the United States of late years, Americans cannot but admit the debt which their country owes to the Academy of Natural Sciences for the leading part which it has taken for so many years in the advancement of knowledge of the natural sciences."

Mr. Ball gives a somewhat detailed account of the American Museum of Natural History, New York, which, however, we need not quote, as we recently referred to it in some detail.

The well-known Massachusetts Institute of Technology, Boston, was founded by charter in 1841, its objects, as sketched out by its first President, Prof. Rogers, being threefold, namely, the establishment of a Society of Arts, a Museum of Arts, and a School of Industrial Science. The Society of Arts was the first part of the scheme to be organised. It holds fortnightly meetings, from October to May, the objects of which are to "awaken and maintain an active interest in the practical sciences, and to aid generally in their advancement and development in connection with arts, agriculture, manufactures, and commerce." Discoveries and inventions are described and discussed at these meetings. Judging from the titles and characters of the subjects which have been communicated, the results of these meetings are often doubtless of such a character as to confer great benefit on the community at large. Abstracts of the proceedings are published in the annual reports.

In the new building a spacious and suitable hall has been provided for an Industrial Museum; but, although varied and valuable collections have been made of material suitable for such a Museum, it has been necessary to make use of them in the different departments of the school, where they are placed so as to be easy of access to teachers and students, which would not be the case were they centralised in the main building. The most important branch of the institution, Mr. Ball states, which has excited the admiration of so many visitors, is the School of Industrial Science.

This school was founded in 1865, and two subsidiary schools have since been organised under the control of the Corporation of the Institute. These are, respectively, the Lowell School of Practical Design and the School of Mechanic Arts. The studies in the school "are so arranged as to offer a practical and liberal education in preparation for active pursuits, as well as a thorough training for most of the active professions."

The regular courses, each of four years' duration, are as follows:—

I. Civil and topographical engineering.
II. Mechanical engineering.
III. A. Mining engineering.
III. B. Geology and mining.
IV. Architecture.
V. A.B.C. Chemistry.
VI. Metallurgy.
VII. A. Natural history.
VII. B. Preparatory to the professional study of medicine.
VIII. A. Physics.
VIII. B. Electrical engineering.
IX. A.B.C. General courses.

For proficiency in any one of these courses the degree of Bachelor in Science (S.B.), in the course pursued, is conferred.

The first six of these courses and VIII. B. are distinctly professional. The general courses IX. A.B.C. are for students who, though not desiring to enter a distinctly scientific profession, desire an education of a pre-eminently scientific character. Advanced courses of study may be pursued with or without reference to the higher degree of Doctor of Science. Women who are properly qualified are admitted to any of the courses of the school, and special laboratories in the different branches of study have been provided for their use. Schedules of prescribed studies in the various courses indicate very clearly the wei ht which is given to the modern languages and other branches of a liberal but strictly non-classical education.

The staff of professors and assistants is a large and highly competent one, and the practical part of the instruction appears to be carried on in a very earnest and sound manner. The fee for regular students is 400 dollars per annum, to which in estimating the total cost must be added board and lodging in the town, books, instruments, and personal expenditure. There are at present about 440 students on the roll. From the records of the School it would appear that numbers of its graduates occupy important positions all over the country, for which their special training has qualified them.

The School of Mechanic Arts is for the benefit of those who, from want of time or means, are unable to go through one of the regular courses of the School of Industrial Science. "The object is to develope the bodily and mental powers in harmony with each other." Its exact and systematic method affords the direct advantage of training the hand and the eye for accurate and efficient service with the greatest economy of time. The instruction in the mechanic arts given to each regular student at present embraces:—I. Carpentry and joinery; II. Wood turning; III. Pattern making; IV. Foundry work; V. Iron forging; VI. Vice work; VII. Machine tool work. The regular course includes two years of study in English, French, and elementary mathematics and physics. The general plan of the School is founded upon the systems followed in the Imperial Technical School of Moscow, the Royal Mechanical Art School of Komotan in Bohemia, the École Municipale d'Apprentis of Paris, and the Ambachts Schoole of the principal cities of Holland, modified, however, to suit local conditions. Applicants for entrance must be at least fifteen years old, and must pass an examination in arithmetic, geography, and composition. Fifty-six students have been on the roll during the current year.

The Lowell School of Practical Design was established by the trustees of the Lowell Institute for the purpose of promoting industrial art in the United States, but it is under the administration of the Corporation of the Institute of Technology. Tuition is free to all pupils. A considerable degree of skill in freehand drawing from nature and in the use of the brush is positively required for entrance to the school, which does not undertake to teach drawing

"*Course of Study.*—Students are taught the art of making patterns for prints, ginghams, delaines, silks, laces, paperhangings, carpets, oil-cloths, &c. The course is of three years' duration, and embraces (1) technical manipulations; (2) copying and variations of designs; (3) original designs or composition of patterns; (4) the making of working drawings and finishing of designs."

The school is provided with looms for different fabrics, and the pupils have the opportunity of working their designs in various materials. A constant supply of samples of novelties in textile fabrics of all kinds is received from Paris. Those students who, at the close of the half-year, do not show evidence of progress are permitted to withdraw. Some sixty students have received certificates from this school, and the majority of them have found employment in various factories and other places of business.

Among other institutions referred to in this Report are the Harvard Museum of Comparative Zoology, the Meteorological Museum, Harvard, the Peabody Museum, Connecticut, the Peter Redpath Museum, Montreal, and the Geological Museum, Ottawa. The Report is illustrated by numerous views and plans.

SCIENTIFIC SERIALS

Königliche Gesellschaft der Wissenschaften, Göttingen, January to March, 1885.—Memoir on Jacob Grimm, by F. Frensdorff.—On the optical properties of very thin metal plates, by W. Voigt.—Seventh annual report on the treatment of ear complaints in University Hospital, Göttingen, by Dr. K. Bürkner.—A contribution to the history of the Papacy during the tenth century, by Ludwig Weiland.—On the electric conductivity of liquid solutions in a state of extreme dilution, by Friedrich Kohlrausch.—On the Eris of Greek mythology, her outward appearance and representation in plastic art and literature, by Friedrich Wieseler.—On the theory of complex magnitudes formed of *n* units, by R. Dedekind.—The organic Aryan inflection of the locative case singular of the *u* declension, by A. Bezzenberger.—On Euler's integral in connection with Cauchy's "Mémoire sur les Intégrales définies," by A. Enneper.—A demonstration of the multiplication theorem for the determinants, by M. Falk.—A contribution to the study of the sympathetic nerves in the higher mammals, by Fr. Huth.—On some definite integrals by A. Enneper.—On the maximum of a four-sided figure of given dimensions, by A. Enneper.

Rendiconti del Reale Istituto Lombardo, July 9.—Principles of criminal law; preventive measures and police offences, concluded, by Dr. Raffaele Nulli.—The conflict between Julius Cæsar and the Senate, continued, by Prof. J. Gentile.—Direct oxidation of the iodides and of ammoniacal and organic nitrogen, especially by means of the bioxides of lead and manganese, by Prof. E. Pollacci.—Effects of the phosphates and other fertilisers on the wheat crops, by Prof. Gaetano Cantoni.—An exposition of Riemann's memoir on the theory of the Abelian functions, by Prof. Giulio Assoli.

SOCIETIES AND ACADEMIES

EDINBURGH

Royal Society, July 20.—Mr. David Milne-Home, LL.D., Vice-President, in the chair.—Dr. Harvey Gibson read the second part of his paper on *Patella*.—Prof. Tait read a paper by the Rev. T. P. Kirkman on the unifilar knots with ten crossings; and also a paper of his own on the census of ten-fold knottiness. There are 364 different forms of ten-fold knottiness, when the crossings are alternately over and under, included in 124 types, 50 of which are unique, while 74 have multiple forms.—Prof. Tait also communicated a paper by Messrs. Crocket and Creelman on the thermal effects produced in solids and in liquids by sudden large changes of pressure, and a paper by Mr. W. Peddie on a method of determining the resistance of electrolytes without endeavouring to prevent polarisation.—Prof. MacFadyean and Dr. G. S. Woodhead submitted an account of the construction of the auricles of the pig's heart. Beating of the heart and the superior *vena cava* may continue under proper stimulation for a few hours after death.—Mr. A. P. Laurie communicated a note of the heat of solution of zinc iodide. The heat of solution was determined by observations of the electromotive force of a voltaic cell invented by himself for the purpose.—Dr. J. McFarlane read a second paper on pitchered insectivorous plants.—Mr. H. R. Mill, of the Scottish Marine Station, read a paper on the salinity of the Tay estuary and of St. Andrew's Bay.—The meeting, which was the last for the session, was concluded by an address from the chairman.

PARIS

Academy of Sciences, August 10.—M. Bouley, President, in the chair.—Note on the chief momenta of terrestrial inertia, by M. F. Tisserand.—Remarks on the third part of the Map of Tunis, published by the French War Office, and presented to the Academy by Col. Perrier. The map is to the scale of 1 : 200,000, and the present sheets comprise the districts of Gafsa, Maharès, Kebili, Gabès (Cabes), and Zarzis. Three sheets only remain to complete the whole work, and for these the surveys have already been made.—The sixth part of the General Map of Africa, executed for the War Office to the scale of 1 : 2,000,000 by Capt. de Launoy. This part contains eight sheets comprising the districts of Tabora, Zanzibar, Livingstonia, Vicloux, Mossamedes, Linyanti, Tete, Quilimané.—Note on a registrar of the calorific intensity of solar radiation (one illustration), by M. A. Crova. The apparatus here described is intended faithfully to record the readings of an actinometer giving the calorific intensity of solar radiation to which it is *directly* exposed, while protected from the disturbing action of the winds.—On the treatment of mildew (*Peronospora vitis*) by means of sulphurous acid, by M. Emile Vidal.—A certificate, prepared by Dr. Ferran and signed by several physicians, respecting the results of anti-choleraic inoculations at Benifayo, accompanied by a diagram showing the progress of the epidemic before and after these inoculations, was presented to the Academy, by M. F. Angla. Similar documents are promised for other districts. A telegram was also received from M. Paul Gibier regarding the experiments made by him with hypodermic inoculations of the cholera bacillus.—Observation on Tuttle's comet, the return of which was noticed on August 8 and 9 by M. Perrotin at the Observatory of Nice.—Remarks on a demonstration of the law of reciprocity in mathematical analysis, by M. A. Genocchi.—On the temperatures and critical point of pressure for the chloride of ethyl, and another series of homologous bodies comprising ammonia, gas, and the three methylamines, by MM. C. Vincent and J. Chappuis.—On aqueous evaporation in a disturbed state of the atmosphere, by M. Houdaille. — On a method of obtaining a true standard volt; cause of previous errors, by M. A. Gaiffe.—Products of the oxidation of carbon by the electrolysis of an ammoniacal solution, by M. A. Millot.—On certain alloys of cobalt and copper, by M. G. Guillemin. The alloy with 5 per cent. of cobalt is described as specially interesting, being capable of resisting oxidation, malleable as ordinary copper, tenacious and ductile as iron. It might be largely used in the manufacture of rivets, tubes, and a great variety of copper-ware articles in daily use.— On the thermic phenomena attending the transformation of the protochloride of chromium into a sesqui-chloride, by M. Recoura.—On the crystallographic characters of the substituted derivatives of camphor, by MM. P. Cazeneuve and J. Morel.—On a new species of land turtle (*Testudo yniphora*) brought by M. Humblot from the Comoro Islands, and presented by him to the Natural History Museum of Paris, by M. Léon Vaillant.—On the Brisingidæ fished up from great depths by the *Talisman* Expedition, by M. Edmond Perrier.—Position of the embryo and formation of the cocoon in *Periplaneta orientalis*. The author describes the results of his observations, continued throughout the whole formation and evolution of the egg of this insect for the purpose of determining the exact relations existing between the organic axis of the egg, the principal axis of the embryo, and that of the maternal organism.—On the local treatment of fibrinous pneumonia by means of intra-parenchymatose injections, by M. R. Lépine.—On the cystitis and nephritis produced in the healthy animal organism by the introduction of the micrococcus ureæ (Cohn) into the urethra, by MM. R. Lépine and Gabriel Roux.—Note on the microbe of typhoid fever in man, its cultivation and inoculation, by M. Tayon.—Transmission of pathogenetic microbes from mother to fœtus, by M. Koubassoff.—An explanation of the abnormal development of the grape occasionally occurring in the vineyards of the Vaudois district, by M. J. B. Schnetzler.—On a specimen of pine found embedded in the upper Tschingel glacier at an altitude of 2475 metres, far above the present zone of the pine in this region, by M. Paul Charpentier.—Note on the employment of atmospheric heat for the purpose of obtaining a motor power capable of raising water to a certain height, by M. Ch. Tellier.

THE LIFE OF FRANK BUCKLAND

Life of Frank Buckland. By his Brother-in-Law, George Bompas. (London: Smith, Elder, and Co., 1885.)

FEW Englishmen were unacquainted with the central figure of this admirably written memoir. His ubiquity as a lecturer and inspector, the happy self-forgetfulness and adaptability of manner which associated him with royal princes as readily as with seaside fishermen, and the strong personality by which he permanently impressed all who came in contact with him, made him beyond all other men of his time the representative and the preacher of the subject to which he devoted all the energies of his life. That subject was natural history, a term not without meaning even in the present day of minute and subdivided scientific work, but conterminous with science half a century ago, when comparative anatomy was hardly known, when the microscope was costly and imperfect, when the provinces of nature had not been mapped nor its workers differentiated.

Frank Buckland was born a naturalist, into a home crammed with animals, living, preserved, fossil; his mother a woman of rare intellectual accomplishment and scientific taste, his father the first geologist of the age. At three years old he could "go through all the natural history books in the Radcliffe Library"; at four we find him lispingly explaining to a Devonshire parson who had brought with pride to Dr. Buckland "some very curious fossils," that they were the vertebræ of an Ichthyosaurus; at five he is rapturous over the teleology of the "tongue-bone" in the skeleton of a whale; and in the archæology of Worcester Cathedral can find only one object of interest—the figure of a lady who had been starved by a disease in the throat.

At twelve he went to Winchester, not the least barbarous school of that barbarous scholastic time. He was "launched," and "tin-gloved," and "toe-fit-tied," and "tunded," and "clowed," and "watched out" at cricket, and "kicked in" at foot-ball, living for two or three years the wretched life of a college junior amid a mob of boys not overlooked by any master and influenced by the bad traditions of a savage past. He used to say that it had done him good, had cured him of "bumptiousness" and arrogance, but he cherished painful memories of individual tyrants and of special acts of tyranny, and was wont when a senior boy to criticise with a bitterness alien from the ordinary conservatism of schoolboys the coarseness of a system which turned a gentleman's son, bred in the refinement of a cultured home, into an abject domestic serf.

Buckland's fagging days over, he was happy, for he could follow his bent undisturbed, and the pages which describe his later Winchester life are amongst the most amusing in the biography. Fond of school work he was not; he was, in fact, looked upon as a "thick," and his compulsory fagging experiences had given him a dislike for games. But he wired trout and eels in the clear Itchen streams, dug out mice on "Hills," chased badgers on Twyford Down, skinned and dissected cats, moles, and bats, articulated skeletons, baked squirrel pies, and cooked mice in batter. A buzzard, an owl, and a racoon tenanted his lockers in "Moab," a viper lived in his "scob" amongst his books, his hedgehogs kept open a perpetual fosse at the base of the college wall, and a regiment of tame jackdaws looked up to him as their patron. On "Saints' days" he attended the Winchester Hospital, bringing back gruesome fragments of humanity in his pocket-handkerchief, talked medical language, treated confiding boys professionally. Applying for admission to the sick house on behalf of a patient who had partaken too generously of "husked gooseberry fool," he informed the surprised second master that the invalid had a "stricture of the colon;" he was wont to offer sixpence to any junior who would allow himself to be bled; and he treated surgically a football-wounded shin with such results that the leg when shown eventually to a doctor was pronounced to be in imminent danger of amputation.

The Winchester life found fuller development at Oxford. No one who knew Frank Buckland there will forget those merry breakfasts in the corner of Fell's Buildings; Frank in the blue pea-jacket and the German student's cap, blowing blasts out of a tremendous wooden cow-horn; the various pets who made it difficult to speak or move: the marmots, and the dove, and the monkey, and the chamæleon, and the snakes, and the guinea-pigs, and the after-breakfast visits to the eagle or the jackal or the bear or the pariah dog in the little yard outside. His Long Vacations were spent in Germany, whence he brought back little besides collections of red slugs and green frogs; in 1848 he entered at St. George's Hospital, and in 1854 was gazetted Assistant-Surgeon to the second Life Guards.

The next eight years were very pleasant ones. His father's position as Dean of Westminster threw open to him all the best society in London: we read of parties at Miss Burdett-Coutts's, at the Duke of Wellington's, at Chief Baron Pollock's; microscopic evenings at Dr. Carpenter's; walks around the Abbey with Prince Albert; conversations with Sir B. Brodie, Mr. Gladstone, Whewell, Whately, Prof. Owen, Sedgwick, Bunsen, Ruskin. He was beginning to feel his strength and strike out his line in life; in these years he wrote his first magazine article, delivered his first lecture, published his first book. In 1865 he resigned his commission, married, took the house in Albany Street which he has made historic, started *Land and Water*, devoted himself to fish culture, became Inspector of Fisheries, and worked in his vocation till 1880, when he died at the age of fifty-four, worn out by excessive overwork and by the exposure to wet and cold in all seasons which his professional duties, as he interpreted them, involved.

His power as a lecturer was unrivalled. He could keep an audience in ecstasies of laughing enjoyment for two hours at a stretch. He had inherited his father's remarkable felicity of illustration; his own keen delight in his subject was contagious, his comedy incessant and irresistible. Never was a memory more stored with interesting facts. He was all eyes; noted everything, remembered everything, used everything. Through London streets, as he surveyed them from his favourite seat on the knife-board of an omnibus, on the walls of exhibitions, on sea-coast, river-shore, and hill-side, in the belfry at Ross, by Dean Gainsford's grave—phenomena which others overlooked or passed as trivial were by him pounced upon and analysed and made to bear fruit in discovery and correlation and historical association and practical scientific use. Of human prodigies in every department he was the recognised Proxenus and patron. Miss Swann the giantess and her husband Captain Bates the giant, and the Two-headed Nightingale, and the Siamese Twins, and the New Zealand Chiefs, and Fatima, and Zariffa, and Julia Pastrana the hairy woman, and Benedetti the sword swallower, and the Wild Man of the Woods, and the man who could sing two notes at once, and the man who could drink a bottle of milk under water,—all looked up to him as a father, or sat as guests at his table. He came by degrees to be accepted as an *Arbiter monstrorum;* as the necessary referee whenever any strange revelation or any novel puzzle presented itself in the world of nature. If a whale ran on shore at Gravesend, or a dolphin at Herne Bay; if an unusual sturgeon or tunny was consigned to a London fishmonger; if the lawyers at Nisi Prius were at issue whether a hole in a ship's bottom could have been made by the beak of a swordfish, or the Gloucester Magistrates hesitated over the identity of elvers with young eels; if a sick porpoise arrived at the Zoological Gardens in a condition requiring brandy and water to be exhibited internally and caustic applied without; if the Chief Rabbi felt searchings of heart as to whether oysters might for edible purposes be inserted in the Mosaic catalogue of things that creep; if a sea-lioness were ill in the Aquarium, or a plague of frogs occurred at Windsor; if search were required for John Hunter's coffin in St. Martin's Church, or the skeleton of William Rufus had to be exhumed in Winchester Cathedral,—it was inevitable that Frank Buckland should be telegraphed for first of all. And the influence he exerted was often highly beneficial. To his interference we owe the close time for seals and the Bill for the preservation of marine birds. A description in *Land and Water* of a neglected Museum at Canterbury shamed the Curator into setting it to rights; his good-humoured criticism, from a naturalist's point of view, of the pictures in the Royal Academy, taught the artists beneficially that an eye as keen as Ruskin's was noting their performances in a region beyond Ruskin's reach.

His home in Albany Street was one of the sights of London; but to enter it presupposed iron nerves and a stomach like those of Horace's reapers. Iron nerves—for, introduced at once to some five-and-twenty poor relations, exempt from shyness and deeply interested in your dress and person, to Jacko, and the Hag, and the Nigger, and Jenny, and Tiny, and the parrot and the jaguar, and the laughing jackass, and Jemmy the suricate, and Dick the bear, and Arslan the Turkish wolf-dog, you felt, like Jaques in the play, as if another flood were toward, and the animals were parading for admission. Dura ilia—for the genius of experiment, supreme in all departments of the house, was nowhere so active as at the dinner-table. We read of panther chops, rhinoceros pie, bison steaks, kangaroo ham, horse's tongue, elephant's trunk; of whale boiled with charcoal to refine the flavour; of tripang and lump-fish; of stewed whelks and land-snails, roasted hedgehog, potted ostrich. We notice in the diary such entries as "seedy from lump-fish;" "very poorly indeed, effects of horse;" and we sympathise with a departing guest who notes—"tripe for dinner—don't like crocodile for breakfast."

He was the Samson of science; the "Sunny One" amongst *savants*, as was Manoah's son amongst judges; roars of genial laughter accompany the heroism and the feats of both. But the comic recollections which surround him ought not to mask the serious admiration which is his due;—first, as a public teacher, circulating popular science, generating field clubs and microscopical societies, preparing a public to appreciate and to support the more purely scientific labourer; secondly, as a material benefactor, raising in fifteen years the commercial value of English and Scottish salmon to the extent of 100,000*l.* per annum; thirdly, as having in a manner rare, if not unique, passed behind the veil which hangs between us and the animal creation. He understood their gestures and expressions as we interpret those of one another, and they understood him in their turn; the creatures at the Gardens, the beasts at Jamrach's, the pets at home, seemed to know him in a human fashion; his dying words—"God is so good to the little fishes that I do not think He will let their inspector suffer shipwreck at the last"—show his identity of feeling with them; no one could talk to him long without a strangely new and reverential sense of brotherhood with these existences who were to him so entirely fraternal as people of his Father's pasture and sheep of his Father's hand. Science has had very many greater sons; none more simple, modest, blameless; none more genial, more humane, or more beloved. W. TUCKWELL

COMPENSATION OF COMPASSES

Practical Guide for Compensation of Compasses without Bearings. By Lieut. Collet, French Navy, Tutor in the Polytechnique School of France. Translated by W. Bottomley. With a Preface by Sir W. Thomson, F.R.S., &c. (Portsmouth: Griffin and Co., 1885.)

THIS work appears in its English garb under the auspices of Sir W. Thomson.

In the published instructions for the adjustment of his patent compass, Sir William Thomson gives short directions for the use of the deflector, an instrument to facilitate correcting that compass by magnets and soft iron when neither bearings of sun nor terrestrial objects can be obtained. With this deflector a fog is not the unwelcome visitor it generally is, for with the fog there is often a smooth sea, a condition favourable to a successful use of this delicate instrument.

As an invention of Sir W. Thomson it is certain that the inquirer into the use of the deflector will at once be disposed to look for an instrument theoretically correct in conception and of great refinement in construction. The useful work of fully describing the practical applications and several uses of this instrument has, however, been left to an able writer on subjects connected with the compass in iron ships—Lieut. Collett, of the French Navy—and the book now under review is the result.

It may be remarked that Sir W. Thomson, in the preface, fully recognises it as a complete and able exponent of the uses of this deflector, which is an important point to those desirous of using the instrument.

In four chapters of his Practical Guide M. Collet has given, in detail, practical rules for correcting the errors of the compass without bearings, illustrated by numerous examples, and including instructions for the graduation of the deflector, or measuring the magnetic force for each division of its scale. Collected in a tabular form, the results of this graduation will be found of great use to observers, and of the five advantages arising from it enumerated by the author, not least is that which gives an approximate value of the coefficients of deviation. This would prove useful when the observer, wishing to leave the magnets undisturbed, required only to know if any change of deviation had taken place.

Another advantage of this graduation is that it forms an additional method of measuring the diminution of the mean directive force of the compass on board ship as compared with that on land, or the term λ of the text-book. λ is a necessary element in the exact correction of the heeling error—a part of the correction to which the author devotes a chapter, as it rightly comes under the denomination of a compensation requiring no bearings.

Lieut. Collet, in his introductory chapter and elsewhere, strongly urges that the deflector, concerning the uses of which he has written so fully, should in the immediate future become the chief instrument used in the compensation of compasses, on account of the rapidity and sufficiency of precision with which it may be made, and that it be adopted for frequent if not daily use on board ships at sea. Before remarking on this proposal it may be as well to inquire into the present customs with regard to the standard or navigating compass at the time of its first compensation and subsequent changes of deviation.

In the Royal Navy the adjustment of compasses is invariably made by bearings, and the instances are rare when the adjustments of the standard compass alone, including the final swinging of the ship, occupy more than an hour or two with results absolutely correct. Subsequently to this one adjustment the compensating magnets are not moved during their three or four years' period of service, but the deviations of the compass are carefully observed on all occasions when bearings can be taken—in other words, from day to day—and noted for guidance when bearings cannot be taken. In the Mercantile Marine a large number of ships are fitted with Sir W. Thomson's standard compass with the accompanying magnets adjustable at pleasure. This compass is often compensated by experts in the use of the deflector and the magnets left in a given position.

Now, what is the almost universal practice of the commanders of these vessels subsequent to this adjustment by means of the deflector? They observe the deviation frequently by day and night when possible, note the results in a compass journal for present and future guidance, and object most strongly to any alteration of the magnets.

In the paragraph headed "Weather" it will be seen that a moderately smooth sea is required when using the deflector, and in another place it will be seen that it is no certain guide to navigation unless observations are made on all the cardinal points. The question therefore arises, Are the necessary conditions for using this instrument often available in the North Atlantic and "roaring forties," when bearings are at times unobtainable for some days?

The result of the foregoing consideration is to show that there is long custom of very practical men—and possibly prejudice—to overcome before Lieut. Collet's future of frequent use of compensation without bearings becomes general.

The nautical world has had the deflector as invented by Sir W. Thomson before it for some years; it now has an excellent practical guide to its use in the book under review, and it remains to be seen how far that world will avail itself of the invention.

It may probably suggest itself to some minds that the book would lose none of its value by being shortened somewhat in detail; indeed, the shorter the better, if combined with accuracy for the practical navigator, and should a new edition be required the translator who has done his part well, and knows the deflector thoroughly, will perhaps try his hand at the work of condensation.

THE FORBES MEMORIAL VOLUME

In Memoriam. The collected Scientific Papers of the late William Alexander Forbes, M.A., Fellow of St. John's College, Cambridge, Lecturer on Comparative Anatomy at Charing Cross Hospital, Prosector to the Zoological Society of London. Edited by F. E. Beddard, M.A., Prosector to the Zoological Society of London. With a preface by P. L. Sclater, M.A., Ph.D., F.R.S., Secretary to the Zoological Society of London. (London: R. H. Porter, 1885.)

THE death of Alfred Henry Garrod at the early age of thirty-three was a great misfortune to the cause of zoology in this country. But that his distinguished successor, William Alexander Forbes, a man full of vigour and in the best of health, should have suddenly succumbed to the influence of a pernicious climate at the age of twenty-eight, was perhaps a still more severe blow, and one that will long be felt by the naturalists of the present day. We do not seek to compare Forbes with Garrod, but it must be recollected that Forbes was a man of undoubtedly strong physique, for whom there was every prospect of a long and successful career. There can be not the slightest doubt that, had he not lost his life from the accidental force of circumstances, Forbes would have left a considerable mark on the progress of science As regards natural history at least, if not in some other matters, Forbes was a universal genius. Of the whole zoological series he had an enormous knowledge, ranging from one end of the animal kingdom to the other. Possessed of a most retentive memory and of an abundant stock of energy, he was unremittingly at work on his favourite subject, and never forgot what he had acquired either by reading or by experience. Not only was he thoroughly up in zoological literature, but he was also an accurate observer and a diligent collector in the field, where nothing came amiss to him. Mammals, birds, butterflies, and beetles were perhaps the groups which he knew best; but Forbes had, as already stated, an excellent general knowledge of the whole animal series. Whatever novel object might be shown to him he was very rarely at a loss for its correct name, nor for where to refer to for information about it.

It can thus be well understood, even by those who never had the good fortune to know Forbes, that the loss of such a man was keenly felt by his numerous friends and fellow-workers. Soon after his death, in 1883, it was resolved, at a meeting of the Zoological Club, that some sort of memorial of him should be carried out. After due consideration of the question it was unanimously determined by the Committee to whom the subject was referred that the best scheme would be the republication of Forbes's numerous papers in a connected form. This had been the course adopted in the case of Garrod, who had preceded Forbes in the Prosectorship of the Zoological Society of London. It was found that Forbes's contributions to science would make a volume of about the same size as the scientific papers of Garrod, and would not, it was believed, be of inferior interest.

The memorial volume, prepared and issued under these circumstances, contains sixty-seven papers published by Forbes in different periodicals from 1875 to 1882. The original illustrations have been in every case reproduced, and to increase the usefulness of the reprint, exact references to the paging of the original articles are added in the margin. At the end of the volume is given Forbes' last journal, reprinted from the *Ibis* for 1883, and containing a most interesting account of his observations during his fatal expedition up the Niger. Forbes died at Shonga, one of the stations of the United African Company on that malarious river, on January 14, 1883. Up to two days before his death the entries in the journal are in his own writing. The fatal termination of his illness, recorded by another hand, concludes the volume.

OUR BOOK SHELF

Elementary Algebra for Schools. By H. S. Hall, B.A., and S. R. Knight, B.A. (Macmillan, 1885.)

THIS is, in our opinion, the best *elementary* Algebra for school use. It is the combined work of two teachers who have had considerable experience of actual school teaching, aided by the advice of such men as the present Head of Clifton College, and so successfully grapples with difficulties which our present text-books in use, from their authors lacking such experience, ignore or slightly touch upon. Up to the point to which the subject is carried in this volume, it is treated with sufficient completeness for ordinary school purposes: the last four chapters present a somewhat concise account of ratio, proportion, and the progressions, which, however, covers enough ground for the ordinary examinations which schoolboys have to encounter. The authors propose to treat these parts in fuller detail in a *Higher Algebra*, which they are preparing. We do not propose to examine the book at any length, but confidently recommend it to mathematical teachers, who, we feel sure, will find it the best book of its kind for teaching purposes. Many subjects of interest are also treated of, and a vast collection of (3500) examples will furnish ample exercise for the boys, and save the teacher the trouble of concocting illustrations of the best methods. Answers are furnished at the end, so that those teachers who do not care that their pupils should have them handy, may have them sewn up.

Key to the Elements of Euclid. By J. S. Mackay, M.A. (W. and R. Chambers, 1885.)

THIS is a most valuable pendant to the edition of the "Elements" which we recently had occasion to notice so favourably. It is a book of nearly the same size as the "Elements" and yet contains, in consequence of the general omission of diagrams, solutions of the very large collection of admirable deductions which Mr. Mackay collected for the student in that work. De Morgan's words, quoted in the short preface, furnish ample ground for the omission of figures: "I am satisfied, from sufficient trial, that when proper description of the diagram is given in the text, the person who draws his own diagram from the text will arrive at the author's meaning in half the time which is employed by another to whom the successive appearance of the parts is prevented by his seeing the whole from the beginning."

The Essentials of Histology. By E. A. Schäfer. (London: Longmans, Green and Co., 1885.)

THIS will prove a useful book for students. It is arranged in forty-two lessons and appendix. Each lesson commences with a short statement of methods for the microscopic examination of the tissue described in the lesson. All simple tissues and organs are thus passed in review, and their most essential characters are succinctly described and illustrated. It is to be regretted that Prof. Schäfer has deviated from the customary plan of giving some kind of reference both for the text and the illustrations. The latter are mostly taken from Prof. Schäfer's portion of Quain's Anatomy, and their original source, although mentioned in Quain's, is here omitted.

An index at the end of the book would be a desirable addition.

E. KLEIN

An Atlas of Practical Elementary Biology. By G. B. Howes. (London: Macmillan, 1885.)

THE anatomical drawings of Mr. Howes have for some years been well known in all laboratories where animal morphology is taught. In his "Atlas of Elementary Biology" he has now published a very complete series of figures illustrating the chief of those animal and vegetable types which are generally given to students in their first session. The need for such a work as this is well known to every one who has any experience of biological teaching; and the name of its author is a sufficient guarantee of the careful accuracy and artistic excellence of the drawings it contains. The low price at which a student's text-book must necessarily be sold has precluded the use of colour, which might in a few cases have given some additional clearness to the figures; but all that could be done with black and white has been done, and every figure is evidently a faithful copy of an actual dissection, such as a student may reasonably hope to repeat for himself.

In the case of every animal chosen, a series of drawings showing the gross anatomy of the adult is followed by a few illustrations of the minute structure of its tissues, and of its main developmental features.

The drawings of adult anatomy are throughout excellent; the others, though the size of the work has somewhat restricted their number, will probably suffice for most of the needs of commencing students. It is however to be regretted that there is no figure showing the minute structure of the gill in Anodon, and also that Mr. Howes has not been able to accept Spencer's statement as to the conversion of the frog's blastopore into the permanent anus.

The botanical portion of the Atlas contains an admirable series of figures, showing the structure of the plants described in Huxley and Martin's well-known text-book, and completes a work which cannot fail to be of the greatest service both to teachers and to students of biology.

W. F. R. W.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

Radiant Light and Heat

I AM sure that all students must be grateful to Prof. Balfour Stewart for his exposition in last week's NATURE (p. 322) of the errors and absurdities into which recent scientific men had fallen, and out of which they are now groping their way. But if it be not trespassing too much on his good nature, may I ask him one or two questions in order to further educe his views on points which he cannot but have given much thought to, though they are points which, without further explanation, some of us are liable to misunderstand. We have some of us had the "advantage of being wrong first," combined with the further advantage of thinking ourselves right, but I for one will now gladly admit that I was wrong, if I may thereby hope to join "the generation which is right."

The following are the five points I wish to receive help in understanding:—

(*a*) "It is absurd to suppose that particles of air are shot . . . with a constant velocity of 1100 feet a second."

I am disposed to agree; but am unable to see clearly how far this absurdity destroys the validity of the so-called "kinetic theory of gases," and of the mode in which sound is considered to be conveyed by such a medium, if indeed it is still so considered at all.

(*b*) "Can it be thought that hot bodies emit myriads of very small particles, which pass through space with the enormous velocity of 187,000 miles per second? Or again, is it likely that this velocity should be precisely the same for all bodies and for all temperatures?"

I should say it was highly *un*likely, in fact, that the idea is ludicrously absurd. This is a triumphant refutation of the corpuscular theory, but I am rather troubled by the thought that the argument seems equally to refute the wave-theory, if for "particles" in the above sentence, we substitute the word "waves." I know it is only my stupidity which causes me to feel this difficulty.

Again, it sometimes seems to me that the undulatory theory itself requires a good deal of "propping up;" and that several phenomena—for instance, "aberration"—explain themselves more easily and simply on the corpuscular.

(*c*) In speaking of the "transmutation of *visible energy* into heat," we are surely justified in calling heat "*invisible* energy" in contradistinction to the other; but, suppose the blow is so intense as to make a flash, are we to consider that flash as part of the invisible energy which has been "created," or are we to consider it a portion of the visible energy which has escaped destruction? The notion of a certain quantity of visible energy disappearing from the universe at one place, and an equivalent quantity of invisible energy being simultaneously created at another, is so beautifully simple and satisfying that I am sure the process can be made quite clear to any mind of common intelligence with a little more trouble.

(*d*) "This train of thought enables us . . . to assert that there is a definite mechanical relation between the amount of heat which leaves a hot body as it cools, and the radiant energy which accompanies the act of cooling."

I fear I am too stupid to understand this sentence. As I read it, it sounds like the following:—"There is a definite mechanical relation between the number of people which leave a train as it empties, and the number of people who get out of it and go away during the act of emptying." And the paragraph seems to go on thus:—"If, for instance, ten people get out of a train, and all of them enter an omnibus so as to be entirely absorbed by it, then, while the train has become ten people emptier, the omnibus has gained an equal number and has become ten people fuller."

I know that this is absurd, but I am unable to seize the point properly, and therefore venture to put my difficulty in this plain and outrageous way.

(*e*) "Radiant heat is physically similar to radiant light, the only difference being that its wave-length is greater, and its refrangibility less, than those of light."

May I ask if it is known *how much* greater "the wave-length of radiant heat" is than "those of light"? The modern distinction between them is evidently so simple and numerical that it must be possible to definitely draw the line and to specify the exact wave-length which characterises each, or at any rate which partitions the one from the other.

Similarly it would be a help to us students to have the refrangibility of radiant heat specified and distinguished from those of light, too.

There are one or two other matters concerning which I should have been glad of further information; but I will not now trespass further upon your space or upon the good nature of the professor.

A STUDENT

IN reply to the remarks of a student I may state as follows:—

(*a*) In the kinetic theory of gases the pressure of a gas is regarded as being due to a bombardment by the molecules of the gas, and the velocity of sound in any gas can by this theory be shown to be definitely related to the velocity with which these molecules move about.

(*b*) It is no doubt true that the demonstration of "aberration" on the corpuscular theory of light is of a simpler nature than its demonstration on the undulatory theory, but I have yet to learn that the geometrical simplicity of a demonstration is always a characteristic of truth. The question is rather, Can "aberration" be shown to be a legitimate consequence of the theory of undulations quite apart from the mathematical difficulty or easiness of demonstration? If the demonstration is *valid* its *easiness* can wait.

(*c*) While admitting that our nomenclature regarding energy is of a temporary nature, I have hitherto confined the term "invisible energy" to that kind of energy the motions constituting which are on so small a scale and so rapid that they cannot by any means be rendered visible. No doubt we see a red-hot body, but we do not and cannot see the motions of the individual molecules of the hot body.

(*d*) The train of thought referred to was that which concluded that the particles of a hot body (like those of a sounding body) are in a state of vibration and (in both cases) communicate their energy of vibration to a medium which surrounds them. It is thus a question regarding energy, therefore a mechanical question, and we are thus entitled to assert that there is a definite mechanical relation of equivalence in energy between the amount of absorbed heat which leaves a hot body as it cools and the radiant energy which accompanies the act of cooling.

We have now so clear and definite a conception regarding energy that "A Student's" simile of a train and an omnibus represents the truth, and it may perhaps look a trifle ridiculous to assert such an obvious equivalence. But my remarks were partly historical, and to the physical student of a past generation the equivalence would not be equally clear. The meaning is that the radiant heat and light given out by a body when cooling, measured in any way you like and used up in any way you like, will always be mechanically equivalent to the amount of ordinary heat which the body has lost.

(*e*) Your correspondent asks how much greater the wave-length of radiant heat is than that of light. Let me refer him to a diagram which was given in a recent number of NATURE in illustration of a lecture by Prof. Langley, and which will likewise be reproduced in the course of this present series of articles.

BALFOUR STEWART

Pulsation in the Veins

THE writer of a very long and exhaustive article on "The Heart," occupying forty-one pages in Rees's "Cyclopædia," quotes, among other authorities, Bichat, who says "that the blood, when it has arrived at the veins, is no longer influenced by the heart's action; *consequently these vessels have no pulsation*" . . . "that the blood's return in the veins is involved in an obscurity;" and he propounds as a "contrast" "the fact of general pulsation in the arteries, the absence of this in the veins." The writer of the article states that "many authors, particularly Haller, considering that this [the venous] system has no agent of propulsion, have ascribed to the veins some peculiar structure" of which the evidence is insufficient; also "that there is no analogy to the course of the blood in the arteries where the action of the heart produces the whole effect," and adds: "There is much obscurity on the subject, as well as in the course of the blood in the general veins; and every judicious mind cannot fail to observe that there is a great vacuum to be filled up."

The object of this paper is to contribute to the solution of this mystery—first by proving that there *is* pulsation in the veins, and that therefore the heart's action *is* directly concerned in the return of the venous blood, and secondly, by suggesting the mode in which it is exerted.

I had observed that, on very close and careful inspection, there was in the veins (in those at the back of the hand, for instance) a visible though exceedingly delicate pulsatory undulation; but so minute that I have generally (but not always) failed to show it to others. It therefore became desirable to devise some means by which the fact might be made more manifest.

In the first instance I requested a lady, who was unable to perceive any pulsatory movement in the veins on the back of her hand, to feel and silently count her own pulse while I counted aloud the beats as indicated by what I could perceive in those veins. She was surprised to find that my counting corresponded exactly with hers, but observed that the beats of her pulse came intermediately and *alternately* with my counting. This I had not thought of or suggested. But it is, in fact, what would be the necessary result of the heart's action, and corresponds with its *alternate* contraction and dilatation.

In order to make more evident this venal pulsation the following experiment was successfully tried:—A small piece of silvered glass (about ⅜ inch by ¼ inch) was made to adhere to the surface of a swollen vein on the hand in such manner that *one* edge of the glass rested on the central ridge of the vein, while the other was in contact with the surface clear of the visible vein by the side of it. This, applied in the sunshine, of course afforded a spot of light, the movement of which reflected from the mirror, would indicate the slightest tilting of its plane by the undulating action of the vein, and the result was beautifully conclusive. The light spot vibrated in accordance with the pulse, and its vibrations were in the direction which corresponded with the tilting which should be the result of the position of the mirror in relation to the vein. Then a second mirror was applied on the *opposite* side of the vein, and the vibrations of the light spot took an *opposite* direction, which was to be expected, as the result of a tilting anticlinal to the first. A mirror placed on the knuckle (where are no veins of sensible importance) showed no sensible vibration. Thus the objection which I anticipated, that the vibration of the light spot might be caused by the general response in the limbs to the ordinary arterial pulsation, is answered by the evidence that a varied position of the mirror in respect of an individual vein was productive of a correspondingly varied motion of the light spot.

If, then, it is proved that, notwithstanding all previous authorities (to which I have had access), pulsation in the veins does exist, pulsation corresponding in rhythm with that of the arterial system, it becomes a corollary that the heart's action *does* extend to the motion of the blood in the veins, and an evident solution of the mystery of the return of the blood from the extremities appears to result. The expulsive effect of the heart's contraction is familiar, but the effect of its expansion, much in consequence of the venous pulsation having been unseen and denied, has been, as far as I know, ignored. Every one knows how an indiarubber ball syringe is filled by its expansion after compression. Apply this analogy to the expansion of the heart, and the return of the venous blood, the valves in the veins cooperating, would be equally certain. But this involves the existence of a corresponding venal pulsation, the supposed absence of which supported the theory that the direct action of the heart was limited to the arterial system.

I add some directions for the successful trial of the mirror experiment. The pulsatory motion is very small, and the action of neighbouring veins seems to cause parts of the surface to be neutral in respect of the displacement of the plane of the mirrors. It is, therefore, desirable to search experimentally for the best place for them; that is, where the resulting displacement becomes most evident; also the use of some sort of vigorous movement of the body or limbs, such as would cause a general exaggeration of the heart's action, naturally causes the vibrations of the light spot to become more conspicuous. The hand should be supported in the most steady manner, otherwise the pulsatory vibration becomes mixed up with an indefinite movement of the light spot due to general unsteadiness. The mirrors should not be more than ⅜ inch square or thereabouts. The silvering is liable to be detached from the glass by adhesion to the skin, if the glutinous substance is applied directly to the back of the mirror; to prevent this its back and edges should be covered with thin gummed paper (such as the margin of a sheet of postage stamps affords). This protects the silvering, so that the mirrors may be used repeatedly, and their position changed as often as may be required; whereas without this precaution they may be spoilt on the first application. Any sticky glutinous substance which does not dry readily (such as indiarubber dissolved in mineral naphtha) is convenient, because by its use the mirror may be with the least trouble shifted from one spot to another, in the search for a place where the venous pulsation is most visibly effective; and this will not always be found exactly where from the appearance of the veins it might be expected to occur. Stoneaston Park, Bath, August 10

The Fauna of the Sea Shore

IN the recent correspondence in NATURE on the "fauna of the sea shore," an ambiguity has arisen in the use of the term "littoral."

I, following Prof. Moseley, on whose lecture I was commenting, used the word in the extended sense of describing areas and faunas that were neither "deep-sea" (in the modern acceptation of the term) nor "pelagic." Mr. Hughes, on the other hand, has employed it in its common acceptation as descriptive of the shore area between tide marks.

The portion of the sea-bottom disturbed by waves has at present no term told off to describe it. It is not necessarily "littoral" in any sense, as that word will not cover the case of sand-banks far from the coast; such, for instance, as the banks of Newfoundland, where, according to both zoological and nautical evidence the waves act strongly on the sea-bottom. Some such term as "undal zone" might be used to describe those marine areas where the waves can sensibly affect the fauna.

The downward limit of this undal zone has not, I believe, been hitherto defined. In the case of oscillating waves (the ordinary ocean waves) 50 fathoms seems to approach the practical limit of disturbance, but, according to the evidence of marine charts, the waves appear to make themselves felt at greater depths.

In the late Mr. R. A. C. Godwin-Austen's map of the English Channel (*Q. J. G. S.*, vol. vi. p. 96), the following deposits are indicated, viz.:—

40 to 50 fathoms, fine granite shingle with fragments of *Haliotis tuberculata*.
50 to 60 fathoms fine granite shingle with fragments of *Patella vulgata*.
70 to 80 fathoms, coarse sand and gravel, with decayed *Patella vulgata*.
90 to 100 fathoms, coarse sand, fine gravel, *Cardium edule*, *Turbo littoralis*, and *Patella vulgata*.
Outside 100 fathoms, very fine shell sand, *Pecten varius*, *Cardium edule*, *Patella vulgata*, and *Turbo littoreus*.

Referring to one of these collections of shells (in upwards of 90 fathoms) between Ushant and the Little Sole Bank, the distinguished author remarks:—"Taking the two phenomena together, the occurrence of littoral shells and of marginal shingle, we may safely infer that we have at this place the indication of a coast line of no very distant geological period, buried under a great depth of water, and removed to a great distance from the nearest present coast-line."

The fact that shells are perishable owing to decay, corrosion, and the ravages of marine organisms, seems to me to militate against the probability that the shells in question are of geological antiquity; and their occurrence in connection with sand and shingle instead of mud would rather indicate the present action of currents strong enough to keep the sea-floor clean. This ordinary tidal currents cannot do, though wave and tidal currents combined can.

Under the joint influence of storm waves and storm-engendered currents, light shells may well travel down the channel bed to 40 or 50 fathom soundings. Theory and observation agree in the efficacy of wave and current to this extent. But to account for the presence of fresh littoral shells in 100 fathoms, we require the assistance of waves of sufficiently long period to affect the bottom at that depth, and to this extent theory in the case of ordinary ocean waves will not go.

In a paper submitted last year to the Dublin Society (*Proc.*, vol. iv. p. 241) I recorded observations of waves with an average period of 3½ minutes, and suggested that these waves arose from wind pressure on the surface of the sea; it would be interesting to know at what depth such very long, though irregular, waves would be capable of disturbing light deposits on the sea-bottom. In sheltered localities I have seen these waves attain the height of about three feet; in exposed localities they would doubtless be higher. ARTHUR R. HUNT

On the Terminology of the Mathematical Theory of Electricity

IN a letter (NATURE, vol. xxxii. p. 76) Mr. W. J. Ibbetson invites suggestions for a convenient abbreviation for "total or resultant pressure"; at the same time he suggests the adoption of "traction" for "intensity of tensile stress." As it seems a pity to employ two totally distinct words to express such closely related ideas as intensity of tensile stress and total tensile stress, I would suggest that, on the analogy of pressure, "*tensure*" should be introduced for "intensity of tensile stress;" and then, on the analogy of "tension" for "total tensure," "*pression*" for "total pressure." New words are hard to grow in a language, but in this case pressure and tension might interchange their suffixes as grafts and yield two fresh useful words.

As regards physical and mathematical terminology in general, is not the time ripe for the introduction of a prefix which will modify the meaning of a term as the adjective "negative" does? *Mega* and *micro* have proved useful for multiplying and dividing by a million, but how much greater scope would there be for a prefix "ne" or "neg" for reversing the sign of a quantity. Thus negative electricity might be called "*nelectricity*," a quantity of negative electricity as so many "*necoulombs*," a negative magnetic pole as a "nepole," a negative potential as of so many "nevolts," a negative angle could be spoken as of so many "negradions" or "nedegrees," a negative temperature as of so many "nedegrees." In many cases there would be no appreciable advantage, but if there was a general understanding as to the operation of the prefix "ne" in any case, it could be used wherever it would render the phraseology less cumbersome.

Melbourne, July 10 WILLIAM SUTHERLAND

An Encysting "Myzostoma" in Milford Haven

I HAVE recently had occasion to examine a number of *Comatulæ* from Milford Haven which were kindly given to me by Mr. W. Percy Sladen, F.L.S., and appear to belong to the type that was figured by Miller under the name of *Comatula fimbriata;* and I was surprised to find many of the pinnules presenting distinct traces of an encysting *Myzostoma*. In each of the dozen individuals the joints of one or more pinnules are abnormally developed, and in some cases they form definite cysts, which are, however, much smaller than those found on the pinnules of many *Comatulæ* and *Pentacrinidæ* from the Pacific and Oceania; but they are obviously of the same character and due to the presence of a parasitic *Myzostoma*. According to Prof. L. von Graff eight species of encysting *Myzostoma* are at present known, but they are limited to depths of 120 to 600 fathoms in the Pacific, the Eastern Archipelago, and the Caribbean Sea, with the exception of one which was dredged by the *Hassler* in 35 fathoms off Cape Frio, Brazil.

Mr. Sladen's dredgings at Milford, therefore, have considerably extended both the bathymetrical and the geographical distribution of these encysting species. The five *Comatulæ* found in the British area have yielded six of the free-living *Myzostomas*, four of which were discovered by the *Porcupine* and *Triton;* and we may probably take it for granted that the encysting form from Milford is another addition to the British fauna.

I propose to send all my material to my friend, Prof. von Graff, for examination; and as there will, no doubt, be much shore-dredging carried on during the next few weeks, I would call the attention of British naturalists to the facts mentioned above, and ask them to look carefully on the pinnules of any *Comatulæ* which they may find for cysts or other enlargements of the joints. P. HERBERT CARPENTER

Eton College, August 22

Solid Electrolytes

IN reference to Prof. S. P. Thompson's letter dated August 17 (NATURE, vol. xxxii. p. 366), may I be allowed to say that I too have observed the secondary currents which are produced by cells containing sulphides of silver and copper after being disconnected from a battery? I mentioned the fact at the meeting of the Physical Society on June 27, in a communication which will probably be printed in the *Phil. Mag.* next month. Indeed, the observation of these secondary currents preceded and led to the construction of the primary cells with solid electrolytes which I have recently described.

I should be glad to know whether Prof. Thompson can explain the curious effect produced by passing a battery-current for a moment through a cell containing a mixture of sulphide of copper and sulphur between silver electrodes. When the cell is first connected with the galvanometer the usual secondary current appears, but in a few minutes, or even seconds, this current falls to zero and is succeeded by a third, which is in the same direction as the battery-current, and generally continues for some hours. August 23

THE SQUARE BAMBOO

THE cylindrical form of the stems of grasses is so universal a feature in the family that the report of the existence in China and Japan of a bamboo with manifestly four-angled stems, has generally been considered a myth, or, at any rate, as founded on some diseased or abnormal condition of a species having stems, when properly developed, circular in section.

Of the existence of such a bamboo there cannot, however, now be any kind of doubt. It is figured in a

Japanese book, the "Sô moku kin yô siû" (Trees and shrubs with ornamental foliage), published at Kyoto in 1829, and the figure is reproduced by Count Castillon in the *Revue Horticole* (1876, p. 32).[1] It is further figured in a work for a copy of which we are indebted to my friend Prof. Kinch (formerly of Tokiyo), called the "Ju-moku Shiri-yaku"—*i.e.* a short description of trees (of Japan). Finally, in 1880, Messrs. Veitch presented to the Kew Museum fine specimens of the stem of the square bamboo,

[1] The woodcut also appeared in the *Gardeners' Chronicle* for January 29, 1876, p. 147. I am indebted to the Editor for its use on the present occasion

brought from Japan by their intelligent collector Mr. C. Maries.

M. Carrière states, in an editorial note to Count Castillon's article, that the plant had been introduced into France at that date, and was indeed actually on sale in the nurseries near Antibes.

Nothing, however, till quite recently, appears to have been known as to the existence of the square bamboo in China,' from which country, however, it is extremely probable that the Japanese procured it. Thus, Mr. F. B. Forbes, whose personal knowledge of the Chinese flora is only second, perhaps, to that of Dr. Hance, informs me:—"I have never seen the square bamboo growing, and I have always supposed that its 'squarity' was artificially produced."

The first authentic account of its occurrence in China is, as far as I know, due to Mr. Frederick S. A. Bourne, of H.B.M. Chinese Consular Service. Mr. Bourne wrote to us, October 15, 1882, that he had made a journey from Foochow to a distance of 300 miles to the western border of the Fokien province, reaching Wu-i-kung, the celebrated monastery in the Bohea hills—a place, Mr. Bourne states, "only visited by a European once before, I believe—*i.e.* by Mr. Fortune, about the year 1845." In the gardens of this monastery he found several clumps of the square bamboo growing to the height of about eight feet.

The *Tropical Agriculturist* (an astonishing repertory of everything relating to the economic botany of the East) contains in its issue for November, 1882 (p. 445), an article extracted from the *North China Herald*, also relating to the square bamboo, plants of which, destined for the park at San Francisco, had been obtained by Dr. Macgowan at Wenchow. I extract from this article the following particulars, which show the interest the Chinese themselves attach to the plant:—

"Pre-eminence is assigned to the square variety of this most useful as well as ornamental plant, which has been a favourite in Imperial gardens whenever its acclimatisation has been effected in the north. The Emperor Kao Tsu once inquired of his attendants, who were planting bamboos, concerning the various kinds. In reply he was informed concerning several remarkable species. Chekiang in particular furnished one that was an extraordinary curiosity, in that it was square, and for that quality and its perfect uprightness was much esteemed by officers and scholars. They also told him that it was used for many purposes of decoration and utility, including, among others, that of being made into ink-slabs. Subsequently specimens were obtained, polished, and sent to his majesty, who thereon signified his respect for the article by rubbing ink with his own hand on the inkstand, and inditing an essay on the curiosity. In 650 A.D. the reigning Emperor sent a eunuch to Chekiang to obtain specimens for the Imperial Park. Besides being furnished from scattered portions of this province, it is found in Honan, Szechuen, Yunnan and Hunan; in the latter province it appears to present its peculiar characteristic in a marked degree, being as square, with corners, and as well defined as if cut with a knife. The Chekiang varieties have slightly rounded corners, and moreover they are more slender, being used only as pipe-stems, whereas the western kind is large enough to serve as staves for the aged. In its early stage of growth the square bamboo is nearly round, assuming the anomalous figure it afterwards presents as it advances towards maturity. Like several other kinds of bamboo it is thorny, abounding in small spines."

Dr. Macgowan being well known to botanists for his intelligent interest in all that relates to the vegetable productions of China, I ventured to write to him to ask his aid in procuring living specimens of this interesting plant for the Royal Gardens. Through his kindness and that of Mr. E. H. Parker, late acting consul at Wenchow, we were fortunate enough to receive a Wardian case filled with plants of the square bamboo, some of which at least appeared to be alive and likely to grow. Besides these Dr. Macgowan sent us specimens of walking-sticks and pipe-stems made from it.

I quote the following passages from the very interesting communication with which Dr. Macgowan was also good enough to favour us:—

"Its geographical range is from 25° to 30° N. latitude, littoral, and westward farther than I have been able to discover. Unlike other varieties of bamboo here, its shoots are developed in the autumn, not in the spring. It sprouts in September or October, and the stems grow until they are arrested by December cold, by which time they attain a height of from two to four or five feet. In the spring following their growth recommences, when the grass attains its full height, ten to fourteen feet. The lower portion of the culms bristle with short spines; in the second or third year their squareness is far less striking than when matured by several years' growth; that quality is sometimes so marked that a native botanist describes them as appearing like rods pared by cutting instruments. I have seldom found the corners much more sharply defined than in the largest of the specimens herewith transmitted. It is cultivated chiefly for ornament in gardens, in temple courts, &c.; the larger stems (sometimes as much as an inch and a half through) are used for staves; the smaller and less squarish for stems of opium-pipes; and the smallest and less mature for tobacco-pipes."

He further adds:—"Its anomalousness is attributed by the Chinese to supernatural powers—occult agencies varying with each district. The *Ningpo Gazetteer* tells how Ko Hung, the most famous of alchemists (fourth century A.D.), thrust his chopsticks (slender bamboo rods pared square) into the ground of the spiritual monastery near that city, which, by thaumaturgical art, he caused to take root and to appear as a new variety of bamboo—square."

As no flowering specimens of the square bamboo have reached the hands of botanists, its taxonomic position must at present be regarded as doubtful. Rivière ("Les Bambous," p. 315) refers to it as the *Bambou carré*, and Fenzi, quoting from Rivière (*Bull. Soc. Tosc. di Ort.*, 1880, p. 401), gives it the name *Bambusa quadrangularis*.

I can discover no reference to it in the late General Munro's classical monograph of the *Bambusaceæ* (*Trans. Lin. Soc.*, vol. xxvi.). Of the three groups into which he divides the genera, in only one, *Triglossæ*, is there any tendency to depart from the habit of the order in having anything but round stems; and this only occurs in the small genus *Phyllostachys*, in which they are somewhat laterally flattened. The stems of *Phyllostachys nigra* are often used in Europe for walking-sticks and light broom-handles.

But I do not think the square bamboo will turn out to be a *Phyllostachys*. Munro has a *Bambusa angulata* which is distinguished from all its allies by having the branches of the panicle angular. This is the only tendency to angularity of stem which I have discovered among the true *Bambuseæ*.

For the present, at any rate, the species must be known provisionally as *Bambusa quadrangularis*, Fenzi.

W. T. THISELTON DYER

FORECASTING BY MEANS OF WEATHER CHARTS

THE Meteorological Office has issued a work on the "Principles of Forecasting by Means of Weather Charts," which has been prepared at the request of the Council by the Hon. Ralph Abercromby.[1] The object of

[1] "Principles of Forecasting by Means of Weather Charts." By the Hon. Ralph Abercromby, F.R.Met.Soc. Issued by the Authority of the Meteorological Council. Official No. 60. 8vo. Pp. 123 + viii. London: 1885.

the author has been to give an account of the modern method of forecasting weather by means of synoptic charts; and although the general principles laid down hold all over the world, the details he gives refer only to Great Britain. The whole system of synoptic forecasting depends entirely on the observed association of different sets of phenomena, and is totally independent of any theory of atmospheric circulation.

The synoptic charts prepared at the Meteorological Office are constructed in the following manner. Every day at 8 A.M. and 6 P.M. telegraphic reports are sent up to London from about fifty stations in the United Kingdom, giving the readings of the barometer and thermometer, the direction and force of the wind, and the state of the weather. These readings are then plotted on a map, and the "isobars" and "isotherms" drawn, representing lines of equal pressure and equal temperature. The isobars are the most important element in forecasting. The direction of the wind is shown by arrows which have a number of "fleches" proportional to the force, while the weather is indicated by the letters of Beaufort's notation. While the force of the wind depends on the closeness, and the direction on the trend, of the isobars, the weather is governed by the shape of the lines. Although the shape of the isobars is continually changing, several well-defined forms are always reproduced. Seven of these are described, to which the following names have been given:—1. Cyclone—an area of low pressure, bounded by circular or oval isobars; 2. Secondary cyclone—a small, circular depression, subsidiary to the cyclone; 3. V-shaped depression—an area of low pressure bounded by V-shaped isobars, something like a secondary, but differing from it in many important particulars; 4. Anticyclone—an area of high pressure bounded by circular or oval isobars; 5. Wedge-shaped isobars—an area of high pressure bounded by isobars converging to a point like a wedge; 6. Straight isobars—a barometric slope, down which the isobars lie in straight lines; and 7. *Col* or neck of low pressure lying between two adjacent anticyclones.

Cyclones.—A cyclone may be of any diameter, from 100 to 3,000 miles. The most common are between 1,000 and 2,000 miles; and anything less than 1,200 miles across is a small one. The path of a cyclone is the path described by the centre. In this country 90 per cent. move towards some point of east, the most frequent direction being about east-north-east. The velocity is that of the centre; it may be anything from 70 miles an hour eastwards to 10 miles an hour westwards. About 20 miles is a common velocity, but sometimes a cyclone is stationary. The life of a cyclone is measured by the number of days during which it can be traced on synoptic charts; the length of life may be anything from a few hours to 20 days. The details of wind, weather, &c., in the different portions of a cyclone may be briefly summarised as follows:—The temperature is always higher in the front than in the rear; the warm air in the front having a peculiar close, muggy character, quite independent of the actual reading of the thermometer. The cold air in the rear, on the contrary, has a peculiarly exhilarating feeling, also quite independent of the thermometer. The front is always very damp, especially the right-front, while the rear is dry to a marked degree. The wind blows around the centre in the direction contrary to the motion of the hands of a watch; but as the direction is slightly inclined to the isobars, on the whole the circulation is an ingoing spiral. The amount of incurvature is usually greatest in the right-front, and least in the rear; so that sometimes the passage of the trough is marked by a sudden shift of wind. The force of the wind depends almost entirely on the gradients; in the centre it is a dead calm, and the steepest gradients are usually found at some distance from the centre. The direction from the centre in which the strongest winds are found depends on the position of the surrounding areas of high pressure.

There is no difference between ordinary weather and a storm, except in that property called *intensity*, and in this country a summer breeze and winter gale are equally the product of cyclones which differ only in intensity. Hence in forecasting storms it is necessary not only to foresee the arrival of a cyclone, but of one possessing sufficient intensity to cause a gale, and in tracking cyclones it by no means follows that the same one causes a storm during every day of its existence. Observation has also shown that a deepening cyclone is increasing in intensity, while one which is filling up is decreasing. When in watching the progress of cyclones by telegraph it is very important for forecasting to note changes in depth, as well as any other indications derived from the configurations of the isobars, or even from weather prognostics, which experience has shown to be associated with intensity.

Though the general characteristics of a cyclone are invariably maintained, still, individual cases vary much in detail. The principal sources of variation which modify, but do not alter, the general characteristics are:—1, the type; 2, the intensity; 3, the size; 4, local; 5, diurnal; and 6, seasonal variation.

Secondaries.—The secondary is a small cyclone formed on the side of a larger one which is called the "primary." Secondaries are almost invariably formed either along the prolongation of the trough of a cyclone, or else on that side of the primary which adjoins the highest adjacent pressure. The most important feature about them is the manner in which they deflect the isobars of the primary, so as to leave an area of slight gradients and light winds on the side of the secondary next the primary, and a line of steeper gradients and stronger winds on the side furthest from the primary. Their motion is usually parallel to that of the primary. The most striking difference between a secondary and a primary cyclone is the great amount of rain and cloud with absence of wind developed in the former, compared with the less rain and cloud but the stronger wind developed in the latter. In a secondary when the rain comes on, it is usually very heavy and falls straight; and in its general appearance and surroundings is very different from the driving or drizzling rain, so characteristic of the front of a primary cyclone. In forecasting, the principal indication of secondaries is rain, without much wind, and thunder-storms in summer; and their sudden formation very often unexpectedly disturbs and vitiates former forecasts. Sometimes several secondaries are seen on the chart; this is a sign of great intensity, and the indication in such cases is always for wild, broken weather, often with thunder-storms, but not for widespread gales.

V-shaped Depressions.—These are generally formed along the southern prolongation of the trough of a cyclone, or in the col or furrow of low-pressure which lies between two adjacent anticyclones. Their motion is generally eastwards along with their associated cyclone, but they are very often short-lived. They are entirely non-cyclonic. The line of the trough, along which the barometer rises, marks out the line along which the weather changes very abruptly, and this change is very often accompanied by a violent squall.

Anticyclones.—Anticyclonic isobars enclose an area of high pressure which is associated with fine weather and light winds circulating in the direction of the hands of a watch, but a little outcurved. The whole system is usually stationary for many days together. The general characteristics are a cold, dry air, and fine, or at least quiet, weather. The calms, or light winds, give free play to the radiation of the season, so that very hot days occur in summer and very cold nights and fog in winter. In forecasting, the indications are for settled fine weather, the details depending much on the season and local peculiarities.

Wedge Isobars.—These consist of isobars converging almost to a point, but enclosing an area of high pressure, instead of a low one, as in the case of the V's. The wedges seem to shoot up in front of cyclones and V depressions and to travel along before them. On the front, or east side, the weather is very bright, and the wind is north-west and moderate, while the temperature is that due to excessive radiation. On the rear, or west side, where the barometer begins to fall, the wind turns to south-west, and the sky overcasts in that peculiar manner which first gives a halo, and then gradually becomes black, without true cloud as the cyclone approaches. At the extreme north point of the wedge a shower or thunderstorm is sometimes observed.

Straight Isobars.—In these the pressure is high on one side and low on the other, without any definite cyclone, the isobars running straight across the slope which joins the regions of high and low pressure. Straight isobars are never persistent, and the area which they have occupied is usually traversed by a cyclone of greater or less intensity. For forecasting purposes the indications are for cool, cloudy, unsettled weather, the wind from moderate to fresh, according to the gradients, to be followed soon by rain, as a cyclone forms or comes up.

Cols.—The col consists of a neck of low pressure between two anticyclones. The wind is always light and the weather quiet, but variable in appearance, owing to the local influence of radiation. Though the general position is sometimes nearly stationary, the weather is rather variable, owing to the tendency of the depression which lies on the north-west to develop a secondary in the col. Hence in forecasting, though it is possible to tell what the weather would be in the col at any moment, the future course of the weather is subject to much uncertainty.

Mr. Abercromby devotes a considerable portion of his work to a discussion of weather-types and sequence. With reference to Western Europe, there are at least four well-marked types of weather: 1. The Southerly, in which an anticyclone lies to the east or south-east of Great Britain, while cyclones coming in from the Atlantic either beat up against it or pass towards the north-east. 2. The Westerly, in which the tropical belt of anticyclones is found to the south of Great Britain, and the cyclones which are formed in the central Atlantic pass towards the east or north-east. 3. The Northerly, in which the Atlantic anticyclone stretches far to the west and north-west of Great Britain, roughly covering the Atlantic Ocean. In this case cyclones spring up on the north or east side, and either work around the anticyclone to the south-east, or leave it and travel rapidly towards the east. 4. The Easterly, in which an apparently non-tropical anticyclone appears in the north-east of Europe, rarely extending beyond the coast-line, while the Atlantic anticyclone is occasionally totally absent from the Bay of Biscay. The cyclones then either come in from the Atlantic and pass south-east between the Scandinavian and Atlantic anticyclones, or else, their progress being impeded, they are arrested or deflected by the anticyclone in the north-east of Europe. Sometimes they are formed to the south of the north-east anticyclone, and advance slowly towards the east, or, in very rare instances, towards the west.

Mr. Abercromby next explains the use of various aids to forecasting, and gives some detailed examples of successful and unsucessful forecasts.

In concluding his work, Mr. Abercromby gives some remarks on forecasting generally, and points out that in many cases of small disturbances the minor features are so local that it is only the general character of the weather which can ever be forecast. Owing to the rapid nature of all meteorological changes, forecasts can never be issued very long in advance. The British forecaster labours under peculiar difficulties from his geographical position. Situated on the most outlying portion of Europe, and in the very track of storms which almost always advance from the westward, he has no intimation of an approaching cyclone till it is actually on him. Mr. Abercromby's opinion is that, however carefully the relation of weather to isobars may be defined and the nature of their changes described, the judgment which experience alone can give to enable a warning to be issued must ever depend on the professional skill of the forecaster.

RADIANT LIGHT AND HEAT[1]

II.

The Theory of Exchanges

It was known at a comparatively early period that if a body be placed in an enclosure of constant and uniform temperature, it will ultimately attain the temperature of this enclosure.

To fix our ideas, let us suppose that we have a chamber surrounded on all sides by walls which are kept at the temperature of boiling water (100° C.), and let us further suppose for the sake of simplicity that there is no air in this chamber, so that no heat can be carried about by movable particles of gas. If under these circumstances we put a cold body into the chamber, it will ultimately reach 100°, at which temperature it will remain. This is a statement of the doctrine of temperature equilibrium; but this equilibrium may be of two kinds—for it may either be a statical equilibrium, in virtue of which two bodies at the same temperature cease to radiate to each other, or it may be a dynamical equilibrium, in virtue of which each of these bodies independently radiates heat to its neighbour, receiving back, however, just as much heat as it gives out. In either case the ultimate result will be equality of temperature, and the only difference is with regard to the physical machinery by which this is brought about. In the theory of statical equilibrium the behaviour of two bodies of equal temperature with respect to heat may be compared to that of a man with respect to money who is getting neither richer nor poorer, because he is neither giving away nor receiving any money, whereas in the theory of dynamical or movable equilibrium the comparison is with the man who is getting neither richer nor poorer because he is receiving back just as much money as he is giving out.

Now, we are all of us conversant with frequent examples of individuals of this latter class, but the condition of things in this world is such that we cannot have any permanent example of the former, and similar considerations might convince us that if radiant light and heat be in reality a kind of energy, the theory of a movable or dynamical equilibrium must be much more suitable to such a constitution of things than that of a statical or tensional equilibrium. Historically, however, the question of temperature equilibrium was not decided by considerations regarding energy, our conceptions of which were not then sufficiently advanced to be of much service to those who were engaged in the discussion.

As the subject is one of great theoretical and practical importance, we shall proceed to give a short account of the circumstances attending the origin and development of what is now known familiarly as the *theory of heat exchanges*. About a century ago Prof. Pictet of Geneva made the following experiment:—He took two concave metallic reflectors, and, reversing the ordinary mode of procedure, put ice or a freezing mixture in the focus of the one and a thermometer in that of the other, upon which the temperature of the thermometer was observed to fall. This effect would at once be explained if we could suppose that cold was a substantial entity capable of radiation and reflexion like heat. But it was immediately recognised that such an hypothesis is quite inadmissible, and Prof. Pierre Prevost, also of Geneva, was thus driven to propose for the explanation of this experiment the theory of a movable equilibrium of heat.

It is very evident that such a theory will explain the

[1] Continued from p. 327.

fact. For, n accordance with it, bodies of the same temperature continue to radiate heat to one another, and hence the thermometer will radiate heat to the concave reflectors, which we may suppose to be of the same temperature as itself.

This heat will ultimately in great measure be reflected upon the ice or freezing mixture. Now, had this ice been of the same temperature as the other portions of the apparatus, it would have given back to the reflectors, and through them to the thermometer exactly as many heat rays as the latter had given to it.

But the ice being of a lower temperature, does not radiate back as many rays to the thermometer as this instrument gives out to the ice, and the temperature of the thermometer falls in consequence. It will be noticed that the same laws of reflexion and arrangement of mirrors that in the case where a hot body is placed in the one focus would have heated the thermometer in the other will, in the case of a cold body, cool the thermometer in the other; so that, without resorting to the unlikely assumption that cold is a separate principle, we may explain the above experiment on the supposition that bodies of the same temperature radiate heat to one another, or, in other words, on the hypothesis of a movable equilibrium.

Prevost's first memoir was in 1791, and in 1804 Leslie published his inquiry into the nature and propagation of heat. He there demonstrated the fact that good reflectors of heat, such as metals, were bad radiators. Prevost, in a treatise on radiant heat, published in 1809, showed that Leslie's conclusions followed from his theory, remarking that in a place of uniform temperature a reflector does not alter the distribution of heat, which it would do if it possessed at the same time the power of being a good reflector and a good radiator. Prevost seems to have entertained very correct views upon this subject, inasmuch as he conjectures that a good reflector is a bad radiator because, as it reflects the heat from without, so it also reflects the heat from within. Internal radiation, we shall afterwards see, follows as a consequence from the theory of exchanges.

Some time afterwards Dulong and Petit published their well-known memoir on radiation, which affords evidence of a peculiar kind in favour of the theory of exchanges. To illustrate the bearing of the experiments by Dulong and Petit on this theory, let us imagine that we have a hollow, blackened enclosure which is at the same time a vacuum, and that we have in its centre a large thermometer likewise blackened, the temperature of which is higher than that of the enclosure. We are supposed to be engaged in observing the rate of cooling of this thermometer, or, in other words, the excess of its radiation to the enclosure above that of the enclosure to it. Now let A denote the total radiation of the thermometer, which we may imagine to have the temperature a. Also let B denote that of the enclosure, which we may imagine to have the temperature b. Then $A - B$ will, by the theory of exchanges, represent the rate of cooling of the thermometer. In the next place let the thermometer have the temperature b and radiation B, while the enclosure has the temperature c and radiation C. Here $B - C$ will, by the theory of exchanges, represent the rate of cooling of the thermometer. Finally, let a be the temperature of the thermometer, and c that of the enclosure. Then $A - C$ will, on the theory of exchanges, represent the radiation or rate of cooling of the thermometer. Now $A - C = (A - B) + (B - C)$, that is to say, the rate of cooling in the third case will represent the sum of the two preceding rates *if the theory of exchanges be true*.

It was found by Dulong and Petit that this was actually the case, for with $a = 140°$ and $b = 80°$, $A - B$ was found to be 2·17.

Again, with $b = 80$ and $c = 20$, $B - C$ was found to be 1·40.

Finally, with $a = 140$ and $c = 20$, $A - C$ was found to be 3·56. Now this is very nearly equal to 3·57, or the sum of the two preceding rates, so that the evidence deduced from these experiments is decidedly in favour of the theory of exchanges.

In 1848 Provostaye and Desains made a definite advance towards a clearer conception of this theory. It may be stated thus. If we place a thermometer in our hypothetical chamber of constant temperature it is well known that the instrument will give the same indication, in whatever manner we alter the substance of the walls, provided only that their temperature be left the same.

It follows from this that the heat radiated, together with that reflected from any portion of the walls, forms a constant quantity independent of the nature of the substance of which this portion is composed. We thus see that it is not correct to assert that the reflective power of a substance is inversely proportional to its radiative power, the true statement being that in the case of an enclosure of constant temperature such as that we are now considering, the sum of the heat radiated and reflected from any portion is a constant quantity.

It was likewise perceived by Provostaye and Desains that this constant sum, while equal to that of a lampblack radiator, must be unpolarised, since heat from lampblack is unpolarised; and hence that, since the reflected heat is frequently polarised, the radiated heat must be polarised in an opposite manner, that is to say, in a perpendicular plane, in order that the sum of the two should be virtually unpolarised. Experimentally these observers found this to be the case.

It will thus be seen that the inquiry had now reached a stage at which a perfectly clear conception had been formed of the character with respect to intensity and polarisation of the heat emanating from any portion of the surface of an enclosure of constant temperature.

No attempt had however been made to split up the heterogeneous body of heat into its constituent wavelengths, nor was it perceived that an extension of the argument must necessarily lead to a separate equilibrium for every individual description of heat.

Internal radiation too, as a subject for experiment (if we except the remark made by Prevost), appears to have been overlooked, and its essential connexion with the theory of exchanges does not appear to have been perceived.

In March, 1858, I communicated to the Royal Society of Edinburgh a memoir in which these desiderata were supplied. In this memoir it was shown by a simple process of reasoning that the heat-equilibrium must hold for every individual description of heat, and that as a consequence this would lead to various conclusions, all of which were experimentally verified. The following facts were thus established:—

(1) The radiating power of thin polished plates of different substances was found to vary as their absorbing power: so that the radiation of a plate of rock-salt was only 15 per cent. of the total lamp-black radiation for the same temperature.

(2) It was shown that the radiation from thick plates of diathermous substance is greater than that from thin plates, no such difference being manifested when the substances are athermanous.

(3) It was found that heat radiated by a thin diathermous plate is less transmissible through a screen of the same material than ordinary or lamp-black heat, the difference being very marked in the case of rock-salt.

(4) Lastly, heat from a thick diathermous plate is more easily transmitted through a screen of the same material than that from a thin plate.

All these facts can be explained by a legitimate extension of the theory of exchanges.

Let us recur to our hypothetical chamber, outside the walls of which we may suppose there is a boiling-water arrangement, in virtue of which these walls are kept at the temperature of 100° C. The inside we shall suppose to be a vacuum. Let us in the first place hang up in this chamber two thermometers, one covered on the outside of its bulb with lamp-black, the other with polished silver. The former of these will absorb all the rays that fall upon it from the walls of the chamber, the latter, on the other hand, will absorb very few of these rays. Ultimately, however, both thermometers will attain the temperature of the walls. Since, therefore, according to the theory of exchanges the equilibrium of temperature is kept up by an equality of absorption and radiation, it is manifest that the radiation from the lamp-black thermometer must be great, because the absorption is great, and the radiation from the silvered thermometer small, because the absorption is small.

It will be noticed that this connexion between the two qualities, absorption and radiation, is deduced from a hypothetical case where everything is at a constant temperature. To prove it experimentally we may without any breach of scientific propriety take out the two thermometers from the enclosure, exposing them to a lower temperature, and noticing their velocity of cooling, when it will be found that the blackened thermometer cools more rapidly than the silvered one.

Or we may allow their radiation to fall upon a thermopile, and to be registered by a galvanometer, when it will be found that the indication of the galvanometer will be much greater for the blackened than for the silvered thermometer.

Let us next hang up in our enclosure a plate of glass and one of polished rock-salt.

The plate of glass will absorb all or nearly all the rays of dark heat that fall upon it from the sides of the enclosure. The plate of rock-salt will, on the other hand, absorb only a few of these rays. A similar argument to that already given will enable us to see that if the theory of exchanges be true, the radiation from a plate of rock-salt must be decidedly less than from one of glass, and this is found to be the case.

Next, let us hang up two plates of rock-salt, a thick one and a thin one. The thick one will absorb more rays than the thin one, and we shall therefore expect it to radiate more. This, too, will be found to hold experimentally, thus proving the fact of internal radiation. On the other hand, we shall observe no sensible difference if we hang up two plates of glass, one thick and one thin, the reason being that the thin plate of glass already absorbs all the heat which falls upon it, so that no increment of absorption, and hence of radiation, can take place by increasing the thickness. We thus see that it is only in the case of diathermanous bodies that the radiation increases with the thickness, while for athermanous bodies there is no such increase.

We are now in a better position for realising what takes place in our hypothetical enclosure.

There is a stream of heat from the walls which falls upon any substance which we may introduce into our chamber. Now this stream is not altered in intensity by altering either the shape or substance of the walls. Suppose, for instance, that they are of polished metal instead of being covered with lamp-black, then, while the heat radiated from them will be less, the reflexion of this heat will be so bandied backwards and forwards between these walls as to swell up the total amount to an equality with the lamp-black radiation, the only difference being that in the lamp-black radiation there is little or no reflexion, while in the other there is much reflexion and comparatively little radiation. Nor will the stream from the walls be altered by hanging up a plate of any substance between them and the body we introduce. For the plate will radiate on its own account just as much heat as it absorbs from the walls, so that the joint radiation of the two will be the same as if the plate were taken away.

Our remarks have hitherto applied only to the total intensity of this stream of radiant heat, and not to its quality—that is to say we have left out of consideration the specific mixture of various kinds of rays differing either in wave-length or in polarisation which go to make up the whole heterogeneous radiation. Now a little reflection will convince us that this specific mixture—this *quality* of the radiation-stream—must, as well as its *quantity* remain the same under any change made in the shape or substance of the enclosure. For suppose that we introduce a thermometer coated with some substance which exercises a selective absorption for certain rays of the stream, and not for others, then a change of quality would mean for this thermometer a change of absorption as truly as if there were a change of quantity. But by the theory of exchanges the absorption must remain the same, being equal to the radiation, and hence this can only be brought about by the quantity and the quality of the radiation-stream remaining each unaltered whatever change be made in the walls of the enclosure, or whatever substance be introduced between these walls and the thermometer. Carrying out this train of thought, we see why, as was proved by Provostaye and Desains, the sum of the radiated and reflected heat from any portion of the walls must be unpolarised, the reason being that the radiated heat from lamp-black is unpolarised and the one radiation must be equal to the other not only in quantity but in quality also. Again, the radiation of any surface or of any plate must be equal to its absorption, both as regards quantity and quality, so that the stream of heat may emerge from the surface or from the plate unaltered both in quality and in quality.

Thus the putting up of a plate between the walls and our coated thermometer will produce no effect, inasmuch as the stream of radiant heat which falls upon the coating will be unaltered both in quantity and quality by the interposition of the plate. We thus see why the radiation from a thin plate of rock salt should be of a quality which renders it much absorbed by a cold plate of the same material, the reason being that a body radiates that kind of heat which it absorbs.

We see, too, why heat from a thin plate of rock salt should be more absorbed by a cold screen of this material than that from a thick plate, inasmuch as the former consists of that kind of heat which is strongly absorbed, even by a thin plate, while the latter contains likewise a number of other rays which are not so strongly absorbed.

The conclusion to be derived from these remarks is that we have in reality a separate equilibrium for every description of heat, an equilibrium which is independent of the shape of the enclosure and of the substances of which it is composed. Furthermore, the stream of radiant heat may be supposed to circulate in the interior of a substance such as glass, water, or even metal, the radiation of each particle which it meets being exactly equal to its absorption, so that the stream proceeds through the interior, being virtually the same at one part of its path as at another. Again, it can be shown that it is essential to equilibrium that in the interior of a substance this stream of heat should be proportional to the *square of the refractive index*. That is to say, in an enclosure containing glass whose refractive index is 1·5 the stream of radiant heat in the heart of the glass will be 2·25 times greater than that proceeding through a vacuum; we cannot, however, tell what takes place in the heart of a crystal. It also appears that, for an enclosure of given temperature, the stream of a given kind of heat has a definite value, the amount of this increasing as the temperature increases.

We are, however, ignorant of the exact function of the temperature which expresses the value of this stream, but we know that this value increases more rapidly for the more refrangible rays of the spectrum than for those of greater wave-length and smaller refrangibility.

We now come to consider the luminous rays, and here the wondrous power of the eye can aid us to an extent far surpassing that of the most delicate pile and galvanometer for the dark rays.

Wollaston and Fraunhofer were the first to show that in the solar spectrum numerous dark bands occur, which indicate the absence of certain definite kinds of light.

Sir David Brewster afterwards showed that similar bands make their appearance when the spectrum is made to pass through nitrous acid gas, and it was thus rendered probable that the bands which appear in the solar spectrum were due to absorption likewise.

Brewster, J. Herschel, Talbot, Wheatstone, and W. A. Miller were amongst the first to make observations upon the luminous spectrum obtained by heating various substances, and it was soon perceived that such spectra consist of bright lines on a dark background, and thus appear to be a reversal of the solar spectrum, which consists of dark lines on a bright background. Fraunhofer was the first to notice a coincidence in spectral position between the dark double line D occurring in the solar spectrum and the bright yellow flame produced by incandescent sodium. Swan afterwards showed that the correspondence between the two black lines and the two bright lines is very exact, and that a very small quantity of salt is sufficient to call forth the bright lines. Ångström (*Phil. Mag.*, May, 1855), referring to a conjecture of Euler that a body absorbs all the series of oscillations which it can itself assume, expresses his conviction that the same body, when heated so as to become luminous, must emit the very rays which at ordinary temperatures are absorbed, and that the explanation of the dark lines in the solar spectrum embraces that of luminous lines in the electric spectrum. Probably, however, the first to give definite expression to this conception was Prof. Stokes, who, about the year 1850, commented on an experiment recently made by Foucault. This observer had found that, when a voltaic arc formed between charcoal poles was placed in the path of a beam of solar light, the double line D is thereby rendered considerably darker. If, on the other hand, the sun and the arc jut out the one beyond the other, the line D appears darker than usual in the solar light, and stands out bright in the electric spectrum. Thus the arc, remarks Foucault, presents us with a medium which emits the rays D on its own account, and which at the same time absorbs them when they come from another quarter.

The explanation given by Stokes of this experiment assumes that the vapour of sodium must possess, by its molecular structure, a tendency to vibrate in periods corresponding to the degrees of refrangibility of the double line D.

Hence the presence of sodium in a source of light must tend to originate light of that quality. On the other hand, vapour of sodium in an atmosphere around a source must have a great tendency to absorb light from the source of the precise quality in question.

In the atmosphere around the sun, therefore, there must be present vapour of sodium, which, according to the mechanical explanation thus suggested, being particularly opaque for light of that quality, prevents such of it as is emitted from the sun from penetrating to any considerable distance through the surrounding atmosphere.

It appears, from the historical sketch here given, that two independent lines of research were progressing towards the same conclusion. The one of these had for its basis the theory of exchanges, and endeavoured theoretically and experimentally to render this theory complete. The other was founded upon spectroscopic investigation, and endeavoured to apply to light an analogy deduced from sound, believing that, just as a string or tuning-fork when *at rest takes up* that *note* it gives out when *struck*, so a molecule when *cold absorbs* that *ray* which it gives out when *hot*.

In October, 1859, Prof. Kirchhoff of Heidelberg made a communication to the Berlin Academy on the subject of Fraunhofer's lines. His observations were made on this occasion by an examination of the spectrum of coloured flames made by Bunsen and himself, and he derived from them the following conclusions:—He concluded that coloured flames in the spectrum of which bright sharp lines present themselves so weaken rays of the colour of these lines, when such rays pass through the flames, that, in place of the bright lines, dark ones appear as soon as there is brought behind the flame a source of light of sufficient intensity in the spectrum of which these lines are otherwise wanting. He concluded further that the dark lines of the solar spectrum which are not evoked by the atmosphere of the earth exist in consequence of the presence in the incandescent atmosphere of the sun of those substances which in the spectrum of a flame produce bright lines in the same place.

Carrying out this train of thought, Kirchhoff, about the end of 1859, shows that as a mathematical consequence of the theory of exchanges, a definite relation must subsist between the radiating and absorbing power of bodies for individual descriptions of light and heat.

It will be noticed in this historical statement that I made my first experiments on dark heat; afterwards I proceeded to the subject of light. Meanwhile, however, Kirchhoff had independently been led to experiment in this direction, and, although his memoir slightly preceded mine in publication, I shall now give the experiments which I was led to make, more especially as they are very similar to those of Kirchhoff. In February, 1860, I communicated to the Royal Society of London a paper in which I showed that the light radiated by coloured glasses is intense, in proportion to their depth of colour, transparent glass giving out very little light. I also showed that the radiation from red glass has a greenish tint, while that from green glass has a reddish tint. It was likewise shown that polished metal gives out less light than tarnished metal and that when a piece of black and white porcelain is heated in the fire the black parts give out much more light than the white, thereby producing a curious reversal of the pattern.

Finally, in a paper communicated in May of the same year, it was shown that tourmaline, which absorbs in excess the rays of light polarised in a plane parallel to the axis of the crystal, also radiates, when heated, this kind of light in excess, but that when it is viewed against an illuminated background of the same temperature as itself, this peculiarity disappears. All these facts are a natural consequence of a movable equilibrium of temperature holding separately for every variety of heat, the word "variety" embracing any difference either in wave-length or polarisation which is the cause of unequal absorption.

The theory of exchanges, as here exhibited, has been founded upon the fact that in an enclosure of constant temperature all bodies will ultimately attain the temperature of the walls of the enclosure. This is the experimental foundation upon which our structure has been built, and we have not attempted to work under it or to find whether in its turn it be not founded upon some principle of a still deeper and more fundamental nature. We shall now briefly indicate that such is the case, and that this law of ultimate equality of temperature is a consequence of the theory of energy in which we are told that no work can possibly be got out of heat which is all at the same temperature. For if the ultimate result in our enclosure should be a variety of temperatures, then it would be possible to utilise this temperature-difference and convert heat into work, so that there would practically result a case of perpetual motion. Now, it is one of the most fundamental axioms of physical science that such a motion is impossible.

I have endeavoured to make use of this method of viewing the problem, in order to point out what forms the natural limit to our conception of a movable heat-equilibrium. Suppose, for instance, that we have a large spherical chamber of the temperature of 100° C., and that this chamber is removed from all gravitating influence, so that a solid spherical body, also of the temperature of 100° C., may rotate on its axis in the centre of this chamber without requiring the support of an axle. The chamber may likewise be supposed to be void of air, so that there is nothing but the ether to bring the revolving body to rest. Now, if a sort of diaphragm or rim be introduced into the chamber, as in Fig. 9, the result will

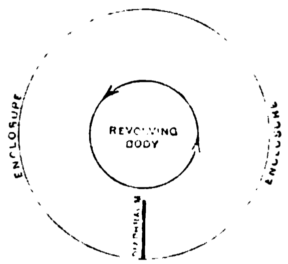

Fig. 9.

be that the particles of the enclosure to the left of the diaphragm will only receive heat from that portion of the revolving body which is approaching them, while those to the right of the diaphragm will only receive heat from those portions of the same body which are receding from them.

But the wave-length of light is altered in one way by a body which is approaching us, and in another way by a body which is receding from us, so that the particles to the left of the diaphragm will, in reality, receive a different kind of radiation from those to the right. Here, then, we have something which upsets the temperature equilibrium, and we may even conceive that the particles to the left of the diaphragm will absorb more heat, and therefore become hotter than those to the right. If so, we shall have the possibility of creating work out of this difference of temperature, or, in other words, of starting a kind of perpetual motion.

We thus begin to see that, somehow, the revolving body must lose as much energy as we gain by means of these differences of temperature, for otherwise we should have the transmutation of heat originally of the same temperature into work, which we cannot admit. But this means that a revolving body placed under these circumstances must gradually part with its energy of visible motion, although it is not in contact with anything else than the ethereal medium.

Before concluding this branch of my subject let me say a few words about phosphorescence and fluorescence.

It is well known that certain substances remain luminous—that is to say, continue to emit light for some time after they have been exposed to the light of the sun or of some other powerfully luminous body. Such substances are said to be *phosphorescent*.

It is likewise known that other substances, more especially certain liquids, emit light in a peculiar way while the luminous source acts upon them, but do not enjoy this property for an appreciable time after it has been withdrawn. Such bodies are said to be *fluorescent*.

It is manifest that the difference between phosphorescence and fluorescence is one of time, the bodies implied by the first term continuing to give out light for some time after the exciting source is withdrawn, while those implied by the second do not retain this property for an appreciable time after the withdrawal of the luminous source. Prof. Stokes, who has done much to advance this subject, has shown that the exciting cause of phosphorescence and fluorescence is more especially the rays of high refrangibility—even rays beyond the violet of the visible spectrum. On the other hand, the rays which the body gives out are generally of a lower refrangibility than the exciting rays. Hence invisible rays may, by means of a phosphorescent or fluorescent body on which they fall, render themselves visible. This phrase, however, is perhaps not strictly correct, inasmuch as, before becoming visible, they have been changed into other rays of lower refrangibility.

The object of introducing this subject here is rather, however, to discuss its bearing upon the theory of exchanges than to treat it as a separate branch of inquiry; and I may commence by remarking that at first sight it seems to contradict the general law that the quantity and quality of the light and heat given out by a body depend upon its temperature, and upon this only. Thus, a thermometer at 100° C. is supposed to radiate from the surface of its bulb heat which will be the same in quantity and quality whether the instrument has been heated by the sun's rays or by plunging it into boiling water. Now in such a body as luminous paint we have the light which we usually associate with a high temperature given out long after the sun has ceased to shine upon it, and when we know its real temperature to be that of the bodies around it. Do phosphorescent bodies form, therefore, an exception to the general law which represents the quality of the radiant heat as a function of the temperature?

I think we shall find, on examination, that in this general law it is taken for granted that no chemical change is taking place in the body in question, and no other molecular change than that implied in the cooling of the body. In a chemical action we have generally the transmutation of chemical energy into heat, and in molecular action we have generally the transmutation of molecular energy into heat likewise. That is to say, the body undergoing these changes becomes heated, and so gives out light and heat peculiar to the temperature to which it has been raised. But there seems to be no reason why molecular energy should not be somehow changed at once into radiant light and heat. In this case there would no doubt be an apparent breaking of the law above mentioned, which associates a certain temperature with a certain quantity and quality of radiant heat, but the exception would be only apparent. for, as we have stated, the law presupposes that no molecular change of this nature is taking place.

In like manner our argument regarding an enclosure of a constant temperature and the theory of exchanges in general, while it allows of the greatest possible variety of substance and form in the enclosure, virtually assumes that no chemical or molecular change is going on amongst the substances introduced. We are, in fine, supposed to be dealing with radiant energy and absorbed heat, and with no other form of energy, and indeed we have just seen that if we have a body in visible motion in the enclosure, the equilibrium no longer holds.

Thus we get rid of the difficulty by rejecting the bodies in question as not fulfilling strictly our requirements. No doubt the phenomena of phosphorescence and fluorescence are comparatively trivial exceptions, but we may imagine an enclosure in which all the substances are at the temperature of 100°, while some one substance is gradually changing its molecular state, until at length we have a violent explosion accompanied with light and heat. Here the result is so obvious that we have no hesitation in recognising such a body as an exception not contemplated by the theory of exchanges. We are persuaded that phosphorescent bodies are equally an exception, the only difference being that the character of this exception is not nearly so pronounced.

It has been pointed out by Prof. Tait that the conclusions of the theory of exchanges are only statistically true. That is to say, if we take a sensible time, such as a second, and a sensible quantity of any substance, such as a milligramme, then in an enclosure of constant temperature the absorption of that matter during one second is equal to its radiation during the same time, and this holds for all kinds of heat. On the other hand, if we take a single molecule and a billionth of a second, we cannot affirm the same equality. This is no doubt correct; in fact, if the equality between radiation and absorption were to hold for the smallest conceivable mass and the smallest conceivable increment of time, our equilibrium would in reality be a tensional one instead of being movable or dynamical. I shall conclude by repeating the words of Tait ("Heat," p. 253):—"It is vain, at least in the present state of science, to look for a truly *rigorous* investigation of the relation between radiating, absorbing, and reflecting powers. In all the professedly rigorous investigations which have been given the careful reader will detect one or more steps which are to be justified only by the statistical process of averages."

BALFOUR STEWART

(*To be continued.*)

THE LIFE OF AQUATIC ANIMALS AT HIGH PRESSURE[1]

THE magnificent expeditions of the *Talisman* and the *Travailleur* have called the attention of naturalists and physicists to the conditions of life at the bottom of the sea. A learned physiologist, Dr. Regnard, has conceived the happy idea of studying experimentally these condition of life at high pressure. With apparatus designed by M. Cailletet, he has subjected aquatic animals to enormous pressure, such as prevails in the depths of the ocean, and has examined the results when those inhabiting the surface are suddenly placed at great depths. Since his first experiments Dr. Regnard has invented an ingenious method by which he can see, notwithstanding the great pressure, what goes on inside the apparatus.

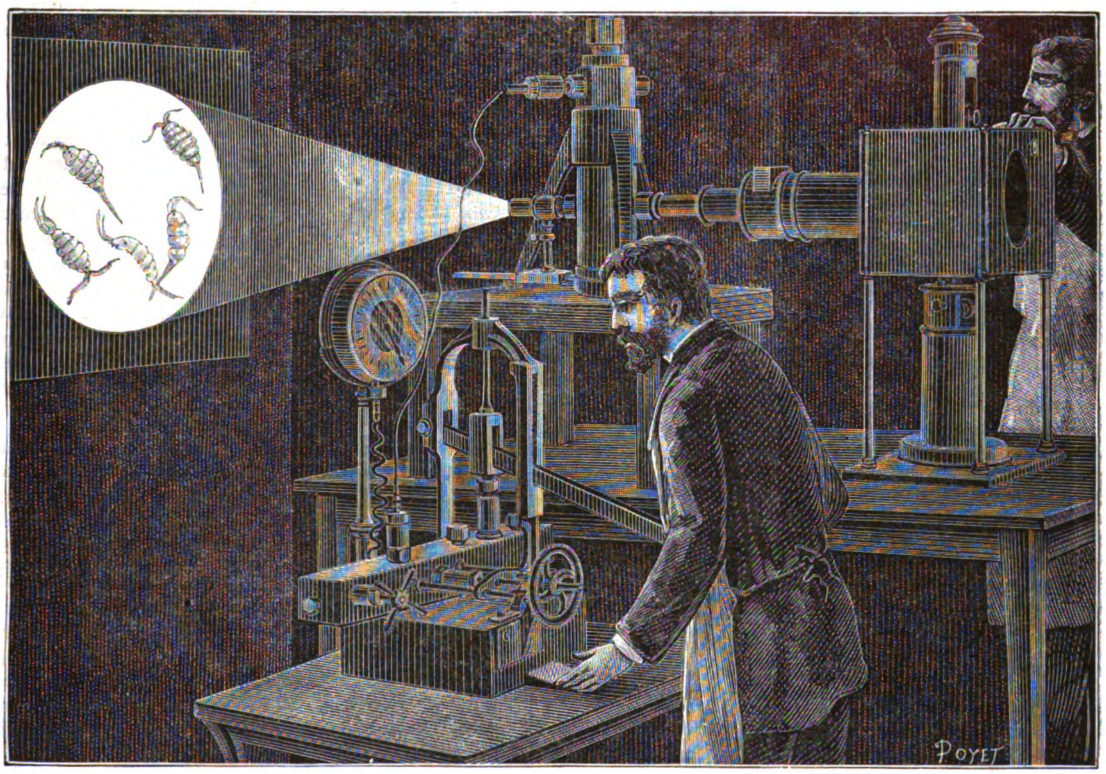

FIG 1.—General View of Dr. Regnard's Apparatus.

Hitherto the operator simply placed the animals on which he experimented in the iron block of the Cailletet pump, and subjected them to the pressure corresponding to a given depth; he then released them, sometimes very slowly (after several days), sometimes rapidly and even instantly. He examined then, physiologically and microscopically, the lesions produced. But all the intermediate stages between the entrance of the animals and the time they were taken out escaped the observer. But now the apparatus in Fig. 1 allows him to follow each minute the effects. The following is Dr. Regnard's description of his apparatus to the Academy of Sciences:—

Two holes are pierced through and through across the lower part of the Cailletet block, M (Fig. 2). In these two holes, placed in a straight line, are inserted two tubes in *r* and *r'*. These are hollow, and in each of them is solidly fixed a cone of quartz, B, the extremity of which joins the edges of the hole which is pierced in the screw nut E. A ray of light thrown by the orifice *r* will thus traverse the apparatus and emerge at *r'*. Experiments have shown that a similar apparatus will resist easily a pressure of 650 atmospheres, which represents that of the greatest depths that have been dredged—about 6500 metres. Across one of the quartz cones are sent the concentrated rays of an electric lamp. These rays cross the block full of water, and emerge on the opposite side, where they are received by an achromatic object-glass which projects them on to a screen. The observer therefore works at a distance from the apparatus, where he is sheltered from all danger (Fig. 1). This arrangement has another advantage. The orifice pierced at *r* is hardly half a centimetre in diameter, and one can experiment with animalculæ so small as to be scarcely perceptible

[1] From *La Nature*

with the naked eye in the vessel immersed in the block M. By projecting them with a lens they are increased about 200 times, and it is even possible to see by transparence the state of their organs." In the experiment represented in Fig. 1, one of the operators is occupied in regulating the electric lamp and in setting the microscope of projection, while the other commences to apply the pressure. The animalculæ projected on the screen are the *Cyclops*, small crustaceans which are met with at this time of the year in brooks, and which are scarcely a millimetre in length. These are so enlarged, and appear with such transparency, that we can follow on the screen the movements of their branchia, and even of their heart, during the experiment. Dr. Regnard is pursuing at present his

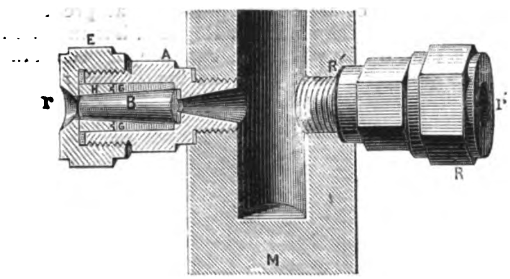

FIG. 2.—Details of apparatus in Fig. 1.

studies into life under high pressures. He showed last year that the unequal compressibility of the liquids and solids which form the organism caused the latter after a long pressure, to be soaked with water, become turgid, and consequently lose their functions. But, with the apparatus here described, he has been able to follow the phenomena which precede this. From the pressure at 1000 metres (about 200 atmospheres) the object shows inquietude, at 2000 metres it falls to the bottom of the vessel struggling; towards 4000 it remains inert and benumbed. When its normal pressure returns it recommences moving, unless the pressure has been long and its tissues are not soaked. This seems to show that the effect is a compression of the nervous system.

NOTES

WE understand that Mr. Francis Galton has already obtained valuable results from the Family Records sent him last year in response to his offer of prizes, and that he purposes to make much use of them in his Presidential address to the Anthropological Section of the British Association at Aberdeen.

WE have already intimated that Prof. Bonney has decided to retire from the Secretaryship of the Association after the Aberdeen meeting. We understand that Mr. A. T. Atchison will be proposed as his successor.

MANY interesting excursions have been arranged by the Local Committee of the Aberdeen meeting of the Association. One of them will, of course, be to the great granite quarries in the neighbourhood of Aberdeen. Her Majesty has invited 150 of the members to Balmoral, where they will be shown over the grounds and have lunch. It is not to be expected that the Queen will personally receive all the members, though it is possible that a few representative men of science may be presented to Her Majesty. Other excursions will be to Haddo House, Dunecht, Dunnottar, Drum and Crathes, Loch Kinerd, on the Saturday; while on the Wednesday and Thursday of the second week parties will be taken to Braemar, Invercauld, Haddo House, Huntly Castle, Elgin, Banff, Portsoy, and other places. The efforts which the Local Committee are making to render the meeting a success are all that could be desired. It is only to be hoped that they may succeed in persuading the Aberdeen hotel and lodging-house keepers to reduce their exorbitant charges. The arrangements for important discussions in Sections A and B we have already referred to.

IN connection with the meeting we venture to recommend to our readers the new edition of Baddeley's "Guide to Scotland," Part 1, a copy of which has been sent us. It includes all the country from the Borders to as far north as Aberdeen, Inverness, Gairloch, and Stornoway. No more useful, practical, and trustworthy guide to the region exists, while the thirty-seven admirably executed maps and plans will be found a great comfort and convenience. Dulau and Co. are the publishers.

M. JANSSEN will shortly begin a new series of experiments on the influence of gases in spectrum analysis, in continuation of those which he made about fifteen years ago at La Villette gasworks. The tubes in which the gas will be contained and compressed will have a length of more than 100 metres, and be able to bear an unusual amount of pressure. Thus a new degree of accuracy may be expected from these researches, which are progressing favourably at the Meudon Physical Observatory.

FOR more than a year some important measurements of the altitude and movements of clouds have been carried on at Upsala by the aid of two theodolites, one of which is mounted in the Linnæus and the other in the Botanical Gardens. These instruments, which belong to the Academy of Science, were used for auroral and cloud measurements by the Swedish expedition to Spitzbergen, 1882–83. The object of the measurements of the altitude and movements of clouds is not so much to obtain their mean altitude as to derive some knowledge of their movements in the upper part of the atmosphere, a matter which is of great importance to meteorology. The researches have advanced so far that it has been found possible to fix astronomically the movements and altitude of the cirrus clouds.

ACCORDING to the *Tägliche Rundschau* the population of Ratisbon has been greatly frightened by the sudden disappearance recently of thousands of jackdaws, which dwelt in the spire of the cathedral of the town, on account of a similar phenomenon occurring before the outbreak of the last cholera epidemic in the place. In Munich a similar phenomenon is also stated to have taken place.

REFERRING to "sonorous sand," the report of the secretary of the Smithsonian Institution says that an interesting problem to physicists and geologists has been the sand found in certain localities, which, when placed in motion by sliding, sometimes produces a very sonorous or resonant sound, peculiar in character and difficult of explanation. Prof. Bolton, of Trinity College, Hartford, desirous of making researches on the subject, and especially of studying the microscopical, chemical, and physical peculiarities of the grains, requested the aid of the Institution in obtaining materials for the purpose. A considerable variety of specimens was collected in the Sandwich Islands, the coast of Oregon, Germany, and many other places. These are now in Prof. Bolton's hands, and he will prepare a report on the subject.

THE Chesapeake Zoological Laboratory, as the marine station maintained by the Johns Hopkins University is designated, is *Science* states, established for the present summer session at Beaufort, on the coast of North Carolina. Dr. W. K. Brooks, the director, who was prevented last year by ill-health from giving as much time as usual to the laboratory, is fortunately quite restored to his usual strength, and is in full activity at his post. Twelve collaborators are with him. Several of these are already teachers in various branches of zoological science, and all of them are well prepared to make use of the opportunities which are afforded at this station. An unusual number are engaged in original researches. The season of 1885, although uncomfortably hot, has thus far been exceptionally favourable for collection. The weather has been calmer than heretofore in June and July, and specimens were found in June which have usually not appeared until the middle of August. The company, notwithstanding their personal discomfort from the heat, have maintained their full enthusiasm in the work upon which they are engaged; and it now appears as if the eighth session of the laboratory would be more fruitful in results than its predecessors, good as they have been.

A DUNFERMLINE correspondent writes to us that one of the most important and certainly the most complete cemetery of the Stone Age which has been laid bare in recent times has just been discovered in the grounds of Pitreavie, Dunfermline, Fifeshire. In connection with rebuilding operations a sand-pit was opened, and here, in a space of 15 yards by 10 yards, no fewer than five cists have been discovered. The cists were constructed of rough sandstone flags, and four of these measured about 42 inches in length, 20 inches in breadth, and 16 inches in depth. The fifth was little more than 18 inches square. A cinerary urn of baked clay was found in each of the large cists, but in the small "grove" nothing was found but a quantity of apparently calcined bones. A couple of flint scrapers and a bottle-shaped piece of limestone—which may have done duty as a hammer—were also among the finds. The urns measure from 5 to 6 inches across the mouth and from 4½ to 6 inches in height, and, strange to say, the construction of the bowls indicate that they have been made at different successive periods. No. 1 urn is an unshapely piece of sun-dried pottery; No. 2 showed an advance in the shape; and Nos. 3 and 4 are neatly formed and ornamented with a simple dotted pattern. The explorations will be continued, and it is expected that several other important finds will be made. Dr. Munro, the author of "Ancient Scottish Lake Dwellings," has visited the tumuli with a view to place a report in the hands of the Antiquarian Society of Scotland. A tradition exists that the site of the mound was an old graveyard, and some people who have been engaged in the district in agricultural pursuits for the past half a century state that numerous flagstones and pieces of urns have been turned up by the plough or grubbed, and Dr. Munro attaches great importance to the flint scrapers, and was of opinion that the bones found in the small cist were human bones.

AT the recent Railway Congress at Brussels the question whether it would be economical and desirable to use iron or steel instead of wooden sleepers was fully discussed. It was stated that metal sleepers of various patterns are being used in Holland and India to a considerable extent, and that they are being tried experimentally in Belgium, England, and other countries. An opinion was expressed that sleepers of the description which is being tried in England would afford good material support for the rails on main lines, although some inconvenience might be felt from a quoin of wood being used with it. It was also considered that other metal sleepers which are being tried in Holland and elsewhere had given satisfactory results. The cost of metal sleepers is higher than that of wood. They require good ballast, and there had not been sufficient experience from their use, in regard to their duration and maintenance, to enable the section to state specifically the relative advantages of the new description of sleepers. It was therefore considered that further experience is necessary. The difficulty of arriving at a conclusion as to what would be applicable in all countries and under all circumstances was exemplified in the discussion of this subject by the representative of the Egyptian railways. He stated that iron or steel sleepers cannot be economically used in Egypt, because they become corroded by the sand. The representative of the Indian railways, on the other hand, informed the section that iron or steel sleepers only can be used in India, because the white ant destroys wooden sleepers. Considerable discussion took place as to the construction of railways in regard to the curves, gradients, and works generally, including the question whether lines with a comparatively small traffic should be laid with heavy or light rails. It was, however, found impossible to lay down any general propositions which could be adopted under all the circumstances in which railways have to be made.

IT may be remarked that François Arago was born at Estagel in the beginning of February, 1786, so that a centennial celebration may be expected next year. A statue was erected in this place twenty-nine years ago at the expense of the late M. Pereire.

AN exhibition of labour was opened a few weeks ago at the Palais de l'Industrie, Paris. An electrical railway with a single rail was exhibited by M. Lartigue, and is carrying passengers with regularity on a zigzag line of about 200 metres' length. A series of popular exhibitions with magic lanterns on the new features of microscopy is largely attracting public attention. So-called antediluvian music is played on a series of irregular stones which have been selected so that they represent two octaves when suspended by strings.

THE American Ornithologists' Union will hold its next meeting in New York on Tuesday, November 17.

WE have received catalogues of electrical apparatus from two new firms: the first of these is the Kinetic Engineering Company, who are agents in this country for the well-known firm of Breguet. They are now exhibiting Lippmann's ingenious mercurial galvanometer. The second catalogue is that of Messrs. P. Jolin and Co., of Bristol. This enterprising firm describes several instruments of great use in the physical laboratory, especially the dead-beat galvanometer of D'Arsonval's type, and adjuncts therefore. This instrument appears to be specially adapted for private laboratories. We are glad to see new firms taking such good standing in the character of the apparatus they offer to the scientific world.

THE Java newspapers report that volcanic activity in the island continues to increase. Another mountain, called Raun, broke out on June 21, casting out much steam and ashes. In the evening smoke was ejected in such quantities as to darken the horizon on the windward side, until a shower of ashes fell, upon which the sky cleared up. Raun appears to be an active volcano, but no such violent eruption has been known in recent years. On the night of July 8 a new eruption of Mount Smeru took place; it was a heavy explosion followed by a stream of red-hot lava, which came down to the same spot which was laid waste by the former eruption. In the evening of July 9 another explosion followed.

"RESULTS of Twenty Years' Observations on Botany, Entomology, Ornithology, and Meteorology, taken at Marlborough College, 1865-84," is the title of a large pamphlet embracing a summary of twenty years' work. The tables are accumulations of facts properly registered. In the botanical notices the first appearances in each year are given, the day being noted as the day of the *year*, not of the month. This method is readiest for comparison and for striking the average. In addition the average for the twenty years, the earliest and latest days, the amplitude and the number of observations are given. The entomological notices are arranged in the same way, except that the earliest and latest appearances and the amplitude are omitted; these are not a great loss, for they can be ascertained from the tables in a moment by any reader. In ornithology the observations include the date when first seen, and when an egg and the young have been found. The meteorological notices include for each month of each year the highest, lowest, and mean readings of the barometer, the maximum and minimum temperature in the shade, the number of times the thermometer stood above certain points varying with the seasons of the year, the maximum in the sun, the minimum on the grass, amount of rain collected, and the number of rainy days. The wettest year of the twenty was 1882, when the rainfall was 43·79 inches; the dryest, 1870, with 23·41 inches. The weather records in these tables have been kept by one observer, with properly verified instruments, and all the observations have been critically examined at the Royal Meteorological Society; the botanical notices, though obtained by a large staff of observers, have all been recorded by one person, who saw all the specimens; but entomological and ornithological notes were taken by a series of recorders, and there is therefore not the same uniformity as in the two previous cases.

WE have received the annual report of the West Kent Natural History, Microscopical, and Photographic Society for the past year. It contains abstracts of several papers read during the year. It is a pity there is no abstract of the discussion introduced by the president at the annual dinner at Gravesend, on "Bacon and Beans." There are two papers on subjects connected with photography.

MR. W. F. STANLEY has recently brought out a new form of protractor and goniometer, which has the special merit of measuring an angle right up to the vertex. This new form of protractor will be very convenient to civil engineers in measuring angles upon ordnance maps which are most frequently subtended by short lines, and many other cases. Used as a goniometer, it will be very convenient to measure the angles of large crystals and planes of cleavage, also to draw the same direct from the instrument. The instrument consists of two concentric circles, the outer one carrying the graduation, the inner a Vernier; each supports an arm with an edge extending to the centre. The angles are measured by slipping the inner circle with its attached arm and Vernier round the groove on the outer circle, which keeps it in position. We believe the instrument has all the good points which Mr. Stanley claims for it, and it will be useful to artists as well in determining angles of perspective.

THE whitefish (*Coregonus albus*) now in the ponds at the Delaford Fishery are growing rapidly, some of them reaching seven inches in length. It will be remembered that the ova of these fish were brought from America last spring, and hatched out at South Kensington.

A REMNANT of the great forests which once covered the south of Sweden was recently dug out of a bog at Kiuneved, consisting of a boat 6 feet in diameter hollowed out of a log. The tree from which it was obtained must have been 20 feet in circumference. The wood, which was blue in colour, was very hard, and the boat so heavy that two bullocks could not move it.

MR. HENRY PHILLIPS, jun., one of the secretaries to the American Philosophical Society, has performed a very useful work in compiling a register of all the papers published in the *Transactions* and *Proceedings* of the Society since its commencement. The "register" forms a small pamphlet of fifty-six pages, the titles being arranged according to the authors' names. It is therefore an index to all the publications of the Society—but a name, not a subject, index.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus* ♂) from India, presented by Mr. E. Pelditch; a Bosmani Potto (*Perodicticus potto* ♂) from West Africa, presented by Mr. C. R. Williams; two Gerbilles (*Gerbillus* ——) from Suakim, presented by Surgeon-Major J. A. Shaw; two White-faced Tree Ducks (*Dendrocygna viduata*) from West Africa, presented by Mr. Cecil Dudley; three Green Turtles (*Chelone viridis*) from the West Indies, presented by M. C. Angel, F.Z.S.; a Bonnet Monkey (*Macacus sinicus* ♀) from India, presented by Mr. J. C. O'Halloran; two Narrow-barred Finches (*Munia nisoria*) from Java, an Indian Silver Bill (*Munia malabarica*) from India, an Amaduvade Finch (*Estrelda amandava*) from India, presented by Mr. Horace Sanders; a Short-toed Eagle (*Circaetus gallicus*) from Southern Europe, presented by Mr. Henry Sotheran; a Mona Monkey (*Cercopithecus mona* ♂) from West Africa, presented by Mr. White; a White-necked Crow (*Corvus scapulatus*) from West Africa, deposited; nine Gold Pheasants (*Thaumalea picta*), received from the Right Hon. George Sclater-Booth, M.P.; a Barred-shouldered Dove (*Geopelia humeralis*), a Coquerel's Lemur (*Chirogaleus coquereli*), a Collared Fruit Bat (*Cynonycteris collaris*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN

THE BINARY-STAR 70 OPHIUCHI.—Notwithstanding the care with which the orbit of this double-star has been discussed, the companion appears to be again deviating from its predicted position to a considerable extent. It will be remembered that from the anomalous motion of the smaller star Madler was led to the suspicion that the law of gravitation does not apply in this system, while Jacob thought there was indication of disturbance from a third body.

M. Perrotin gives the following epoch resulting from his measures made at Nice in 1883:

1883·49 ... Position 45°·6 ... Distance 2″·28

On comparing with the orbit assigned in No. 1 of "Astronomical Observations made at the University Observatory, Oxford," which accords closely with the measures up to 1878, and with the orbits Flammarion, Tisserand, and Schur, we find the following differences taken in the order, observation—calculation:—

	Position.	Distance.
The Oxford orbit	− 9°·9 ...	−0″·60
Flammarion	−12·8 ...	−0·18
Tisserand	−13·5 ...	−0·57
Schur	−17·4 ...	−0·73

It is very possible that in this case the difficulty of representing the position of the companion-star may be attributed to the paucity of measures near the peri-astron, rather than to an anomalous motion which has not been remarked in most of the other binaries. However this may be, the object no doubt is one deserving of continued attention. The Oxford orbit, which, it will be seen, is the nearest as regards the position angle in 1883, gives for 1885·5—position, 44°·6; distance, 2″·64.

TUTTLE'S COMET.—On September 10, at midnight, this comet will be in about R.A. 136° 33′, Decl. +3° 48′, rising at Greenwich two hours before the sun, and with an intensity of light one-third greater than when first observed at Nice on August 8. It may perhaps be observed after perihelion in the southern hemisphere if the more powerful telescopes are utilised. On August 13 the correction to Herr Raht's ephemeris was −13s. in right ascension and +5′·5 in declination. The comet is about 2′ in diameter, without very apparent central condensation.

THE COMET OF 1652.—At present we have only one calculation of the orbit of this comet—that of Halley, founded upon the observations of Hevelius in the scarce volume of the "Machina Cœlestis." It would be interesting to investigate the orbit anew from the observations made by Richard White at Rome, though he gives no nearer time for his distances of the comet from stars between December 21, 1652, and January 3, 1652, than "hora 2 post occasum solis." The observations will be found in *Zeitschrift für Astronomie*, vol. iv., where they are entitled "Observationes Cometæ, qui exeunte anno 1652 comparuit, habitæ Romæ per Riccardum Albium, Anglum." Zach supposed the observer to be Richard White, and there can be little doubt that he is the Mr. White repeatedly mentioned by Evelyn in his Diary. Zach has the remark, "Diese Beobachtungen können leicht besser als die des Hevelius seyn," and an examination of the latter will show that there is some foundation for this remark. On December 21, according to Halley's elements, the distance of the comet from the earth was only 0·14; on January 3 it had increased to 0·42.

The fact that the place of the ascending node of the comet of 1698, as it is printed in Halley's "Synopsis of Cometary Astronomy," is 180° in error, or, in other words, the place of the descending node has been given for that of the opposite one, furnishes a hint that it is not safe to accept a single calculation of the orbit of any of the earlier-computed comets without examination.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, *AUGUST* 30 *TO SEPTEMBER* 5

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on August 30

Sun rises, 5h. 11m.; souths, 12h. 0m. 23·0s.; sets, 18h. 49m.; decl. on meridian, 8° 52′ N.: Sidereal Time at Sunset, 17h. 26m.

Moon (at Last Quarter on Sept. 2) rises, 20h. 28m.*; souths, 3h. 15m.; sets, 10h. 12m.; decl. on meridian, 8° 11′ N.

Planet	Rises	Souths	Sets	Decl. on meridian
	h. m.	h. m.	h. m.	° ′
Mercury ...	6 1 ...	12 17 ...	18 33 ...	2 28 N.
Venus ...	8 7 ...	13 57 ...	19 47 ...	2 47 S.
Mars ...	0 36 ...	8 48 ...	17 0 ...	22 50 N.
Jupiter ...	5 48 ...	12 28 ...	19 8 ...	7 6 N.
Saturn ...	23 43* ...	7 52 ...	16 1 ...	22 25 N.

* Indicates that the rising is that of the preceding day.

Occultations of Stars by the Moon

† Occurs on the following day.

The Occultations of Stars are such as are visible at Greenwich.

Sept.	h.	
2 ...	18 ...	Mercury in inferior conjunction with the Sun.
4 ...	3 ...	Saturn in conjunction with and 4° 17′ north of the Moon.
5 ...	7 ...	Mars in conjunction with and 5° 33′ north of the Moon.

GEOGRAPHICAL NOTES

Sad news has been received from the Dutch African Expedition; its leader, Mr. D. D. Veth, died from disease on May 19, in the camp on the banks of the Kala-Kanga River, between Benguella and Humpata. This is a real loss for science as well as to his venerable father, Prof. P. J. Veth, who has given his whole industrious life to scientific work.

The Austrian Government, with the consent of the Porte, has undertaken to make a geographical survey of the Albanian coast, with a view to preparing new maps. Two Austrian gunboats have accordingly left for Corfu with officials of the Chart Department on board. Here they will be joined by the Turkish officers, under whose superintendence the survey will be made.

It is stated in the latest *Ergänzungsheft* to *Petermann's Mittheilungen*, that there are in Peking four institutions at which astronomical and meteorological observations have been made for a number of years: (1) the Chinese Observatory, called *Kuan sang tai*, which has existed for about six centuries. In 1674 the Jesuits provided it with new astronomical instruments, without lenses, which are well preserved to this day. It is situated on the eastern wall of the Manchu town. (2) Bethang, or the Northern Church, the *Collegium Gallorum*, near the Imperial palace. Here in the middle of the eighteenth century the Jesuits erected an observatory, and made many astronomical observations, amongst them the transit of Venus of June 3, 1769. Besides these Père Amiot made meteorological observations for six years, from 1757 to 1762. (3) The Russian Legation, near the southern wall of the Manchu town. The astronomer Fuss, who made a great journey between 1830 and 1832 from St. Petersburg to Eastern Siberia, and by Kiachta to Peking, at the orders of the Academy of Sciences of St. Petersburg, spent seven months here, and organised astronomical, geographical, magnetic, and meteorological observations. (4) Beguan, about 300 metres from the north-eastern corner of the wall surrounding the Manchu city. Here the members of the Russian missionary body, and the native Christians under their direction, carried out a series of magnetic and meteorological observations between 1841 and 1860. In 1864 this Observatory was separated from the missionary establishment, and in 1867 the St. Petersburg Academy of Sciences selected Dr. H. Fritsche for its director, a position which he held for sixteen years. For twelve of these he lived in Peking, while the other four were spent for the most part in journeying through the Chinese Empire and Siberia, in order to inspect the meteorological stations and the three magnetic observatories at Ekaterinburg, Barnaul, and Nerchinsk, to establish new stations, and specially to obtain astronomical, geographical, and hypsometric observations in as large a number of places as possible. His investigations into the meteorology of Eastern Asia were published by the Academy in 1877, and he now publishes in the *Ergänzungsheft* above alluded to the results of his sixteen years' observations in other departments. He describes his numerous journeys in China, Mongolia, and Manchuria, and gives a mass of data with regard to the latitude and longitude of places, and their heights above the sea-level. There are also, in the second part of the paper, a large number of measurements connected with earth magnetism. The title of the paper, which is a long one, and represents a vast amount of travel and labour, is "Ein Beitrag zur Geographie und Lehre vom Erdmagnetismus Asiens und Europas," von Dr. H. Fritsche, *Petermann's Mittheilungen Ergänzungsheft*, No. 78.

In the current number of *Petermann's Mittheilungen* the principal article is an account, historical and geographical, of "a lava desert in the interior of Iceland," and the largest lava area in Europe. The "desert" in question is situated in that part of the plateau in the interior which lies between the Vatnajökull and the rivers Skjálfandafljót and Jökulsá. It is known to the inhabitants of the neighbouring coasts as Odádahraun. The author, Th. Thoroddsen, describes his journey from Myvátn in detail.—Prof. Nell explains Fischer's perspective projection for maps, and gives a map of Asia on this system; while Herr Flegel describes his journey in 1879 with the Henry Venn expedition up the Pico Grande from the Cameroons.

The *Zeitschrift* of the Gesellschaft für Erdkunde at Berlin (Band 20, Heft 3) is almost wholly occupied with an account by Herr Schmidt of the travels of the friar Rubruk between 1253 and 1255 into the heart of Central Asia, and to the borders of China. This remarkable journey is described and explained with much painstaking learning. The only other contribution to the number is a table of lengths of the principal Russian rivers from General Tillo's survey.

From the latest reports the Australian New Guinea expedition appears to have progressed satisfactorily so far. The Government of Queensland had offered to hold frequent communication with the party by means of the steamer *Advance*, with a view of obtaining information of the progress of the work of exploration. A branch of the Geographical Society of Australasia is to be formed at Brisbane.

A Parliamentary blue-book (Corea, No. 3, 1885) lately published contains the report of a journey made by Mr. Carles, the Vice-Consul at Seoul, from that place to Phyöng Kang, where some gold mines exist. These lie to the west of the main road between Seoul and Gensan, and were stated to be of greater extent than any existing in Corea. They are in the Phyöng Kang district, in the neighbourhood of the town of Pai-namou-tjang, about 100 miles from the capital. Part of the road lay across a vast lava-field, which appears to exceed in extent even the largest in Iceland. Between Chhöl-wön and Pai-namou-tjang, a distance of 40 miles, there is only one break in its bed, which Mr. Carles attributes to the action of the stream which flows near Phyöng Kang; the uniform depth of the lava is about 100 to 140 feet, and it has a continuous and gradual ascent towards the north. Local statements as to its extent beyond Pai-namou-tjang were vague, but the plain could be seen stretching 13 miles farther up the divide of the eastern and western watersheds. Twenty miles north of this divide Mr. Carles left a similar plane last year, stretching from Anbyön to Kosan, but nearly 1000 feet below the level of the present plain. There are thus three great oval fields of lava passing almost in a straight line through the mountain chain which runs from the north to the south of Corea at a height of about 1500 feet above the sea near the divide, and of 500 feet in the lower levels. There is also another plain about 4 miles wide and 12 miles long to the east in Keum-sŏng district, the direction of which is not so well defined, but in which the depth of lava is apparently even greater than that in the others. No crater is visible in any direction to account for the enormous mass of lava; no hot springs were heard of within 30 miles, and sulphur is said to be imported from China, so that the gigantic overflow would appear to have taken place in the valley, and to have completely buried the volcano from which it came, if such were its source. At the first gold-washing visited about 270 men were said to be employed. Trenches were being dug in a bed of shingle by the river-side, and being driven parallel with the course of the stream. The men worked in parties of six, with one washer, who managed his wooden bowl very cleverly. Only small particles of gold are found, but the results seemed uniform and far superior to those of any other place visited by Mr. Carles in Corea. At two different washings which he witnessed, and which were said to give about the average yield, three basins of good earth, representing less than an hour's labour of six men, produced about fifteen pieces of gold—small indeed, but clearly visible at three yards' distance. Farther up the valley, where the men were working in smaller gangs, the yield was about the same in proportion to the number of men. On the western slope are other workings, where some 300 men are engaged, but these do not appear to be so productive. It appears that this valley has never before been worked for gold; in other places it has been sought for ages, and always found after the summer floods had brought down fresh detritus; but here the shingle seemed never to have been disturbed, or, rather, arranged in walls, before. The country here also seemed more promising than elsewhere, and to be worth the visit of an experienced miner.

For many years it was believed that the highest mountain in Sweden was Sulitjelma, on the frontier between Sweden and Norway, the height of which is about 6000 feet. A couple of years ago it was, however, discovered that the mountain of Sarjektjåkko, in Swedish Lappland, was a thousand feet higher. Lately, Dr. Svenonius, well known for his explorations of this provinee, has declared that neither of these mountains is the highest in Sweden, the honour belonging to Kebnekaisse, another peak in the same province, which the topographical surveyor of the province of Norrland has measured and found to be 7192 feet in height.

According to recent advices from the Faroe Islands, a well-known landmark has disappeared there, viz. the rock called "the Monk," situated about five miles south of Sumbö. Its height was nearly 100 feet. On the top of it lay some large boulders, which could be seen distinctly. Already last year part of the top fell down, but the body remained until last winter or this spring, when its disappearance was discovered.

MINERAL PRODUCTS OF THE UNITED STATES

The second Report on "The Mineral Resources of the United States," by Albert Williams, jun., Chief of the Division of Mining Statistics and Technology, United States Geological Survey, is now in press and will be issued shortly. This Report is for the calendar years 1883 and 1884, and contains detailed statistics for these periods and also for preceding years, together with much descriptive and technical matter. The following are the totals of the production of the more important mineral substances in 1884:—

Coal.—The only statistics in which the trade is interested are those relating to the amount of coal which is mined for and reaches the market. There is, besides, a local and colliery consumption which is usually disregarded in statistics, and which ranges from 5 to 6½ per cent. of the total shipments. Of what may be called the commercial product the quantities in 1884 were as follows:—Pennsylvania anthracite, 30,718,293 long tons; bituminous and brown coal, lignite, and small lots of anthracite mined elsewhere than in Pennsylvania, 66,875,772 long tons; total, 97,594,065 long tons. The spot value of the commercial product was: Pennsylvania anthracite, $61,436,586; bituminous and all other coals, $70,219,561; total, $131,656,147. Including the local consumption, &c., the total product in 1884 may be stated at 106,906,295 long tons—namely, 33,175,756 long tons of Pennsylvania anthracite and 73,730,539 long tons of bituminous and all other coals; and the value at the mines was: Pennsylvania anthracite, $66,351,512; bituminous and all other coals, $77,417,066; total, $143,768,578. The total production (that is, including colliery and local consumption) of anthracite was 1,160,713 long tons less than in 1883, while its value was $10,905,543 less, the disproportionate decline in value being due to a fall of 25 cents. per ton in spot price ($2·25 to $2). The total bituminous coal production increased 5,199,039 long tons over that of 1883, but its value was $4,820,734 less, the average valuation at the collieries having fallen from $1·20 to $1·05. The total output of all coals showed a net gain in tonnage of 4,038,326 long tons, and a decline in value of $15,726,277.

Coke.—There were 4,873,805 short tons of coke made in 1884, worth $7,242,878 at the ovens. This production consumed 7,951,974 short tons of coal. The amount of coke made was 590,916 tons less than in 1883, and the value was $878,729 less.

Petroleum.—The production of crude petroleum in 1884 was 24,089,758 barrels of 42 gallons each, of which the Pennsylvania and New York oil-fields produced 23,622,758 barrels. The total value, at an average spot price of 85 cents, was $20,476,294. As compared with 1883 the production was 689,529 barrels greater; but the total value was $5,263,958 less, the average sp t price having fallen from $1·10, or 25 cents per barrel.

Natural Gas.—The estimated value of the natural gas used in the United States in 1884 was $1,460,000, as against $475,000 in 1883. The value is computed from that of the coal superseded by natural gas.

Iron.—The principal statistics for 1884 are as follows:—Iron ore mined, 8,200,000 long tons; value at mine, $22,550,000. Domestic iron ore consumed, 7,718,129 long tons; value at mine, $21,224,854. Imported iron ore consumed, 487,820 long tons; total iron ore consumed, 8,125,949 long tons. Pig iron made, 4,097,868 long tons—a decrease of 497,642 tons as compared with 1883; value at furnace, $73,761,624, or $18,148,576 less than in 1883. Total spot value of all iron and steel in the first stage of manufacture, excluding all duplications, $107,000,000, a decline of $35,000,000 from 1883. Fuel consumed in all iron and steel works, including blast furnaces, 1,973,305 long tons of anthracite, 4,226,986 long tons of bituminous coal, 3,833,170 long tons of coke, and 52,110,660 bushels of charcoal, besides a notable quantity of natural gas. Limestone used as flux, 3,401,930 long tons; value at quarry, $1,700,965.

Gold and Silver.—The mint authorities estimate the production in 1884 at $30,800,000 gold and $48,800,000 silver (coining rate); total, $79,600,000. This was an increase of $800,000 gold and $2,600,000 silver as compared with 1883. The gold production was equivalent to 1,489,949 troy ounces, and the silver to 37,744,605 troy ounces.

Copper.—The production in 1884, including 2,858,754 pounds made from imported pyrites, was 145,221,934 pounds, worth $17,789,687, at an average price of 12¼ cents per pound in New York City. The amount was 28,070,139 pounds greater than the production of 1883; but the value was $275,120 less than that for 1883, owing to the decline in price. In 1884 4,224,000 pounds of bluestone (sulphate of copper, "blue vitriol") were made; worth, at 4·3 cents per pound, $181,632.

Lead.—Production, 139,897 short tons. Total value, at an average price of $75·32 per ton on the Atlantic sea-board, $10,537,042. The production was 4060 tons less than that of 1883, while the decrease in value was $1,785,677. The production of white lead (carbonate) is estimated at about 65,000 short tons, worth, at 4⅞ cents per pound, $6,337,500, almost all of which was made from pig lead. The production of litharge and red lead has not been ascertained.

Zinc.—Production of metallic zinc, 38,544 short tons; worth, at an average price of 4·44 cents per pound in New York City, $3,422,707. The output was 1672 tons greater than in 1883, and the value increased $111,601. Besides the spelter and sheet zinc, about 13,000 short tons of zinc white (oxide) were made directly from the ore, the total value of which, at 3½ cents per pound, was $910,000.

Quicksilver.—Production, 31,913 flasks (of 76½ pounds net = 2,441,344 pounds), or 14,812 flasks less than in 1883. Total value, at an average price of $29·34 per flask at San Francisco, $936,327, a decline of $317,305 as compared with the total value of the product of the previous year. During the year 600,000 pounds of quicksilver vermilion were made, worth $288,000.

Nickel.—Production of nickel contained in copper-nickel alloy, 64,550 pounds, worth, at 75 cents per pound, $48,412; an increase of 5,750 pounds, but a decline of $4508 in total value, owing to the falling off in price.

Cobalt.—The amount of cobalt oxide made in 1884 was about 2000 pounds, as against 1096 pounds made in 1883. Its value, as $2·55 per pound was $5100. The value of cobalt ore and matte cannot be ascertained, as it is chiefly dependent on the nickel contents.

Manganese.—The output of manganese ore in 1884 was about 10,000 long tons, or 2000 tons more than in 1883. The total value, at $12 per ton at the mines, was $120,000, or about the same as in 1883, the average price having declined $3 per ton.

Chromium.—The production of chrome iron ore, all from California, was about 2000 long tons, or about two-thirds as much as in 1883. At an average value of 17·50 per ton at San Francisco, the total value was $35,000.

Tin.—A little tin ore was taken out in the course of development work in Dakota, Wyoming, Virginia, and Alabama, but the only metallic tin made was a few hundred pounds from ore of the Black Hills (Dakota) mines, made in sample tests at New York City pending the building of reduction works at the mines.

Platinum.—The amount mined in 1884 was about 150 troy ounces, worth, crude, $3 per ounce.

Aluminium.—The amount made in the United States in 1884 was 1800 troy ounces, an increase of 800 ounces over the production in 1883. At 75 cents per ounce the total value was $1350.

Building Stone.—It is estimated that the value of the building stone quarried in 1884 was $19,000,000, as against $20,000,000 in 1883, the decline being due partly to dullness of trade and partly to the increased use of other structural materials.

Brick and Tile.—The output was about the same as in 1883, but as manufacturers cut down expenses still further, meeting a lower market, the total value is estimated at $30,000,000 as against $34,000,000 in 1883.

Lime.—There were 37,000,000 barrels (of 200 pounds) made in 1884, the average value per barrel at the kilns being not over 50 cents, or $18,500,000. The production was about 5,000,000 barrels greater than in 1883, but owing to the fall in price the total value was about $700,000 less.

Cement.—About 100,000 barrels (of 400 lbs.) of artificial Portland cement were made, or 10,000 barrels more than in 1883; the total value, at $2·10 per barrel, being $210,000. The production of cement from natural cement rock was 3,900,000 barrels (of 300 lbs.), or 200,000 barrels less than in 1883; worth, at 90 per cents per barrel, $3,510,000. The total production of all kinds of cement was about 4,000,000 barrels, valued at $3,720,000.

Precious Stones.—The estimated value of American precious stones sold as specimens and souvenirs in 1884 was $54,325, and the value of the stones sold to be cut into gems was $28,650; total, $82,975. About $140,000 worth of gold quartz was saved as specimens or made into jewelry and ornaments.

Buhrstones.—The value of the buhrstones yearly made in the United States is about $300,000.

Grindstones.—Dealers estimate the value of the grindstones made in 1884 at $570,000.

Phosphates.—The production of washed phosphate rock in South Carolina during tne year ending May 31, 1884, was 431,779 long tons, worth $2,374,784, or 53,399 tons more than in the previous year, wtth an increase of $104,504 in value. The average spot price, $5·50 per ton, was 50 cents less than in the preceding year. The recent discoveries of phosphate rock in the adjoining States of North Carolina, Alabama, and Florida will probably lead to a still further increase in production. Of manufactured fertilisers, 967,000 short tons, worth $26,110,000, were made in the year ending April 30, 1884, and 1,023,500 short tons, worth $27,640,000, were made in the year ending April 30, 1885.

Marls.—In New Jersey about 875,000 tons, worth $437,500 at the pits, were dug in 1884. In addition, small quantities were produced for local use in some of the Southern States. The production is declining, owing to competition with fertilisers made from phosphate rock, &c.

Gypsum.—In the Atlantic States, from Maine to Virginia, 65,000 long tons of land plaster and 60,000 tons of stucco, total 125,000 tons, were made in 1884, of which nearly all was from Nova Scotia gypsum. The statistics for Michigan have not been reported, but the production did not vary greatly from that in 1883, in which year it was 60,082 short tons of land plaster and 159,100 barrels (of 300 lbs.) of stucco. In Ohio 4217 short tons of land plaster and 20,307 barrels of stucco were produced. There was also a small production in other parts of the country; but the total amount of domestic gypsum used is not known.

Salt.—The production in 1884 was 6,514,937 barrels of 280 pounds (equivalent to 1,824,182,360 pounds, or 32,574,685 bushels, or 912,091 short tons, according to the unit used). The total value, computed on average wholesale prices at the point of production, was $4,197,734. The apparent output was 322,706 barrels greater than in 1883, while the value was $13,308 less; but the production figures do not include a considerable stock on hand in the Onondaga district, not officially reported because not inspected.

Bromine.—The production is estimated at 281,100 pounds, all from the Ohio and West Virginia salt district; worth, at 24 cents per pound, $67,464.

Borax.—Production about 7,000,000 pounds, or 500,000 pounds more than in 1883. The total value, however, was less than that of the product of 1883, being about $490,000 at San Francisco rates, as against $585,000 in 1883.

Sulphur.—No exact statistics. The production was only 500 tons, worth about $12,000.

Pyrites.—About 35,000 long tons were mined in the United States, worth about $175,000 at the mines. Some 33,500 tons of imported pyrites were also burned, making a total consumption of 68,500 tons.

Barytes.—Full statistics not received. The production is estimated to have been about 25,000 tons; worth, at $4 per ton, unground, at the point of production, $100,000.

Mica.—The production of merchantable sheet mica, not including mica waste, was 147,410 pounds, valued at $368,525.

Feldspar.—The production was 10,900 long tons, or 3200 tons less than in 1883. Its value at the quarries was $55,112.

Asbestos.—The amount mined was about 1000 short tons, worth about $30,000.

Graphite.—Production nominal, the supply being drawn from the stock accumulated in 1883.

Asphaltum.—The annual production is about 3000 tons, having a spot value of $10,500.

Alum.—About 38,000,000 pounds were made in the United States in 1884, or 3,000,000 pounds more than in 1883. At an average spot value of 1⅞ cents per pound, the product was worth $712,500.

Copperas.—The amount made in 1884 was 15,500,000 pounds, worth, at 60 cents per hundredweight, $93,000.

Mineral Waters.—The sales of natural mineral waters in 1884 amounted to 68,720,936 gallons, valued at $1,665,490, an apparent increase of 21,431,193 gallons, and $526,007 upon the figures for 1883. While the sales are undoubtedly increasing, it is possible that the excess in the reported quantity and value of the waters sold in 1884 as compared with 1883 may be partly due to the greater fullness of the returns for 1884. Besides the waters bottled and placed on the market there is a large local consumption, not included in the foregoing figures.

Totals.—As was remarked in the former report, it is impossible to state the total mineral product in any form which shall not be open to just criticism. It is evident that the production statistics of such incongruous substances as iron ore, metallic gold and silver, the spot value of coal mined, and the market value of metallic copper after having been transported hundreds of miles, the spot value of a crude substance like unground, unrefined barytes, and the value of a finished product like brick (in which the cost of manufacture is the leading item) cannot well be taken as items in a general summary. The statistics have been compiled with a view to giving information on those points which are of most interest and utility, and are presented in the form usual in the several branches of trade statistics. The result is that the values stated for the different products are necessarily taken at different stages of production or transportation, &c. Theoretically perfect statistics of mineral products would include first of all the actual net spot value of each substance in its crudest form, as taken from the earth; and yet for practical purposes such statistics would have little interest other than the fact that the items could be combined in a grand total in which each substance should be rated on a fairly even basis. The following groupings, therefore, are presented with a full realisation of the incongruity of many of the items. The grand total might be considerably reduced by substituting the value of the iron ore mined for that of the pig iron made, by deducting the discount on silver, and by considering lime, salt, cement, borax, &c., as manufactures. It will also be remarked that the spot values of copper, lead, zinc, and chrome iron ore are much less than their respective values after transportation to market. Still the form adopted seems to be the only one which admits of a comparison of the total values of the mineral products from year to year.

Résumé of the Values of the Metallic and Non-metallic Mineral Substances produced in the United States in 1884.

Metals	$186,097,599
Mineral Substances named in the foregoing Table	220,007,021
	406,104,620
Fire-clay, kaolin, potter's clay, common brick clay, terra cotta, building sand, glass sand, limestone used as flux in lead smelting, limestone in glass making, iron ore used as flux in lead smelting, marls (other than New Jersey), gypsum, tin ore, antimony, iridosmine, mill-buhrstone, and stone for making grindstones, novaculite, corundum, lithographic stone, talc and soapstone, quartz, fluorspar, nitrate of soda, carbonate of soda, sulphate of soda, native alum, ozokerite, mineral soap, strontia, infusorial earth and tripoli, pumice-stone, sienna, umber, &c., certainly not less than	7,000,000
Grand Total	$413,104,620

The total value of the metals and minerals produced in 1884 was $39,100,008 less than in 1883, and the decline in 1883 from 1882 was $3,012,061; that is, the falling off in value began on a small scale in 1883, but was accentuated in 1884. The net decline has been due rather to a depression in price than a decrease in quantity; indeed, several important substances show a decided increase in production, notwithstanding the general dullness of trade. The over-production, taking the whole field into consideration, has been less than was generally feared.

PROF. L. SOHNCKE ON THE ORIGIN OF THUNDERSTORM ELECTRICITY [1]

In order to express more than mere surmises as to the origin of thunderstorm electricity we must, above all, be familiar with the atmospherical conditions under which thunderstorms usually occur. For this purpose we must first take into consideration two general facts in meteorology: first, the average decrease of temperature with increase of height in free air; and secondly, the nature of the upper clouds.

With regard to the first point, a considerable amount of data is available in the observations of several scientific balloonists, especially those of Mr. J. Glaisher. Glaisher has constructed a table, based upon his numerous ascents, showing the average decrease of temperature for the altitudes of 1000, 2000, 3000 feet, &c. This table shows that even in the warm summer months the temperature of the freezing-point is met with generrally at the level of between 3000 and 4000 metres (say 10,000 to 13,000 feet).

Generally speaking, the aggregate of those points of space in which the temperature of 0° C. prevails at any given moment must lie on a certain surface, which may be denoted as the "isothermal surface of zero C." It is of especial interest to ascertain whether the result yielded by Glaisher's ascents as to the height of this surface in midsummer is confirmed by other ascents. In order to obtain an opinion upon this point I have grouped together those ascents which afford a sufficient number of data, in order to deduce therefrom the height of the isothermal surface of zero. This table includes twenty-three ascents by eight different balloonists at different seasons of the year; about half the ascents were made during the summer months. The following are the conclusions drawn from this table:—

In the warmest summer months the isothermal surface of zero was found to be at an height of about 3000 to 4000 metres, but occasionally sinks even at this season to about 2000 metres (say 6500 feet) above the level of the sea. It generally rises in the course of the forenoon, and, apparently, more rapidly the nearer noon is approached. It sinks in the course of the afternoon, and, apparently, more rapidly with the greater distance from noon. Its level may vary about 2000 metres in from one to two hours. The change from rising to sinking does not occur exactly at noon, but perhaps one hour or even more after noon, according to season.

A knowledge of the decrease of temperature on days of thunderstorms, especially just before the storm, presents therefore especial interest. Only few data exist on this point.

Glaisher made an ascent at 6 p.m. on the 31st August, 1863, after a thunderstorm had taken place at 8 a.m. He did not reach the isothermal surface of zero, but found a temperature of 1° C. at a height of 2300 metres (say 7500 feet). I have never found such a low temperature at a similar height in any of the six ascents in August and the beginning of September.

Flammarion made an ascent during the night of the thunderstorm of the 14-15 July, 1868, and met with 0° C. at a height of 2400 metres (say 6500 feet), but this was at 4h. 26m. a.m. Among all the midsummer ascents there is only one in which the isothermal surface of zero was met with at a lower level.

Welsh made an ascent in the afternoon of the 17th August, 1852, two hours before the occurrence of a thunderstorm; at 5 p.m. the isothermal surface of zero lay at a height of 3500 metres (say 11,500 feet), but it was rapidly sinking. Welsh did not find such a rapid decrease of temperature upwards in any of his other three ascents as in this one.

Kämtz has drawn the conclusion, based upon the great refraction which has often been observed with sultry thunderstorm air, that the rapid change of temperature with height is an important condition for the formation of thunderstorms, especially in summer. In order to obtain more precise data upon this point I have undertaken a small meteorological investigation as to the difference of temperature existing just before thunderstorms between Freiburg in the Breisgau and the Höchenschwand in the Black Forest, 2326 feet above it. I found that in seventeen cases which were suitable for comparison, in the years 1880 and 1881, the difference of temperature just before the thunderstorm was less than the average for the day and season in three cases only; in other cases it was greater.

From this it appears that, in most cases, the abnormally rapid decrease of temperature with height, and, in connection with this, the abnormally low position of the isothermal surface of zero may be taken as characteristic of the condition of weather before thunderstorms.

Secondly, attention must be paid to the nature of the upper clouds not only generally, but also more especially before thunderstorms. The clouds which lie above the isothermal surface of zero must of course mainly consist of ice particles, although, of course, the formation of clouds of superfused water particles is not excluded. The appearance of the ice clouds is, moreover, somewhat different from that of the water clouds. The former are known as "cirrus" and the latter as "cumulus" clouds. Observations on the height of clouds, made either in balloon ascents or on the ground, agree in showing that the limit of both kinds of clouds in midsummer lies about 4000 metres (say 13,000 feet) high, which agrees pretty well with the above calculation of the level of the isothermal surface of zero. It is not surprising, therefore, that balloonists frequently reach snow-clouds even in midsummer—for instance, Glaisher on June 26, 1863, between 3300 and 4200 metres (say 11,000 and 14,000 feet); Fonvielle on July 4, 1875, at 3450 metres (say 11,300 feet); Barral and Bixio on July 27, 1850, between 4500 and 6300 metres (say 15,000 to 20,500 feet); Welsh on August 17, 1850, at 5990 metres (say 19,500 feet).

While the distinction between ice and water-clouds, from their mere appearance as seen from the earth, is always somewhat difficult to be made out, we have in many cases an infallible

[1] Extract from "Sitzungsberichte der Jenaischen Gesellschaft für Medecin und Naturwissenschaft." Jahrg 1885. Sitzung vom 1 Mai.

means of distinguishing between them—namely, by the character of the solar and lunar halos which are very often seen in thin veils of clouds. It has been established beyond doubt that the rings of light of larger size, or halos of about 22° diameter, are caused by refraction in ice crystals. (This angle is that of the least deviation for rays of mean refrangibility in passing through ice-prisms of 60°). On the other hand the smaller rings (coronæ) of from 1° to 6° diameter owe their origin to the refraction of light through spheres of uniform size. Halos are not nearly so rare as is commonly supposed. M. Galle observed seventy-eight halos and about as many parhelia in a year and a half, and often even in the heat of summer. Kämtz laid great stress on the importance and infallibility of this optical means of distinguishing between the two classes of clouds.

After these preliminary considerations let us turn to thunderstorms. The local or heat thunderstorms (identical with most summer thunderstorms) are best known, while the large cyclonic thunderstorms have been less investigated. In the first case, the appearance of the clouds which rise high in the sky as gigantic columns of cumulus, show that they owe their origin to a strong ascending current of great humidity. According to Dr. Reye, the principal condition for the formation of a continuous ascending moist air current is the abnormally rapid decrease of temperature in its vicinity, while in the current itself the decrease of temperature with height is essentially retarded, owing to the latent heat set free by the condensation of vapour. Under these conditions, the distribution of temperature in the atmosphere is therefore such that the isothermal surface of zero in the ascending current is raised especially high, while outside this current the surface has an abnormally low position. In this way, therefore, water still in a liquid state reaches the ice-region; ice-clouds and water-clouds must exist side by side. If the moist current rises sufficiently high its temperature sinks below 0° C. and this gives rise to cirrus clouds of snow and hail, which latter frequently accompanies thunderstorms. Kämtz has shown from his observations in high mountains that the height of the locus of thunderstorms must not be placed too low; the usual estimations of the height of thunderstorms based upon observations of lightning and thunder cannot be taken into account here, for they only show (and that very inaccurately) the position of the lowest structure of the thunderstorm clouds.

Both Hann and Kämtz agree that water and ice clouds always exist simultaneously in the sky, and not only during local thunderstorms but also during those of the other kind. Hann describes the layers of "cirrostratus" cloud as always existing with thunderstorms. Kämtz has always been able to recognise halos *i.e.* the characteristic indication of the presence of ice particles before thunderstorms, as soon as he could trace the change from clear sky to thick clouds. And in all three of the previously mentioned balloon ascents on days of thunderstorms ice particles have been observed in the air.

We may take it that it has been established that in every thunderstorm clouds composed of water particles and others of ice particles exist simultaneously side by side, and that, of course, they are mutually changing places it is very easy to suppose that the friction of water particles and ice particles may serve as a source of electricity. But this is in no way a mere supposition, for it is a fact already established by Faraday. In his experiments on the cause of the production of electricity in Armstrong's steam electrical machine, which was considerably modified by him, he frequently caused compressed air to strike against solid objects. The cooling arising from the expansion of the air caused a copious formation of fog, and the friction of these particles against the objects always excited the particles with + electricity and the solid objects with − electricity. It was only by the friction of the particles against ice that the latter became + on every occasion, while wood and metal were excited with − electricity by the friction of the particles.

I have frequently repeated these experiments of Faraday's, and, as was to be expected, entirely confirmed them. Of course several precautions must be taken if we do not wish to be checked by evidently contradictory results. The principal causes of disturbance may arise by the carrying away of particles of grease from the greasing of the taps, and on the other hand by the friction of the particles on the walls of the tube, if the turning on is not quick enough. In the latter case the particles become + and communicate this electricity to the objects they meet, and thus, therefore, the character of the electricity by friction with these bodies is partially or wholly masked. The colder the ice the more powerfully it becomes electrified—a fact which appears to be in connection with the increase of its insulating power with decreasing temperature.

If, therefore, air-currents flow against each other, one being of ice particles and the other of water particles, the ice particles become positively and the water particles negatively electrified, and as by no means a rapid mixing of both kinds of air-currents is requisite, which may be seen *inter alia* from various observations on smoke-laden air-currents in laboratories, the oppositely electrified bodies are quickly repelled from each other.

The real cause of thunderstorm electricity appears to me to lie in the sequence of phenomena above described. It is not my intention to discuss the behaviour of the further phenomena connected with thunderstorms.

A more detailed exposition of the theory very briefly sketched here, as well as the observations used for its proof, will be found in my Treatise on the Origin of Thunderstorm Electricity and of the Ordinary Electricity of the Atmosphere, just published by G. Fischer, Jena. ("Der Ursprung der Gewitter-Elektricität, und der gewöhnlichen Elektricität der Atmosphäre.")

CYSTOLITHS

M. J. CHAREYRE[1] has made a detailed examination of these structures in plants belonging to the Urticaceæ, and to many other families. The following are some of the chief results:—

In the Urticaceæ the prolonged action of darkness causes complete disappearance of the calcium carbonate in the cystolith, though without their mass sustaining any diminution; they retain completely their original form. This takes place before the etiolation which is the result of placing the plants in question in the dark. It is due probably to the cessation of the action of chlorophyll. Calcium oxalate disappears in the same way from the cystoliths. The lime set free by the decomposition of these salts collects in the stem, where it exists in combination with some other acid.

In the Acanthaceæ, on the other hand, none of these phenomena are exhibited, and the cystoliths undergo no change from the action of darkness; and this difference in the behaviour of the cystoliths in these two natural orders appears to correspond to no less important differences in their constitution. The calcium carbonate appears in one family in the crystalline, in the other family in the amorphous, form.

All the seeds of Urticaceæ examined before germination presented reservoirs of food-material consisting exclusively of aleurone, in each of which was a rounded globoid. The same was the case with the Acanthaceæ, except *Acanthus* and *Hexacentris coccinea*, plants containing no cystoliths, and in which the reserve-material of the seeds consists chiefly of starch. The calcareous reserve-material contained in the seeds in the form of globoids disappears more rapidly when they germinate in a soil formed of pure silica than in ordinary soil, or in one composed of calcium carbonate. But no part of this reserve-material contributes to the formation of deposits of calcium carbonate, whether as cystoliths or in any other form, nor to the production of crystals of calcium oxalate. In seeds which germinate in pure silica the cystoliths do not arrive at full development; the pedicel is formed, but no deposition of either cellulose or lime takes place at its extremity. In soil composed of calcium carbonate the cystoliths appear at the same time as in ordinary soil, *i.e.* at the moment when the green cotyledons are disengaging themselves from the seminal envelopes, but their development is somewhat more rapid. Seeds sown in ordinary soil or in calcium carbonate, but kept in darkness, give rise to rudimentary cystoliths without any calcium carbonate.

Yellow dying leaves of many Urticaceæ present, as contrasted with green leaves, cystoliths containing a smaller quantity of calcium carbonate, but this is not the case with Acanthaceæ or with *Pilea*.

Both the calcium carbonate in the cystoliths and calcium oxalate are believed by the author not to be merely products of excretion, but to play an important part in the life of the plant.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

THE following list has been issued by the Science and Art Department of successful candidates for Royal Exhibitions, National Scholarships, and Free Studentships, May, 1885:—William Burton, aged 22, science teacher, Manchester, National Scholarship; Philip L. Gray, 19, assistant master, Southampton, National Scholarship; Charles Lang, 22, engineer, Johnstone, N.B., National Scholarship; Thomas Clarkson, 20, engineer, Pendleton, Manchester, National Scholarship; Harry E. Hadley, 18, student, Worcester, Royal Exhibition; William Scudamore, 16, student, Northampton, National Scholarship; Frederic W. Lanchester, 16, architect's assistant, Southampton, National Scholarship; Thomas H. Holland, 16, student, Helston, National Scholarship; Harold E. Hey, 14, student, Manchester, National Scholarship; William Blackmore, 18, student, Sheffield, National Scholarship; Hugh O. Bennie, 20, engineer, Glasgow, Royal Exhibition; William Kelsall, 17, student, Bradford, National Scholarship; Henry Sowerbutts, 17, student, Manchester, National Scholarship; Frederick Chattaway, 24, chemist, Birmingham, National Scholarship; James Young, 23, shoemaker, Belfast, Royal Exhibition; Arthur J. Moulton, 20, engineer's apprentice, Preston, Royal Exhibition; Harold C. Coote, 17, student, London, Royal Exhibition; Robert H. Unsworth, 20, engineer, Pendleton, Manchester, Royal Exhibition; Sidney H. Woolhouse, 15, student, Weaste, Manchester, Royal Exhibition; David Wilkinson, 21, agent, Preston, Free Studentship; Henry P. Motteram, 19, student, Small Heath, Birmingham, Free Studentship; Albert E. Briscoe, 17, machinist, Birmingham, Free Studentship; Orlando J. Preston, 16, student, Bristol, Free Studentship; James McKenzie, 20, engineer, Glasgow, Free Studentship; Philip C. Coultas, 18, student, Bristol, Free Studentship.

We have received the calendars for the ensuing session of the University College, Dundee, and of the Durham College of Science, Newcastle-on-Tyne. A very important addition to the educational programme of the former is the establishment of a new Chair of Biology. This chair was needed on account of the recognition of the science department of the college by the University of Edinburgh, and also because the science curriculum was incomplete for graduation in London University. The new chair has been filled by Mr. D'Arcy Thomson, of Cambridge.

SOCIETIES AND ACADEMIES

Paris

Academy of Sciences, August 17.—M. Bouley, President, in the chair.—Observations of the minor planets made at the Observatory of Paris (large meridian instrument) during the second quarter of the year 1885, communicated by M. Mouchez.—Note on typhoons and the so-called "grains arqués" of the eastern hemisphere (two illustrations), by M. Faye. From the descriptions of these meteorological phenomena made by observers in the Indian and Pacific Oceans, and in Senegal, the author concludes that all such cyclonic movements of the atmosphere affect a circular form. The importance of this conclusion is obvious in connection with the theory which regards these atmospheric disturbances as sharply defined whirlwinds of circular shape, not as the result of currents converging towards a common centre of attraction without definite outer limits.—Researches on the present and the prehistoric races of Brazil, in connection with the sixth volume of the Natural Museum of the *Archives* of Rio de Janeiro, presented to the Academy on behalf of the Emperor Don Pedro II., by M. de Quatrefages. The contents of this volume are of great importance for the comparative study of the Brazilian races past and present, and of the primitive cultures of the more civilised populations in North and South America. It contains papers by M. Hartt on the river and marine shell heaps occurring in various parts of Brazil; by M. J. B. de Lacerda on the human remains found from time to time in these deposits, and by M. Peixoto on the Botocudos still surviving in the eastern provinces of Brazil. But the chief attraction of the volume is the valuable and richly illustrated memoirs of M. Ladislaus Netto, on the remarkable artificial hill of Pacoval, which is now fully described for the first time. This hill, entirely the work of man, stands on the margin of a lake in the island of Marajo, and although reduced by erosion and weathering to a fifth or a sixth of its original size, is still 300 metres long, 250 broad, and 6 high. It presents the outlines of a gigantic Jabuti turtle (*Emys faveolata*), in this respect showing analogies with the works of the mound-builders in the Mississippi basin. Its contents are of the most varied character, including stone implements of all kinds, idols, amulets, and a vast quantity of earthenware, funeral urns, vases, *tangas*, &c., covered with ornamental designs remarkable for their delicacy and taste, either painted, incised, or modelled in relief. Some of the signs appear to be of a hieroglyphic character, presenting certain analogies to the early Chinese, Egyptian, and Mexican writings. One inscription, which M. Netto has attempted to interpret, seems to speak of long migrations, most probably from the Andes highlands down the Amazons basin, towards the Atlantic seaboard.—Experimental researches on cholera, by MM. Paul Gibier and van Ermengem. Appointed by their respective Governments to study Dr. Farran's method of preventive vaccination, these biologists have independently arrived at the same conclusion, that the sub-cutaneous injections of the cultivated virus (comma bacillus) does not preserve from cholera the animals on which their experiments have been made.—Observations of Tuttle's comet made at the Observatory of Nice (Gautier's equatorial), by M. Perrotin.—Equatorial observations of Barnard's comet (*a*) made at the Observatory of Algiers with the 0·50 m. telescope, by M. Ch. Trépied.—Account of a remarkable solar protuberance observed on the eastern edge of the disk at Paris on August 16, by M. E. L. Trouvelot.—Description of a new magnifying apparatus for the projection of microscopic objects as well as of images of large dimensions, by MM. Théodore and Albert Duboscq.—On the action of the iodide of phosphonium on the oxide of ethylene, by M. J. de Girard.—On the elective alcoholic fermentation of sugar, by M. H. Leplay. Against the objections of MM. Bourquelot and Maumené the author maintains from his own experiments that the elective alcoholic fermentation as originally discovered and described by M. Dubrunfant really exists and must be accepted as a scientific although hitherto unexplained phenomenon.—On the organisation, anatomy, and digestive function, of *Pachydrilus enchytræoides*, by M. Remy Saint-Loup.—Extraction and composition of the gases contained in the foliage of floating and submerged aquatic plants, by MM. N. Gréhaut and J. Peyrou.—Recurrence of the superficial earthquake at Escarpel and in the neighbourhood of Douai, Département du Nord, by M. Virlet d'Aoust.

CONTENTS

THURSDAY, SEPTEMBER 3, 1885

THE ANDAMAN ISLANDERS

On the Aboriginal Inhabitants of the Andaman Islands. By Edward Horace Man, Assistant Superintendent, Andaman and Nicobar Islands, with Report of Researches into the language of the South Andaman Islands, by A. J. Ellis, F.R.S. Reprinted from the *Journal* of the Anthropological Institute of Great Britain and Ireland. (London: Trübner and Co.)

"IN considering the habits, customs, and physical peculiarities of a savage race, it is important to acquire as much information as possible regarding the land they inhabit, and also to ascertain the nature and extent of the influences exercised by, or resulting from, their intercourse with other nationalities."

The author of the work from which the above extract is quoted has proved himself fully qualified to treat of this interesting race of people, among whom he resided for four successive years in his capacity of Assistant Superintendent, from the scientific point of view which he has so well defined in the foregoing passage. The volume before us consists essentially of a series of papers communicated at various times since 1880 to the Anthropological Institute, and now republished, with the sanction of the Institute, in a separate form, with an introduction and fourteen short appendices. The report on the language of the South Andaman Islands concludes the volume, and bears a separate title-page indicating that it has been drawn up by Mr. A. J. Ellis, F.R.S., from the materials furnished by Mr. Man and Lieut. R. C. Temple, of the Bengal Staff Corps.

The Andaman Islands consist of a group situated in the Bay of Bengal between the 10th and 14th parallels of N. latitude, and comprise Great and Little Andaman, the former consisting of North, Middle, and South Andaman, together with the Archipelago, Interview, Rutland, and many other small islets. The entire area of the islands is estimated at about 2508 square miles, of which about 2000 square miles are comprised in Great Andaman. Some pages of the introduction are devoted to a description of the physical features, climate, and scenery, the author calling special attention to the numerous fine harbours which offer safe anchorage during all seasons. With respect to the population, Mr. Man estimates the total number of the aborigines of Great Andaman as probably about 2000, and of those inhabiting Little Andaman 1000 to 1500; the aggregate population of all races is about 15,000, nearly four-fifths of this number being made up of the convicts inhabiting the penal settlement. A succinct history of the settlement is given, from which it appears that the modern history of the Andamans dates from 1857, although a previous attempt to found a penal station had been made by the Honorable East India Company, but this was abandoned in 1796 on account of the high death-rate.

The author recognises eight distinct tribes of aboriginal inhabitants in Great Andaman and one in Little Andaman. The natives with which the officers in charge of the station at first came into contact displayed much hostility and considerably harassed the operations of the working parties; but improvements have gradually been effected in the relationship between the aborigines and the settlers chiefly through the establishment of Government homes, and now, as Mr. Man states in a passage quoted from Dr. Day, "the convicts are left unmolested, the implements of agriculture are not stolen, the fishing stakes are left undisturbed, the gardens are no longer pillaged, runaway convicts have been recaptured, and shipwrecked sailors assisted." The author, who had charge of one of the homes, also states that these "have effected good in bringing together members of the various tribes, between whom the way has thus been paved for intermarriages, which were of course formerly of rare occurrence; tribal feuds have also here been amicably arranged, while, through visits paid to Port Blair and other homes by members of all the Great Andaman tribes, as well as by our visits in the station steamer to the more distant encampments, the knowledge of our power, resources, and kindly intentions has spread throughout their respective territories." The aboriginal inhabitants of Little Andaman are, however, still unreclaimed, and all attempts to civilise them have hitherto failed; their hostility towards strangers is such that any persons unfortuate enough to be cast on their shores would be as ruthlessly slaughtered now as at any period prior to our annexation of the islands.

The effect of the contact with civilisation upon those more friendly tribes who have accepted the advantages offered by the homes is however similar to that which invariably results from all such attempts:—"in proportion as they gain in intelligence and tractability, the more fat and indolent do they become, and, having no incentive towards exertion, frequently lose in great measure their quondam skill in hunting." Still more serious is the moral deterioration which has taken place through contact with the convict population, and Mr. Man is careful to point out that his observations have been confined to those primitive communities which have not yet had time to be affected by the virtues and vices of modern civilisation. One interesting point which has been brought out by an attempt to educate the native children is that up to the age of ten or eleven they are as intelligent and can learn as well as the children of civilised races, but after this age no further progress is possible. This feature in the mental evolution of savage races has, if we remember correctly, been observed in the case of many other uncivilised tribes.

In the succeeding portions of the volume we have an immense amount of detailed information upon all the points which are likely to be of value to the anthropologist. With regard to the vexed question of the origin of the race, Mr. Man considers that the natives are the direct descendants of the prehistoric inhabitants, that they all belong to the same race, and that the tribal differences are the effects of isolation by the natural barriers of the country and the constitutional jealousies and hostilities which formerly prevented the tribes from living on amicable terms with each other. Ethnologically the author regards these people as Negritos, and "racial affinity—if there be any—may possibly some day be found to exist between them and the Semangs of the Malayan Peninsula, or the Aëtas of the Philippine Islands."

T

Following the section on the ethnology of the Andamanese we have an excellent description of their form and size, forty-eight males and forty-one females having been most carefully weighed and measured, with the result that the average height of the men is 4 feet 10¾ inches and of the women 4 feet 7¼ inches, and the respective average weights 98⅛ lbs. and 93¼ lbs. To give an idea of the thoroughness with which the author has dealt with his subject, under the heading "Anatomy and Physiology," we have a series of five sets of observations on the temperature and rate per minute of respiration and of the pulse on five subjects ranging in age from seventeen to twenty-two years. Descriptions of the pathology, medicine, physiognomy, physical powers and senses, psychology and morals, magic and witchcraft, of the tribal distribution, topography, arithmetical faculties, and of their habitations, government, laws, crimes, &c., complete the first part.

With respect to diseases it appears that pulmonary consumption and other pectoral complaints are or were the chief causes of mortality among these people; to these have unfortunately now to be added that "terrible scourge" which has spread over the greater part of Great Andaman, and which, as in Australia, unless successfully dealt with, threatens, as Mr. Man informs us, "the early extermination of the race."

The morals of the Andamanese in their primitive state appear to be of a distinctly high standard, as will appear from the following extracts:—

"Much mutual affection is displayed in their social relations, and, in their dealings with strangers, the same characteristic is observable when once a good understanding has been established . . . every care and consideration are paid by all classes to the very young, the weak, the aged, and the helpless, and these, being made special objects of interest and attention, invariably fare better in regard to the comforts and necessaries of daily life than any of the otherwise more fortunate members of the community. Andamanese children are reproved for being impudent and forward . . . they are early taught to be generous and self-denying . . . the duties of showing respect and hospitality to friends and visitors being impressed upon them from their early years," &c. With regard to their modesty Mr. Man states that the esteem in which this virtue is held, "and the self-respect which characterises their intercourse with each other may even be said to compare favourably with that existing in certain ranks among civilised races." It is much to be regretted that the so-called "civilisation" with which these people have been brought into contact should have led to the moral deterioration which the author with scientific candour does not scruple to disclose. It is perhaps hardly necessary to add that the stories concerning the prevalence of cannibalism among these tribes have been completely disproved both with respect to the present time and to former periods of their history.

In the second part of his interesting monograph the author treats of the language, relationships, names, initiatory ceremonies, marriage, death and burial, superstitions, religious beliefs, demonology and mythology. In the third part we have an account of the social relations of the Andamanese, their mode of life, games and amusements, and a description of their weapons, manufactures, &c. Want of space forbids anything more than a mere mention of the ground covered by these sections, but it will suffice to say that they are characterised by the thoroughness which is such a valuable feature of Mr. Man's work. The few slight defects which we have noticed are on matters of quite minor importance, such, for instance, as the statement in the introduction, that "the water in the harbour of Port Blair has been found to be remarkable for its high density, as is evidenced by the rapid oxidation of iron immersed in it;" in its present form this reads rather like a case of *non sequitur*.

It remains only to add that in the fourteen appendices we have a mass of most valuable information on various subjects connected with these islands and their inhabitants: most of these appendices are philological; one is devoted to a list of the native trees, and another to a list of the shells.

The Report on the language of the South Andaman Islanders is reprinted from the *Transactions* of the Philological Society, before which body it was delivered by its author, Mr. A. J. Ellis, F.R.S., as his retiring presidential address in 1882. The volume is illustrated by a good series of typical photographs of the natives and five plates of weapons, ornaments, &c., and a map of the islands forming a frontispiece.

In concluding this notice we must not omit to mention that Mr. Man's mode of treatment is based upon the instructions drawn up by Col. Lane-Fox (now General Pitt-Rivers) on behalf of a Committee of the British Association, and published among the Reports for 1873. This Report was afterwards issued in an expanded form as a Manual of Anthropological Notes and Queries, and the work now under consideration may be regarded as one of the most important practical results of the labours of the Committee referred to. We believe that Mr. Man is at present engaged in a similar study of the inhabitants of the neighbouring Nicobar Islands, one of which—Camorta—was selected as a station by the Eclipse Expedition of 1875. We shall look forward with much interest to the continuation of the author's labours in this new field.

R. M.

COMMERCIAL ORGANIC ANALYSIS

Commercial Organic Analysis. Vol. I. By Alfred H. Allen, F.I.C., F.C.S. (London: J. and A. Churchill, 1885.)

NOTWITHSTANDING the fact that enormous numbers of text-books on chemical subjects have been appearing during recent years, a few comprehensive works on the subject of commercial analysis have been long and greatly needed. When it is considered how every day commerce has been availing itself more and more of the powers of scrutiny and control afforded by chemical analysis, this delay may appear remarkable. But the truth is that to produce such a work very exceptional qualifications and a very unusual degree of experience are necessary. A work on commercial analysis must be thoroughly practical if it is to be useful, and prescribe methods of analysis only which experience has proved to be accurate and serviceable. Analysts as a rule have their specialities—these specialities often being determined by local industries—and long experience frequently leads them to devise or modify processes without any record appearing outside their own laboratories. Almost every analyst has his own manuscript "process-book," according to which he expects his assistants or pupils to work, and so it becomes a matter of extreme difficulty for an author to produce a work that shall be generally acceptable as a laboratory guide. The too frequently occurring discrepancies in commercial analyses may in a measure be attributed to the same cause, and there can be no doubt that a unification in the methods of conducting and recording analyses is greatly to be desired. This end will doubtless be greatly furthered by the production of standard books such as the present one.

A first edition of the work before us appeared in 1879. It has undoubtedly taken already a very high position, and has been welcomed as filling a conspicuous gap in the literature of analytical chemistry. The value of a division between organic and inorganic analysis to the ordinary analyst may not be great, but it is useful to the author in enabling him to keep his work within bounds. The first edition of the book appeared in two volumes; in the new edition a rearrangement and extension is being made, and it will now occupy three volumes. The first volume deals with organic bodies of the fatty series and of vegetable origin, and includes chapters on the alcohols, ethers, and other neutral derivatives of the alcohols, sugars, starch and its isomers, and vegetable acids. The second volume, which is to appear shortly, will be devoted chiefly to coal-tar products and bodies of the aromatic series, to hydrocarbons generally, fixed oils and the products of their saponification, and the tannins. Nitrogenised organic substances, including cyanogen compounds, alkaloids, organic bases, and albumenoids will be treated of in the third and concluding volume. This arrangement of the subject is, we think, a great improvement on the previous one, and makes the book much more convenient for reference.

Mr. Allen treats his subject in as scientific a manner as possible, and this gives quite a peculiar character to his work. It is not, like so many books on analysis, merely a series of receipts or processes of chemical handicraft; but a work assuming the possession of some really scientific knowledge on the part of those using it. It would be easy to go too far in attempting to generalise in such a subject as commercial analysis and in introducing theoretical details; but although the author goes so far, for instance, as to introduce structural formulæ for many of the substances dealt with, it cannot be said that he demands more knowledge than should be forthcoming from those engaging in this difficult and often obscure branch of analysis.

The introduction, extending over thirty-five pages, embraces a description of some general methods, such as the determination of specific gravity, of melting- and boiling-points, optical properties, &c. The rest of the volume is devoted to a consecutive account of substances comprised under the several headings. After the author has described briefly but sufficiently what the substance is or ought to be, he gives the methods for its detection, estimation, or analysis, and intersperses the account with such general information as is likely to be of value to the analyst. We cannot attempt to enumerate the somewhat remarkable collection of products dealt with in the course of the work. Wines, beers, cordials, tinctures chloroform, sugars, confectionery, starch, vinegar, the commercial acetates, tartrates, and citrates—are examples taken at random, which will serve to give some idea of the variety. They are, however, treated in a connected manner, in illustration of which we may refer with special approval to the division on sugars, and starch and its isomers.

With regard to the methods recorded by Mr. Allen we may say that on the whole they are such as have borne the test of experience, whilst new processes or modifications of old ones are duly referred to and discussed. The author acknowledges assistance from many men of experience, and has, we think, used it to the best purpose. His descriptions are clear and concise, and the book is remarkably free from errors of any kind. We think it really an excellent enterprise, excellently carried out, and congratulate Mr. Allen on having produced a scientific and thoroughly practical book which, we are confident, will find a place in the library of every practical chemist.

RECENT TEXT-BOOKS OF DETERMINANTS

Lecciones de Coordinatoria con las Determinantes y sus principales aplicaciones. Por D. Antonio Suarez y D. Luis G. Gascó. (Valencia, 1882.)

Traité Élémentaire des Déterminants. Par L. Leboulleux. (Genève, 1884.)

Die Determinanten, für den ersten Unterricht in der Algebra bearbeitet. Von Dr. H. Kaiser. (Wiesbaden 1884.)

Lessons Introductory to the Modern Higher Algebra. By George Salmon, D.D. Fourth Edition. (Dublin, 1885.)

THE first of these works is outwardly a very handsome volume, and on examination we find that the authors have also done their part in the most painstaking and methodical way. The main part of the title, "Coordinatoria," is apt at first to mislead, and indeed after a cursory glance at the contents a cosmopolitan reader might be pardoned for thinking that "Coordinatoria" was a misprint for "Combinatoria," for what our grandfathers spoke of as the *Ars Combinatoria* is the subject of the opening chapters. "Coordinatoria" it is, however, and in the preface it is placed as a science side by side but in contrast with the science of Quantity.

There are in all twenty chapters in the book. The first seven (146 pp.) deal with permutations, combinations derangements or inversions of order, substitutions, and difference-products: they form a lengthy and most carefully prepared introduction to the theory which follows. The next ten chapters (242 pp.) deal with determinants, and expound all the more important properties in the most methodical, simple, lucid and ungrudging manner. The learner, for example, is prepared for the evaluation of a determinant whose elements are expressed in figures by—

§ 327. Simplification by addition.
§ 328. Simplification by subtraction.
§ 329. Simplification by addition and subtraction.
§ 330. Simplification by multiplication.

And so on, up to—

§ 335. Simplification by multiplication, addition, and subtraction.

An impatient Briton might be tempted to call this "simplification to the death," but after calmly perusing the whole he might be induced to confess that he had said so in his haste. The last three chapters deal with applications of determinants: one is arithmetical, and is mainly concerned with continuants and magic squares—a rather invidious juxtaposition; one is algebraical, and gives the determinantal solution of a set of simultaneous linear equations; and the last is geometrical. A very valuable feature of the book is a *résumé* in 40 pp. of all the definitions and theorems given in the preceding 410 pp. No one but a most enthusiastic and painstaking teacher would have thought of adding such an admirable abstract.

The next book on our list might have been more accurately described as a *very* elementary treatise: it must have been intended for pupils with exceedingly little algebraical training. The first 18 pp. are occupied with determinants of the second order, and they are followed by 33 pp. treating of those of the third order. It may be safely affirmed that the pupil who requires 18 octavo pages to teach him the theory of such abstruse functions as determinants of the second order would do well to redirect the expenditure of his mental energy. The book is carefully and accurately written, and there is a wealth of simple exercises in it, worked and unworked.

Dr. Kaiser's pamphlet is of the same ultra-elementary character—considerately restricted, however, to 23 pp. On a former occasion (NATURE, vol. xxix. pp. 378, 379) we drew attention to the fact that a new Introduction of this kind appears every year in Germany, and that of late they have not been improving. We merely notify, therefore, that this is the production for 1884.

The preparation of a new edition of Salmon's "Modern Higher Algebra" has been entrusted to Mr. Cathcart. It contains about 40 pp. of new matter, the chief increase arising from the expansion of the chapter on "Applications to Binary Quantics" into *two* chapters, the first with the old title, and the second headed "Applications to Higher Binary Quantics." The changes made on the portion which deals with determinants are slight, and consist chiefly in the insertion here and there of well-chosen examples.

OUR BOOK SHELF

The Three First Years of Childhood. By Bernard Perez. Edited and translated by Alice M. Christie. With an introduction by James Sully, M.A. (London: W. S. Sonnenschein and Co., 1885.)

THE earliest years of infancy are of importance to two classes of inquirers—to the educator who knows how much evil results from the wrong treatment of young children, and to the evolutionist who, rejecting the *tabula rasa* of Locke, looks to infancy as the time freest from any effect of artificial training. In the study of other *men's* minds the observer is as likely as not to be purposely deceived by them, whereas deceit is an accomplishment which few infants have attained to.

Mr. Bernard Perez seems well to combine these characters. He is an educator who has published various works on school matters, and he describes man as an animal which ought to be reasonable, while he is not necessarily so, as criminal scandals and the success of bad novels prove. He notes that the preponderating elements in a child's will are impulsiveness and stubbornness, incapability of fixed attention, qualities most opposed to the temperament of philosophy and discipline. Much of his book is advice to practical educators, whom he urges to study the manifestations of infancy and to endeavour to lead their youngest pupils by example and not check their behaviour by authority; their intellect should be helped, not controlled. He specially points out the danger of deceit before even the youngest of children.

But, on the other hand, there is little of the tone of the pedagogue in his book. Far more is it a book of suggestion than one teaching with authority, and it will encourage the spirits of fruitful doubt and inquiry in the mind of every reader. He enters heartily into the teaching of modern science, even to using the argument that infants have not certain sensations *because* they would be of no use to them at that age; and, thinking it necessary to caution his readers against leaving everything to hereditary dispositions and powers. He urges the importance of comparing early human life with animal life, thus making cats, dogs, birds, and babies more interesting than before. We may enjoy his book without accepting the teaching that human language has grown out of such involuntary signs as laughter, sobs, and screams, afterwards performed voluntarily. No doubt these involuntary sounds are of more use to an infant than more sober utterances, and have therefore become innate and involuntary, while language is an artificial acquirement. We think that few who have watched their vigorous antics will feel sure that a state of equilibrium, a passive state of health, or even that of moderate and appropriate exercise in moving their limbs, is the most enjoyable sensation to infants, though this latter pleasure is sufficient to explain many actions of infants for which our author seeks a deeper reason. On the other hand, we think that the moral sense has become more deeply impressed than he suggests, and is far from entirely the result of approbation and disapprobation.

Attention and vivid perception seem strangely shaken up in his remarks; the latter faculty explains the dislike which children have to hearing a tale repeated with variations. They have indeed got it all "by heart."

Mr. Sully, in his very suggestive introduction, raises the question, Who is best qualified to follow up this delicate business of observing and rightly explaining all the movements and utterances of such young objects? Neither father, mother, nurse, nor doctor is completely qualified for the study. Mr. Sully concludes that the father and mother must conjointly undertake the work, the cooler intellect of the one checking and steadying the close and loving knowledge of the other. Let us suggest that an elder sister is most likely to succeed, and thus indicate a path to intellectual usefulness and even eminence well fitted for a lady's sphere. It will elevate every little labour from drudgery into a scientific study of variations and resemblances of the greatest importance, and add immensely to the interest of nursery life in a large family. On such observations may be based, by herself or by more ambitious philosophers, theories of racial varieties, of biology, and of education. Sir W. Hamilton points out that the study of the human mind requires no scholarship or costly apparatus, and the principal acquirement necessary for success in the study we suggest is a little close knowledge of one's own thoughts and feelings. In recording observations Darwin's golden rule must always be strictly adhered to: Theorise freely—every other observer will help to demolish anything that will not hold water, and whether true or not it may be a suggestive hypothesis. Be most scrupulous as to recording as a fact anything not strictly correct; no one can disprove it, and it may throw back the reception of a useful truth for a generation.

W. ODELL

Un Capitolo di Psicofisiologia. Da Enrico dal Pozzo. Foligno, 1885.)

A GOOD book on abnormal mental phenomena of all sorts was to be expected from Prof. dal Pozzo, one of the very oldest living investigators of this branch of physiology in Europe. The present excellent little treatise comprises the substance of seven lectures delivered during the current year to the medical students at the University of Perugia on "Hypnotism," "Animal Magnetism," "Somnambulism," "Human Radiation," and "Psychism." The whole field is thus covered from the time of Mesmer down to Mr. Crookes's experiments, and the still more recent "Thought Readings" of Mr. Bishop and Mr. Cumberland. As a philosopher of the monist school, the author naturally rejects the spiritualistic conception, accepts the term "psychism" only in Mr. Crookes's sense, and regards all these manifestations as strictly co-related and explicable on physiological grounds. Human radiation he is also disposed to admit as a biological property, hence has no difficulty in believing in such well-attested facts as may be explained by it. But whatever cannot be so explained he regards as unworthy of credence, and treats the terms "spiritual," "transcendental," and the like, as synonymous with ignorance. The power claimed by paid mediums to hold commune with the departed is, of course, emphatically denied, and it is cogently argued that the medium can tell us nothing regarding present or past facts of which the audience may be ignorant. He cannot, for instance, say how many chairs are in the next room if the number is unknown to all present, whereas the somnambulist will often tell it exactly. Hence if these psychic manifestations did not depend on human radiation, but were the work of spirits, it would follow that these spirits are more ignorant than ordinary somnambulists. And to the assertion that psychism produces phenomena absolutely inexplicable by human radiation, the answer is that who cannot do the less can scarcely do the more in matters of this sort.

At the end of the work a chapter is added on Giordano Bruno, and his philosophic system, which, although not directly connected with the subject, will repay perusal.

Die Nutzbaren Pflanzen und Tiere Amerikas und den alten Welt vergleichen in Bezug auf ihren Kultureinfluss. Dr. L. Höck. (Leipzig: E. Engelmann, 1884.)

IN a pamphlet of fifty-eight pages Dr. Höck institutes a comparison between the useful plants and animals employed by man in the two hemispheres. Although the comparison is made in a somewhat rambling manner in the text, the conclusions arrived at are clearly tabulated in the form of an appendix. The influence of useful plants and animals on civilisation seems almost lost sight of, except on p. 10, where guesses at their mode of influence, rather than evidence proving it, are offered. Only those species considered by Dr. Höck to be the most important to mankind are noticed; hence the comparison can only be regarded as approximate to the truth. The author finds that the Old World or eastern hemisphere affords 269 useful plants and 58 animals against 52 plants and 13 animals derived from the New World. In consideration, however, of the larger area of the eastern than of the western hemisphere, which he estimates as being in the proportion of 9 to 4, he concludes that the New World only affords rather more than half so many as the Old.

The tables in the appendix indicate a certain amount of carelessness or confusion, which slightly vitiates the conclusions arrived at. Thus, *Citrullus Colocynthis* and *Momordica Elaterium* are classed under fruits used as food, instead of under medicinal plants; *Rumex Patentia* is indicated as English spinach, and *Haematoxylum campechianum*, which is stated in the text to be a New World plant, is given in the appendix as belonging to the Old World. It is difficult to understand the principle upon which the "more important" plants have been selected, many of them being by no means so extensively used as others which are omitted; this is particularly noticeable in the list of medicinal plants and those used in the arts. But, in justice to the author, it must be admitted that the task he has undertaken is a most difficult one, and cannot be fully treated in so small a space as he has given to it. His claims that the greater proportion of the present work was already completed before De Candolle's "Origin of Cultivated Plants" fell into his hands must also be allowed due weight.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Iona

BEFORE the close of the season when there is easy, and indeed luxurious, access to the Island of Iona by steamers from Oban, I would call attention to the high interest which attaches to its geology in connection with the rocks now called "Archæan."

Although the rocks of Iona are lithologically very distinct from the old gneiss of the Hebrides (which is the true "Laurentian" and closely resembles the rocks near Quebec), yet they are equally distinct from the mica slate series of Argyllshire, and I have always regarded them as undoubtedly belonging to the pre-Cambrian horizons. I had never seen, however, until last week, the beautiful sections exhibited in the precipices of the south-west corner of the island. Tourists often visit the little "Bay of the Coracle," where St. Columba is said to have landed, and I had not myself gone farther west. But the very calm sea of last week tempted me to boat round the farther coast to the south-west, and I was much struck by the sections there seen. The rocks are quite free from vegetation, and the exhibition of the strata is very striking. They are intensely hard and highly silicious—beautifully coloured with red, green, and black—and the beds dip at a high angle with remarkable flexures and faults of all kinds.

On the side of the island where the cathedral is, and which tourists visit, the rock is entirely different in its mineral aspect and character—being a dark or black slaty rock, thinly bedded, and with no bright colouring at all. It belongs, however, evidently to the same series, and has generally the same dip and strike as the beds farther west.

I should be very glad if some geologist acquainted with the different horizons of the Archæan series so largely developed in Canada could visit Iona, and determine to which of these horizons its rocks belong. Between them and the mica slates of the mainland of Argyllshire there is interposed the massive granite of the Ross of Mull—which comes up close to the eastern shore of Iona, and on the other side of which, near Bornepan, the mica schists are in the same relative position; while underneath the granite itself, and sometimes interbedded with it, there are some beds of a dark hornblendic gneiss.

The whole neighbourhood is evidently one of great interest in connection with the oldest metamorphic rocks of our island.

S.S. *Columba*, Campbelltown, August 30 ARGYLL

Radiant Light and Heat

THERE are two points in my article of last week which I should like to have the opportunity of discussing at somewhat greater length.

(1) In this article I made use of the following expression, having especial reference to phosphorescent bodies which continue after excitement to emit luminous rays at a comparatively low temperature:—"*There seems to be no reason why molecular energy should not be somehow changed at once into radiant light and heat.*" Let me now explain what I meant by this statement. The concluding quotation from Prof. Tait leads us to see that the definite connexion between the quantity and quality of the heat and light given out by a body and the temperature of that body, which the theory of exchanges asserts, is only statistically true. I can imagine, therefore, a few neighbourin g

molecules of some phosphorescent substance to be in a state of constraint, and to relieve themselves, thus causing vibrations which are communicated to the ether—the whole change taking place so quickly and on so small a scale that the statistical law above-mentioned does not apply, and is not therefore broken. Nay, further, I can imagine an enclosure, the walls of which are coated internally with an excited phosphorescent body performing for all practical purposes the part of an enclosure of low temperature under the theory of exchanges, and yet it may be continuing for some time to emit visible rays.

(2) I can, however, imagine the following question to be put: Let there be a phosphorescent substance which is capable of being excited by certain rays coming from a black body at the temperature T, these rays being apparently converted into others of lower refrangibility which continue to be given out for some time by the phosphorescent body. Let us further suppose that the phosphorescent body does not suffer chemical decomposition at the temperature T.

Now imagine a temperature enclosure kept at temperature T, the interior walls of which are lined in part with this phosphorescent substance. What will happen in this enclosure?

I think there can be little doubt that if there be such an enclosure capable of existing permanently and without decomposition of the substances which compose it, then the rays which it gives out must be those required by the theory of exchanges, But if the further question be asked in what way does the phosphorescent body conform to the theory of exchanges, we may, I think, plead ignorance. As far as I am aware we have experimentally little or no knowledge of what the phosphorescent substance will do under these conditions, presuming that it can exist undecomposed. All our knowledge is limited to its behaviour at a low temperature when acted on by high temperature rays, and its peculiar behaviour under these conditions cannot, I think, be viewed as a valid objection to the theory of exchanges.

BALFOUR STEWART

The Eleven-Year Meridional Oscillation of the Auroral Zone

THIS very remarkable law, in favour of which Mr. Tromholt quotes a short series of observations made at Godthaab, which, he says, are supported by a few in other Polar regions, would, it seems to me, if satisfactorily proved, not only advance the science of terrestrial magnetism a stage, but also materially help to elucidate the exceedingly mysterious bond of union between the aurora and weather. As long as we simply knew that the manifestations of the Aurora Polaris increased and diminished *everywhere* with the spotted area of the solar surface, we were obliged to conclude that there was a similar increase and decrease in the electrical energy of terrestrial currents, and meteorological evidence did not favour the idea that the eleven-year variation in terrestrial currents was on such an extensive scale as the amplitude of the auroral oscillation would imply. But now if the law which Tromholt has indicated, really exists, a great deal of the difficulty in correlating the two phenomena disappears, since it is obvious that a comparatively small displacement of the zone would cause the annual average number of auroræ to increase or diminish by their normal amount. Thus from lat. 60° N. to lat. 65° N., a distance of only 350 miles, the annual average number of auroræ diminishes from 80 to 40.

I will not now dwell upon analogous eleven-year oscillations of isobars, such as Blanford's Asiatic seesaw, and the indications of similar secular displacements of the Atlantic isobars noticed by Allan Brown and others, or upon the extraordinary resemblance in form between the auroral zone and the mean storm track of the northern hemisphere charted by Prof. Loomis in his latest contribution to meteorology; but I would merely say that Tromholt's discovery seems likely to become the touchstone which may, in the hands of an intelligent and comprehensive worker, clear up the entire question, and I earnestly hope that no efforts will be spared to corroborate it.

I will conclude by adding my mite. In looking over Fritz's monograph on the connection between solar spots and terrestrial magnetism and meteorology, I have found a series of observations at Godthaab and Jakobshavn (69° 22′ N.) further north, which do not appear to have been utilised by Mr. Tromholt, and which, when combined in the form of percentages, cover a space of ten years, and add strong corroboration to the law indicated by Tromholt.[1]

TABLE I.—*No. of Auroræ seen annually at Godthaab and Jakobshavn, compared with Wolf's Sunspot Numbers*

Years ...	1840	41	42	43	44	45	46	47	48	49	50
Godthaab ...	—	60	93	84	87	74	32	—	—	—	—
Jacobshavn.	10	15	15	18	12	24	21	17	14	11	21
Sunspots ...	63·2	36·8	24·2	10·7	15·0	40·1	61·5	98·4	124·3	95·9	66·5

TABLE II.—*The above numbers of Auroræ converted into percentages of their means and compared after smoothing with smoothed Sunspot Numbers*[1]

Years ...	1840	41	42	43	44	45	46	47	48	49	50
Godthaab ...	—	84	131	118	122	104	45	—	—	—	—
Jacobshavn.	62	93	93	111	74	148	130	105	86	68	130
Smoothed means of both	70·5	87	106·2	129	109	109·2	101·2	95·7	86·2	88	109
Smoothed sunspots	54·4	40·2	23·9	15·1	20·2	39·1	65·3	95·6	110·7	95·6	76·3

The figures in Table II. speak for themselves.

To corroborate this law by further observation will necessitate a prolonged sojourn in some region *north* of the maximum auroral zone, and Greenland appears to be almost the only region where this could be done in the absence of a regular Polar expedition.

On Cases of the Production of "Ohm's (or Langberg's) Ellipses" by Biaxial Crystals

IN examining the macled crystals of potassium chlorate, which are so extremely common in the ordinary crystallised salt, I have found that all those which consist of two hemitrope plates only, nearly equal in thickness, give the above-mentioned secondary interference-curves when placed in homogeneous convergent plane-polarised light.

This result is no more than we should expect if the crystals were uniaxial, as Prof. Langberg showed (*Pogg. Annalen Ergänzungsbd.*, I., 540) many years before the curves were independently discovered by Prof. G. S. Ohm (see NATURE for November 27, 1884, p. 83). But potassium chlorate is a biaxial crystal, the angle included by the optic axes being 28° 30′ (determined in olive oil), and I do not find that the production of the curves in such crystals has been hitherto noticed.

The plane of the optic axes, however, makes so large an angle, viz. 38° 30′ (as determined in olive oil), with the normal to the surfaces of the plates in which potassium chlorate usually crystallises, that the isochromatic curves in the vicinity of this normal belong to a very high order, and do not sensibly differ from portions of circles of large radius. Thus in a macle, in which the crystallographic position of one of the components differs by 180° from that of the other, the planes of the optic axes make equal angles of 38° 30′ with the normal on opposite sides of it, and so the conditions determined by Langberg for the production of the secondary ellipses are fulfilled. I have, in fact, made artificial twins of this kind by cementing together plates of the salt oriented as above indicated; and I find that they show the ellipses precisely as the natural macles do. Of course, in order to see them, the compound plate must be so placed that the plane which includes the normal and the two acute bisectrices makes an angle of 45° with the plane of polarisation of the light. In a good micropolariscope the four optic axes and portions of the lemniscates immediately surrounding them are visible at the edges of the field.

It is possible, but not common, to find crystals of potassium chlorate consisting of three plates nearly equal in thickness, the top and bottom plates being symmetrically disposed, while the intermediate one differs from them in crystallographic position by 180°. In such cases the secondary interference-curves are much more complicated, two sets of ellipses being generally visible, one on each side of the centre of the field (the exact position, of course, depending on the relative thickness of the plates, as Langberg has shown). One macle I have found to consist of five or six distinct plates, and the secondary curves produced by this are too complicated to be easily described.

I do not find any marked difference between the curves produced by the iridescent twins and those given by the ordinary macles. Many of the iridescent crystals show, when the plane of symmetry is either parallel or perpendicular to the plane of polarisation of the light (the analyser being crossed), a few broad, black, curved bands crossing the main black band lying in the plane of symmetry, which are probably portions of the isochromatic curves of a very thin plate. But, on the other hand, some non-iridescent crystals show these bands, and some iridescent crystals do not show them at all. Also the iridescent crystals which reflect D light at moderate incidences show very perfectly the circular band described by Prof. Stokes (NATURE for April 16, 1885, p. 566, par. 9) as sharp black crescents, the horns of which nearly touch each other at the plane of symmetry.

Almost the whole of the ordinary commercial crystallised potassium chlorate seems to consist of macles; so that, in order to get a single individual crystal for examination, I have always had to cut away one component of a twin.

It seemed worth while to try whether other biaxial crystals would, when similarly combined, give similar phenomena. I took a crystal of barite (barium sulphate), the angle included by the optic axes of which is, according to Groth, 63° in air, and cut a plate of it in such a direction that the plane containing the optic axes made an angle of 53° with the normal to the surfaces of the plate. I then cut it in half and cemented one of the portions upon the other in a reversed position. The compound plate thus produced shows the secondary ellipses (which, however, are very nearly circles) in great perfection. I have also made similar compound plates of borax, nitre, and citric acid, and found them to give similar results. H. G. MADAN

Eton College, August 24

The August Meteors

BETWEEN August 4 and 20, 174 shooting stars were recorded here in 16½ hours of observation. These included about 37 Perseids, chiefly seen on August 5, 8, and 13, but the shower was not well observed owing to cloudy weather. The following are the chief radiant points determined from the paths registered:—

No.	Epoch August	Radiant α °	δ °	Notes
1	16–20	5	+12	Meteors bright, max. Aug. 20.
2	13	51	+58	Perseids.
3	4–17	292	+52	Near χ Cygni.
4	5–13	296	±0	On equator near η Aquilæ.
5	5–20	317	+22	Meteors slow and faint.
6	8–17	318	−9	Slow, S.W. of β Aquarii.
7	15–17	328	+27	Slow, faint.
8	11–15	329	+8	Slow, bright, E. of ϵ Pegasi.
9	16–20	345	±0	Rather swift, bright.
10	8–20	345	+53	Very swift, short.
11	16–20	351	+38	Swift, E. of o Andromedæ.

Many other shower centres were less distinctly shown. Nos. 4 and 9 fall exactly on the equator, and were sharply defined.

As to the shower of Perseids on August 10, I believe it was more brilliant than usual, though I made no regular observations on that night this year in consequence of overcast sky. Many meteors were, however, noticed in the clear spaces which now and then occurred, and judging from the frequency of the apparitions the display was a fine one. As to the duration of the shower it was still visible, though very feebly, on August 20, for I registered 2 undoubted Perseids during a watch of 3¼ hours, when 31 meteors were recorded.

With regard to the minor displays of this epoch they are more remarkable for their number than for individual intensity. The most active of these radiants, as recently observed, was No. 10 at 345° + 53°, which supplied about 10 meteors, but the rate was less than one per hour, so that it cannot be ascribed much importance. W. F. DENNING

Bristol, August 25

Disinfection of Sewers

IN the last number of the *Lancet* (August 15, 1885) I have read of the measures taken by the Metropolitan Board of Works for the deodorising and disinfecting of London sewers. Between 30,000 to 40,000 tons of sodium manganate and from 10,000 to 12,000 tons of sulphuric acid are daily poured in the London sewers.

By what experiments has it been ascertained that the quantities of disinfectants used are sufficient, and how is it proved that the sewers have been properly disinfected?

I need not point out the difference between the deodorising and the disinfecting of sewage. The latter may be perfectly deodorised, and yet be quite adapted to favour the vegetation of bacteria.

The oxidising and deodorising action of sodium manganate cannot be sufficient to prevent bacterial life, unless when the salt is present in large quantities. Considering the enormous volume of London sewage, it is not to be believed that even such a vast amount of manganate as 40,000 tons *per diem* would suffice to destroy bacterial life in the sewers.

The adding of sulphuric acid to the manganate must certainly enhance the disinfecting action of the latter. Only, I do not understand why the quantity of sulphuric acid is relatively so small in comparison with the quantity of manganate. I do not see why manganate should be used at all when sulphuric acid, a more powerful and less costly disinfectant, can be used alone.

It is well known to all who occupy themselves with the cultivation and study of bacteria that these micro-organisms do not grow well in acid media, and that the addition of acids, especially of mineral acids, checks their growth completely.

It can be said that the antiseptic action of acids is of household knowledge, for vinegar is constantly used in the preservation of animal and vegetable products. That mineral acids have a greater disinfecting action than vegetable acids is also well known, unfortunately even by dealers in vinegar, who give durability to this condiment by the addition of a tiny proportion of sulphuric acid.

It is probable that pathogenic bacteria, even more than the bacteria of ordinary fermentations and of putrefaction, are in need of alkaline media, and therefore are more sensitive to the action of acids. In the animal body bacteria invade those fluids and tissues where the alkaline reaction prevails; and it is proved that the germs of disease are easily spread by milk, a liquid generally alkaline. Moreover, it has been proved by experiments on some pathogenic bacteria that gastric juice, although of so slight acidity, easily, and sometimes effectively, checks their development.

Sewage contains all the elements necessary for the nourishment of bacteria, and its alkaline reaction renders it very favourable to their growth and preservation. Disinfection means the destruction of existing bacteria and preventing the development of newly-sown bacterial germs. Therefore I am persuaded that the cheapest and more simple method for effectively disinfecting sewage is to render its reaction *permanently acid* by the addition of a sufficient quantity of mineral acid.

There are of course disinfectants far superior to mineral acids in antibacterial energy. But they are generally costly substances, that cannot be applied to the disinfection of such an enormous quantity of matter as the sewage of a town. As for cheap disinfectants, such as ferrous sulphate, ferric chloride, sodium manganate, their action is inferior to that of mineral acids. Especially of the two former it can be said that their deodorising action is due to their saline constitution, and their disinfecting action to their acid reaction.

The great difficulty in extensive disinfections is to ascertain if the disinfection has been complete—*i.e.* if the substance disinfected has been rendered unfit for the development and preservation of bacteria. Even laboratory experiments, to ascertain the *minimum* of disinfectants necessary for the destroying of bacteria, are not easily conclusive. But, in using acids, the disinfection can be considered complete when a permanent acid reaction is obtained.

I do not believe the quantities of sulphuric acid poured in the London sewers sufficient to give a permanent acid reaction to the sewage. Disinfection must be done completely, or not at all: there are no half measures in disinfection. Therefore I maintain that the London disinfection is useless, and the sewage remains likely to become the culture fluid of infectious germs, unless the sewage is rendered permanently acid. All the sodium manganate added to a sewage that remains alkaline, gets decomposed; the manganese precipitates as sulphide, or is deposited in combination or mixture with the organic sediment. The sewage will thus be cleared and deodorised for a while; but it still contains in solution all the elements necessary for the nourishment of Bacteria, and is still favourable to their growth and preservation. The disinfecting action of sodium manganate would avail only if large quantities of the salt remained dissolved in the sewage, over and above of the quantities decomposed in deodorising and clearing the putrid fluid.

It might be objected that, even if mineral acids stop the development of bacteria—a point that cannot be doubted—they may not kill the spores, thus permitting the germs of disease to escape. There are no experiments (of which I am aware) to answer this objection. But there is reason to believe that pathogenic germs do not resist for a very long time when in unfavourable media; even in sewers, that are not over-filled and stagnant, and that are well ventilated, infection does not easily linger. If inside the sewers disinfection is complete, and bacterial growth checked, and all disease germs rendered inactive, until carried for away from all populous centres, I think we can leave it to air, and to the other natural agents, to ultimately destroy the surviving germs, or completely alternate their pathogenic qualities.

Amongst the mineral acids, hydrochloric would, of course, be the cheapest. But I think sulphuric acid ought to be preferred, nitric acid being too costly and too corrosive. Sulphuric acid does not attack easily calcareous cements; and if the sewers have their walls well plastered, the action of a *slight excess* of sulphuric acid in the sewage would be very slight indeed. Cements, more resisting than plaster, could be prepared. Moreover, if some portions of teh sulphuric sewage get carried in the air, or are dried in the higher parts of the sewers, the germ-laden particles do not rid themselves of the acid by evaporation; on the contrary, the acid becomes more concentrated and active, and finally must disorganise and destroy the noxious germs. This is very important in preventing the effects of sewage air.

Since 1881 Prof. Beilstein of St. Petersburg (NATURE, vol. xxiii. p. 394), experimentally concluded that sulphuric acid is the best disinfectant, although he did not advise its use because of its corrosive action. Strange to say, Beilstein thought that, practically, aluminous sulphate was to be preferred to the free acid.

It is not only during the fear of cholera invasions, but at all times, that I would wish the sewage to be *slightly* acidified with sulphuric acid. Strict supervision should be maintained over all the sewers, to ascertain that the whole mass of flowing sewage is permanently acid. I am persuaded that this simple mode of disinfection would diminish considerably many infectious diseases.

During the cholera epidemic of 1884, in Naples, I did my best, in a series of letters I then published, to persuade the sanitary authorities of this mode of disinfection. But a strange confusion of ideas was then prevalent in Naples. Through the goodwill of Prof. Cantani, Member of the Sanitary Commission, some trials of the method I proposed were done, but not in a complete and systematic manner. Such experiments cannot be done easily in Naples, and the results cannot be conclusive until the system of sewers is in good working order. Indeed, in some parts of the soil of Naples it is difficult to know if there is more sewage inside or outside the sewers. It is no easy problem to disinfect and cleanse such an impure soil, and it is indeed to be wondered that the ravages of cholera were so limited in 1884.

My letters caused sulphuric acid to be used abundantly in the sewers and *pozzi neri* of Portici, Castellamare, Taranto, and, I believe, in other places; but this, like all other disinfections, was done under pressure of approaching cholera, and abandoned as soon as the danger passed, no observation being made to measure the influence of the sanitary method adopted on local infectious diseases. The defective system of sewers and of drainage in many Italian towns renders thorough disinfection scarcely possible, and prevents precision in testing any kind of disinfection.

In English towns sewers are generally well arranged, and often well ventilated; and vital statistics have taken sufficient development to permit the testing of sanitary reforms. When it is proved (and I think the proof can be easily given) that the present systems of sewage disinfection are not sufficient to prevent *entirely* bacterial development in the sewers, these systems cannot be considered good. I venture to hope that beneficial results would soon become evident if the sulphuric acid disinfection of sewage were thoroughly applied in English towns.

Portici, August 20 ITALO GIGLIOLI

Ozone at Sea

THE presence of this element in the atmosphere is alleged to be indicative of its healthiness, and it has been *investigated on land* frequently by observers with varying and uncertain results.

Records of its presence may be seen daily in the *Times*, furnished from the Observatory on Ben Nevis, but as yet little notice has been taken of its *prevalence at sea*, though it has been supposed to be more plentiful there than on land.

During a voyage around the United Kingdom on the s.s. *Ceylon* in August last, we entered into the investigation of its existence at sea, and used Moffatt's papers for the purpose, obtained from Negretti and Zambra. They were exposed in a perforated light wooden box, hung up in the open air on the deck of the ship in the shade, and noted and changed twice a day.

It was found most prevalent in *Cork Harbour* (4), less so in Bantry Bay (2) and Oban Harbour (2), and nearly absent in Kingstown Harbour (1) and Leith Roads (1).

In the open sea it was most shown in the *Irish Channel* (4) and off the Lands End (4); next in the North Seas (3) and in the English Channel (2), and least in the Irish seas (1) and western coasts of Scotland (1).

Ozone was found to be indicated in greater intensity during the prevalence of *westerly winds* in the English and Irish Channels, and Atlantic seas and Dutch seas, and less with *easterly* winds prevailing in the Irish seas, Firth of Forth, and west coasts of Scotland.

The *velocity* of the winds seemed also to create a higher manifestation, as was seen during the gale from the south-west in Cork Harbour and the fresh north-westerly breezes on the south coasts of Ireland and east coasts of England. None, however, of the observations approached those registered in the *Times* from Ben Nevis (8-9), which amounted to double those noticed in the seas around our coasts during the same period (August), supposing that the same papers and scale (Moffatt's) were used for both sets of observations.

Ozone was also found to exist in the *cabin of the ship* both day and night, but at a half intensity to that on the deck, due probably to the great difference in the movement of the air in the two places.

The degrees of manifestation of ozone at sea here shown by no means come up *to expectation* that it prevailed in all its potentiality on the ocean, but of course a whole year's observation would be required to enlighten the subject and furnish a comparison with that on the land.

Again, it may be possible that *altitude* may have something to do with its prevalence, more or less, as it appeared more on the top of Ben Nevis than on the level of the seas of the same coasts near it and at the same period of the year (August).

Should this idea be of any significance it might be as well to search for manifestations of ozone at the base as well as on the top of mountains, and if similar results followed to these here pointed out it would establish the *reputation of high* level sites for great salubrity of atmosphere. W. J. BLACK

August, 1885

THE INTERNATIONAL BOTANICAL AND HORTICULTURAL CONGRESS, ANTWERP, 1885

THE International Botanical and Horticultural Congress met at Antwerp on Sunday, August 2, in the hall of the Artistic, Literary and Scientific Club, the opening meeting being honoured by the presence of a good many ladies. The gathering was a representative one, and included many well-known European botanists and horticulturists. The Burgomaster of Antwerp opened the proceedings with a few appropriate remarks, and Prof. Ed. Morren, of Liége, having been made President of the Congress, took the chair, and a discussion was held on the flora of the Congo. After a short discussion the meeting adjourned to the Exhibition building, where the International Horticultural Show was being held, and which was formally opened at one o'clock. Many of the plants exhibited were of great interest, and the whole of the collections were nicely and artistically arranged. At five o'clock the Congress visited the Plantin Museum, the old printing office of the Plantin Moretus family. The Museum is full of interest, and as the printing office from which the works of Lobel, Dodonaeus, and Clusius issued, doubly interesting to all botanists. Through the kindness of the Burgomaster of Antwerp a sheet had been struck off for the members of the Congress, so that each was presented with a souvenir of the three great herbalists.

In the evening there was a concert in the garden of the Exhibition in honour of the members of the Congress.

During Monday, Tuesday, and Wednesday the two sections of the Congress—the Botanical and Horticultural—met in the Botanic Garden in the upper and lower halls of the Botanical Institute. The different subjects contained in the programme were duly discussed, and a resolution of Congress on the different points raised terminated each discussion. The method adopted at these meetings was one which might well be followed in other assemblies, and is one which reflects great credit on the President of the Organisation Committee, M. Charles de Bosschere. All the subjects to be discussed were treated of in longer or shorter papers, all of which were printed in the four fasciculi of the *Preliminary Reports* issued to the adherents of the Congress. In this way all the members had the subjects before them in a tangible form, and discussion was easy. Might not the British Association take a hint from this? Without giving up the method at present followed, let the British Association add to their work a discussion on one or two subjects of importance, papers by special men to be printed beforehand, so as to be in the possession of those who can discuss the subject at the meeting.

The subjects of discussion—twenty-two in number—were mostly of considerable botanical interest, others being purely horticultural, the question of the Congo being general. Perhaps the most important subjects were the discussions on botanical laboratories, on the amount of instruction in cryptogams to be given in different parts of the botanical course of study and the recent progress of botany in different countries. It is important to notice that the general opinion of the Congress was in favour of two kinds of botanical laboratories, those of instruction and those of research, and there can be no doubt that in every society research should be encouraged in every way and be the highest object of their organisation.

On the evening of August 3 the Burgomaster of Antwerp held a reception at the Hôtel de Ville, which was very largely attended by the members. On the evening of August 4 Dr. Henri Van Heurck, the Director of the Botanic Garden, gave a most interesting series of microscopical demonstrations in the meeting-room of the Botanical Section. The application of the electric light to microscopic work was shown, and nothing could exceed the perfection of the arrangement employed by Dr. Van Heurck. *Surirella gemma*, *Amphipleura pellucida*, and Noberts's 19th band were shown in a manner which left nothing to be desired; and in the case of Amphipleura, not only were the striæ shown as distinctly as one is accustomed to see them in *Navicula rhomboides*, but, by illumination through the object-glass, the striæ were distinctly resolved into beads; by oil-immersion lenses, of which, as of other object-glasses by all the best makers, Dr. Van Heurck possesses a remarkable series. The electric light employed is obtained by a bichromate battery (Trouvé's) and Dr. Helot's photophore. As the photophore works equally well with an accumulator, and where there is no difficulty in getting the accumulators charged, no better illumination can be got, and this I would strongly recommend to all microscopists. Altogether Dr. Van Heurck's demonstration will be remembered as one of the most interesting things connected with the Congress. On the evening of Wednesday there was a grand banquet, when the members spent a very pleasant evening together.

On Thursday morning the Congress left by train for Brussels. On arrival, the members went to the Natural History Museum, and were shown through the building by the Director, who kindly admitted the members of the Congress at an early hour. Next, the party proceeded to the Botanic Garden, where they were received by Prof. Crepin and others. The herbarium, museum, garden, and hot-houses were all inspected, and then the Members of the Congress were entertained in the orangery of the garden to a luncheon given by the Members of the Royal Botanic Society of Belgium. After luncheon the party proceeded by tramway to Laeken, to visit the Winter Garden, which had been opened to them by his Majesty the King of the Belgiums. Mr. Knight, the Inspector of the Royal Gardens, accompanied the party, and pointed out the objects of interest. Friday was to be devoted to an excursion to Ghent, and Saturday to a botanic excursion in the neighbourhood of Herrenthals, Dolen, and Gheel, where the Members of the Congress were to disperse. I left the party at Brussels, spending Friday at Liége with Prof. Morren, who showed me the splendid new laboratory in the pretty little garden under his charge. I afterwards visited Prof. Suringar at Leyden, and saw some of the treasures he has just brought back with him from the Dutch West Indian Islands, where he has been able to make extensive botanic collections of living and dried specimens. W. R. McNab

August 31

THE FAUNA OF THE SEA-SHORE[1]

THE marine fauna of the globe may conveniently, in the pursuit of certain lines of scientific study, be divided into three groups according to the regions inhabited by it. There is the littoral fauna comprising the animals inhabiting the sea-shore and the shallow waters in its immediate neighbourhood, the deep-sea fauna, and the pelagic fauna, the latter occupying the surface waters of the ocean. Each of these regions presents certain marked peculiarities of conditions of existence, and exhibits, in accordance with these, certain special characteristics in the composition and history of the origin of its fauna. The deep-sea is devoid of sunlight and therefore of plant life. It is dark, cold, and monotonous, being devoid of day and night and periodical or irregular changes of any kind. Its habitation probably dates from no very great antiquity. The ocean surface can support only a peculiar fauna of animals adapted for floating or constant swimming, and affords no shelters nor resting-places.

As Prof. Lovèn writes[2]: "The littoral region comprises the favoured zones of the sea, where light and shade, a genial temperature, currents changeable in power and direction, a rich vegetation spread over extensive areas, abundance of food, of prey to allure, of enemies to withstand or evade, represent an infinitude of agents competent to call into play the tendencies to vary which are embodied in each species and always ready, by modifying its parts, to respond to the influences of external conditions." It is in this littoral zone where the water is more than elsewhere favourable for respiration because of its aëration by the surf and where constant variation of conditions is produced by the alternation of the tides that the ancestors of all the main groups of the animal kingdom came into existence, and all the primary branches of the animal family tree first commenced to grow. It is here, probably, that the first attached and branching plants were developed, thus establishing a supply of food, and rendering possible the colonisation of the region by animals.

The animals inhabiting the littoral region are adapted in most various ways to withstand and endure the special physical conditions which they there encounter—the action of the surf, the retreat of the tides, the numerous enemies. Either they burrow deep in the sand, or cling tight to, or even bore into, the rocks, or develop hard shells or skeletons, or protect themselves by other modifications. Probably all hard shells and skeletons of marine invertebrata have thus originated in the littoral

[1] A Friday evening lecture at the Royal Institution, delivered January 23, 1885, by Prof. H. N. Moseley, F.R.S.

[2] "On Pourtalesia, a genus of Echinoidia." by Sven Lovèn. (Stockholm, 1883, p. 86.)

zone for purposes such as these. It is found that these hard structures tend to degenerate and disappear both in the pelagic and deep-sea regions.

It is a most remarkable fact that almost all these shore animals in their early development from the egg pass through free-swimming larval stages which are closely alike in form for very widely different zoological groups. As a familiar example may be taken the case of the common oyster. The egg of the oyster develops into a peculiar free-swimming larva known as a Trochosphere. It is globular in form and divided by a transverse band of cilia into a smaller anterior and larger posterior area. The mouth opens just behind the ciliated band. The larva swims actively by means of its cilia. After a time it develops a pair of shells, and becomes metamorphosed into an oyster, and attaches itself immovably by one of its shells to the sea-bottom. Its shells increase in size and thickness, and form a protection against its enemies. This same trochosphere larva is common to a very large number of Mollusca of all varieties and shapes in the adult condition, and an essentially similar trochosphere is common to a large number of annelids. It is most remarkable that there should be so close a resemblance between the larva of two adult forms so widely different in all respects as an oyster and a worm. An old explanation of such facts was that such actively-moving larvæ were contrivances for procuring the wide diffusion of sedentary or less active adult forms, which might thus be conceived as of later origin than the forms themselves. But if this were the case, it is inconceivable that having arisen from so widely different starting points, the larvæ should have attained so closely similar a structure. The only real explanation of the matter is that the common larval form represents a common ancestor, from which the various adult forms, in the existence of which it is now only a phase, diverged. There was thus a common freely-swimming ancestor of the annelids and mollusca, and it seems probable that the entire littoral fauna must have been derived originally in remote antiquity from small primitive and simply organised free-swimming ancestors. All evidence seems further to point to the conclusion that the primitive ancestors of all plants were also free-swimming. The free-swimming ancestral representatives of life no doubt partly inhabited the open sea, leading a pelagic existence, partly swarmed in sheltered bays and pools on the coasts, as the larvæ of the littoral animals do now. The free-swimming plants gradually produced attached descendants, which colonised the shores, and the animals, finding there a supply of food, gradually adapted themselves to the more complicated conditions of shore life. The late Prof. Balfour, in his far-famed work on "Embryology," in discussing the character of larvæ of the kind under consideration, spoke of them as possibly reproducing the characters of some ancestral forms "which may have existed when all marine animals were free swimming."[1]

A peculiar instance in which there can be but little doubt, is that of the common barnacles. These in the adult condition are firmly fixed to supports of various kinds, and withstand the most violent action of the surf. The common acorn barnacles cover the most exposed bare rocks of our coasts, where the waves are heaviest, and nothing else can live. They have developed the stoutest of shells to protect themselves. In the young larval condition, however, they are actively free-swimming larvæ of typical crustacean structure, evidently adapted for pelagic existence, and to be found in swarms at the sea-surface, actively engaged in it. They attach themselves, and become immovably adherent and sedentary, and invested by a shell. There can be no doubt in this case that the locomotive larva represents the ancestral form, for allied crustacea still exist in abundance as adults.

[1] F. M. Balfour, "Comparative Embryology," vol. ii. p. 305.

A most important instance is that of the Echinoderms, the adults of the various groups of which, the sea-urchins starfish, brittle stars, holothurians, and crinoids are most, widely different in form, and adapted in most various ways to shore life. Yet these all pass through free swimming larval stages which are most remarkably alike. Supposing the adult forms to have been antecedent, it is quite impossible that a series of larvæ could have been developed independently from starfish, echini, holothurians, and brittle stars, and have attained this remarkable coincidence of structure. This common larval form must represent the ancestral condition, the free-swimming pelagic ancestor from which the echinoderms have sprung.

The fixed and inert sponges are developed from free-swimming ciliated larvæ, and Prof. W. J. Sollas[1] has observed that the young larvæ of the sponge *Oscarella lobularis* are retained longer within the parent in the case of specimens occurring on the coast of Brittany than in that of specimens found in the Mediterranean. He attributes this difference to the influence of the quieter sea and absence of tides in the latter case. The larvæ have come to be longer retained where the risk of their loss by current and tide is greater. By the gradual action of similar influences, no doubt, the loss of larval stages in so many instances has come about. It is probable that there is a special tendency to such loss in the case of deep-sea animals. Hoek[2] has recorded the loss of the nauplius stage as a free-swimming one in the case of a deep-sea scapellum from a depth of 506 fathoms. One of the best examples of the special adaptation by modification of animals sprung from pelagic ancestors for littoral existence is that of the Madreporarian corals, the far-famed builders of reefs. Each coral colony is sprung from a locomotive planula larva, swimming by means of cilia. The larva attaches itself, and developes into a polyp, and acquires a hard skeleton, and by budding produces a large colonial stock. The massive stocks thus formed and strengthened form reefs which are barriers to the waves. They flourish in the water churned by themselves into surf, and thus specially aërated and fitted for their respiration, and between their branches and interstices they sift out the fine pelagic animals on which they feed from the surface water. Probably the advantages thus gained is the cause of their assumption of the colonial form and development of their stout and massive skeletons. Possibly this is the reason why scarcely any colonial Madreporaria occur in deep water, although other colonial animals are abundant in the depths.

The origin of the vertebrata is a complex question, but they are probably sprung from a very simple free-swimming ancestor, as is shown by the survival of a simple ciliated gastrula as an early stage in the developmental history of Amphioxus. An exactly similar developmental stage precedes the trochosphere form in the oyster, and the characteristic larvæ in the case of the echinoderms, and occurs as an early stage in a wide range of other forms. From this ciliated gastrula develops Amphioxus, one of the most interesting components of the fauna of the coasts, one of the most primitive of vertebrates now existing. The Ascidians, which are in the adult condition as inhabitants of the coasts, mere inert sacs, extreme instances of degeneration, are derived from free-swimming larvæ of pelagic habits which show distinct vertebrate structure and have myelonic eyes, which, as Prof. Lankester has pointed out, could only have originated in an animal of pelagic habits. The Ascidians, before reaching their vertebrate larva stage, pass through a gastrula stage like Amphioxus. It is possible, therefore, that their ancestors have twice taken from pelagic to littoral existence, having relinquished the shore for a period after their first experience of it, and returned to it again; whilst some of their close allies, such

[1] W. J. Sollas, *Quart. Journ. Micro. Sci.*, 1884, p. 612.
[2] Report on the Cirripedia. *Challenger* Report, Zoology, vol. viii. p. 75.

as Appendicularia, have never resought the shore, and consequently have never degenerated to qualify for littoral life. The peculiar breathing apparatus adopted by the vertebrata occurs nowhere else in the animal kingdom except in the extraordinary worm-like Balanoglossus. The apparatus, as is well known, consists of a series of slits, opening from the exterior at the sides of the fore part of the body directly into the throat, the anterior part of the digestive tract. The water to be respired is taken in at the mouth and ejected through the gill slits. The late researches of Mr. W. Bateson, of Cambridge, have shown that Balanoglossus, besides breathing by gill slits, shows many other remarkable affinities, both in structure and development, with the vertebrata. Now, Balanoglossus, a shore-inhabiting form which lives buried in the sand, is developed from a most remarkable larva known as Tornaria, which is intermediate in form between a Trochosphere and a star-fish larva. It is quite possible that this extraordinary larva Tornaria may point to the former existence of a primitive pelagic ancestor common to the Annelids, Echinodermata and Vertebrata. Possibly the use of gill slits as a respiratory apparatus first arose in a shore-inhabiting ancestral form, such as Balanoglossus, and hence their presence at the anterior extremity of the body, that nearest to the surface when the animal is concealed in the sand.

It appears not impossible that Amphioxus may once have possessed a larval stage somewhat resembling Tornaria, following on its gastrula stage, and has lost it just as one species of Balanoglossus has lost the Tornaria stage. The developmental history of only one species of Amphioxus is as yet known, and investigation of that of other species may yet reveal something of the kind suggested.

The littoral zone not only became itself stocked with an immense variety of specially adapted inhabitants, but has given off colonists to the three other faunal regions. The entire terrestrial fauna has sprung from colonists contributed by the littoral zone. Every terrestrial vertebrate, every frog, reptile, bird, and mammal, bears in its early stages of development the gill slits still perforating its throat as in its aquatic ancestor. The tadpole still uses them when young for breathing, though they close up completely in the adult frog and in all the higher vertebrates before birth. In some of the tailed Amphibia, like the Axolotl, the breathing is by external gills and also by lungs which are modifications of the air-bladder of fish. In these the gill slits remain open, although they have no longer any respiratory function. It is amusing to watch tame Axolotls when fed in aquariums with large worms. They snap the prey down hurriedly and close their mouths, but usually in a moment or two their throat begins to twitch uncomfortably as if intensely tickled, and one end of the worm appears out of one of the gill slits, and the worm soon wriggles its way out again. Often the Axolotl catches it again by the free end before the other is completely out of the gill slit, and begins another attempt to swallow it, and the process is sometimes repeated several times before actual deglutition is effected. The gill slits are evidently a considerable inconvenience to the Axolotl. The frog is much better off in having them closed, but man himself is not in a position entirely to despise the Axolotl: his lungs are derived from the same source originally, namely, modifications of the air-bladder of a remote aquatic ancestor, an inhabitant of the sea-coast, and they open into the throat just behind the tongue. In man there is a lid to close this opening and a contrivance to pull it under the tongue when swallowing takes place; but every one knows the agony entailed by getting a crumb the wrong way—an accident very much akin to that of the Axolotl, and similarly entailed by the use of a single passage for two different purposes—feeding and respiration. At such moments of suffering the naturalist is inclined to turn traitor and long that he had been produced in accordance with the hypothesis of special creation rather than evolved under the laws of natural selection. The existing arrangement must not be regarded as of inevitable necessity. The vertebrates are the only animals which breathe through their mouths. All other animals have separate passages for respiration and feeding. The common snail has a separate breathing passage completely apart from its mouth, the land crab breathes by openings at the bases of its legs, the scorpion by openings on its abdomen, and the insect by numerous apertures on the sides of its body. All these animals cannot, like man, choke themselves.

Only the pentadactyle vertebrata have adapted themselves completely for terrestrial respiration, but several fish have, by special modification of their gills, become able to remain out of water for almost indefinite periods. Most remarkable amongst these is Periophthalmus, one of the Gobiadæ inhabiting mud flats on the sea-shore in Australia, Ceylon. Fiji, and other eastern tropical regions. It hops along the mud with the greatest agility and so fast that it is most difficult to capture, and even refuses to take to the water when driven to it, skipping along its surface, and resting on projecting stones. It even climbs high up the mangrove trees and sits on the branches. All modes of air-breathing are derived by modification from aquatic breathing apparatus, except, perhaps, in the case of the air-breathing tracheata, the insects and their allies, in the ancestor of which, represented by Peripatus, the respiratory tubes or tracheæ were probably first formed as modifications of skin glands.

Littoral animals of most various kinds have taken from marine to terrestrial life no doubt by gradual adaptation, owing to exposure by the tides. Crustacea seem to have the greatest power of thus adapting themselves to aërial respiration by slight modification of their gill apparatus, so as to permit it to act as a lung. Nothing is more astonishing to the naturalist in tropical countries than to find large crabs amongst the vegetation far inland and high up mountains. But land crabs are not confined to the tropics; in Japan they may be met with walking across the high roads far inland, and 4000 feet above sea-level. One of the most remarkable instances is that of the cocoanut climbing crab, *Birgus latro*, which has developed, as Prof. Semper has shown, a regular pair of lungs out of the walls of its gill cavities. The animal was originally a hermit crab, but got too large for any shell, and thus developed hard plates on the surface of its body for protection instead. Close allies, but of much smaller size, swarm in some Pacific islands. They always bear shells, and carry them with them when they climb the trees and bushes. I have caught hold of the shell of one of them as it clung to the top of a branch, thinking that it was a land-mollusk, and have been astonished by receiving a sharp nip from a pair of claws.

The oldest-known air-breathing animals, so far as geological evidence goes, are scorpions and insects. An ally of the cockroach and two scorpions have lately been obtained from Silurian strata. The close affinities of the scorpions with the king crabs, and thus with the Trilobites, is a most interesting matter, which has lately been urged by Prof. Ray Lankester. He suggests that the lungs, by means of which the scorpions breathe air, are modifications of the gill plates of the king crab, which have become inverted for the purpose. The lung openings of Scorpio correspond with the gill plates of Limulus in position and number. Hence, possibly, the scorpions, and with them the rest of the Arachnida, are sprung from ancestral allies of the king crab and the Eurypterids, having passed from a littoral to a terrestrial existence.

It seems possible that birds were originally developed in connection with the sea-coast, and were fish-feeders. The tooth-bearing birds discovered by Prof. Marsh, such as Hesperornis and Ichthyornis, were marine aquatic birds. Hesperornis lived in a shallow tropical sea surrounding the present Rocky Mountains, then a group of islands. The modern penguins show some remarkable points of affinity to reptiles in the structure of their feet, and probably their embryonic development, when worked out, may throw much light on the past history of birds.

Some of the extinct Dinosauria which show remarkable affinities with birds were at least aquatic in habits.

The fauna of the coast has not only given origin to the terrestrial and freshwater faunas, it has throughout all time since life originated given additions to the pelagic fauna in return for having received from it its starting points. It has also received some of these pelagic forms back again to assume a fresh littoral existence. The terrestrial fauna has returned some forms to the shores, such as certain shore birds, seals, and the Polar bear; and some of these, such as the whales and a small oceanic insect, Halobates, have returned thence to pelagic life.

The deep-sea fauna has probably been formed almost entirely from the littoral, not in most remote antiquity, but only after food derived from the *débris* of the littoral and terrestrial faunas and floras became abundant in deep water. It was in the littoral region that all the primary branches of the zoological family tree were formed; all terrestrial and deep-sea forms have passed through a littoral phase, and amongst the representatives of the littoral fauna the recapitulative history, in the form of series of larval conditions, is most completely retained. It is for this reason that the researches carried on at marine laboratories on the coasts have yielded in the last few years such brilliant results.

BALLOON PHOTOGRAPHY[1]

RECENT experiments in photographic aërostation, carried out by M. Gaston Tissandier, with the assistance of M. Ducom, have been attended with very complete and satisfactory results. The photograph reproduced by heliogravure in Figs. 1 and 2 was taken at an altitude of 605 metres over Paris; others which were taken did not give such perfect results; nevertheless, some of them surpass in distinctness any yet taken by the same method. The ascent took place at Auteuil on June 19, M. Ducom attending specially to the photography, while M. Tissandier looked after the balloon. The photographic apparatus arranged in the car is shown in Fig. 3. The ascent took place at 1.40 p.m. with a south-west wind. Ten minutes after starting a first photograph was taken at 670 metres; soon afterwards another was taken at about the same height, in which a bridge, quay, public office, fifteen cabs, a tramway, and the people in the streets were clearly reproduced. At 605 metres the photograph here reproduced was obtained, but unfortunately heliogravure does not produce an exact *fac-simile* in the fineness of the details. The smaller plan (No. 2) shows the exact topography of the place. When the photograph itself is examined through a magnifying glass many details are discovered, such as the coils of a rope mooring a boat to the shore, the passers-by, &c. On the photograph, too, the chimneys may be counted forming a number of small black spots on the roofs. A picture of great clearness, but rather greyish, was taken a few minutes later at an altitude of 800 metres above the prison of La Roquette; and another at the moment of leaving Paris at 820 metres. Beyond the city two more

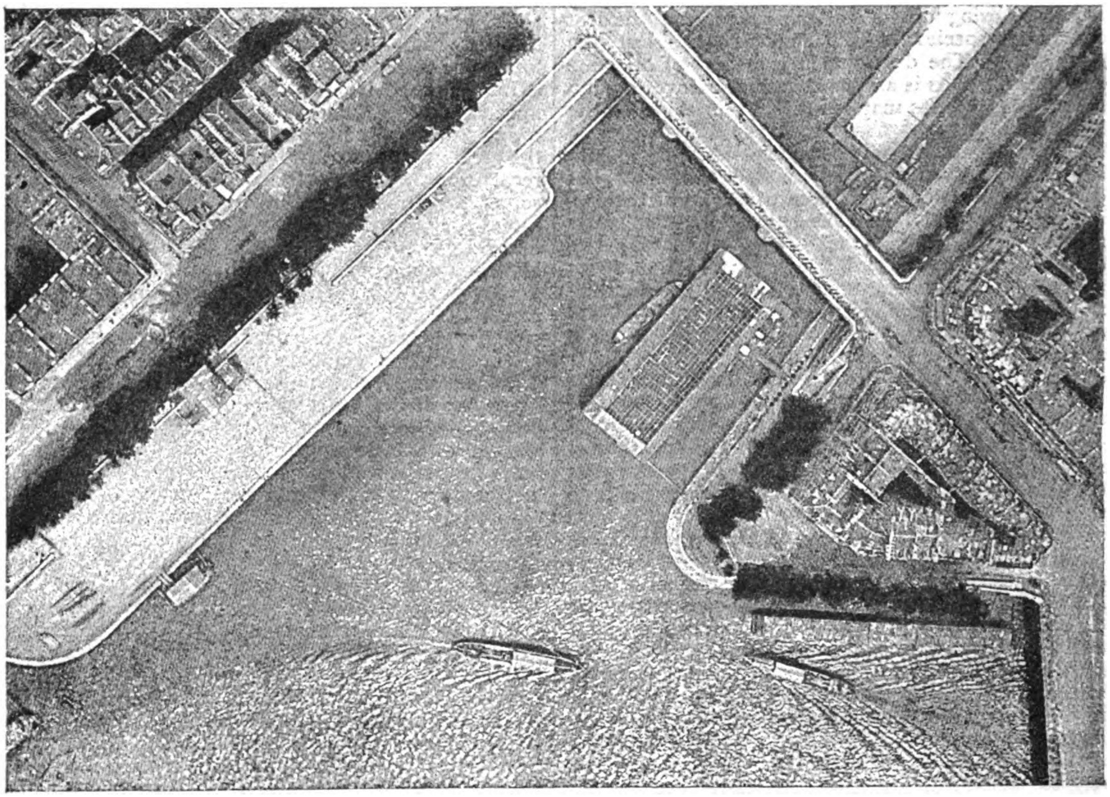

FIG. 1.—Reproduct'on by heliogravure of a pla:e taken at a height of 605 metres above Paris, showing the Seine, with two boats, Pont Louis-Philippe, gate of the Hôtel de Ville, &c.

[1] Abstract from *La Nature*.

photographs were taken at greater altitudes—one at 1000, and one at 1100 metres. Hence in crossing Paris, between 1.40 and 2.12, or in twenty-two minutes, five photographs were obtained. It would be easy to have two or three photographic apparatus with an operator in the car for each, and thus to obtain a series of views. By this method a series of topographical documents of incomparable precision might be obtained. Amongst the views taken during this ascent those which are perfect in point of clearness are those taken at the moment when the rays of the sun fell directly on Paris. Good light is absolutely indispensable, and, in spite of the photographs being instantaneous, the car should be kept perfectly free from oscillation at the moment the picture is being taken. The operator and occupants of the car must at that moment remain perfectly still. The movement of the balloon has no injurious effect on the clearness of the proofs obtained; in the present instance the current of air was somewhat rapid, for the balloon traversed Paris at its greatest width, 11 kilometres, in thirty-two minutes. The rapidity of the wind increased subsequently to much more than this. After taking photographs of the earth below, the apparatus was turned upwards to obtain views of the clouds; but the white clouds which reflect the rays of the sun with great intensity, did not give good results. The apparatus will require special arrangement for this work, and in their next expedition the aëronaut-photographers hope to obtain something more complete than they have done. Their experience on the whole is that photographs may be obtained in a balloon as beautiful and clear as the best produced on *terra firma*. Thanks to the instantaneous process, to the extra-sensitive plates produced to-day, and to other modern improvements, aërostatic photography has a great future. It will give plans which will exceed in precision and clearness the most pains-taking maps; it will be a powerful ally of military art, for it will admit of obtaining a reliable plan of fortresses or of hostile works. At a height of 600 metres a balloon has nothing to fear from artillery fire,

and the photographer can operate as safely in his car as in his studio. It will also add to the resources of photography, for there are no places on the earth's surface inaccessible to a balloon.

The ascent here described had for its main purpose photography; but it had also some meteorolcgical interest. The ascent began at 1.20; and at 3.20, at an altitude of 1100 metres above Meaux, another balloon, which ascended some time after them, was met with. They were actually in a frequented aëronautical route—an aërian river. At Meaux Nadar descended in 1863; M. Tissandier himself landed at the same place in 1872, and several other descents were made there. A little farther, at Château-Thierry, on a prolongation of the line from Paris to Meaux, M. Tissandier and M. de Fonvielle made an extraordinary descent in a storm in 1869, when they were dragged along the ground four kilometres in five minutes. They travelled from Paris to Château-Thierry, a distance of 80 kilometres as the crow flies, in 35 minutes—the most rapid balloon voyage on record. On the present ascent, at an altitude of 1000 to 1400 metres, an aërial current of considerable speed prevailed; it was estimated at about 40 kilometres an hour. At 1400 metres a mass of white translucid clouds stretched across the sky and floated in the upper part of the aërial current. Above this, again, the air was calm; small white clouds remained immovable at 2000 metres, and the sun was very hot. After having descended close to the earth above Château-Thierry, it was decided to rise above the clouds amongst which the aëronauts had just been. At 6 o'clock, at a height of 1900 metres, they observed the shadow of the balloon projected on a white ground of clouds; the latter formed a small greyish circle, surrounded by an aureole of the seven colours of the rainbow. When they approached the clouds, it was only the shadow of the car and of the lower part of the balloon of which the projection could be distinguished, and the aureole assumed a larger diameter. This remarkable and beautiful phenomenon resembles that of the spectre of the Brocken. At 6.10 the descent commenced; the balloon crossed the bank of clouds, and the surface of the earth, when it came in sight, looked grey and dull compared with the magnificent regions of the upper atmosphere.

RADIANT LIGHT AND HEAT[1]

III.

Radiation and Absorption—Terrestrial Applications.

HAVING now established the Theory of Exchanges, let us inquire at greater length into the nature of the radiation from bodies of different kinds. For this purpose we shall adopt the well-known classification into solids, liquids, and gases, and shall select as the type of a solid body (as far as radiation is concerned) a black substance like carbon. We must do this because, in order to obtain the greatest amount of radiation from such a body at a given temperature, it must be of sufficient depth to be practically opaque, or *athermanous*, for the heat of that temperature, and it must have a non-reflective surface. Now carbon or lamp-black possesses these properties, if not completely, yet to greater perfection than any other substance that we know of; and on this account we shall select it as the type of radiating solid bodies.

Then as regards liquids, we have no doubt an amount of surface-reflexion, which will have the effect of diminishing the radiation, and also of polarising it, to some extent. In this respect a liquid surface may be regarded as equivalent to a polished solid surface, so that liquids and polished solids may be classed together as giving out an amount of heat somewhat less than that given out by the typical black surface.

But while there is no marked distinction in radiation between solids and liquids, if only the depth of substance be sufficiently great, the radiation of gases is essentially different. This difference consists in the fact that while solids and liquids radiate all kinds of heat possible to the temperature, gases radiate only a few. We shall best perceive this distinction if we confine ourselves to rays which affect the eye, and view these by means of the spectroscope.

We have already explained how this instrument draws out a thread of white light into a parti-coloured ribbon, red at the one end and violet at the other. Now if our thread of white light be a thread of platinum, or, better still, of carbon rendered incandescent by means of electricity, we shall no doubt obtain the spectrum above mentioned. But if our source of light be a row of incandescent gaseous particles, we shall obtain something very different. Instead of a long, continuous, variously-coloured ribbon, we shall have a few discontinuous threads of light emerging from a dark background, each such thread or image having of course its proper spectral position; that is to say, if the gas gives out a yellow ray, this will appear in the yellow region of the spectrum; if a red ray, in the red region, and so on. Such spectra may either be thrown upon a screen, or viewed through a telescope—sometimes it is possible to throw them upon a screen and render them visible to a large audience, but sometimes this is not possible. In all cases, however, they may be thrown into a telescope and viewed by the individual observer.

We are thus in a position to formulate the distinguishing characteristic between the spectra of solids and liquids, and those of gases, the former giving out a continuous spectrum, consisting of all the rays of light possible to the temperature, while the latter give a discontinuous spectrum, consisting of a few bright lines on a dark background.

We can, in an imperfect manner, assign a reason for this behaviour. In a solid, or even a liquid, the various molecules are near together, so that no individual is free from the trammels of its neighbour in its vibrations. On the other hand, it is not so in a gas, or at least in a gas of which the molecules are very far from one another.

Here one individual is for the most part of its existence free from the trammels of its neighbours, and is able to vibrate after its own fashion and in a way to suit itself, just as freely as a bell, or the string of a musical instrument. It thus gives out, as it were, its own peculiar note, or series of notes, these notes being here, however, rays which have a definite place in the spectrum, instead of sounds which have a definite place in the musical scale. But whilst there is a great amount of freedom amongst the molecules of a gas, we must not carry this conception of things too far, or suppose that in a compound gas at ordinary temperatures we have nothing but a series of perfectly similar molecules practically independent of one another.

The particles or molecules of such a gas are far from being in a state of rest, and we may imagine them to be running about in straight paths, except when they are deflected by dashing against a neighbour, or against the sides of the containing vessel. It will thus be seen that the molecules are not quite free. In fact, a molecule perfectly remote from neighbours, travelling, for instance, in free space, and remote from the sun, would have no more inducement to vibrate than a bell would have under similar circumstances. It is the collision with its fellows that will generally cause it to vibrate, but it is sufficiently independent to vibrate according to its own laws. Indeed, we are in a position to assert that a great portion of that energy which constitutes ordinary heat in a gas is derived from this motion of the molecules in straight lines, while, again, the radiation of the gas is caused by the vibrations of the molecules after they have been in collision with one another, or with the sides of the containing vessel.

[1] Continued from page 399.

Now in a compound gas these collisions sometimes cause dissociation of the compound molecule into more elementary constituents, which constituents will probably afterwards combine again, so that we may imagine that in such a gas (see "Heat," by Prof. Tait, page 203) equilibrium is maintained by a constant amount of dissociation, accompanied by an equal amount of recombination. It is thus apparent that we have not here perfect simplicity and uniformity of molecular structure, and without discussing the question whether a simple molecule might or might not be expected to vibrate in only one way, we can readily imagine that the spectrum of such a gas should present us with more than one mode of vibration; that is to say, more than one spectral line.

Again, circumstances which conduce to proximity of molecules, and to the action of molecules upon each other, tend to bring about a state of things similar to that which we have in liquids and solids; that is to say, they will favour the emission of various kinds of rays, while on the other hand, the characteristics of a gaseous spectrum will be best shown by a perfect gas, that is to say, by a gas which is far removed from any tendency to condensation. A rare gas at a high temperature will possess these properties.

Having now defined the characteristics of the spectra of solids, liquids, and gases, let me say a few words about the methods by which we obtain gaseous particles heated to a high temperature. These are obtained in two ways. First, by means of flames, such as that of a Bunsen's burner, into which the particles are introduced. In such flames we may imagine that we have before us a certain number of the particles of a certain gas all, or nearly all, heated to a temperature somewhat approaching that of the flame. The substance will probably have been introduced into the flame in a different chemical state from that in which it appears in giving out the light; for instance, we may introduce into a spirit-lamp a little chloride of sodium, or into a Bunsen's burner a little bicarbonate of soda. The flame becomes immediately of a yellow nature, giving us the double line D, or the yellow line of incandescent sodium vapour, and this affords us evidence that dissociation has taken place. In like manner the red line produced by salts of Lithium, the green line produced by those of Thallium, and so on, are indications that the compound saline molecules have become dissociated in the flame.

The second way of producing gaseous spectra is by an application of electricity, as when a high tension spark is sent through a tube containing a small quantity of a given gas, or a vacuum tube, as this is sometimes called. We have then a momentary flash, consisting of the rays which characterise the spectrum of the gas through which the discharge has passed. It is probable that in this case only a portion of the particles filling the tube have been brought to the high temperature which is denoted by the discharge.

Before proceeding further, it may be well to mention that while from the title of our subject we must necessarily consider the spectrum to some extent, yet this is not to be regarded as a treatise on the spectroscope and its applications, which formed the subject of a previous set of essays in the NATURE Series by Mr. Lockyer. We shall discuss the subject in a somewhat different manner, and also give more especial attention to those branches which had not yet been developed when Mr. Lockyer wrote his work. With these preliminary remarks, we shall divide the subject before us into two sections.

(1) Radiation and its consequences.

(2) Absorption and its consequences.

In the first we shall discuss radiant spectra to a considerable extent, but shall not entirely confine our remarks to these phenomena; while in the second we shall discuss absorption spectra to a considerable extent, but shall not entirely confine ourselves to spectral absorption.

There is likewise another convenient way of dividing our subject, namely, in its application to terrestrial and celestial phenomena.

Combining, therefore, these two principles of subdivision, we shall, in the first place, treat of terrestrial applications of the laws of radiation and absorption, and in the next place of their celestial applications; and, finally, we shall discuss the light which both of these branches together appear to throw upon the ultimate constitution of matter.

With regard to our own Earth, it is abundantly evident that the great bulk of the heat which it receives is from the radiation of the sun, while, on the other hand, the great bulk of the heat which it loses is through radiation into space.

There is a sort of balance kept up between the gain on the one hand and the loss on the other, in virtue of which we are placed under conditions in which life is endurable, and for the most part pleasant. The variations in these conditions in temperate latitudes may sometimes cause distress to the weak, but they are not less the source of enjoyment and vigour to the strong; and, as a matter of fact, the most energetic races of mankind are they which dwell in those favoured regions that are neither too cold nor too hot.

Inasmuch as the regions near the equator are hotter than those near the poles, it follows that there is greater radiation into space from the former of these than from the latter. If, therefore, we could imagine an observer to be placed many thousand miles above the earth, having an eye capable of distinguishing dark rays, and to regard that portion of the earth unilluminated by the sun, his eye would receive more rays from the equatorial than from the polar regions.

On the other hand, the polar regions being manifestly colder than those of the equator, we have convection currents of hot air passing in the upper atmospheric regions from the equator to the poles, and currents of cold air passing in the lower atmospheric regions from the poles to the equator. These latter are known as the Trade Winds, and the former as the Anti-Trades. In like manner we have in all probability currents of hot water passing in the upper oceanic regions from the equator to the poles, and currents of cold water passing in the lower oceanic regions from the poles to the equator. It is not, however, our object to dwell on these phenomena here; suffice it to say, that our well-being depends on the balance between the radiant heat which we receive from the sun and that which we give out into empty space.

The phenomena of dew form an exceedingly good illustration of the laws of radiation. This subject was first investigated by Dr. Wells, an English physician. When the sun has sunk beneath the horizon of any place, bodies of small mass and great radiating power for dark heat, such as the leaves of plants, become quickly cooled by their uncompensated radiation into space. They thus cool the air around them, until this air becomes so cold that it can no longer retain in the viewless state the aqueous vapour which it holds; part of this is consequently deposited in the form of dew, or of hoar-frost, if the temperature be sufficiently low.

The following are the laws which regulate the deposition of dew:—

(1) Dew is most copiously deposited under a clear sky.

(2) And with a calm state of the atmosphere.

(3) It is most copiously deposited on those substances which have a clear view of the sky.

(4) And which are good radiators and of small mass.

(5) And which are placed close to the earth.

The first of these conditions is essential, because the cooling which precedes the deposition of dew is owing to radiation into free space.

If there are clouds, these will radiate back to the body, and thus prevent it from cooling fast enough. We see, likewise, the necessity for a calm atmosphere, when we reflect that dew can only be deposited by means of the body cooling the air around it; now if this air is constantly renewed, it cannot cool this large body of air to any great extent, and hence dew cannot be formed.

It is very manifest why the body must have a clear view of the sky, and why it must be a good radiator in order to promote the deposition of dew. Also why it must not be of a great mass, for, if it were, the heat from the interior might be conducted to the surface, and thus keep up the temperature.

Finally, the substance must be near the earth, for, if not, the cooled air will fall down, giving place to warmer air. The body will thus have a larger mass of air to cool, and it will less easily succeed in bringing this mass below the dew point. I shall return to this subject at a later stage, when the part played by the aqueous vapour of the air is taken into account. Let me here state that there are regions in the earth where dew forms an important factor in agricultural operations.

The artificial warming of our rooms is at present accomplished very much by radiation. An ordinary fire of coal or wood acts by this process. The heated carbonic acid gas which is the product of the combustion is carried up the chimney and out into the air, so that all that remains to heat the room is the light and heat given out by the glowing fire.

It is by no means an economical use of heat, but there are other considerations besides those derived from economy, and an open fire will always be cherished by those nations whose social life is greatly within doors.

The burning of gas in order to obtain illumination has nothing to recommend it. As it is used at present, it gives out a great deal of heat compared to its light, as well as a quantity of carbonic acid, and other products still more deleterious.

It ought to be replaced by some kind of electric light, such as that proposed by Swan, where a thread of carbon is kept at a high temperature in a glass vacuum by means of an electric current. There the luminous effect is very large in comparison with the heat produced, besides which there is no foul air or other hurtful product.

If we regard radiation as a means of increasing our knowledge, apart altogether from its primary and indispensable action in rendering us acquainted by means of vision with the objects around us, we cannot have a better instance than that which is given us in spectrum analysis. Here, in the first place, a little reflection will convince us that we can gain hardly any knowlege by this means of the nature of a luminous solid or liquid body, for all such bodies at the same temperature will give out all the various rays which are possible to that temperature. There is, therefore, no means afforded us by their spectra of distinguishing one from another, so that spectrum analysis is here impossible.

It is very different, however, when we come to gases which give out spectra consisting of bright lines in a dark background. Here there are various laws which combine not only to make spectrum analysis possible, but to constitute it an extremely delicate instrument of research. *In the first place*, we have the law that the lines given out by any one elementary vapour are different in spectral position from those given out by any other. *Secondly*, as a rule such bright lines remain in their places throughout a great temperature range. *Thirdly*, an exceedingly small amount of the element in question is generally sufficient to produce the lines.

It is stated that by means of the spectroscope the presence of less than one two-hundred-millionth part $\left(\frac{1}{200,000,000}\right)$ of a grain of sodium may be detected. Indeed, the difficulty is to get rid of the sodium line in an insular climate like ours, surrounded by sea-water which contains chloride of sodium.

There are three chief points for consideration in the study of gaseous spectra:—

(1) The effect produced by increasing the pressure of the gas.

(2) The effect produced by giving the gas a motion to or from the observer.

(3) The effect produced by increasing the temperature of the gas.

The effect produced by increase of pressure consists in a widening of the bright lines. This subject was first studied by Frankland and Lockyer, who found that all lines are not affected by pressure to nearly the same extent. The F line produced by incandescent hydrogen was found by them to be peculiarly subject to an increase of pressure, widening out in certain cases to a really remarkable extent.

Lockyer, who has since greatly studied this subject, is of opinion that it is not *pressure per se* that is influential in thickening the lines, but rather *the frequency of encounters of precisely similar molecules*. An important application of this law of pressure has been made by Lockyer, who has for this purpose used the electric arc, placing the slit of his spectroscope so as to embrace a section of this arc mid-way between its terminals and at right angles to its length. Now in the heart or central axis of this arc the gaseous particles which give out the light may be supposed to be somewhat near together, whereas at the border or circumference they are comparatively far apart. When the spectrum of such a transverse section is taken, this is found to consist of a number of bright lines, some long and some short. The long lines are those which remain visible even when the particles are far apart, while the short lines are those which require a greater nearness of particles to come out, and are therefore confined to the central regions of the arc.

Suppose now that we take the spectrum of such an arc, from terminals composed of absolutely pure iron, and that by this means we obtain a number of long and short lines, characterising the spectrum of this metal in the state of vapour.

Suppose next that we obtain the spectrum of some other metal, such as copper, which is not chemically pure, but which, we suspect, contains a little iron. We shall obtain, of course, the copper lines well defined and intense, *plus* an indication of the iron lines; but inasmuch as the iron particles are here few and far between, the iron lines which make their appearance will be those which do not require great nearness of particles in order to come out—in other words, they will be the long iron lines, and not the short ones. In searching spectroscopically for an impurity it is thus only necessary to direct our attention to the long lines of the various metals which we suspect to be present. Thus the whole process of comparison is made much simpler, and we are enabled likewise to obtain with comparative ease the true spectra of the various elements.

Let me now say a few words about the effect produced by a motion of the radiating gas to or from the observer. Suppose that a tram car starts from a station every five minutes in a certain direction, and that we are walking briskly *towards* this station, we shall meet the cars oftener than every five minutes. On the other hand, if we are walking briskly *from* the station, they will overtake us less frequently than every five minutes. Suppose, again, that the whistle of a locomotive engine strikes the air 1,000 times every second, then if the locomotive be at rest, we know from the theory of sound that the one blow will have advanced about 13 inches before the next is delivered to the air.

If, however, the locomotive engine be itself travelling in this direction, it is evident that the interval between the blows will be less, for the engine may have itself advanced one inch during the time that the last blow has advanced 13 inches, and thus the distance between the two blows will be 12 inches, or one foot. If, therefore, an observer be standing on a railway platform and a railway engine be advancing at full speed whistling as it comes, the interval between the blows will be less than usual, or the note will be shriller than if the engine were at rest. On the other hand, when it has passed the station and is rapidly receding from the observer, the interval will be greater than usual, and the note less shrill.

It is precisely the same with regard to light. If a luminous body emitting rays of definite wave length be moving towards the observer, the wave length will be lessened and the ray pushed forwards to the more refrangible side of the spectrum. If, on the other hand, it be moving from the observer, the wave length will be increased, and the ray pushed backwards to the less refrangible side of the spectrum.

The only difference between light and sound is that the former moves so fast, that in order to get an appreciable alteration in wave length we must have a luminous body moving from or towards us with velocities much greater than we can produce experimentally, whereas in the case of sound we can make the experiment.

Nevertheless if we go to the surface of the sun, or to the fixed stars, we shall find luminous objects moving from or towards us with velocities sufficiently great to suit our purpose.

Let me now say a few words on the effect produced on some gaseous spectra by increasing the temperature of the gas. It is quite certain that at comparatively low temperatures such spectra are more complicated than they are when the temperature is high. In the former case they frequently present a fluted appearance, while in the latter we have spectra composed of a few bright lines on a dark background.

In some cases an increase of temperature entirely changes the character of the spectrum, so that certain so-called elementary substances may be said to have two or more spectra. In general, however, we have, notwithstanding these remarks, the great feature already mentioned of a persistence of the more permanent spectral lines, more especially in the case of metals, throughout a large temperature range.

By means of spectrum analysis we have discovered the existence of several new elementary metals, all of which are very sparingly distributed.

Bunsen was the first to detect two new elementary metals, cœsium and rubidium. Shortly afterwards Crookes discovered thallium, Messrs. Reich and Richter indium, and other elementary metals have since been discovered by the same means.

It is now time that something should be said about the phenomena of absorption. Since gases have small radiating powers, they may naturally be supposed to have small powers of absorption. We know, for instance, how feeble is the absorption of pure air for luminous rays, or even for ordinary heat rays. Tyndall has studied the absorptive power of gases for low temperature heat, and has come to some very interesting conclusions. The following table embodies the results of his experiments:—

Comparative absorption of various gases, each of the pressure of 1 inch.

Air	1	Nitric oxide	1590
Oxygen	1	Nitrous oxide	1860
Nitrogen	1	Sulphide of hydrogen	2100
Hydrogen	1	Ammonia	7260
Chlorine	60	Olefiant gas	7950
Bromine	160	Sulphurous acid	8800
Hydrobromic acid	1005		
Carbonic oxide	750		

By this we learn that the absorptive power of the three permanent simple gases for dark heat is very small, while that of compound gases is very considerable. Tyndall imagines that the molecule of a compound gas may be more inert and less nimble in its vibrations than that of a simple gas. That is to say, the compound molecule will vibrate more slowly than the simple one, and will thus give rise to rays of great wave length; and inasmuch as its absorption and radiation are connected together, it will be peculiarly liable to absorb rays of great wave length.

Its absorption for dark heat may therefore be very great, even although it may appear perfectly transparent for ordinary light rays.

Tyndall has found, as the result of his inquiries, that aqueous vapour absorbs many more dark rays than dry air, and justly concludes that the aqueous vapour present in the atmosphere plays a very important part in terrestrial economy. Being transparent for rays of high temperature it stops but a small proportion of those which come to us from the sun; on the other hand, being comparatively opaque for rays of low temperature, it stops the radiation into space from the surface of the earth. To speak more accurately, it does not absolutely prevent this radiation, but absorbs it and returns as much or nearly as much again. Its action, in fine, is virtually the same as that of a cloud in preventing the refrigeration which accompanies dew. Tyndall remarks that in those regions where the air is very dry the nights are often intolerably cold, owing to this uncompensated radiation into space.

Such regions are those in Central Asia and the great African desert, in the latter of which water can readily be frozen after the sun has sunk. The glass of a greenhouse acts in the same way as the aqueous vapour of the air. It allows the sun's rays freely to penetrate and to heat the air within; but it stops the dark heat of the plants and of the soil from being radiated outwards into free space. Even a loose frame of glass may save the tender blossoms of the peach, and other wall fruit, from being destroyed by nocturnal refrigeration.

BALFOUR STEWART

(*To be continued.*)

NOTES

ON Monday Prof. Michel Eugene Chevreul entered upon his 100th year. Apart from the fact that among men whose lives have been devoted to active scientific research no one has before attained such an age, M. Chevreul stands conspicuous for the vast amount of work he has done and for the great practical effect his work has had on the industries of the world. When Dumas in 1852 addressed M. Chevreul on the occasion of handing to him the *prix* of 12,000 francs accorded to him by the Société d'Encouragement pour l'Industrie Nationale, he said:—"Le prix consacre l'opinion de l'Europe sur des travaux servent de modèle à tous les chimistes; c'est par centaines des millions qu'il faudrait nombrer les produits qu'on doit à vos découvertes." More recently, in 1873, when the award of the Albert medal was made by our Society of Arts, the terms in which the Council expressed the grounds of the award were:—"For his chemical researches, especially in reference to saponification, dyeing, agriculture, and natural history, which for more than half a century have exercised a wide influence on the industrial arts of the world." His scientific work, apart from its commercial outcome, was in this country recognised by the Royal Society as far back as 1826, when he was elected a foreign associate. In 1857 the Copley medal was awarded to him. Other countries have also paid him honour, while the distinctions of his native land have showered upon him. Born in Angers in 1786 (on August 31), where his father was a physician of note, he was but seventeen when he went to Paris to be "manipulateur" in the laboratory of the celebrated Vanquelin. At the age of twenty he published his first chemical paper, and in the next half dozen years he had published more than a score on different subjects. Then began that series of papers (commencing in 1813), "Recherches chimiques sur plusieurs corps gras, et particulièrement sur leurs combinasions avec les alcalis," which extended for many years and were compiled and rearranged in the volume "Les corps gras," issued in 1823 with the dedication "à Nicolas-Louis Vanquelin, mon maître." In 1824 he was appointed Professor of Chemistry at the famed factory of Gobelins, and the energy and untiring industry which was one characteristic of his work soon accumulated stores of knowledge based on experiment. To exact experiment he attached the highest importance. He wrote in 1823 "experiment is not chemistry, facts alone do not constitute that science, but we cannot have discoveries without exact experiment." His "Recherches sur la Teinture" is an elaborate work, and his "Moyen de définer et nommer les couleurs" occupies the whole of vol. xxxiii. of the *Memoirs* of the Institut. It has often been remarked that it is difficult to believe that the Chevreul of "Corps gras" fame and the Chevreul who wrote on colours are one and the same man.

WE regret to have to announce the death, on August 27, of Lieut. L. Brault, of the French navy, who had charge of the Meteorological Service at the Depôt des Cartes et Plans, Paris. M. Brault was the author of several important meteorological works, among which may be specially mentioned one on the circulation of the atmosphere in the North Atlantic and a treatise on astronomy and nautical meteorology. But the great work to which he devoted the larger part of his energy was the preparation and publication of wind charts for the Atlantic, Indian, and Pacific Oceans, a work begun in 1869 and finished in 1880. It consisted of sixteen large charts giving for each *quarter*, and for squares of 5°, the probable direction and force of wind over those oceans. At the time of his death he was employed in the extraction and tabulation of observations from ships' logs, with the view of publishing *monthly* charts of various elements as soon as he had collected sufficient data. It is sad to see so able a man cut off in the midst of such useful work.

MR. GEORGE FREDERICK ARMSTRONG, M.A., F.G.S., C.E., some time Professor of Engineering in the M'Gill University, Montreal, and in the Yorkshire College, Leeds, has been appointed to the Regius Professorship of Engineering in the University of Edinburgh, vacant by the death of Mr. Fleeming Jenkin, LL.D., F.R.S.

THE Queen has been graciously pleased to confer the distinction of Knight Commander of St. Michael and St. George on Mr. John Fowler, C.E.

WE regret to learn that Mr. Trelawney Saunders has retired from the post of geographical assistant to the India Office, a position which he has held with credit to himself and advantage to the public service for the period of seventeen years.

PROF. CALLADON, of Geneva, writes a correspondent to the *Times*, has communicated to the local press a description of a remarkable atmospheric phenomenon which was noticed on August 6. Until after five o'clock p.m. the sky had been calm and serene over all the valley of the Leman, but at half-past five, albeit the atmosphere above the lake and neighbouring mountain remained remarkably still, vapours were seen at a great height (evidently produced by a strong and warm south-west wind in the upper air) advancing rapidly towards the north-east, and taking the undulatory forms which characterise clouds strongly charged with electricity. At half-past eight the aspect of the sky had become decidedly stormy. The thick cloud-masses were oscillated wildly, albeit their general movement was still from south-west to north-east. After nine o'clock these clouds, drawing away, rendered visible the sheet of cirrus which stretched above them. The cirrus was phosphorescent, and looked as if lighted up by a bright moon. On the north-western horizon the sky along all the chain of the Jura was obscured by thick clouds that from time to time were illuminated by flashes of lightning. It was the same over Mont Galène, above which the lightning played every few minutes. A long black cloud stretching from the Dôle to the Galène presented on each side a broad phosphorescent border, and about a quarter past nine there became suddenly visible in that part of the cloud nearest the Jura a luminous centre whence escaped two or three phosphorescent rays pointing towards the south-west. This phenomenon lasted some twenty minutes, and was sufficiently striking to be remarked by many observers. From a quarter past nine to eleven o'clock, moreover, the south-western extremity of Mont Galène was illuminated by a phosphorescent light so intense that its rays were visible from every part of the horizon. The general appearance of this south-west section of the Galène resembled that which is presented by the city of Geneva in thick weather when the mists of evening are lighted up by the gas of the streets. Some rare instances are on record of forests of resinous trees becoming phosphorescent in stormy weather, but the distance from Geneva was too great to enable observers to determine whether the light resulted from the phosphorescence of the fir trees which cover the sides of the Galène or from that of other parts of the mountain. The Central Meteorological Bureau publishes, about eight o'clock every morning daily, accounts of the general condition of the atmosphere throughout Europe, and special reports from twelve stations in Switzerland at eight o'clock a.m. and one o'clock p.m. These reports are received at Geneva on the following day, and those of August 5 and 6 show that on the dates in question there took place a complete change in the atmospheric equilibrium of western Europe, and that the high pressures which for several weeks previously had prevailed over England and the Channel suddenly ceased and gave place to warm, vapour-charged winds from the south-west.

IF original scientific work has been poured forth principally from the old settled countries of Western Europe, it is not a small labour which America seems to be undertaking to thoroughly collect and arrange in available order, not indeed the knowledge, but even the confused heaps of publications from which such knowledge may be painfully extracted. Another valuable catalogue compiled by Dr. H. C. Bolton appears as one of the valuable publications of the Smithsonian Institution. With the unexplained exception of medical science, it contains a list of all the scientific and technical periodicals published in Europe or America since the rise of this literature. It does not include the *Proceedings* and *Transactions* of Societies already indexed in Mr. S. H. Scudder's Catalogue of Scientific Serials, published in 1879. As this latter did not contain the titles of technical journals, the two publications are complementary, and together make up a most valuable list to any seeking information; a large proportion of papers, however, neither technical nor Societies' Proceedings, being, of course, found in both. The many large libraries open to the public which form such an item in the wealth of the United States have much assisted in this work, and a list most useful to a student is appended, showing in which of more than 120 of them each publication is to be found. A table, in chronological order, commencing with 1728, is also given, showing during which years each of 500 publications was carried on, and this is provided also with an index by which the place of each in the list may be found. Another index of subjects referring the reader to the principal publications in which each is treated adds greatly to the practical value of the whole work.

DR. JOSIAH PARSONS COOKE has just published a volume entitled "Scientific Culture and other Essays." *Science*, in referring to the volume, says that the most important statements which are made in these essays are quite independent of the subject-title. They should be printed after the manner of certain biblical texts, and displayed on the walls of every collegiate hall in the land. We append a few of these paragraphs:—"There is no nobler service than the life of a true teacher; but the mere taskmaster has no right to the teacher's name, and can never attain the teacher's reward" (p. 85). "The teaching which a professorship implies, instead of being a hindrance, ought to be a great stimulus to scientific investigation. Of course this influence is greatly impaired, if, as in many of our colleges, the available energies of the teacher are exhausted by the daily routine of instruction, or by outside work required to supplement his meagre salary; but if the teaching is only moderate in amount, and in the direction of the professor's own work, there is no stimulus so great as that which the association with a class of earnest students supplies" (p. 280). "Men of affairs should resign the endowments intended for the maintenance of scholars to those whose zeal is sufficient to induce them to make gladly the sacrifices which the advancement of knowledge usually entails" (p. 277).

MR. EDWARD SAUNDERS writes as follows to the September number of the *Entomologist's Monthly Magazine*, under date August 6, on the subject of "Dead Humble-bees under Lime Trees." Dead humble bees, more or less mutilated, have often been observed in large numbers under lime trees, and various suggestions have been offered to account for their presence in such a position. Some observations which I was able to make the other day suggest the probable reason for the death and evisceration of such bees, and, therefore, may be worth recording. While walking on Hayes Common, Kent, on the 3rd of this month, I noticed, under a large spreading lime tree, in full flower, that the ground was strewn with bodies of humble-bees of several species; I and one of my children picked up a number of them, and found several still moving their legs, and evidently only quite recently mutilated, nearly every specimen appearing to have been killed in the same manner, having a large hole in the upper surface of the thorax, and another at the apex of the abdomen, the apical segments being removed; thinking that it would be a good opportunity to try and find out who or what was the cause of their death, I sat down close to the tree and watched. The tree was covered with bloom, and hive-bees and humble-bees abounded, but I could not see any wasps, so I at once abandoned the idea that they were the culprits, as some have thought probable; everything seemed peaceable, and for some time I could see no possible enemy to suspect. At last, I saw among the higher branches a bird, and from the exact spot where it was fidgeting about down dropped a carcase of a bee. I at once picked it up, and found the legs still twitching convulsively; although I did not actually see the bird drop the bee, I think there can be little doubt that it did. I went back again, and sat down to try and discover what bird it was, and after a little time a bird, which was in all probability the same, although I had lost sight of it while examining the bee, came out into a less leafy part of the tree, and I was able to identify it as a great tom-tit; and although I have no positive evidence whereby to convict *Parus major*, I think the probabilities of his being the culprit are so strong, that it is hardly necessary to seek further for the murderer of these humble innocents.

ADVICES received by the last mail from Iceland state that the weather in the island during the summer has, in common with everywhere else in North Europe, been very cold and stormy. Even in the middle of July night-frosts occurred frequently in the higher-lying districts, and sometimes also by the coast. The grazings have suffered greatly in consequence of the weather, being in many places in a miserable state. During June and July severe storms devastated the island, killing the sheep in many places, notably in the Westfjord. The fishing has been fairly good in some places where the herring have been plentiful this summer. The fish was fat and in excellent condition.

ON the west coast of Norway, too, very unusual weather has been experienced this summer, snow having fallen in several places, whilst night-frosts have injured the crops. Tourists from the interior state that they never have experienced so backward a season in that part. The cold weather is being ascribed to the enormous ice-masses which have descended from the Polar regions into the Gulf Stream in the spring, and the large quantity of drift ice in motion to the north and north-east of Norway.

INTELLIGENCE received from North and Central Sweden states that the migratory birds are already leaving in large numbers. Between August 16 and 18 thousands of wildfowl were seen passing over Stockholm, their progress lasting for hours at the time. During the night, too, their calls were heard. That the birds have previously left their summer haunts so early is unknown.

A QUICK change of temperature arrived on the U.S. Atlantic coast on the afternoon of August 25, the mercury falling 40°. A hurricane along the Florida and Caroline coasts accompanied it, causing serious damage. Charleston, South Carolina, had one fourth of its houses unroofed; church steeples were blown down and the wharves were overflowed and damaged, the wind blowing at the rate of seventy miles per hour. The hotels and summer-houses on Sullivan's Island were partly destroyed. The damage is reported to amount to $1,000,000. Savannah reports serious losses from the overflow and the wind. Jacksonville and and Fernandina, Florida, report heavy losses with wrecked vessels. The storm, which extended northward with less severity, was general along the Atlantic coast.

AT the last meeting of the Asiatic Society of Japan (reported in the *Japan Mail*) a paper by Mr. H. Pryer was read on the relation between the Lepidoptera of Great Britain and Japan. From the statistics given it appears that about 16 per cent. of the British species are found in Japan. At first sight there does not seem to be any strong resemblance between the Japanese and British specimens of certain species; but the differences are demonstrably due simply to the effect of temperature. In Japan the temperature forms are very numerous, because of the fluctuations in temperature which are so peculiar to the country. When the great distance separating the countries and the striking climatic differences are considered, the identity of such a large percentage of species is a fact of the highest interest to the entomologist.

THE syllabus of the day and evening classes of the Mason Science College, Birmingham, for the session 1885-86 has been published.

THE Asiatic Society of Bengal has just issued a centenary review of the work accomplished by it. The first meeting of the Society took place during the Governor-Generalship of Warren Hastings, in the year 1784.

IT is stated that various lines of telegraphs are to be constructed in Corea under the superintendence of Chinese officials. The preliminary surveys have already been commenced between Gensan and Seoul, and at various points on the Chino-Corean frontier. The length of the lines actually undertaken is over 400 miles.

THE recent earthquakes in Java appear to have extended all over the Eastern Archipelago. The official journal of Batavia contains a report from the Government resident at Amboyna stating that on April 30 violent shocks were felt at Amboyna, in

Banda, and Kayeli, and on the following day at Kairatu. Villages on the beach were overwhelmed by the sea. At intervals of about twenty minutes the sea receded to a distance of 300 yards from low water mark, and then returned to overflow to a depth of 34 feet the broad plain near the beach, fifteen miles west of Kayeli. This phenomenon does not appear to have been general, but to have confined itself to the locality mentioned.

EARTHQUAKE shocks were felt on August 26 in the valley of the little river Mürz, in Styria. They caused no damage beyond loosening the foundations of a few cottages. Several shocks were felt in the same district last May.

THE *Nacion* of Guayaquil gives details of the eruption of the volcano of Cotopaxi early on the morning of July 23. It states that about one o'clock in the morning people were awakened by a sound as of heavy artillery fire, apparently from guns of the heaviest calibre. The explosions followed one another with wonderful rapidity, sometimes causing a continuous roar, shaking the earth and causing the windows and the doors of the houses to rattle. At Chimbo, which is situated almost at the foot of the volcano, there was what the residents along the river Yana-Yacu call an "aluvion." The phenomenon so-called is really the stream of lava which descends the mountain sides, melting the snow with which it is covered, and pouring down a tremendous mass of lava, mud, stones, and all obstacles encountered in its progress. Investigations during the day showed that the shocks produced by the explosions during the night were exceedingly heavy. The smoke hung like a pall over the face of the country, and the steady fall of ashes thrown constantly out of the terrible crater intensified the darkness. Accounts from Latacunga state that the eruption began with a terrible storm. The damage done was considerable, but the number of victims is not known A similar catastrophe occurred in June 1877.

THE "Bureau Scientifique Central Néerlandais," established in 1871 at Haarlem, after the death of its first Director, the lamented Prof. E. H. von Baumhauer, has been taken in hand by Dr. P. P. C. Hoek, at Leiden. The Bureau is in relation with the Smithsonian Institution, Washington, the "Ministère de l'Instruction publique en France," the "Commission des Echanges Internationaux à Bruxelles," with bureaus in Christiania, Stockholm, Copenhagen, &c. Packages sent as *donations* or *exchanges*, and destined for Dutch learned societies or scientists, henceforth are to be sent to the new Director at Leiden or to be delivered to the agent of the Bureau at London *free of expense*. The agents of the Bureau are Messrs. Williams and Norgate, 14, Henrietta Street, Covent Garden, London.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♀) from India, presented by Mr. H. J. Thimbleby; a Binturong (*Arctictis binturong* ♂) from Malacca, presented by Mr. T. H. Haynes; a Great Kangaroo (*Macropus giganteus*) from New South Wales, presented by Mr. A. McIlwraith; two Golden-crowned Conures (*Conurus aureus*) from South-East Brazil, presented by Mr. Cuthbert D. Middleton; a Common Cuckoo (*Cuculus canorus*), British, presented by Mr. R. B. Spalding; two Javan Sparrows (*Padda oryzivora*) from Java, presented by Miss Coleman; a Black-headed Gull (*Larus ridibundus*), European, presented by Mr. Humphries; a Horned Lizard (*Phrynosoma cornutum*) from Texas, presented by Miss Simpson; a Common Chameleon (*Chamæleon vulgaris*) from North Africa, presented by Master Cecil Guy Dart; a Robben Island Snake (*Coronella phocarum*) from Robben Island, South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; a Macaque Monkey (*Macacus cynomolgus*) from India, a Siamese Blue Pie (*Urocissa magnirostris*) from Siam, an American Black Snake (*Coluber guttatus*) from North America, a Smooth-headed Capuchin (*Cebus monachus*), a Squirrel Monkey (*Chrysothrix sciurea*) from South America, deposited; two Axolotls (*Siredon mexicanus*) from Mexico, purchased; fourteen Striped Snakes (*Tropidonotus sirtalis*), born in the Menagerie.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, SEPTEMBER 6-12

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on September 6

Sun rises, 5h. 22m.; souths, 11h. 58m. 8·3s.; sets, 18h. 34m.; decl. on meridian, 6° 18′ N.: Sidereal Time at Sunset, 17h. 38m.

Moon (New on September 8) rises, 2h. 11m.; souths, 9h. 44m.; sets, 17h. 6m.; decl. on meridian, 14° 3′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	4 53	11 28	18 3	6 14 N.
Venus	8 29	14 0	19 31	6 23 S.
Mars	0 32	8 40	16 46	22 14 N.
Jupiter	5 30	12 6	18 43	6 31 N.
Saturn	23 18*	7 27	15 35	22 23 N.

* Indicates that the rising is that of the preceding day.

Sept.	h.	
8	4	Mercury in conjunction with and 0° 27′ south of the Moon.
8	—	Total eclipse of Sun, visible only in regions near the south pole.
8	22	Jupiter in conjunction with Sun; also in conjunction with and 1° 57′ north of the Moon.
11	9	Mercury stationary.
11	10	Venus in conjunction with and 2° 27′ south of the Moon.

GEOGRAPHICAL NOTES

MR. GARDNER, British Consul at Newchwang, publishes with his annual trade report this year (China, No. 6, 1885) a most interesting account of his consular district, which embraces the whole of Manchuria. It contains an area of about 300,000 square miles and a population estimated by the Roman Catholic missionaries at 15,000,000. Its boundaries are, on the north, the Amour, separating it from Eastern Siberia, on the east the Ussuri River and Sihoti Mountains separating it from the Russian province of Primorsk, on the south the Tiumen and Yalvo Rivers separating it from Corea, the Yellow Sea and the Gulf of Liao-tung, on the west China, Mongolia, and Russian Siberia. The first part of the report deals with the ordinary trade and productions of Manchuria, and gives a summary of the statistics of foreign trade since the port of Newchwang was opened to trade in 1861. The second part is devoted to geographical notes on Manchuria, its three provinces, Heh-lung-Kiang (or Sagalien), Kirin and Fêngtien being taken separately. The history, government, military force, and divisions in towns are the heads under which these provinces are described. Various appendices contain an account of a journey from Moukden to San-sing, an essay on Christian missions in Manchuria, and a sketch of the botany of South Manchuria by Dr. Morrison. The latter is, from a scientific point of view, the most important part of the report. The lists given are defective, as the greater part of Dr. Morrison's collections remain unidentified, there having been no opportunity of visiting herbaria or consulting published accounts of Northern Chinese plants.

THE report of the Resident in the State of Selangore in the Malay peninsula for the past year contains some curious information with regard to "aboriginal tribes" called the Sakeis, who number between 700 and 800. They are in nine divisions, under head-men called Batins, and they live mainly by collecting gutta, rattans, and other jungle produce. As far as is known they have no form of religious worship, but they are very superstitious, believing in good and bad omens, the sacred character of certain birds, and they always desert a village as unlucky on the death of any member of the tribe. They tattoo figures on their arms, but apparently only for the sake of ornament, and do not use any specially significant figures, peculiar to each tribe, analogous to the totems of the North American Indians. They consider no kind of edible food unclean, but eat even monkeys, snakes, and scorpions, which they kill by means of a blow-pipe, throwing a dart poisoned with the juice of the Ipoh or Upas tree. For large game they use a kind of cross-bow, consisting of a sharpened bamboo spear placed horizontally on a grooved log, and a bent sapling fastened back by a rattan cord. This cord is stretched across a path in the jungle, and, on being touched, releases the sapling with sufficient force to drive it completely through a deer's body. The Sakeis live in small huts built of bamboo and thatched with leaves of the Bertam palm, raised eight feet or more above the ground. They are shy and easily frightened, but are quite harmless, and are gradually becoming accustomed to Europeans, by whom they are employed to track game and to cut paths through the jungle. They are smaller in stature, but are otherwise very similar in appearance to the Malays, from whom they differ, however, in usually having wavy instead of straight-growing hair. A few Malays are attached to every Sakei community to act as go-betweens in the sale of their produce, and the officials have received special instructions to protect these aboriginal tribes.

THE last issue (Bd. xxviii. Nos. 7 and 8) of the Vienna Geographical Society contains a paper by Dr. B. Jirus describing several visits made by him to the Scoglios, or small reefs off the Dalmatian coasts.—Dr. Polek writes on the colonies of Lipporwans, or Ras Kolniks, Russian schismatics who fled in the middle of the seventeenth century into Bessarabia and Moldavia, which they subsequently left for Bukowina in a romantic way. The writer discusses the history of their flight, and describes their manners and mode of life. The charm of mystery hangs around this small sect of the Greek Oriental Church.—Mr. H. Polakowsky discusses the historical value of the Spanish heroic poem "Araucana," recording the struggles the Spaniards for the possession of the central part of the present Republic of Chili. The object of the author of the paper is to draw attention to this poem, and its translation into German, and by a complete critical examination to separate the historical and actual from the poetical and imaginative.—Herr Baumann describes the projected geodetic work of Dr. Lenz's Congo expedition, and also writes from the vessel taking out the expedition on the present position of the question it is going out to solve.

THE Geographical Society of Hamburg has published a memorandum showing the territorial extent of the recent German annexations in the Pacific Ocean. Reduced to English measurements the German estimates are as follows:—Kaiser Wilhelm's Land (German New Guinea), 34,508 square miles; New Ireland, 3,398·8 square miles; New Britain, 9,348·8 square miles; the Bismarck Archipelago, 15,261·6 square miles: in all about 65,512 English geographical square miles. The same authority estimates the area of New Guinea taken under British protection as 65,517·76 square miles, or about the same as the total of the German annexations in the Pacific, and in each case the area acquired is rather more than twice that of Ireland.

THE *Indépendance Belge* announces that the two Portuguese explorers, Capt. Capello and Commander Ivens, who started last year upon an expedition across Africa, have reached the Cape after a most adventurous journey. Leaving Mossamedes in March, 1884, with an escort of 120 men recruited along the coast between that place and St. Paul de Loanda, they reached Quillimane, upon the eastern coast, to the south of Mozambique, in May, 1885, after having discovered the watershed whence the rivers of Central Africa flow north and east towards the sea. They travelled over 4500 miles of territory, and they are said to have discovered the sources of the Lualaba. They also came upon a region which is extraordinarily rich in copper, this being the district of Yaranganga, situated between the Lualaba and the Luapala. The chief of the country, however, was so hostile that they could not visit it in detail, but they think that as this was the first visit of white men his hostility may be appeased by judicious presents. Messrs. Capello and Ivens found that the tsetse fly was very abundant. The *Indépendance Belge* adds that the two explorers started again at the beginning of last month for Mossamedes, with the intention of returning to Europe by way of the Congo.

THE Calcutta correspondent of the *Times* states that the Government of India has conferred the title of Raj Bahadoor and a grant in perpetuity of a rent-free village in Oude on Pundit Kishen Singh Milwal, an *employé* of the Survey Department, who is well known to all geographers for his explorations in Thibet, which have been published under the initials "A. K."

ON August 10 Col. Lockhart was at Hargil, near Gilghit, and is now probably marching to Chilval. His mission is expected to largely increase our knowledge of the country towards the upper waters of the Oxus.

THE IRON AND STEEL INSTITUTE

THE autumn meeting of the Iron and Steel Institute is being held in Glasgow this week, under the presidency of Dr. Percy, F.R.S.

On Tuesday, after the President had acknowledged the welcome given to the Institute by the Corporation of Glasgow and referred to the depression of trade, due, in his opinion, to over-production, and to be remedied only by a diminution of production or increased consumption, the three following papers were read, of which abstracts are given below.

On the Iron Trade of Scotland, by Mr. F. J. Rowan.—The author separates the history of iron-making into two periods—the *empirical*, characterised by rude and imperfect appliances; and the *scientific*, in which exact methods of working are employed, the introduction of the hot-blast in 1830 closing one and opening the other period. At this period there were in Scotland 27 blast-furnaces making 37,5000 tons; at present there are 92 in blast, with an average production of 200 tons per week each, and 269 puddling-furnaces at work, each producing annually 732 tons. There has been a steady increase in the production per furnace, and reduction in the amount of coal used to produce a ton of pig iron, the latter result being due to the introduction of closed tops, higher furnaces, and higher temperatures of blast. About two-thirds of the coal raised have been from the coal-measures, and one-third from the carboniferous limestone series. It is remarkable that the increased production of coal that has recently taken place has been accompanied by a reduction in the proportionate number of persons employed due to mechanical haulage and other improvements both below and above the surface. The increased manufacture of open-hearth steel, which employs a large quantity of Spanish and African ore, has caused a diminution in the output of ironstone, and has also had an influence on the pig-iron trade; this, however. has been compensated for by the malleable iron tube manufacture, the manufacture of boiler tubes having increased ten times in the last twenty-five years. The author claims for Scotland a good record of advancement and improvement in connection with the iron trade—the first cylinder-blowing engine, the first use of raw coal in the blast-furnace, the discovery of blackband ironstone by David Mushet, the invention of the hot blast by Neilson, and the collection and utilisation of the gases from the tunnel-head. The spirit of enterprise is still potent among Scottish ironmasters, and it is hoped more prosperous times will soon reward and further stimulate the energy and ability which are to be found in all branches of the iron trade in Scotland.

The Rise and Progress of the Scotch Steel Trade, by James Riley.—The author first makes a short reference to the manufacture of cast steel in crucibles, which is carried on only to a very small extent.

As regards the Bessemer process, the first trial, which proved unsuccessful, was made in 1857, at the Coats Iron Works, by Mr. T. Jackson, the apparatus being fitted up from the drawings and letterpress in the *Illustrated London News*.

Other attempts on a small scale were afterwards made to introduce the manufacture, but since the application of the basic lining to the Bessemer converter, by which the pig-iron of the district will become available, the process has again received attention, and a large production is anticipated.

The history of the Scotch steel trade really commences with the formation, in 1871, of the Steel Company of Scotland, which manufactured open-hearth steel by the processes of the late Sir William Siemens, their output being principally boiler and ship plates, angles, bars, castings, and forgings. The extension of manufacture in these directions has been dne to the fact that the Admiralty in 1875 declared for steel, "giving Siemens's steel a preference," and that in 1879 concessions were made to steel by Lloyds' and the Board of Trade, which has caused a great demand for shipbuilding and for the purposes of the civil engineer, who has recognised that by the use of steel, difficulties in constructive engineering can be overcome which would otherwise have been most formidable.

Mr. William Jones read a paper on processes for the recovery of tar and ammonia from blast-furnaces fed with raw coal. The coal generally employed is what is known as Scotch splint coal; it contains on an average 40 per cent. of volatile matter and 50 to 55 per cent. of fixed carbon. The average amount of nitrogen in the coal is 1·35 per cent.; if all this nitrogen was evolved as ammonia and this again converted into sulphate, it would amount to 142½ lbs. of pure sulphate, equal to 152·8 lbs. of commercial sulphate containing 24 per cent. of real ammonia; in blast-furnace practice only 17 to 20 per cent. of the theoretical quantity, or 25 to 28 lbs. per ton, is recovered, whilst in gas-works 14½ per cent. is evolved. Two methods are mainly employed: the one depending on the condensation or cooling of the gas from the blast-furnace, and the other on the treatment of the hot gas with either dilute sulphuric acid or sulphurous acid, which absorbs the ammonia in the gas; towers or scrubbers have to be used for washing the gas in both methods of treatment. The paper contains a detailed description of the various processes employed in carrying out these two methods for the recovery of by-products. The make of sulphate of ammonia from blast furnaces in Scotland has been greatly exaggerated. Even a year hence, when the whole plant being laid down will be available, the make will not exceed 4000 tons per annum. If the gases of the whole of the blast-furnaces in Scotland at present in blast were being treated for ammonia, the turn-out of sulphate of ammonia would be some 18,000 tons per annum, equal to about 22 per cent. of the present British production.

With the discussion of this paper proceedings on Wednesday began; after which Mr. J. Riley read a paper descriptive of an experimental cupola-furnace, which it is proposed to employ in connection with the open-hearth process, with the object of shortening the time employed. Many years ago Mr. Hackney tried at Landore the experiment of pre-melting the pig-iron in a cupola, whence the fluid charge was quickly and readily transferred to the melting-furnace. Instead, however, of saving three or four hours by charging fluid metal, it was found, on repeating the experiment at Hallside, that there was only a saving of about a quarter of an hour in time, obtained at the expense of the coke and labour expended at the cupola. This is due to the circumstance that during the melting of a charge in the open-hearth furnace a large proportion of the silicon and carbon is removed, leaving little more than half the carbon to be eliminated in subsequent operations. Now in the case of the fluid charges, which had been pre-melted with coke in the cupola, these changes have not taken place, and the time required to remove the impurities from the fluid metal, after being charged on the open-hearth furnace, is almost as long as that required to melt and purify the solid charge. The idea occurred to the author to substitute gaseous for solid fuel in the cupola. The gas generator has a closed grate and is dependent upon forced blast, and the air for supporting combustion in the body of the furnace is also obtained from the blower, and is heated.

The experiments made with this cupola prove that not only is there a saving in time and fuel, but that the percentage of silicon and carbon in the pig-iron and steel scraps are very much reduced, so that it is anticipated that when the fluid metal can be charged direct into the open-hearth furnace, the time for its conversion into mild steel will be greatly shortened.

This paper caused a very lively discussion, with which the proceedings on Wednesday terminated.

On Thursday amongst other papers was one descriptive of the Forth Bridge by Mr. Baker, which we print below *in extenso*.

In the afternoon of each day the members visited various steel and iron works in the neighbourhood.

THE FORTH BRIDGE[1]

As the members of the Iron and Steel Institute purpose paying a visit to the Forth Bridge works, I have been requested by the Secretary to prepare a short paper on the subject for the information of the members, and do so with pleasure.

The North British Railway Company for many years have striven hard to obtain a physical connection of their lines north and south of the Forth by means of a bridge. Twenty years ago they were authorised by Act of Parliament to build a bridge across the Forth at a point five miles above the site of that now under construction, but borings 120 feet in depth showed nothing but soft silt and mud, and the bridge, which was to have been two miles in length, inclusive of four spans of 500 feet each, was luckily abandoned, as the difficulties with the foundations would have proved practically insuperable. In 1873 another Act was passed for a bridge across a narrower and deeper part of the Forth at Queensferry. At low water the width of the channel there is about 4000 feet; and the island of Inchgarvie affording a foundation for a central pier, it was possible to cross the 200 feet deep portion of the sea-way by a couple of spans from 1600 feet to 1700 feet each in the clear. Sir Thomas Bouch prepared a design for this bridge on the suspension principle, with towers 665 feet in height from base to summit, and the contract for its construction was let to Mr. Arrol. Owing to the subsequent fall of the Tay Bridge, public confidence in Sir Thomas Bouch's design was shaken, and in session 1881 a bill for the abandonment of the Forth Bridge was proceeded with. Whilst in Committee, the different companies interested, namely, the North British, Great Northern, North-Eastern, and Midland Railway Companies, ordered a final reference of the whole question to their respective consulting engineers, with the result that the abandonment bill was dropped, and the design for a cantilever or continuous girder bridge prepared by Mr. Fowler and myself, in consultation with Mr. Harrison and Mr. Barlow, was substituted for the original suspension bridge. In 1882 the necessary Parliamentary powers were obtained, and in January 1883 the works were commenced by Messrs. Tancred, Arrol, and Co., the contractors.

The total length of viaduct included in the contract sum of 1,600,000*l*. is about 1½ miles, and there are—

2	spans of	1710	feet each.
2	,,	675	,,
15	,,	168	,,
5	,,	25	,,

Including piers, there is thus one mile of main spans, and half a mile of viaduct approach. The clear headway is 150 feet above high water, and the tops of the great cantilevers are more than 200 feet higher still. There will be about 45,000 tons of steel in the superstructure of the bridge, and 120,000 cubic yards of masonry in the piers.

Piers.—The *South Queensferry* main pier consists of a group of four cylindrical piers of masonry and concrete, founded by means of pneumatic caissons on the strong boulder clay constituting the bed of the Forth at this point. Owing to the slope of the clay, the caissons required to be sunk to depths varying from about 70 feet to 90 feet below high water. The diameter ranges from 70 feet at the base to 60 feet at low-water level, above which the iron skin of the caisson is replaced by a facing of Aberdeen granite. At the base of the caissons is a working chamber 7 feet in height supplied with compressed air, and electrically lighted, for the men excavating the material. This chamber was kept clear of water by a pressure of air considerably less, as a rule, than that due to the head of water outside. For example, at 90 feet below high water, when the north-east caisson had been sunk through a considerable thickness of silt, the air-pressure required to be maintained at 18 lbs. per square inch only, although at the reduced depth of 57 feet it was found convenient to work at 30 lbs. air-pressure. Three shafts and air-locks were provided for each caisson, two for the excavated material, and one for the men. The former had two horizontal sliding doors actuated by small hydraulic rams, and the skip containing the clay and boulders was hoisted up the 90-feet shaft by a steam-engine mounted on the side of the air-lock. As a rule, from 200 to 300 skips of excavated material were raised per day of 24 hours by a force of from 20 to 30 men. The maximum number of skip-loads was 363, and of men 33. The size of the skips was 3 feet diameter by 4 feet 3 inches high. Owing to the extreme hardness of the clay it was necessary to provide a certain number of spades having hydraulic rams in the handles, which, abutting against the roof of the working chamber, sliced the clay readily.

At the present time three of the South Queensferry caissons have been sunk successfully to the full depth, and the fourth and last would also have been completed but for an unfortunate accident which happened to it at the beginning of the year. By some means the caisson, which had been floated into position for some weeks, accidentally filled with water, and sank and slid forward on the mud. It is now being carefully cased in timber to admit of the water being pumped out and the caisson floated again into position.

[1] Paper read at the Glasgow meeting of the Iron and Steel Institute by Mr. Benjamin Baker, M.Inst.C.E.

At *Inchgarvie* similar pneumatic caissons are used for two out of the four cylindrical piers, and the work on both is in full progress. Owing to the slope of the rock bottom, it is necessary to cut away as much as 18 feet in thickness of whinstone rock to form a level bench for the pier at 70 feet below high water, and the most convenient way of doing this was to convert the base of the pier practically into a great diving-bell 70 feet in diameter. In this case, there being no silt over the rock, the pressure of air necessarily is that due to the depth of water outside, and somewhat sensational "blows" occur with a falling tide. Rock drills are provided, and blasting goes on in the compressed-air chamber without necessitating the withdrawal of the men.

At *North Queensferry*, the four main piers were built either on dry land or within timber and clay cofferdams. Above low water the whole of the main piers are built of Arbroath masonry in cement faced with Aberdeen granite, and hooped occasionally with 18 inches wrought-iron bands. The cantilever end piers, and the viaduct piers, are built of rubble, concrete, and granite in cement.

Superstructure.—Although the piers of the Forth Bridge present many points of interest, it is the enormous span and novel design of the superstructure that has attracted the attention of the engineers of the world to the work now in progress at Queensferry. The chief desiderata in the biggest railway bridge ever proposed to be constructed are durability, strength, and rigidity under express trains and hurricane pressures; facility and security of erection, high quality of material and workmanship, and economy in first cost and maintenance. These, we considered, would be best met by a steel "cantilever" or "continuous girder" bridge. Since the commencement of the Forth Bridge, American engineers, ever bold and ready, have built three cantilever bridges of considerable spans, and practical experience has confirmed our anticipations as to the advantages of the system; the Niagara Bridge, over 900 feet in length, which was manufactured and erected across the rapids in the short time of ten months, having stood all the tests of actual working in the most satisfactory manner.

In the Forth Bridge, each span of 1710 feet is made up of two cantilevers, projecting 680 feet, and a central girder connecting the same, 350 feet in length. The cantilevers are 343 feet deep over the piers, and 40 feet at the ends. The bottom members consist of a pair of tubes tapering in diameter from 12 feet to 5 feet, and spaced 120 feet apart, centre to centre, at the piers, and 31 feet 6 inches apart at the ends.

The top members consist of a pair of box lattice girders, tapering in depth from 12 feet to 5 feet, and spaced 33 feet apart at the piers, and 22 feet 3 inches at the ends. Each tube has a maximum gross sectional area of 830 square inches, and each girder a maximum net sectional area of 506 square inches. Upon each cylindrical masonry pier is bolted a bed-plate carrying a "skewback," from which spring vertical and diagonal columns and struts. The former are 12 feet in diameter, and from 368 to 468 square inches sectional area; the latter are flattened tubes. Horizontal wind-bracing of lattice girders connect the tubes forming the bottom member of the cantilevers, and similar vertical wind-bracing connects the vertical and diagonal tubes, so that the whole structure is a network of bracing capable of resisting stresses in any direction and of any attainable severity.

The rolling load provided for is (1) trains of unlimited length on each line of rails weighing 1 ton per foot run; (2) trains on each line made up of two engines and tenders, weighing in all 142 tons, at the head of a train of 60 short coal-trucks of 15 tons each. The wind provided for is a pressure of 56 lbs. per square foot, striking the whole, or any part of the bridge, at any angle with the horizon, the total amount on the main spans being estimated at no less than 7900 tons. In practice only two trains, weighing 800 tons in all, would be on this length of bridge at the same time, so the wind pressure (if such a hurricane as 56 lbs. per square foot could ever occur) would be ten times as great as the train load. Under the combined stresses resulting from the test load in the worst position, and the heaviest hurricane, the maximum stress on the steel will not exceed 7½ tons per square inch on any portion of the structure, and on members subject to great variation in the intensity and character of stress, the maximum will not exceed 4 tons per square inch. For tubular columns and struts 34 to 37 ton steel, with an elongation of 17 per cent. in 8 inches, is specified, and for tension members 30 to 33 ton steel, with 20 per cent. of elongation. We have now about 15,000 tons of steel delivered and worked up, and are satisfied that the quality as supplied to us by the Steel Company of Scotland and the Landore Company is admirably adapted for bridge construction. In making the tubes the plates are heated in a gas furnace and bent hot between dies in a powerful hydraulic press. A slight distortion takes place in cooling, which is corrected by pressing the plates again when cold. After bending, all four edges are planed and the plates built up into a tube. Travelling annular drill frames surrounding the tube, fitted each with ten traversing drills, bore the holes at once through plates, covers, and stiffeners, so that when again fitted in place for erection every piece comes into exact juxtaposition. Similar travelling drill frames deal with the lattice box-girders, every hole being drilled as the machine advances. Generally the plant designed by Mr. Arrol for drilling the innumerable holes in the 42,000 tons of steel-work for the main spans is of signal merit and efficiency, and well worthy the attention of practical engineers.

At the present time, although, as already stated, about 15,000 tons of steel-work is on the ground, only the approach viaduct girders and some of the bed-plates of the main spans are erected and rivetted up. In a few weeks, however, the erection of the portion of the main spans over the North Queensferry piers will be proceeded with. The "skewbacks" and connecting tube will first be rivetted up, and then a platform of temporary girders and planking will be constructed, and raised gradually by hydraulic rams in the four vertical 12-foot diameter columns as the work of erection and rivetting-up progresses. This platform will carry cranes and other appliances, and the men will be thoroughly protected, so that work may be carried on with as much confidence at a height of 350 feet as at sea-level. When the portion of steel-work over the piers is erected, the first bay of cantilever on each side of the same will be added, the work forming its own staging. This will be followed by succeeding bays until the cantilevers are complete, and the central girders will then be erected, probably on the same plan.

It will be observed that for certain parts of the Forth Bridge we use steel of a higher tensile strength than is at present considered admissible either for ships or boilers. This has not been done without full and mature consideration of the whole question. Our experiments showed that steel, having a tensile strength of from 34 to 37 tons per square inch, offered a decided advantage over very mild steel, when compressive stresses and the flexure of long columns were concerned. Indeed, an inferior quality of steel, such as would be used for rails, will stand compression far better than the best boiler steel or Lowmoor iron. Thus, I found a column twenty diameters in length of common Bessemer steel carry 27 tons per square inch, where one of mild boiler steel has stood but 17 tons. It would be inexpedient, however, to use inferior steel, even for the compressive members of a bridge, and therefore a high quality and high tensile resistance were indicated. Although this steel takes a temper and becomes brittle if cooled in certain ways, it will stand the ordinary Admiralty temper tests, bending to a radius of double the thickness, after being made red-hot and cooled in the usual way. In a boiler the steel plates are subject to great changes of temperature and consequent stresses from expansion and contraction. In a ship almost every plate in the hull is subject to alternate tensile and compressive stresses when amongst waves; and, further, a vessel is liable to severe alternating stresses and shocks on taking ground, dry docking, and under other circumstances. In the compression members of the Forth Bridge the steel is subject only to a steady pressure of varying intensity, and a quality of steel was adopted which combined perfect facility in working with a high resistance to compression. Although an increased tensile strength is accompanied by a decidedly increased resistance to flexure in columns and struts, the latter is not proportional to the former. If the thing were practicable, what I should choose as the material for the compression members of a bridge would be 34- to 37-ton steel, which had been previously squeezed endwise in the direction of the stress to a pressure of about 45 tons per square inch —the steel plates being held in suitable frames to prevent distortion.

My experiments have proved that 37-ton steel so treated will carry as a column as much load as 70-ton steel in the state in which it leaves the rolls, that is to say, not previously pressed endwise. It would be a matter of much practical moment to ascertain if some convenient treatment could be devised which would endow steel with this greatly increased power of resistance to compression without injuring its resistance to tension, or its ductility, which remained unaffected by previous compression in my experiments. At least one-half of the 42,000 tons of steel in the Forth Bridge is in compression, and the same proportion holds good in most bridges, so the importance of gaining an increased resistance of 60 per cent. without any sacrifice in the facility of working, and safety belonging to a highly ductile material, can hardly be exaggerated.

Our experience has led us to the conclusion that sheared edges are a more fruitful source of fracture than partial tempering or other contingencies. All of our bent plates are made red-hot, and the effect of the shearing is thus eliminated even before planing. Those plates which are not heated have the edges carefully planed so as to leave no trace of the shearing, and we find that, whether we are dealing with 30-ton or 37-ton steel, the plates so treated stand all the desired tests. Experiments which I have made, and am still making, on the resisting power of different classes of iron and steel to repeated bendings, such as the shaft of a marine engine undergoes if the bearings get out of line, indicate that the superiority of low-tension steel is considerably greater than the increased ductility would indicate.

In conclusion I may state that the approximate value of the plant now at the Forth Bridge is 250,000*l.*, and of the work executed 600,000*l.*

SOCIETIES AND ACADEMIES

Sydney

Royal Society of New South Wales, June 3.—Prof. Liversidge, F.R.S., President, in the chair.—A paper was read by Mr. G. H. Knibbs on a system of accurate measurement by means of long steel ribands. The chief feature of the method of measurement is the application of such tensions to the riband as eliminate the effects of its suspension when it becomes necessary.—Mr. Law. Hargrave read a paper, notes on flying-machines, which consisted of deductions drawn from close observation of the behaviour of about fifty self-supporting flying-machines of various weights, from three-quarters of an ounce to four ounces. Sixteen models were exhibited. Mr. Hargrave stated that, although he believed the trochoided plane to be the true mechanical power used by birds in flight, he though its rejection as a scientific truth of very trifling importance compared with the judicious variation and adjustment of the details of the models, so that rules could be laid down for work on a larger scale

July 1.—Prof. Liversidge, F.R.S., President, in the chair.—A paper was read by Mr. H. C. Russell, B.A., on local variations and vibrations of the earth's surface.

Paris

Academy of Sciences, August 24.—M. Bouley, President, in the chair.—Note on human locomotion; mechanism of the jump, jointly communicated by MM. Marey and G. Demeny. This first communication on the subject of human locomotion begins with the action of springing or jumping, because, although not the most usual, it is regarded by the authors as by far the simplest, and much less intricate than walking or running, in which the body executes complicate movements in the direction of the three dimensions of space. The paper is illustrated by a *chromo-photograph* showing the successive positions of legs, arms, and shoulders in a man taking a standing leap (*saut de pied ferme*); also by diagrams of two high jumps executed on the dynamograph.—Observations on the prevalence and development of pestilence and cholera in Persia, where quarantine preventive measures have never been adopted, by M. J. D. Tholozan. The author, who has had twenty-eight years' experience of the action of these epidemics in Persia, is inclined to think that the quarantine system would have proved of little or no avail in arresting their progress. The paper was followed by a few remarks by M. Larrey, also pointing at the general inefficacy of quarantine measures.—Note on M. Hirn's paper on the crepuscular lights inserted in the *Bulletin* of the Colmar Natural History Society, by M. Faye. From his observatory at Colmar the author noticed this phenomenon at an altitude far higher than that of the terrestrial atmosphere. Without deciding on the merits of the different theories advanced to explain its origin, he considers that electricity alone would be capable of retaining at such an altitude the particles of matter causing the after-glows, whether these particles were derived from the Krakatoa eruption or from the interstellar spaces.—Observations of the new planet, 249 (discovered by M. Peters on August 16 at Clinton, New York), made at the Paris Observatory (equatorial of the West Tower), by M. G. Bigourdan.—Observations of Barnard's comet made at the Observatory of Bordeaux with the 14-inch equatorial, by M. G. Rayet.—On the theory of revolving mirrors as a means of measuring the velocity of light, by M. Gouy.—Experiments on double refraction (four illustrations), by M. D. S. Stroumbo. By a simple contrivance the author renders visible to a large audience the course of two rays, ordinary and extraordinary, in a birefringent crystal: (1) when the two facets are artificial and perpendicular to the axis; (2) when they are artificial and parallel to the axis; (3) when they are the natural facets of the crystal parallel to each other.—Note on the alcoholic derivatives of pilocarpine, by M. Chastaign.—On the transmission of pathogenetic microbes from the mother to the fœtus and in the milk, by M. Koubassoff. From experiments made on the guinea-pig the author infers that the charbon virus, the bacilli of tubercular affections, and other germs of disease pass into the milk and remain there during the term of lactation, or till the death of the mother; also that the fœtus nourished on such milk do not catch the respective diseases, but survive even the death of the mother; lastly, that the transmission of microbes from mother to fœtus depends probably on the existence in the placenta of direct communications between the vessels of mother and fœtus.—On an alkaloid substance extracted from the liquid in which Koch's microbe was cultivated, by M. A. Gabriel Pouchet. An analysis of this liquid revealed traces of the presence of an alkaloid liquid presenting outward characteristics, such as small and toxic properties, apparently identical with those detected in the dejecta of cholera patients. Should these results be definitely established, they would furnish an indirect proof that Koch's microbe is really the pathogenetic agent in cholera.—Influence of the sun on the vegetation of the spores of *Bacillus anthracis*, by M. S. Arloing.—Action of the antiseptics on the higher organisms: iodine, nitrate of silver; fourth communication, by MM. Mairet, Pilatte, and Combemale.—A note was received from M. Sacc of Cochabamba, on an extremely rich deposit of alunite lately discovered in the Peruvian Andes.

OUR PRESENT NEEDS

IF it be fair to forecast the success of a meeting of the British Association by the quality of the addresses delivered by the various presidents, then we may predict that the meeting of this year at Aberdeen, which began yesterday, will stand out among its fellows. We think it would be hard to find any prior occasion on which such a high standard of excellence had been reached all round.

The growing use as well as the growing feeling for the need of scientific methods comes out in a most unmistakable way, while there is no fear that either hearers or readers will be lulled into a Sleepy Hollow of satisfaction or a rest-and-be-thankful feeling. For that much remains to be done even in the way of initial organisation both of teaching and working, is frankly and fearlessly acknowledged by several of the speakers.

These present needs may well occupy our attention, and we may begin by those pointed out by the President of the Association himself, who speaks both as a man of Science and a politician. No one knows better than Sir Lyon Playfair how Science can aid the body politic, or knows better how each party when in office neglects or uses this powerful engine for the nation's good. He begins by quoting these noble words from the address of the President at the Aberdeen Meeting in 1859—the lamented Prince Consort:—"We may be justified in hoping . . . that the Legislature and the State will more and more recognise the claims of Science to their attention, so that it may no longer require the begging box, but speak to the State like a favoured child to its parent, sure of his paternal solicitude for its welfare; that the State will recognise in Science one of its elements of strength and prosperity, to foster which the clearest dictates of self-interest demand."

One can get no better idea of the Philistine condition of the Government and of the House of Commons in matters of science than from the fact that much of what follows in the President's Address has not been said in the House itself instead of at Aberdeen. The real reason perhaps is to be gathered from a remark made by Prof. Chrystal in his address in Section A:—

"We all have a great respect for the integrity of our British legislators, whatever doubts may haunt us occasionally as to their capacity in practical affairs. The ignorance of many of them regarding some of the most elementary facts that bear on every-day life is very surprising. Scientifically speaking, uneducated themselves, they seem to think that they will catch the echo of a fact or the solution of an arithmetical problem by putting their ears to the sounding-shell of uneducated public opinion. When I observe the process which many such people employ for arriving at what they consider truth, I often think of a story I once heard of an eccentric German student of chemistry. This gentleman was idle, but, like all his nation, systematic. When he had a precipitate to weigh, instead of resorting to his balance, he would go the round of the laboratory, hold up the test-tube before each of his fellow-students in turn, and ask him to guess the weight. He set down all the replies, took the average, and entered the result in his analysis."

Now if this view of our legislators is shared by men of such acumen as Sir Lyon Playfair and others in the House of Commons more or less connected with science, we can well understand their silence in the modern council of the nation which so little resembles the Witanagemote of former times.

In his pleading for more State recognition of science the President points out the present activity of Germany and France, and especially of the United States:

". . . Both France and Germany make energetic efforts to advance Science with the aid of their national resources. More remarkable is it to see a young nation like the United States reserving 150,000,000 acres of national lands for the promotion of scientific education. In some respects this young country is in advance of all European nations in joining Science to its administrative offices. Its scientific publications, like the great palæontological work embodying the researches of Prof. Marsh and his associates in the Geological Survey, are an example to other Governments. The Minister of Agriculture is surrounded with a staff of botanists and chemists. The Home Secretary is aided by a special Scientific Commission to investigate the habits, migrations, and food of fishes, and the latter has at its disposal two specially constructed steamers of large tonnage. The United States and Great Britain promote fisheries on distinct systems. In this country we are perpetually issuing expensive Commissions to visit the coasts in order to ascertain the experiences of fishermen. I have acted as Chairman of one of these Royal Commissions, and found that the fishermen, having only a knowledge of a small area, gave the most contradictory and unsatisfactory evidence. In America the questions are put to Nature, and not to fishermen. Exact and searching investigations are made into the life-history of the fishes, into the temperature of the sea in which they live and spawn, into the nature of their food, and into the habits of their natural enemies. For this purpose the Government give the cooperation of the Navy, and provide the Commission with a special corps of skilled naturalists, some of whom go out with the steamships, and others work in the biological laboratories at Wood's Holl, Massachusetts, or at Washington. . . . The practical results flowing from these scientific investigations have been important. The inland waters and rivers have been stocked with fish of the best and most suitable kinds. Even the great ocean which washes the coasts of the United States is beginning to be affected by the knowledge thus acquired, and a sensible result is already produced upon the most important of its fisheries. The United Kingdom largely depends upon its fisheries, but as yet our own Government have scarcely realised the value of such scientific investigations as those pursued with success by the United States."

He quotes with approval a passage from Washington's farewell to his countrymen: "Promote as an object of primary importance institutions for the general diffusion of knowledge. In proportion as the structure of a Government gives force to public opinion it is essential that public opinion should be enlightened." He next points out that it was not till 1870 that England established a system of education at all, and that now, while all great countries, except our own, have Ministers of Education, we have only Ministers who are managers of primary schools.

Passing on to the State need of abstract knowledge, we read as follows :—

"Ali, the son-in-law of Mahomet, the fourth successor to the Caliphate, urged upon his followers that men of science and their disciples give security to human progress. Ali loved to say, 'Eminence in science is the highest of honours;' and 'He dies not who gives life to learning.' In addressing you upon texts such as these my purpose was to show how unwise it is for England to lag in the onward march of science when most other European Powers are using the resources of their States to promote higher education and to advance the boundaries of knowledge. English Governments alone fail to grasp the fact that the competition of the world has become a competition in intellect."

We have seen how Sir Lyon Playfair twits the heads of the Education Department with being merely managers of primary schools. The President of the Chemical Section, Prof. Armstrong, also shows reason why their functions must be expanded if science is ever to get on here. He holds that without State action the difficulties which at present prevent the existing teaching institutions from exercising their full share of influence upon the advancement of our national prosperity are all but insuperable. He foresees the objection that such an interference would deprive teaching-centres of their individuality, but he denies that this must necessarily follow, and we know no one who has a better right to express an opinion on such a subject.

Some part indeed of Prof. Armstrong's address is terrible reading. The present chemical education and chemical examinations in this country are, according to him, to a large extent shams, and worse. The students who come to the centres of higher instruction are scarcely reasoning beings—they have never been brought to reason; and at those centres the instruction has been of too technical a character, while hardly anywhere is there an atmosphere of research. We commend this part of Prof. Armstrong's address strongly to our readers. He points out, among many other matters, the vital importance of the research atmosphere, and he frankly states the difficulties felt by earnest men. On this point, indeed, we think him a little too sensitive. Many of the remarks so often made now touching the absence of research in our chemical laboratories apply not to such men as him, but to those whose trading spirit and proclivities are well known—men who discredit the profession to which they belong. Still, it is well that the difficulties should be fairly recorded, especially in juxtaposition with a statement that absence of research must always indicate the absence of teaching worthy of the name.

A complete revision of the present system, both of teaching and examining in chemistry, is, therefore, according to Prof. Armstrong, one of the most pressing of our present needs.

Are the other sciences better off? Certainly not mathematics if Prof. Chrystal has a right to speak for that branch:

"All men practically engaged in teaching who have learned enough, in spite of the defects of their own early training, to enable them to take a broad view of the matter, are agreed as to the canker which turns everything that is good in our educational practice to evil. It is the absurd prominence of written competitive examinations that works all this mischief."

But some may think that in the setting of problems mathematics teachers have an advantage over others in preventing unintelligent cramming. This is not Prof. Chrystal's opinion :

"The history of this matter of problems, as they are called, illustrates in a singularly instructive way the weak point of our English system of education. They originated, I fancy, in the Cambridge Mathematical Tripos Examination, as a reaction against the abuses of cramming bookwork, and they have spread into almost every branch of science teaching—witness test-tubing in chemistry. At first they may have been a good thing; at all events the tradition at Cambridge was strong in my day, that he that could work the most problems in three or two and a half hours was the ablest man, and, be he ever so ignorant of his subject in its width and breadth, could afford to despise those less gifted with this particular kind of superficial sharpness. But, in the end, came all to the same: we were prepared for problem-working in exactly the same way as for bookwork. We were directed to work through old problem papers, and study the style and peculiarities of the day and of the examiner. The day and the examiner had, in truth, much to do with it, and fashion reigned in problems as in everything else. The only difference I could ever see between problems and bookwork was the greater predominance of the inspiriting element of luck in the former. This advantage was more than compensated for by the peculiarly disjointed and, from a truly scientific point of view, worthless nature of the training which was employed to cultivate this species of mental athletics. The result, so far as problems worked in examinations go, is, after all, very miserable, as the reiterated complaints of examiners show; the effect on the examinee is a well-known enervation of mind, an almost incurable superficiality, which might be called Problematic Paralysis—a disease which unfits a man to follow an argument extending beyond the length of a printed octavo page."

As to the crying present need, Profs. Chrystal and Armstrong are at one. We want a higher ideal of education in general and of scientific education in particular :

"Science cannot live among the people, and scientific education cannot be more than a wordy rehearsal of dead text-books, unless we have living contact with the working minds of living men. It takes the hand of God to make a great mind, but contact with a great mind will make a little mind greater. The most valuable instruction in any art or science is to sit at the feet of a master, and the next best to have contact with another who has himself been so instructed. No agency that I have ever seen at work can compare for efficiency with an intelligent teacher, who has thoroughly made his subject his own. It is by providing such, and not by sowing the dragon's teeth of examinations, that we can hope to raise up an intelligent generation of scientifically educated men, who shall help our race to keep its place in the struggle of nations. In the future we must look more to men and to ideas, and trust less to mere systems. Systems have had their trial. In particular, systems of examination have been tested and found wanting in nearly every civilised country on the face of the earth."

What we have written will show what food for thought in the matter of our present needs has been provided at Aberdeen for those gathered together for the advancement of science. Surely the three addresses to which we have specially referred in the present article suggest a gap in the organisation of the Association. Why should there not be a section to deal specially with the question of Education and Research?

THE "DECOMPOSITION" OF DIDYMIUM

UNDER the above title the *Chemical News* has recently reprinted from the *Chemiker Zeitung* a notice of an important piece of work recently communicated to the Vienna Academy by Dr. C. A. von Welsbach. The work appears to have resulted in the discovery that the "dyad or triad element" didymium with an "atomic weight" of 48 or 96, or 147, according to the text-books employed, and which since its separation by Mosander in 1841 has been investigated by Marignac, Hermann, Watts, Bunsen, Deville, and Erk, not to mention many others, is no element at all, but is built up of two substances which can be separated from each other by an ordinary chemical process. The "decomposition" was in fact effected by means of the double ammonium or sodium nitrates in presence of lanthanum salt.

The colours of the salts of the two substances are quite different. The salts of that which approaches lanthanum in its chemical characteristics are of a leek-green, those of the other substance are rose or amethyst red, and it is this substance which exists in greatest quantity in didymium. Dr. von Welsbach proposes for these two new substances the names of "praseodymium" and "neodymium."

It will be readily seen that from the chemical point of view alone these results are of very high interest, but there is another from which they assume a very great importance.

The "element" didymium after it was separated by the chemist had been handed over to the physicists. Gladstone, we believe, was among the first to note the characteristic absorption spectrum of the salts. In this work he was followed by Bahr and Bunsen, Erk and others. Thalèn determined its spark spectrum, and in our spectroscopic literature didymium has taken its place by the side of hydrogen and iron as a characteristic spectrum-giving element.

Now one of the arguments which has been used in support of the view put forward some time ago of the dissociation of the chemical elements at solar temperatures is that at one "heat level" in the sun's atmosphere (a term coined because the sun's atmosphere must get hotter as we go down, and we have means of determining which vapours ascend from hotter regions and which descend from cooler ones) we get some lines of the spectrum of a substance, let us say iron, and at another we get others; so that to get the complete spectrum of iron, as we see it when we use iron in our laboratories, we have to add together the two sets of lines seen in the spectra of parts of the sun known to be at different temperatures.

To make our statements more precise we may say that the lines of iron seen bright in the spectra of solar prominences and those seen widened in the spectra of solar spots are so different that it may be said that there is hardly a line common to both. So much so that, as was said years ago, if we did not know iron here, and the fact that its spectrum contains both sets of lines, we should say that the prominences *quâ* iron contained one substance, and the spots *quâ* iron contained another.

These facts were explained by the hypothesis that there were in the so-called element iron at least two different substances or molecular groupings, one of which alone could withstand the higher temperature of the prominences. The reason that *both* sets of lines and many others are seen in the spectrum of iron in the high-tension spark is that the temperature of the spark is sufficient to carry the solid metal through the series of simplifications, whether many or few, which lie between the limits formed by the solid state and the temperature of the prominences.

To this it has been objected that if these things exist in iron they should be isolated and put in bottles. To this it has been replied that the bottles themselves must be incandescent, or the "things" will unite again as they have done before to form iron as we know it.

Now the real importance of Dr. von Welsbach's work is that what has not yet been done for iron—to prove beyond all cavil the above hypothesis—he has done for didymium. He has got into two bottles, which we may mentally label "spot bottle," "prominence bottle," two substances from the "element" didymium, each of which has a characteristic spectrum consisting of different parts of the spectrum of didymium just as the spots and prominences have spectra *quâ* iron, which are different parts of the spectrum of iron. Further, by mixing the substances in these two bottles together in proper proportions he can produce a third, which gives the mapped spectrum of didymium exactly as in the general spectrum of the sun, in which we get, added together, the absorptions of the hotter and cooler regions represented by prominences and spots, we have *quâ* iron, something not unlike the arc spectrum of that substance.

There is no doubt that the interest of both chemists and physicists will be keenly excited by Von Welsbach's work, and that it will be critically examined and repeated. If it be confirmed we may hope that some day similar work will be undertaken here. The way is open, and has been cleared in a remarkable way. Formerly it was imagined that very high temperatures and new chemical methods were the sole agents to which appeal could be made in such a case; it may turn out that there are reagents to hand if chemists will turn their attention to them.

It is further clear that the "elements" with high atomic weight should be the first to be attacked. Those who consider the spectrum of cerium, for instance, which in the blue and violet portion is richer in lines than the spectrum of the sun itself, to be produced by the vibration of "the chemical atom" or "the chemical molecule," no matter which, will find themselves in a hopeless minority, now that the simpler explanation of a mixed origin has apparently received confirmation in the case of another substance.

But although we have chiefly confined ourselves to the spectroscopic bearing of the work, it is not too much to say of it that, if this separation be in the sense as indicated, it is the most important work in mineral chemistry we have had for many years. By patient work the group of cerium, didymium, &c., metals has yielded several new metallic oxides, differing considerably from didymium, but having the same general reactions, being members of the same group in fact. The difference in the ordinary chemical reactions of cerium, lanthanum, didymium, scandium, terbium, ytterbium, and probably samarium is generally very slight, and they can only be separated by long-continued operations, nearly always cases of fractional separation. The close relationship of these metallic oxides has been long recognised, and the group has been considered peculiar in this respect, and in consequence an immense amount of labour has been expended upon it, more than has ever been expended on groups of other metallic oxides. Indeed, the notion that heat is the agent of chemical resolution seems to have gained such a hold that apparently for the last two, or three, decades, with the exception of the cerite metals, it is the only reagent the action of which has been taken as definitive in establishing a thing to be an element. We are not aware that any records of patient work on chromium exist, attempts to isolate any other substance from chromium oxide other than our ordinary chromium. The general properties of this, or these, oxides surely invite to further investigation. And in the case of nickel and cobalt, which appear almost to be isomers, there is a fine field for investigation which might be as profitably cultivated perhaps as an almost infinite series of carbon compounds.

OUR BOOK SHELF

Annuaire géologique univ... et Guide du Géologie autour de la Terre. Par le Dr. Dagincourt. (Paris: Comptoir géologique de Paris, 1885.)

THIS is the first annual issue of a geological guide edited by the Secretary to the Geological Society of France, which cannot fail to be of the greatest use as a book of reference to those concerned with geology all over the world. *Multum in parvo* would be a very suitable motto for the book, for the amount of information which it contains in a small space is really marvellous. The editor does not profess to have carried out the whole of the programme which he has set before himself in the present issue; but it was decided to bring out the volume this year on account of the meeting of the Geological Congress at Berlin, and also in order that he may be able in the ensuing issue to profit by private and public criticism. The best criticism of it will be a bare statement of its contents. It first describes the history, various meetings and utility of the Congress of Geologists, with the proceedings at the meetings in Paris and Bologna. It then takes the continents in alphabetical order, and the countries in them in the same way, and supplies a mass of geological information of all kinds with regard to each. Taking as an example the first country under the head Europe, which is Germany (Allemagne), we find a list of books on the bibliography of German geology, of general (as distinguished from special and detailed) geological maps, and of the leading works on certain districts; these are succeeded by a general sketch of the geological features of Germany, and of the occurrence of the various geological systems; then a detailed account of the organisation for the production of geological maps in the various countries and provinces composing the German Empire; then a sketch of the institutions in which geology is taught, the various universities with their professors, laboratories, collections, museums, &c., the professors at the various polytechnic and agronomical schools, the public and private geological collections, with in some cases, brief descriptions of the principal features (these occupy a considerable space), then the various geological societies, with their organisations; next the periodical publications, their prices, size, general nature of the contents, divided into five classes—(1) those specially geological, (2) those containing from time to time geological papers, (3) geographical periodicals containing geological papers, (4) those devoted to mining, (5) collections of geological and palæontological memoirs. These lists are succeeded by others which form a very important feature of the work—viz. the names, addresses, and special fields of all the geologists in the German empire; and finally the titles of all the books and papers which have appeared during the past year on mineralogy, petrography, geology, and palæontology, arranged in alphabetical order. This description of the volume under the head "Allemagne," will give an accurate idea of the scope and arrangement of the book, for although circumstances have prevented the scheme being carried out with the same degree of thoroughness for every part of the globe, the volume will year by year approach nearer to, doubtless even improve upon, this standard. In the case of Great Britain, for instance, the issue for 1886 will contain a thorough study of our geology, and its teaching in our universities and other public institutions. Its ultimate completeness must naturally depend much on the assistance which the editor receives from geologists all over the world in supplying information, making the necessary alterations required by time, offering suggestions and adding corrections; and the volume is so useful and full in design that we have little doubt Dr. Dagincourt's fellow-geologists will willingly help him to carry it out in all its details. We observe that Tasmania has by an error been put amongst Asiatic countries instead of in Australasia.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Meteoric Cycle and Stonehenge

WE are now passing through the hundredth meteoric cycle of nineteen years, which commenced with A.D. 1882, and will terminate with A.D. 1900. These cycles began with the year of our Saviour's birth, and our prayer books contain tables showing for many successive years on what days Easter days and our movable festivals will occur. At the end of every such cycle the new and full moons happen within an hour and a half of the same time of the year as they did at the beginning.

With these cycles is commonly associated the name of Meton, an astronomer of Athens, who wrote a book on the subject, by which the Greeks regulated the recurrence of their festivals. He flourished 432 years B.C. But the knowledge of these cycles existed in England centuries before the time of Meton, as I will presently show, and it is probable that the four very ancient erections supposed to have been temples of the sun near Penzance, had reference to this cycle of nineteen years, as they each consisted originally of nineteen stones placed upright and rising from 3 to 6 feet above the ground in rude circles varying in diameter from 65 to 80 feet. These temples are still existing, although some of their stones have fallen, and they are miles from each other, but are all called in the printed maps, as well as immemorially, by one and the same name, viz. "*Nine*

Maidens," which is simply an abbreviation for *Nineteen Maidens*.

The following quotation from Diodorus Siculus (Book II. chap. iii. Booth's Trans., page 139), who flourished about forty-four years B.C., will be an historical confirmation of what I have above stated:—

"Amongst those who have written old stories much like fables, Hecatæus (born 549 years B.C.) and some others say that there is an island in the ocean over against Gaul (as big as Sicily) under the Arctic pole, where the Hyperboreans inhabit, so called because they lie beyond the breezes of the north wind; that the soil there is very rich and fruitful, and the climate temperate, inasmuch as there are two crops in the year."

This description does not apply to the whole of the island referred to, but represents Mount's Bay, its most south-western extremity, and we may therefore conclude that those from whom Hecatæus and the others derived their information were the Phœnician traders who for centuries previously frequented Mount's Bay for tin and fish, and who imagined all Britain to possess the same rich soil and mild climate as Mount's Bay where still "there are two crops in the year." But to proceed with the quotation:—

"They say that Latona was born there, that they worship Apollo above all other gods, and the inhabitants demean themselves as if they were Apollo's priests, who has there a stately grove and a renowned temple of a round form, and that there is a city likewise consecrated to this god. The sovereignty of this city and the care of the temple (they say) belong to the Boreades."

This city and this "renowned temple of a round form" are doubtless those of Old Sarum and Stonehenge, the inner oval of which, immediately around the altar, consists of precisely nineteen stones (see the plate in Dr. Stukeley's "Stonehenge," page 20). But the four temples of the sun above described of nineteen stones each, placed upright "in a round form" to represent the cycle of nineteen years, are not mentioned by Diodorus, as they were probably deemed not worthy of notice after alluding to the renowned temple of Stonehenge. The passage concludes as follows:—

"They say, moreover, that Apollo once in nineteen years comes into the island, in which space of time the stars perform their courses, and return to the same point, and therefore the Greeks call the revolution of nineteen years 'the great year.'"

Plymouth, August R. EDMONDS

Nebula in Andromeda

LAST night the nebula in Andromeda was observed here. The stellar-like nucleus was distinctly seen. It appeared to be of a reddish-yellow colour as contrasted with that of the nebula. We think that a change has certainly taken place, no such stellar-like centre having previously been seen in the nucleus. The stellar point was examined with a small prism held between the eye-piece and the eye. A continuous spectrum was seen. Dr. Boeddicher and I were both convinced that there were considerable inequalities in its light, and independently formed the impression that there was at times a bright band or line in the green. The colour of the stellar point appeared much the same as that of Aldebaran. ROSSE

Observatory, Birr Castle, September 8

Sunsets

IN July of this year I spent a short time in the Schwarzwald of Baden. For more than a week the sky was cloudless day and night, yet the heat was not oppressive. The sunsets were beautiful beyond description, and the after-glows magnificent. One evening in particular will always remain impressed upon my memory. It was that of July 26, and the place was a few miles from the town of Neustadt, nearly in the centre of the forest. Wonderful effects began to appear so soon as the sun touched the crest of the western hills. But these were as nothing compared with what followed. The moment the luminary had disappeared behind the hills long streamers began to radiate high up into the heavens, and for a time, as the daylight diminished, they increased both in length and intensity, rivalling any description or figures of the Arctic auroras that I have ever seen; at the same time the most vivid and ever-changing glow lit up the whole western heavens. The scene lasted more than an hour, and its effect was heightened by, and perhaps partly due to, a nearly full moon, which rose from behind a slight dip or pass in the hills on the eastern side of the valley. The inhabitants of the Schwarzwald are indubitably phlegmatic, and not easily moved to excitement; but this display of celestial pyrotechnics was too much for them, and at a small roadside inn the carters and others who were enjoying their beer inside turned out *en masse* to witness it. I am not a strong admirer of Turner's pictures, but, in comparing nature with art, one idea came uppermost—the scene was "Turneresque."

Lewisham, S.E., September 3 R. MCLACHLAN

Pulsation in the Veins

MR. HIPPISLEY will find a very simple way of showing pulsation in the veins, as well as in the arteries, by fixing a long bristle or thread of sealing-wax over the vessel by means of a little tallow. The end of the lever will vibrate and produce all the movements of the sphygmograph. This method was adopted by Mr. Wilkinson King nearly fifty years ago, and the instrument styled by him the sphygmometer. In his paper in the Guy's Hospital Reports for 1837, "On the Safety Valve Function of the Right Ventricle of the Heart," will be found much valuable matter and discussion about venous pulsation.

Red Hail

VU l'intérêt que peut offrir la coloration de la grêle, j'espère que vous voudrez bien insérer ces quelques lignes dans votre journal: "La grêle colorée en rouge, observée par Mr. Mullan et dont il est question dans le No. 812 de ce journal, n'est pas un fait isolé. On a observé un cas analogue en 1880, le $\frac{2}{14}$ juin, en Russie. Les grêlons de cette chute-là étaient intéressants sous plus d'un rapport. Leur forme se ramenait à trois types: parallélipipède, cylindre, sphéroïde très-aplati et muni de cavité aux bouts de la petite axe. Certains de ces grêlons étaient percés de part en part, le long de la petite axe, ce qui leur donnait l'apparence des anneaux. Certains des grêlons étaient colorés en rouge-pâle, d'autres avaient la couleur bleu-pâle, mais pour la plupart les grêlons étaient gris ou blanc. L'observateur, M. Lagounowitch, crut avoir remarqué que la couleur était liée à la forme des grêlons. Je cite ces faits et j'en propose l'explication dans ma brochure, 'Sur l'Origine de la Grêle.'"

On the Terminology of the Mathematical Theory of Electricity

MR. SUTHERLAND'S letter on terminology (NATURE, vol. xxxii. p. 391) leads me to suggest to Mr. Scott the employment of the term *low-pression* for depression in his weather forecasts sent to the newspapers. It is nearly as easily pronounced and written, and will not have such a tendency to mislead the general public as to there being a depressing of the air where it really ascends. HENRY MUIRHEAD

Cambuslang

THE BRITISH ASSOCIATION

Aberdeen, Monday

THIS place has evidently been astir for days in anticipation of the present meeting. Already are the directions necessary for visitors finding their way to the various sections put up in conspicuous places in Union Street and the neighbourhood of Marischal College. The accommodation in the fine building for reception rooms, committee rooms, reading, sectional, and other rooms, seems, so far as can be judged at present, everything that could be desired. It is evident that the Local Committee have been working in earnest to make the second Aberdeen meeting a success, and their efforts have been heartily supported by the citizens and country people. Up to Saturday 1000*l.* worth of tickets had been sold to local people alone, and many more will be sold between this and Wednesday. Of old members of the Association 750 have already written that they intend to be present and it is confidently anticipated that quite 2500 people will take out tickets for the meeting. This great influx of strangers has tasked the available accommodation in Aberdeen, and, as might be expected, the charges in hotels and lodging-houses are somewhat exorbitant.

Of foreigners who are to be present one of the most distinguished is Prof. O. C. Marsh, the well-known American palæontologist, who, it is expected, will take part in the proceedings of both C and D. Others are the Abbé Renard of Brussels, Dr. Max Schuster of Vienna, Dr. von Dechen of Bonn, and Prof. Radlkofer of Munich. It is expected that Mr. Im Thurn, the naturalist, who recently ascended Mount Roraima in British Guiana, will be able to be here, and tell personally of his ascent and its important results.

Of the excursions, that to Balmoral on Saturday is evidently the favourite, and there will be considerable competition to be included among the 150. The Earl of Crawford has for the same day invited sixty members to visit Dunecht, where the observatory will be inspected, and where the archæologists will be shown the "Barnekin of Dunecht." The Earl of Crawford also contributed several very valuable and interesting objects to a fine exhibition of antiquities, old books and manuscripts, that is being arranged. Among the expeditions arranged for Thursday the 17th, is one specially for geologists, to Portsoy; and for the same day the Rev. W. Gordon invites a party of naturalists to Braemar.

Among the local establishments which will be open to the inspection of visitors are several of the great granite works for which Aberdeen is so famous.

Another exhibition of special interest, arranged by the Scottish Geographical Society, will consist of Scottish maps, including some 150 different maps, atlases, guides, and special topographical works.

If one may judge from the present appearance of the weather, the meteorological conditions promise to be favourable, and, if so, the meeting will be sure to be successful, so far as pleasuring is concerned, while the discussions that have been arranged for the Sections A and B are likely to give it considerable scientific importance.

Inaugural Address by the Right Hon. Sir Lyon Playfair, K.C.B., M.P., F.R.S., President

I. *Visit to Canada.*—Our last meeting at Montreal was a notable event in the life of the British Association, and even marked a distinct epoch in the history of civilisation. It was by no mere accident that the constitution of the Association enabled it to embrace all parts of the British Empire. Science is truly catholic, and is bounded only by the universe. In relation to our vast empire, science, as well as literature and art, are the common possession of all its varying people. The United Kingdom is limited to 120,800 square miles, inhabited by 35 millions of people; but the empire as a whole has 8½ millions of square miles, with a population of 305 millions. To federate such vast possessions and so teeming a population into a political unit is a work only to be accomplished by the labours and persistent efforts of perhaps several generations of statesmen. The federation of its science is a subject of less dimensions well within the range of experiment. No part of the British Empire was more suited than Canada to try whether her science could be federated with our science. Canada has lately federated distinct provinces, with conflicting interests arising from difference of races, nationalities, and religions. Political federation is not new in the history of the world, though it generally arises as a consequence of war. It was war that taught the Netherlands to federate in 1619. It was war which united the States in America; federated Switzerland, Germany, and Austria, and unified Italy. But Canada formed a great national life out of petty provincial existences in a time of profound peace. This evolution gave an immense impulse to her national resources. The Dominion still requires consolidation in its vast extent, and applied science is rapidly effecting it. Canada, with its great expanse of territory, nearly as large as the United States, is being knit together by the iron bands of railways from the Gulf of St. Lawrence to the Pacific Ocean, so that the fertile lands of Ontario, Manitoba, Columbia, and the North-Western territories will soon be available to the world. Still practical science has much to accomplish. England and France, with only one-fifth the fertile area of Canada, support 80 millions of people, while Canada has a population not exceeding 5 millions.

A less far-seeing people than the Canadians might have invited the applied science which they so much require. But they knew that without science there are no applications. They no doubt felt with Emerson—

> "And what if Trade sow cities
> Like shells along the shore,
> And thatch with towns the prairie broad
> With railways ironed o'er;
> They are but sailing foam-bells
> Along Thought's causing stream,
> And take their shape and sun-colour
> From him that sends the dream."

So it was with a far-reaching foresight that the Canadian Government invited the British Association for the Advancement of Science to meet in Montreal. The inhabitants of Canada received us with open arms, and the science of the Dominion and that of the United Kingdom were welded. We found in Canada, as we had every reason to expect, men of manly and self-reliant character, who loved not less than we did the old home from which they had come. Among them is the same healthiness of political and moral life, with the same love of truth which distinguishes the English people. Our great men are their great men: our Shakspeare, Milton, and Burns belong to them as much as to ourselves; our Newton, Dalton, Faraday, and Darwin are their men of science as much as they are ours. Thus a common possession and mutual sympathy made the meeting in Canada a successful effort to stimulate the progress of science, while it established, at the same time, the principle that all people of British origin—and I would fain include our cousins in the United States—possess a common interest in the intellectual glories of their race, and ought, in science at least, to constitute part and parcel of a common empire, whose heart may beat in the small islands of the northern seas, but whose blood circulates in all her limbs, carrying warmth to them and bringing back vigour to us. Nothing can be more cheering to our Association than to know that many of the young communities of English-speaking people all over the globe—in India, China, Japan, the Straits, Ceylon, Australia, New Zealand, the Cape—have founded scientific societies in order to promote the growth of scientific research. No doubt science, which is only a form of truth, is one in all lands, but still its unity of purpose and fulfilment received an important practical expression by our visit to Canada. This community of science will be continued by the fact that we have invited Sir William Dawson, of Montreal, to be our next President at Birmingham.

II. *Science and the State.*—I cannot address you in Aberdeen without recollecting that when we last met in this city our President was a great prince. The just verdict of time is that, high as was his royal rank, he has a far nobler claim to our regard as a lover of humanity in its widest sense, and especially as a lover of those arts and sciences which do so much to adorn it. On September 14, 1859, I sat on this platform and listened to the eloquent address and wise counsel of the Prince Consort. At one time a member of his household, it was my privilege to co-operate with this illustrious prince in many questions relating to the advancement of science. I naturally, therefore, turned to his presidential address to see whether I might not now continue those counsels which he then gave with all the breadth and comprehensiveness of his masterly speeches. I found, as I expected, a text for my own discourse in some pregnant remarks which he made upon the relation of science to the State. They are as follows:—"We may be justified in hoping . . . that the Legislature and the State will more and more recognise the claims of science to their attention, so that it may no longer require the begging-box, but speak to the State like a favoured child to its parent, sure of his paternal solicitude for its welfare; that the State will recognise in science one of its elements of strength and prosperity, to foster which the clearest dictates of self-interest demand."

This opinion, in its broadest sense, means that the relations of science to the State should be made more intimate because the advance of science is needful to the public weal.

The importance of promoting science as a duty of statecraft was well enough known to the ancients, especially to the Greeks and Arabs, but it ceased to be recognised in the dark ages, and was lost to sight during the revival of letters in the fifteenth and sixteenth centuries. Germany and France, which are now in such active competition in promoting science, have only publicly acknowledged its national importance in recent times. Even in the last century, though France had its Lavoisier and Germany its Leibnitz, their Governments did not know the value of science. When the former was condemned to death in the Reign of Terror, a petition was presented to the rulers that his life might be spared for a few weeks in order that he might complete some important experiments, but the reply was, "The Republic has no need of savants." Earlier in the century the much-praised Frederick William of Prussia shouted with a loud voice, during a graduation ceremony in the University of Frankfort, "An ounce of mother-wit is worth a ton of university wisdom." Both France and Germany are now ashamed of these utterances of their rulers, and make energetic efforts to advance science with the aid of their national resources. More remarkable is it to see a young nation like the United States reserving 150,000,000 acres of national lands for the promotion of scientific education. In some respects this young country is in advance of all European nations in joining science to its administrative offices. Its scientific publications, like the great palæontological work embodying the researches of Prof. Marsh and his associates in the Geological Survey, are an example to other Governments. The Minister of Agriculture is surrounded with a staff of botanists and chemists. The Home Secretary is aided by a special Scientific Commission to investigate the habits, migrations, and food of fishes, and the latter has at its disposal two specially-constructed steamers of large tonnage. The United States and Great Britain promote fisheries on distinct systems. In this country we are perpetually issuing expensive Commissions to visit the coasts in order to ascertain the experiences of fishermen. I have acted as chairman of one of these Royal Commissions, and found that the fishermen, having only a knowledge of a small area, gave the most contradictory and unsatisfactory evidence. In America the questions are put to Nature, and not to fishermen. Exact and searching investigations are made into the life-history of the fishes, into the temperature of the sea in which they live and spawn, into the nature of their food, and into the habits of their natural enemies. For this purpose the Government give the co-operation of the navy, and provide the Commission with a special corps of skilled naturalists, some of whom go out with the steamships and others work in the biological laboratories at Wood's Holl, Massachusetts, or at Washington. The different universities send their best naturalists to aid in these investigations, which are under the direction of Mr. Baird, of the Smithsonian Institution. The annual cost of the Federal Commission is about 40,000*l.*, while the separate States spend about 20,000*l.* in local efforts. The practical results flowing from these scientific investigations have been important. The inland waters and rivers have been stocked with fish of the best and most suitable kinds. Even the great ocean which washes the coasts of the United States is beginning to be affected by the knowledge thus acquired, and a sensible result is already produced upon the most important of its fisheries. The United Kingdom largely depends upon its fisheries, but as yet our own Government have scarcely realised the value of such scientific investigations as those pursued with success by the United States. Less systematically, but with great benefit to science, our own Government has used the surveying expeditions, and sometimes has equipped special expeditions to promote natural history and solar physics. Some of the latter, like the voyage of the *Challenger*, have added largely to the store of knowledge; while the former, though not primarily intended for scientific research, have had an indirect result of infinite value by becoming training-schools for such investigators as Edward Forbes, Darwin, Hooker, Huxley, Wyville Thomson, and others.

In the United Kingdom we are just beginning to understand the wisdom of Washington's farewell address to his countrymen when he said: "Promote as an object of primary importance institutions for the general diffusion of knowledge. In proportion as the structure of a government gives force to public opinion, it is essential that public opinion should be enlightened." It was only in 1870 that our Parliament established a system of national primary education. Secondary education is chaotic, and remains unconnected with the State, while the higher education of the universities is only brought at distant intervals under the view of the State. All great countries except England have Ministers of Education, but this country has only Ministers who are the managers of primary schools. We are inferior even to smaller countries in the absence of organised State supervision of education. Greece, Portugal, Egypt, and Japan have distinct Ministers of Education, and so also among our Colonies have Victoria and New Zealand. Gradually England is gathering materials for the establishment of an efficient Education Minister. The Department of Science and Art is doing excellent work in diffusing a taste for elementary science among the working classes. There are now about 78,000 persons who annually come under the influence of its science classes, while a small number of about 200, many of them teachers, receive thorough instruction in science at the excellent school in South Kensington, of which Prof. Huxley is the Dean. I do not dwell on the work of this Government department, because my object is chiefly to point out how it is that science lags in its progress in the United Kingdom owing to the deficient interest taken in it by the middle and upper classes. The working classes are being roused from their indifference. They show this by their selection of scientific men as candidates at the next election. Among these are Profs. Stuart, Roscoe, Maskelyne, and Rücker. It has its significance that such a humble representative of science as myself received invitations from working-class constituencies in more than a dozen of the leading manufacturing towns. In the next Parliament I do not doubt that a Minister of Education will be created as a nucleus around which the various educational materials may crystallise in a definite form.

III. *Science and Secondary Education.*—Various Royal Commissions have made inquiries and issued recommendations in regard to our public and endowed schools. The Commissions of 1861, 1864, 1868, and 1873 have expressed the strongest disapproval of the condition of our schools, and, so far as science is concerned, their state is much the same as when the Duke of Devonshire's Commission in 1873 reported in the following words:—"Considering the increasing importance of science to the material interests of the country, we cannot but regard its almost total exclusion from the training of the upper and middle classes as little less than a national misfortune." No doubt there are exceptional cases and some brilliant examples of improvement since these words were written, but generally throughout the country teaching in science is a name rather than a reality. The Technical Commission which reported last year can only point to three schools in Great Britain in which science is fully and adequately taught. While the Commission gives us the consolation that England is still in advance as an industrial nation, it warns us that foreign nations, which were not long ago far behind, are now making more rapid progress than this country, and will soon pass it in the race of competition unless we give increased attention to science in public education. A few of the large towns, notably Manchester, Bradford, Huddersfield, and Birmingham, are doing so. The working classes are now receiving better instruction in science than the middle classes. The competition of actual life asserts its own conditions, for the children of the latter find increasing difficulty in obtaining employment. The cause of this lies in the fact that the schools for the middle classes have not yet adapted themselves to the needs of modern life. It is true that many of the endowed schools have been put under new schemes, but as there is no public supervision or inspection of them, we have no knowledge as to whether they have prospered or slipped back. Many corporate schools have arisen, some of them, like Clifton, Cheltenham, and Marlborough Colleges, doing excellent educational work, though as regards all of them the public have no rights and cannot enforce guarantees for efficiency. A return just issued, on the motion of Sir John Lubbock, shows a lamentable deficiency in science teaching in a great proportion of the endowed schools. While twelve to sixteen hours a week are devoted to classics, two to three hours are considered ample for science in a large proportion of the schools. In Scotland there are only six schools in the Return which give more than two hours to science weekly, while in many schools its teaching is wholly omitted. Every other part of the kingdom stands in a better position than Scotland in relation to the science of its endowed schools. The old traditions of education stick as firmly to schools as a limpet does to a rock; though I do the limpet injustice, for it does make excursions to seek pastures new. Are we to give up in despair because an exclusive system of classical education has resisted the assaults of such cultivated authors as Milton, Montaigne, Cowley, and Locke? There was once an enlightened Emperor of China, Chi Hwangti, who knew that his country was kept back by its exclusive devotion to the classics of Confucius and Mencius. He invited 500 of the teachers to bring their copies of these authors to Pekin, and after giving a great banquet in their honour, he buried alive the professors along with their manuscripts in a deep pit. But Confucius and Mencius still reign supreme. I advocate milder measures, and depend for their adoption on the force of public opinion. The needs of modern life will force schools to adapt themselves to a scientific age. Grammar-schools believe themselves to be immortal. Those curious immortals—the Struldburgs—described by Swift, ultimately regretted their immortality, because they found themselves out of touch, sympathy, and fitness with the centuries in which they lived.

As there is no use clamouring for an instrument of more compass and power until we have made up our minds as to the tune, Prof. Huxley, in his evidence before a Parliamentary Committee in 1884, has given a time-table for grammar-schools. He demands that out of their forty hours for public and private study, ten should be given to modern languages and history, eight to arithmetic and mathematics, six to science, and two to geography, thus leaving fourteen hours to the dead languages. No time-table would, however, be suitable to all schools. The great public schools of England will continue to be the gymnasia for the upper classes, and should devote much of their time to classical and literary culture. Even now they introduce into their curriculum subjects unknown to them when the Royal Commission of 1868 reported, though they still accept science with timidity. Unfortunately the other grammar-schools which educate the middle classes look to the higher public schools as a type to which they should conform, although their functions are so different. It is in the interest of the higher public schools that this difference should be recognised, so that, while they give an all-round education and expand their curriculum by a freer recognition of the value of science as an educational power in developing the faculties of the upper classes, the schools for the middle classes should adapt themselves to the needs of their existence, and not keep up a slavish imitation of schools with a different function. The old classical grammar-schools may view these remarks as a direct attack upon them, and so it is in one sense, but it is like the stroke of Ithuriel's spear, which heals while it wounds.

The stock argument against the introduction of modern subjects into grammar schools is that it is better to teach Latin and Greek thoroughly rather than various subjects less completely. But is it true that thoroughness in teaching dead languages is the result of an exclusive system? In 1868 the Royal Commission stated that even in the few great public schools thoroughness was only given to 30 per cent. of the scholars, at the sacrifice of 70 per cent. who got little benefit from the system. Since then the curriculum has been widened and the teaching has improved. I question the soundness of the principle that it is better to limit the attention of the pupils mainly to Latin and Greek, highly as I value their educational power to a certain order of minds. As in biology the bodily development of animals is from the general to the special, so is it in the mental development of man. In the school a boy shauld be aided to discover the class of knowledge that is best suited for his mental capacities, so that, in the upper forms of the school and in the university, knowledge may be specialised in order to cultivate the powers of the man to their fullest extent. Shakspeare's educational formula may not be altogether true, but it contains a broad basis of truth—

> "No profit goes, where is no pleasure ta'en;—
> In brief, sir, study what you most affect."

The comparative failure of the modern side of school education arises from constituting it out of the boys who are looked upon as classical asses. Milton pointed out that in all schools there are boys to whom the dead languages are "like thorns and thistles," which form a poor nourishment even for asses. If teachers looked upon these classical asses as beings who might receive mental nurture according to their nature, much higher results would follow the bifurcation of our schools. Saul went out to look for asses and he found a kingdom. Surely this fact is more encouraging than the example of Gideon, who "took thorns of the wilderness and briars, and with these he *taught* the men of Succoth."[1] The adaptation of public schools to a scientific age does not involve a contest as to whether science or classics shall prevail, for both are indispensable to true education. The real question is whether schools will undertake the duty of moulding the minds of boys according to their mental varieties. Classics, from their structural perfection and power of awakening dormant faculties, have claims to precedence in education, but they have none to a practical monopoly. It is by claiming the latter that teachers sacrifice mental receptivity to a Procrustean uniformity.

[1] Judges, viii. 16.

The universities are changing their traditions more rapidly than the schools. The *via antiqua* which leads to them is still broad, though a *via moderna*, with branching avenues, is also open to their honours and emoluments. Physical science, which was once neglected, is now encouraged at the universities. As to the 70 per cent. of boys who leave schools for life-work without going through the universities, are there no growing signs of discontent which must force a change? The Civil Service, the learned professions, as well as the army and navy, are now barred by examinations. Do the boys of our public schools easily leap over the bars, although some of them have lately been lowered so as to suit the schools? So difficult are these bars to scholars that crammers take them in hand before they attempt the leap; and this occurs in spite of the large value attached to the dead languages and the small value placed on modern subjects. Thus, in the Indian Civil Service examinations, 800 marks as a maximum are assigned to Latin, 600 to Greek, 500 to chemistry, and 300 to each of the other physical sciences. But if we take the average working of the system for the last four years we find that while 68 per cent. of the maximum were given to candidates in Greek and Latin, only 45 per cent. were accorded to candidates in chemistry, and but 30 per cent. to the other physical sciences. Schools sending up boys for competition naturally shun subjects which are dealt with so hardly and so heavily handicapped by the State.

Passing from learned or public professions to commerce, how is it that in our great commercial centres, foreigners—German, Swiss, Dutch, and even Greeks—push aside our English youth and take the places of profit which belong to them by national inheritance? How is it that in our colonies, like those in South Africa, German enterprise is pushing aside English incapacity? How is it that we find whole branches of manufactures, when they depend on scientific knowledge, passing away from this country, in which they originated, in order to engraft themselves abroad, although their decaying roots remain at home?[1] The answer to these questions is that our systems of education are still too narrow for the increasing struggle of life.

Faraday, who had no narrow views in regard to education, deplored the future of our youth in the competition of the world, because, as he said with sadness, "our schoolboys, when they come out of school, are ignorant of their ignorance at the end of all that education."

The opponents of science education allege that it is not adapted for mental development, because scientific facts are often disjointed and exercise only the memory. Those who argue thus do not know what science is. No doubt an ignorant or half-informed teacher may present science as an accumulation of unconnected facts. At all times and in all subjects there are teachers without æsthetical or philosophical capacity—men who can only see carbonate of lime in a statue by Phidias or Praxiteles; who cannot survey zoology on account of its millions of species, or botany because of its 130,000 distinct plants; men who can look at trees without getting a conception of a forest, and cannot distinguish a stately edifice from its bricks. To teach in that fashion is like going to the tree of science with its glorious fruit in order to pick up a handful of the dry fallen leaves from the ground. It is, however, true that as science teaching has had less lengthened experience than that of literature, its methods of instruction are not so matured. Scientific and literary teaching have different methods; for while the teacher of literature rests on authority and on books for his guidance, the teacher of science discards authority and depends on facts at first hand, and on the book of Nature for their interpretation. Natural science more and more resolves itself into the teaching of the laboratory. In this way it can be used as a powerful means of quickening observation, and of creating a faculty of induction after the manner of Zadig, the Babylonian described by Voltaire. Thus facts become surrounded by scientific conceptions, and are subordinated to order and law.

It is not those who desire to unite literature with science who degrade education; the degradation is the consequence of the refusal. A violent reaction—too violent to be wise—has lately

[1] See Dr. Perkins's address to the Soc. Chem. Industry, NATURE August 6, 1855, p. 333

taken place against classical education in France, where their own vernacular occupies the position of dead languages, while Latin and science are given the same time in the curriculum. In England manufacturers cry out for technical education, in which classicul culture shall be excluded. In the schools of the middle classes science rather than technics is needed, because, when the seeds of science are sown, technics as its fruit will appear at the appointed time. Epictetus was wise when he told us to observe that, though sheep eat grass, it is not grass but wool that grows on their backs. Should, however, our grammar-schools persist in their refusal to adapt themselves to the needs of a scientific age, England must follow the example of other European nations and found new modern schools in competition with them. For, as Huxley has put it, we cannot continue in this age "of full modern artillery to turn out our boys to do battle in it, equipped only with the sword and shield of an ancient gladiator." In a scientific and keenly competitive age an exclusive education in the dead languages is a perplexing anomaly. The flowers of literature should be cultivated and gathered, though it is not wise to send men into our fields of industry to gather the harvest when they have been taught only to cull the poppies and to push aside the wheat.

IV. *Science and the Universities.*—The State has always felt bound to alter and improve universities, even when their endowments are so large as to render it unnecessary to support them by public funds. When universities are poor, Parliament gives aid to them from imperial taxation. In this country that aid has been given with a very sparing hand. Thus the universities and colleges of Ireland have received about 30,000*l.* annually, and the same sum has been granted to the four universities of Scotland. Compared with imperial aid to foreign universities such sums are small. A single German university like Strassburg or Leipsic receives about 40,000*l.* annually, or 10,000*l.* more than the whole colleges of Ireland or of Scotland. Strassburg, for instance, has had her university and its library rebuilt at a cost of 711,000*l.*, and receives an annual subscription of 43,000*l.* In rebuilding the University of Strassburg eight laboratories have been provided, so as to equip it fully with the modern requirements for teaching and research.[1] Prussia, the most economical nation in the world, spends 391,000*l.* yearly out of taxation on her universities.

The recent action of France is still more remarkable. After the Franco-German war the Institute of France discussed the important question: "Pourquoi la France n'a pas trouvé d'hommes supérieurs au moment du péril?" The general answer was, Because France had allowed university education to sink to a low ebb. Before the great Revolution France had twenty-three autonomous universities in the provinces. Napoleon desired to found one great university at Paris, and he crushed out the others with the hand of a despot, and remodelled the last with the instincts of a drill-sergeant. The central university sank so low than in 1868 it is said that only 8000*l.* were spent for true academic purposes. Startled by the intellectual sterility shown in the war, France has made gigantic efforts to retrieve her position, and has rebuilt the provincial colleges at a cost of 3,280,000*l.*, while her annual budget for their support now reaches half a million of pounds. In order to open these provincial colleges to the best talent of France, more than 500 scholarships have been founded at an annual cost of 30,000*l.* France now recognises that it is not by the number of men under arms that she can compete with her great neighbour Germany, so she has determined to equal her in intellect. You will understand why it is that Germany was obliged, even if she had not been willing, to spend such large sums in order to equip the university of her conquered province, Alsace-Lorraine. France and Germany are fully aware that science is the source of wealth and power, and that the only way of advancing it is to encourage universities to make researches and to spread existing knowledge through the community. Other European nations are advancing on the same lines. Switzerland is a remarkable illustration of how a country can compensate itself for its natural di-advantages by a scientific education of its people. Switzerland contains neither coal nor the ordinary raw materials of industry, and is separated from other countries which might supply them by mountain barriers. Yet, by a singularly good system of graded schools, and by the great technical college of Zurich, she has become a prosperous manufacturing country. In Great Britain we have nothing comparable to this technical college, either in magnitude or efficiency. Belgium is reorganising its universities, and the State has freed the localities from the charge of buildings, and will in future equip the universities with efficient teaching resources out of public taxation. Holland, with a population of 4,000,000 and a small revenue of 9,000,000*l.*, spends 136,000*l.* on her four universities. Contrast this liberality of foreign countries in the promotion of higher instruction with the action of our own country. Scotland, like Holland, has four universities, and is not very different from it in population, but it only receives 30,000*l.* from the State. By a special clause in the Scotch Universities Bill the Government asked Parliament to declare that under no circumstances should the Parliamentary grant be ever increased above 40,000*l.* According to the views of the British Treasury there is a finality in science and in expanding knowledge.

The wealthy universities of Oxford and Cambridge are gradually constructing laboratories for science. The merchant princes of Manchester have equipped their new Victoria University with similar laboratories. Edinburgh and Glasgow Universities have also done so, partly at the cost of Government and largely by private subscriptions. The poorer universities of Aberdeen and St. Andrews are still inefficiently provided with the modern appliances for teaching science.

London has one small Government college and two chartered colleges, but is wholly destitute of a teaching university. It would excite great astonishment at the Treasury if we were to make the modest request that the great metropolis, with a population of 4,000,000, should be put into as efficient academical position as the town of Strassburg, with 104,000 inhabitants, by receiving, as that town does, 43,000*l.* annually for academic instruction, and 700,000*l.* for university buildings. Still, the amazing anomaly that London has no teaching university must ere long cease.

It is a comforting fact that, in spite of the indifference of Parliament, the large towns of the kingdom are showing their sense of the need of higher education. Manchester has already its university. Nottingham, Birmingham, Leeds, and Bristol have colleges more or less complete. Liverpool converts a disused lunatic asylum into a college for sane people. Cardiff rents an infirmary for a collegiate building. Dundee, by private benefaction, rears a Baxter College with larger ambitions. All these are healthy signs that the public are determined to have advanced science teaching, but the resources of the institutions are altogether inadequate to the end in view. Even in the few cases where the laboratories are efficient for teaching purposes, they are inefficient as laboratories for research. Under these circumstances the Royal Commission on Science advocated special Government laboratories for research. Such laboratories, supported by public money, are as legitimate subjects for expenditure as galleries for pictures or sculpture; but I think that they would not be successful, and would injure science if they failed. It would be safer in the meantime if the State assisted universities or well-established colleges to found laboratories of research under their own care. Even such a proposal shocks our Chancellor of the Exchequer, who tells us that this country is burdened with public debt, and has ironclads to build and arsenals to provide. Nevertheless our wealth is proportionally much greater than that of foreign States which are competing with so much vigour in the promotion of higher education. They deem such expenditure to be true economy, and do not allow their huge standing armies to be an apology for keeping their people backwards in the march of knowledge. France, which in the last ten years has been spending a million annually on university education, had a war indemnity to pay, and competes successfully with this country in ironclads. Either all foreign States are strangely deceived in their belief that the competition of the world has become a competition of intellect, or we are marvellously unobservant of the change which is passing over Europe in the higher education of the people. Preparations for war will not ensure to us the blessings and security of an enlightened peace. Protective expenditure may be wise, though productive expenditure is wiser.

> "Were half the powers which fill the world with terror,
> Were half the wealth bestowed on camps and courts,
> Given to redeem the human mind from error—
> There were no need of arsenals and forts."

Universities are not mere storehouses of knowledge; they are

[1] The cost of these laboratories has been as follows:—Chemical Institute, 35,000*l.*; Physical Institute, 28,000*l.*; Botanical Institute, 26,000*l.*; Observatory, 25,000*l.*; Anatomy, 42,000*l.*; Clinical Surgery, 26,000*l.*; Physiological Chemistry, 16,000*l.*; Physiological Institute, 13,900*l.*

also conservatories for its cultivation. In Mexico there is a species of ant which sets apart some of its individuals to act as honey-jars by monstrously extending their abdomens to store the precious fluid till it is wanted by the community. Professors in a university have a higher function, because they ought to make new honey as well as to store it. The widening of the bounds of knowledge, literary or scientific, is the crowning glory of university life. Germany unites the functions of teaching and research in the universities, while France keeps them in separate institutions. The former system is best adapted to our habits, but its condition for success is that our science chairs should be greatly increased so that teachers should not be wholly absorbed in the duties of instruction. Germany subdivides the sciences into various chairs, and gives to the professors special laboratories. It also makes it a condition for the higher honours of a university that the candidates shall give proofs of their ability to make original researches. Under such a system, teaching and investigation are not incompatible. In the evidence before the Science Commission many opinions were given that scientific men engaged in research should not be burdened with the duties of education, and there is much to be said in support of this view when a single professor for the whole range of a physical science is its only representative in a university. But I hope that such a system will not long continue, for if it do we must occupy a very inferior position as a nation in the intellectual competition of Europe. Research and education in limited branches of higher knowledge are not incompatible. It is true that Galileo complained of the burden imposed upon him by his numerous astronomical pupils, though few other philosophers have echoed this complaint. Newton, who produced order in worlds, and Dalton, who brought atoms under the reign of order and number, rejoiced in their pupils. Lalande spread astronomers as Liebig spread chemists, and Johannes Müller biologists, all over the world. Laplace, La Grange, Dulong, Gay Lussac, Berthollet, and Dumas were professors as well as discoverers in France. In England our discoverers have generally been teachers. In fact, I recollect only three notable examples of men who were not—Boyle, Cavendish, and Joule. It was so in ancient as well as in modern times, for Plato and Aristotle taught and philosophised. If you do not make the investigator a schoolmaster, as Dalton was, and as practically our professors are at the present time, with the duty of teaching all branches of their sciences, the mere elementary truths as well as the highest generalisations being compressed into a course, it is well that they should be brought into contact with the world in which they live, so as to know its wants and aspirations. They could then quicken the pregnant minds around them, and extend to others their own power and love of research. Goethe had a fine perception of this when he wrote—

> Wer in der Weltgeschichte lebt,
> Wer in die Zeiten schaut, und strebt,
> Nur der ist werth, zu sprechen und zu dichten.

Our universities are still far from the attainment of a proper combination of their resources between teaching and research. Even Oxford and Cambridge, which have done so much in recent years in the equipment of laboratories and in adding to their scientific staff, are still far behind a second-class German university. The professional faculties of the English universities are growing, and will diffuse a greater taste for science among their students, though they may absorb the time of the limited professoriate so as to prevent it advancing the boundaries of knowledge. Professional faculties are absolutely essential to the existence of universities in poor countries like Scotland and Ireland. This has been the case from the early days of the Bologna University up to the present time. Originally universities arose not by mere bulls of popes, but as a response to the strong desire of the professional classes to dignify their crafts by real knowledge. If their education had been limited to mere technical schools like the Medical School of Salerno which flourished in the eleventh century, length but not breadth would have been given to education. So the universities wisely joined culture to the professional sciences. Poor countries like Scotland and Ireland must have their academic systems based on the professional faculties, although wealthy universities like Oxford and Cambridge may continue to have them as mere supplements to a more general education. A greater liberality of support on the part of the State in the establishment of chairs of science, for the sake of science and not merely for the teaching of the professions, would enable the poorer universities to take their part in the advancement of knowledge.

I have already alluded to the foundation of new colleges in different parts of the kingdom. Owens College has worthily developed into the Victoria University. Formerly she depended for degrees on the University of London. No longer will she be like a moon reflecting cold and sickly rays from a distant luminary, for in future she will be a sun, a centre of intelligence, warming and illuminating the regions around her. The other colleges which have formed themselves in large manufacturing districts are remarkable expressions from them that science must be promoted. Including the colleges of a high class, such as University College and King's College in London, and the three Queen's Colleges in Ireland, the aggregate attendance of students in colleges without university rank is between nine and ten thousand, while that of the universities is fifteen thousand. No doubt some of the provincial colleges require considerable improvement in their teaching methods; sometimes they unwisely aim at a full university curriculum when it would be better for them to act as faculties. Still, they are all growing in the spirit of self-help, and some of them are destined, like Owens College, to develop into universities. This is not a subject of alarm to lovers of education, while it is one of hope and encouragement to the great centres of industry. There are too few autonomous universities in England in proportion to its population. While Scotland, with a population of 3¾ millions, has four universities with 6500 students, England, with 26 millions of people, has only the same number of teaching universities with 6000 students. Unless English colleges have such ambition, they may be turned into mere mills to grind out material for examinations and competitions. Higher colleges should always hold before their students that knowledge, for its own sake, is the only object worthy of reverence. Beyond college life there is a land of research flowing with milk and honey for those who know how to cultivate it. Colleges should at least show a Pisgah view of this Land of Promise, which stretches far beyond the Jordan of examinations and competitions.

V. *Science and Industry.*—In the popular mind the value of science is measured by its applications to the useful purposes of life. It is no doubt true that science wears a beautiful aspect when she confers practical benefits upon man. But truer relations of science to industry are implied in Greek mythology. Vulcan, the god of industry, wooed science, in the form of Minerva, with a passionate love, but the chaste goddess never married, although she conferred upon mankind nearly as many arts as Prometheus, who, like other inventors, saw civilisation progressing by their use while he lay groaning in want on Mount Caucasus. The rapid development of industry in modern days depends on the applications of scientific knowledge, while its slower growth in former times was due to experiments being made by trial and error in order to gratify the needs of man. Then an experiment was less a questioning of Nature than an exercise on the mind of the experimentalist. For a true questioning of Nature only arises when intellectual conceptions of the causes of phenomena attach themselves to ascertained facts as well as to their natural environments. Much real science had at one time accumulated in Egypt, Greece, Rome, and Arabia, though it became obscured by the intellectual darkness which spread over Europe like a pall for many centuries. The mental results of Greek science, filtered through the Romans and Arabians, gradually fertilised the soil of Europe. Even in ages which are deemed to be dark and unprolific, substantial though slow progress was made. By the end of the fifteenth century the mathematics of the Alexandrian school had become the possession of Western Europe; Arabic numerals, algebra, trigonometry, decimal reckoning, and an improved calendar having been added to its stock of knowledge. The old discoveries of Democritus and Archimedes in physics, and of Hipparchus and Ptolemy in astronomy, were producing their natural developments, though with great slowness. Many manufactures, growing chiefly by experience, and occasionally lightened up by glimmerings of science throughout the prevailing darkness, had arisen before the sixteenth century. A knowledge of the properties of bodies, though scarcely of their relations to each other, came through the labours of the alchemists, who had a mighty impulse to work; for by the philosopher's stone, often not larger than half a rape's seed, they hoped to attain the three sensuous conditions of human enjoyment—gold, health, and immortality. By the end of the fifteenth century many important manufactures were founded by empirical experiment, with only the uncertain guidance of science. Among these were the compass, printing, paper, gunpowder, guns, watches, forks, knitting-needles, horseshoes, bells, wood-cutting and copper-engraving, wire-drawing, steel, table glass, spectacles, microscopes, glass mirrors backed by amalgams of tin and lead, windmills, crushing and saw mills. These important manufactures arose from an increased knowledge of facts, around which scientific conceptions were slowly concreting. Aristotle defines this as science when he says, "Art begins when, from a great number of experiences, one general conception is formed which will embrace all similar cases." Such conceptions are formed only when culture developes the human mind and compels it to give a rational account of the world in which man lives, and of the objects in and around it, as well as of the phenomena which govern their action and evolution. Though the accumulation of facts is indispensable to the growth of science, a thousand facts are of less value to human progress than is a single one when it is scientifically comprehended, for it then becomes generalised in all similar cases. Isolated facts may be viewed as the dust of science. The dust which floats in the atmosphere is to the common observer mere incoherent matter in a wrong place, while to the man of science it is all-important when the rays of heat and light act upon its floating particles. It is by them that clouds and rains are influenced; it is by their selective influence on the solar waves that the blue of the heavens and the beauteous colours of the sky glorify all Nature. So, also, ascertained though isolated facts, forming the dust of science, become the reflecting media of the light of knowledge, and cause all Nature to assume a new aspect. It is with the light of knowledge that we are enabled to question Nature through direct experiment. The hypothesis or theory which induces us to put the experimental question may be right or wrong; still, *prudens questio dimidium scientiæ est*—it is half way to knowledge when you know what you have to inquire. Davy described hypothesis as the mere scaffolding of science, useful to build up true knowledge, but capable of being put up or taken down at pleasure. Undoubtedly a theory is only temporary, and the reason is, as Bacon has said, that the man of science "loveth truth more than his theory." The changing theories which the world despises are the leaves of the tree of science drawing nutriment to the parent stems, and enabling it to put forth new branches and to produce fruit; and though the leaves fall and decay, the very products of decay nourish the roots of the tree and reappear in the new leaves or theories which succeed.

When the questioning of Nature by intelligent experiment has raised a system of science, then those men who desire to apply it to industrial inventions proceed by the same methods to make rapid progress in the arts. They also must have means to compel Nature to reveal her secrets. Æneas succeeded in his great enterprise by plucking a golden branch from the tree of science. Armed with this even dread Charon dared not refuse a passage across the Styx; and the gate of the Elysian fields was unbarred when he hung the branch on its portal. Then new aspects of Nature were revealed—

"Another sun and stars they know
That shine like ours, but shine below."

It is by carrying such a golden branch from the tree of science that inventors are able to advance the arts. In illustration of how slowly at first and how rapidly afterwards science and its applications arise, I will take only two out of thousands of examples which lie ready to my hand. One of the most familiar instances is air, for that surely should have been soon understood if man's unaided senses are sufficient for knowledge. Air has been under the notice of mankind ever since the first man drew his first breath. It meets him at every turn; it fans him with gentle breezes, and it buffets him with storms. And yet it is certain that this familiar object—air—is very imperfectly understood up to the present time. We now know by recent researches that air can be liquefied by pressure and cold; but as a child still looks upon air as nothing, so did man in his early state. A vessel filled with air was deemed to be empty. But man, as soon as he began to speculate, felt the importance of air, and deemed it to be a soul of the world upon which the respiration of man and the god-like quality of fire depended. Yet a really intelligent conception of these two essential conditions to man's existence—respiration and combustion—was not formed till about a century ago (1775). No doubt long before that time there had been abundant speculations regarding air. Anaximenes, 548 years before Christ, and Diogenes of Apollonia, a century later, studied the properties of air so far as their senses would allow them; so, in fact, did Aristotle. Actual scientific experiments were made on air about the year 1100 by a remarkable Saracen, Alhazen, who ascertained important truths which enabled Galileo, Torricelli, Otto de Guericke, and others at a later period to discover laws leading to important practical applications. Still there was no intelligent conception as to the composition of air until Priestley in 1774 repeated, with the light of science, an empirical observation which Eck de Sulbach had made 300 years before upon the union of mercury with an ingredient of air and the decomposition of this compound by heat. This experiment now proved that the active element in air is oxygen. From that date our knowledge, derived from an intelligent questioning of air by direct experiments, has gone on by leaps and bounds. The air, which mainly consists of nitrogen and oxygen, is now known to contain carbonic acid, ammonia, nitric acid, ozone, besides hosts of living organisms which have a vast influence for good or evil in the economy of the world. These micro-organisms, the latest contribution to our knowledge of air, perform great analytical functions in organic nature, and are the means of converting much of its potential energy into actual energy. Through their action on dead matter the mutual dependence of plants and animals is secured, so that the air becomes at once the grave of organic death and the cradle of organic life. No doubt the ancients suspected this without being able to prove the dependence. Euripides seems to have seen it deductively when he describes the results of decay:—

"Then that which springs from earth, to earth returns,
And that which draws its being from the sky
Rises again up to the skyey height."

The consequences of the progressive discoveries have added largely to our knowledge of life, and have given a marvellous development to the industrial arts. Combustion and respiration govern a wide range of processes. The economical use of fuel, the growth of plants, the food of animals, the processes of husbandry, the maintenance of public health, the origin and cure of disease, the production of alcoholic drinks, the processes of making vinegar and saltpetre—all these and many other kinds of knowledge have been brought under the dominion of law. No doubt animals respired, fuel burned, plants grew, sugar fermented, before we knew how they depended upon air. But as the knowledge was empirical it could not be intelligently directed. Now all these processes are ranged in order under a wise economy of Nature, and can be directed to the utilities of life; for it is true, as Swedenborg says, that human "ends always ascend as Nature descends." There is scarcely a large industry in the world which has not received a mighty impulse by the better knowledge of air acquired within a hundred years. If I had time I could show still more strikingly the industrial advantages which have followed from Cavendish's discovery of the composition of water. I wish that I could have done this, because it was Addision who foolishly said, and Paley who as unwisely approved the remark, "that mankind required to know no more about water than the temperature at which it froze and boiled, and the mode of making steam."

When we examine the order of progress in the arts, even before they are illumined by science, their improvements seem to be the resultants of three conditions:

(1) The substitution of natural forces for brute animal power, as when Hercules used the waters of the Alpheus to cleanse the Augean stables; or when a Kamchadal of Eastern Asia, who has been three years hollowing out a canoe, finds that he can do it in a few hours by fire.

(2) The economy of time, as when a calendering machine produces the same gloss to miles of calico that an African savage gives to a few inches by rubbing it with the shell of a snail; or the economy of production, as when steel pens, sold when first introduced at one shilling apiece, are now sold at a penny per dozen; or when steel rails, lately costing 45*l*. per ton, can now be sold at 5*l*.

(3) Methods of utilising waste products, or of endowing them with properties which render them of increased value to industry, as when waste scrap iron and the galls on the oak are converted into ink; or the badly-smelling waste of gasworks is transformed into fragrant essences, brilliant dyes, and fertilising manure; or when the effete matter of animals or old bones is changed into lucifer-matches.

All three results are often combined when a single end is obtained—at all events, economy of time and production invariably follows when natural forces substitute brute animal force. In industrial progress the sweat of the brow is lessened by the conceptions of the brain. How exultant is the old Greek poet, Antipater,[1] when women are relieved of the drudgery of turning the grindstones for the daily supply of corn. "Woman! you who have hitherto had to grind corn, let your arms rest for the future. It is no longer for you that the birds announce by their songs the dawn of the morning. Ceres has ordered the *water-nymphs* to move the heavy millstones and perform your labour." Penelope had twelve slaves to grind corn for her small household. During the most prosperous time of Athens it was estimated that there were twenty slaves to each free citizen. Slaves are mere machines, and machines neither invent nor discover. The bondmen of the Jews, the helots of Sparta, the captive slaves of Rome, the serfs of Europe, and uneducated labourers of the present day who are the slaves of ignorance, have added nothing to human progress. But as natural forces substitute and become cheaper than slave labour, liberty follows advancing civilisation. Machines require educated superintendence. One shoe factory in Boston by its machine does the work of thirty thousand shoemakers in Paris who have still to go through the weary drudgery of mechanical labour. The steam power of the world, during the last twenty years, has risen from 11½ million to 29 million horse-power, or 152 per cent.

Let me take a single example of how even a petty manufacture improved by the teachings of science affects the comforts and enlarges the resources of mankind. When I was a boy the only way of obtaining a light was by the tinder-box, with its quadruple materials, flint and steel, burnt rags or tinder, and a sulphur match. If everything went well, if the box could be found and the air was dry, a light could be obtained in two minutes; but very often the time occupied was much longer, and the process became a great trial to the serenity of temper. The consequence of this was that a fire or a burning lamp was kept alight through the day. Old Gerard, in his herbal, tells us how certain fungi were used to carry fire from one part of the country to the other. The tinder-box long held its position as a great discovery in the arts. The *Pyxidicula igniaria* of the Romans appears to have been much the same implement, though a little ruder, than the flint and steel which Philip the Good put into the collar of the Golden Fleece in 1429 as a representation of high knowledge in the progress of the arts. It continued to prevail till 1833, when phosphorus matches were introduced, though I have been amused to find that there are a few venerable ancients in London who still stick to the tinder box and for whom a few shops keep a small supply. Phosphorus was no new discovery, for it had been obtained by an Arabian called Bechel in the eighth century. However it was forgotten, and was rediscovered by Brandt, who made it out of very stinking materials in 1669. Other discoveries had, however, to be made before it could be used for lucifer matches. The science of combustion was only developed on the discovery of oxygen a century later. Time had to elapse before chemical analysis showed the kind of bodies which could be added to phosphorus so as to make it ignite readily. So it was not till 1833 that matches became a partial success. Intolerably bad they then were, dangerously inflammable, horribly poisonous to the makers, and injurious to the lungs of the consumers. It required another discovery, by Schrötter in 1845, to change poisonous waxy into innocuous red-brick phosphorus in order that these defects might be remedied, and to give us the safety-match of the present day. Now what have these successive discoveries in science done for the nation, in this single manufacture, by an economy of time? If before 1833 we had made the same demands for light that we now do, when we daily consume eight matches per head of the population, the tinder-box could have supplied the demand under the most favourable conditions by an expenditure of one quarter of an hour. The lucifer-match supplies a light in fifteen seconds on each occasion, or in two minutes for the whole day. Putting these differences into a year the venerable ancient who still sticks to his tinder-box would require to spend ninety hours yearly in the production of light, while the user of lucifer-matches spends twelve hours; so that the latter has an economy of seventy-eight hours yearly, or about ten working days. Measured by cost of production at one shilling and sixpence daily, the economy of time represented in money to our population is twenty-six millions of pounds annually. This is a curious instance of the manner in which science leads to economy of time and wealth even in a small manufacture. In larger industries the economy of time and labour produced by the application of scientific discoveries is beyond all measurement. Thus the discovery of latent heat by Black led to the inventions of Watt; while that of the mechanical equivalent of heat by Joule has been the basis of the progressive improvements in the steam-engine which enables power to be obtained by a consumption of fuel less than one-fourth the amount used twenty years ago. It may be that the engines of Watt and Stephenson will yield in their turn to more economical motors; still they have already expanded the wealth, resources, and even the territories of England more than all the battles fought by her soldiers or all the treaties negotiated by her diplomatists.

[1] "Analecta Veterum Græcorum," Epig. 39, vol. ii. p. 119.

The coal which has hitherto been the chief source of power probably represents the product of five or six million years during which the sun shone upon the plants of the Carboniferous period, and stored up its energy in this convenient form. But we are using this conserved force wastefully and prodigally; for although horse power in steam-engines has so largely increased since 1864, two men only now produce what three men did at that date. It is only three hundred years since we became a manufacturing country. According to Prof. Dewar, in less than two hundred years more the coal of this country will be wholly exhausted, and in half that time will be difficult to procure. Our not very distant descendants will have to face the problem —What will be the condition of England without coal? The answer to that question depends upon the intellectual development of the nation at that time. The value of the intellectual factor of production is continually increasing; while the values of raw material and fuel are lessening factors. It may be that when the dreaded time of exhausted fuel has arrived, its importation from other coal-fields, such as those of New South Wales, will be so easy and cheap, that the increased technical education of our operatives may largely over-balance the disadvantages of increased cost in fuel. But this supposes that future Governments in England will have more enlightened views as to the value of science than past Governments have possessed.

Industrial applications are but the overflowings of science welling over from the fulness of its measure. Few would ask now, as was constantly done a few years ago, "What is the use of an abstract discovery in science?" Faraday once answered this question by another, "What is the use of a baby?" Yet around that baby centre all the hopes and sentiments of his parents, and even the interests of the State, which interferes in its upbringing so as to ensure it being a capable citizen. The processes of mind which produce a discovery or an invention are rarely associated in the same person, for while the discoverer seeks to explain causes and the relations of phenomena, the inventor aims at producing new effects, or at least of obtaining them in a novel and efficient way. In this the inventor may sometimes succeed without much knowledge of science, though his labours are infinitely more productive when he understands the causes of the effects which he desires to produce.

A nation in its industrial progress, when the competition of the world is keen, cannot stand still. Three conditions only are possible for it. It may go forward, retrograde, or perish. Its extinction as a great nation follows its neglect of higher education, for, as described in the proverb of Solomon, "They that hate instruction love death." In sociology, as in biology, there are three states. The first of balance, when things grow neither better nor worse; the second that of elaboration or evolution, as we see it when animals adapt themselves to their environments; and third, that of degeneration, when they rapidly lose the ground they have made. For a nation, a state of balance is only possible in the early stage of its existence, but it is impossible when its environments are constantly changing.

The possession of the raw materials of industry and the existence of a surplus population are important factors for the growth of manufactures in the early history of a nation, but afterwards they are bound up with another factor—the application of intellect to their development. England could not be called a manufacturing nation till the Elizabethan age. No doubt coal, iron, and wood were in abundance, though, in the reign of the Plantagenets, they produced little prosperity. Wool was sent to Flanders to be manufactured, for England then stood to Holland as Australia now does to Yorkshire. The political crimes of Spain, from the reign of Ferdinand and Isabella to that of Philip III., destroyed it as a great manufacturing nation, and indirectly led to England taking its position. Spain, through the activity and science of the Arabian intellect, had acquired many important industries. The Moors and the Moriscoes, who had been in Spain for a period as long as from the Norman Conquest of this country to the present date, were banished, and with them departed the intellect of Spain. Then the invasion of the Low Countries by Philip II. drove the Flemish manufacturers to England, while the French persecution of the Huguenots added new manufacturing experience, and with them came the industries of cotton, wool, and silk. Cotton mixed with linen and wool became freely used, but it was only from 1738 to the end of the century that the inventions of Wyatt, Arkwright, Hargreaves, Crompton, and Cartwright started the wonderful modern development. The raw cotton was imported from India or America, but that fact as regards cost was a small factor in comparison with the intellect required to convert it into a utility. Science has in the last hundred years altered altogether the old conditions of industrial competition. She has taught the rigid metals to convey and record our thoughts even to the most distant lands, and, within less limits, to reproduce our speech. This marvellous application of electricity has diminished the cares and responsibilities of Governments, while it has at the same time altered the whole practice of commerce. To England steam and electricity have been of incalculable advantage. The ocean, which once made the country insular and isolated, is now the very life-blood of England, and of the greater England beyond the seas. As in the human body the blood bathes all its parts, and through its travelling corpuscles carries force to all its members, so in the body politic of England and its pelasgic extensions, steam has become the circulatory and electricity the nervous system. The colonies, being young countries, value their raw materials as their chief sources of wealth. When they become older they will discover that it is not in these, but in the culture of scientific intellect, that their future prosperity depends. Older nations recognise this as the law of progress more than we do; or, as Jules Simon tersely puts it—"That nation which most educates her people will become the greatest nation, if not to-day, certainly to-morrow." Higher education is the condition of higher prosperity, and the nation which neglects to develope the intellectual factor of production must degenerate, for it cannot stand still. If we felt compelled to adopt the test of science given by Comte, that its value must be measured by fecundity, it might be prudent to claim industrial inventions as the immediate fruit of the tree of science, though only fruit which the prolific tree has shed. But the test is untrue in the sense indicated, or rather the fruit, according to the simile of Bacon, is like the golden apples which Aphrodite gave to the suitor of Atalanta, who lagged in his course by stooping to pick them up, and so lost the race. The true cultivators of the tree of science must seek their own reward by seeing it flourish, and let others devote their attention to the possible practical advantages which may result from their labours.

There is, however, one intimate connection between science and industry which I hope will be more intimate as scientific education becomes more prevalent in our schools and universities. Abstract science depends on the support of men of leisure, either themselves possessing or having provided for them the means of living without entering into the pursuits of active industry. The pursuit of science requires a superfluity of wealth in a community beyond the needs of ordinary life. Such superfluity is also necessary for art, though a picture or a statue is a saleable commodity, while an abstract discovery in science has no immediate, or, as regards the discoverer, proximate commercial value. In Greece, when philosophical and scientific speculation was at its highest point, and when education was conducted in its own vernacular and not through dead languages, science, industry, and commerce were actively prosperous. Corinth carried on the manufactures of Birmingham and Sheffield, while Athens combined those of Leeds, Staffordshire, and London, for it had woollen manufactories, potteries, gold and silver work, as well as shipbuilding. Their philosophers were the sons of burghers, and sometimes carried on the trades of their fathers. Thales was a travelling oil merchant, who brought back science as well as oil from Egypt. Solon and his great descendant Plato, as well as Zeno, were men of commerce. Socrates was a stonemason; Thucydides a gold-miner; Aristotle kept a druggist's shop until Alexander endowed him with the wealth of Asia. All but Socrates had a superfluity of wealth, and he was supported by that of others. Now, if our universities and schools created that love of science which a broad education would surely inspire, our men of riches and leisure who advance the boundaries of scientific knowledge could not be counted on the fingers as they now are, when we think of Boyle, Cavendish, Napier, Lyell, Murchison, and Darwin, but would be as numerous as our statesmen and orators. Statesmen, without a following of the people who share their views and back their work, would be feeble indeed. But while England has never lacked leaders in science, they have two few followers to risk a rapid march. We might create an army to support our generals in science, as Germany has done, and as France is now doing, if education in this country would only mould itself to the needs of a scientific age. It is with this feeling that Horace Mann wrote: "The action of the mind is like the action of fire: one billet of wood will hardly burn alone, though as dry as the sun and north-west wind can make it, and though placed in a current of air; ten such billets will burn well together, but a hundred will create a heat fifty times as intense as ten—will make a current of air to fan their own flame, and consume even greenness itself."

VI. *Abstract Science the Condition for Progress.*—The subject of my address has been the relations of science to the public weal. That is a very old subject to select for the year 1885. I began it by quoting the words of an illustrious prince, the consort of our Queen, who addressed us on the same subject from this platform twenty-six years ago. But he was not the first prince who saw how closely science is bound up with the welfare of States. Ali, the son-in-law of Mahomet, the fourth successor to the Caliphate, urged upon his followers that men of science and their disciples give security to human progress. Ali loved to say, "Eminence in science is the highest of honours," and "He dies not who gives life to learning." In addressing you upon texts such as these my purpose was to show how unwise it is for England to lag in the onward march of science when most other European Powers are using the resources of their States to promote higher education and to advance the boundaries of knowledge. English Governments alone fail to grasp the fact that the competition of the world has become a competition in intellect. Much of this indifference is due to our systems of education. I have ill fulfilled my purpose if, in claiming for science a larger share in public education, I have in any way depreciated literature, art, or philosophy, for every subject which adds to culture aids in human development. I only contend that in public education there should be a free play to the scientific faculty, so that the youths who possess it should learn the richness of their possession during the educative process. The same faculties which make a man great in any walk of life—strong love of truth, high imagination tempered by judgment, a vivid memory which can co-ordinate other facts with those under immediate consideration—all these are qualities which the poet, the philosopher, the man of literature, and the man of science equally require and should cultivate through all parts of their education as well as in their future careers. My contention is that science should not be practically shut out from the view of a youth while his education is in progress, for the public weal requires that a large number of scientific men should belong to the community. This is necessary because science has impressed its character upon the age in which we live, and, as science is not stationary, but progressive, men are required to advance its boundaries, acting as pioneers in the onward march of States. Human progress is so identified with scientific thought, both in its conception and realisation, that it seems as if they were alternative terms in the history of civilisation. In literature, and even in art, a standard of excellence has been attained which we are content to imitate because we have been unable to surpass. But there is no such standard in science. Formerly, when the dark cloud was being dissipated which had obscured the learning of Greece and Rome, the diffusion of literature or the discovery of lost authors had a marked influence on advancing civilisation. Now, a Chrysoloras might teach Greek in the Italian universities without hastening sensibly the onward march of Italy; a Poggio might discover copies of Lucretius and Quintilian without exercising a tithe of the influence on modern life that an invention by Stephenson or Wheatstone would produce. Nevertheless, the divorce of culture and science, which the present state of education in this country tends to produce, is deeply to be deplored, because a cultured intelligence adds greatly to the development of the scientific faculty. My argument is that no amount of learning without science suffices in the present state of the world to put us in a position which will enable England to keep ahead or even on a level with foreign nations as regards knowledge and its applications to the utilities of life. Take the example of any man of learning, and see how soon the direct consequences resulting from it disappear in the life of a nation, while the discoveries of a man of science remain productive amid all the shocks of empire. As I am in Aberdeen I remember that the learned Dutchman Erasmus was introduced to England by the encouragement which he received from Hector Boece, the Principal of King's College in this University. Yet even in the case of Erasmus—who taught Greek at Cambridge and did so much for the revival of classical literature as well as in the promotion of spiritual freedom—how little has civilisation to ascribe to him in comparison with the discoveries of two other Cambridge men, Newton and Cavendish. The discoveries of Newton will influence the destinies of mankind to the end of the world. When he established the laws by which the motions of the great masses of matter in the universe are governed, he conferred an incalculable benefit upon the intellectual development of the human race. No great discovery flashes upon the world at once, and therefore Pope's lines on Newton are only a poetic fancy :—

> "Nature and Nature's laws lay hid in night,
> God said, 'Let Newton be,' and all was light."

No doubt the road upon which he travelled had been long in preparation by other men. The exact observations of Tycho Brahe, coupled with the discoveries of Copernicus, Kepler, and Galileo had already broken down the authority of Aristotle and weakened that of the Church. But though the conceptions of the universe were thus broadened, mankind had not yet rid themselves of the idea that the powers of the universe were still regulated by spirits or special providences. Even Kepler moved the planets by spirits, and it took some time to knock these celestial steersmen on the head. Descartes, who really did so much by his writings to force the conclusion that the planetary movements should be dealt with as an ordinary problem in mechanics, looked upon the universe as a machine, the wheels of which were kept in motion by the unceasing exercise of a divine power. Yet such theories were only an attempt to regulate the universe by celestial intelligences like our own, and by standards within our reach. It required the discovery of an all-pervading law, universal throughout all space, to enlarge the thoughts of men, and one which, while it widened the conceptions of the universe, reduced the earth and solar system to true dimensions. It is by the investigation of the finite on all sides that we obtain a higher conception of the infinite—

> "Willst du ins Unendliche schreiten,
> Geh nur im Endlichen nach allen Seiten."

Ecclesiastical authority had been already undermined by earnest inquirers, such as Wycliffe and Huss, before Luther shook the pillars of the Vatican. They were removers of abuses, but were confined within the circles of their own beliefs. Newton's discovery cast men's minds into an entirely new mould, and levelled many barriers to human progress. This intellectual result was vastly more important than the practical advantages of the discovery. It is true that navigation and commerce mightily benefited by our better knowledge of the motions of the heavenly bodies. Still these benefits to humanity are incomparably less in the history of progress than the expansion of the human intellect which followed the withdrawal of the cramps that confined it. Truth was now able to discard authority, and marched forward without hindrance. Before this point was reached Bruno had been burned, Galileo had abjured, and both Copernicus and Descartes had kept back their writings for fear of offending the Church.

The recent acceptance of evolution in biology has had a like effect in producing a far profounder intellectual change in human thought than any mere impulse of industrial development. Already its application to sociology and education is recognised, but that is of less import to human progress than the broadening of our views of Nature.

Abstract discovery in science is then the true foundation upon which the superstructure of modern civilisation is built; and the man who would take part in it should study science, and, if he can, advance it for its own sake and not for its applications. Ignorance may walk in the path lighted by advancing knowledge, but she is unable to follow when science passes her, for, like the foolish virgin, she has no oil in her lamp.

An established truth in science is like the constitution of an atom in matter—something so fixed in the order of things that it has become independent of further dangers in the struggle for existence. The sum of such truths forms the intellectual treasure which descends to each generation in hereditary succession. Though the discoverer of a new truth is a benefactor to humanity, he can give little to futurity in comparison with the wealth of knowledge which he inherited from the past. We, in our generation, should appreciate and use our great possessions—

> "For me your tributary stores combine.
> Creation's heir; the world, the world is mine."

SECTION A.

MATHEMATICAL AND PHYSICAL SCIENCE.

Opening Address by Prof. G. Chrystal, M.A., F.R.S.E., President of the Section.

When a man finds himself unexpectedly in some unusual situation his first impulse is to look around and see how others have done in like circumstances. I have accordingly run through the addresses of my predecessors in the honourable office of president of Section A, which is fated this year to be filled somewhat unworthily. This examination has, I am bound to say, comforted me not a little. I have found precedents for all kinds of addresses, long and short, even apparently for none at all. The variety of subjects is also suggestive of great latitude. I have found reviews of the progress of mathematical and physical science, discussions of special scientific subjects, dissertations on the promotion of scientific research, and on the teaching and diffusion of science, all chosen in their turn for the subjects of this opening address.

Following some of the most eminent of my forerunners, I propose to be brief; following the last of them, Prof. Henrici, I shall take for my subject, so far as I have one, the Diffusion of Scientific Knowledge. Apart from the fact that Prof. Henrici's address greatly interested me, and that I find many of his conclusions in agreement with the results of my own experience, and that, therefore, I wish to second him with all my power, I have other reasons for this choice, For more than half the year I am employed with absolute continuity in teaching mathematics, and it has happened for the last eight years or so that the other half has been mainly occupied in a variety of ways with science-teaching generally. This is the thing concerning which I have had most experience, and I hold it to be the most respectful course towards my audience to speak to them on the subject that I know best.

Ever since I began to study science I have been deeply interested in the question of how it could best be taught. I believe my meditations in that direction were awakened by some unsuccessful boyish efforts to apply to the satisfaction of a ploughman, who was my friend and confidant, certain principles of natural philosophy to explain the action of his plough. Wisely and unwisely I have always been ardent about the improvement of scientific teaching. I was so long before I dreamt that I should one day be called upon to put my ideas through the cold ordeal of practice. It would not be becoming that I should speak at any time, more particularly to-day, regarding the success of my own efforts, or even regarding my alternate fits of hopefulness and despair. It is enough to say that, in such a cause,

> "'Tis better to have loved and lost,
> Than never to have loved at all."

The British Association, by its title, exists for the advancement of science. Now, I hold that one of the essential conditions for that advancement is the existence of a scientific public—a public, like the Athenians of old, eager to hear and tell of some new truth ; eager to discuss and eager to criticise ; ready to appreciate what is novel ; to receive it if sound, to reject it if unsound. It is to such a public that the British Association appeals, and certainly in the past it has not found its public wanting in generosity. What I should wish to see is less of mere friendly onlooking and more participation in the dance.

I am not speaking now merely of a professional public, such as is so prominent in Germany for instance, made up of teachers and others professionally concerned with science. I refer mainly to that amateur but truly expert public which has always been so honourable a feature of English science, as examples of which I may mention Boyle and Cavendish in former days, and Joule and Spottiswoode in our own. It is quite true that much of that scientific public came in days of yore from the leisured class, whose ratio to the rest of the nation will not improbably decrease in the course of our social development. I think, however, that the loss we may thus sustain will be more than compensated by the continual increase of those who have received higher education of some kind or other, and whose daily occupations give them an interest, direct or indirect, in one or more branches of science.

It may not be amiss to insist for a little on the advantages to science of a great body of men unofficially engaged in scientific research, in writing regarding science, or even in merely turning scientific matter over in their minds. It will not have escaped the notice of those among you who have studied the history of science, that few scientific ideas spring up suddenly without previous trace or history. It is perfectly true that in many cases some mind of unwonted breadth and firmness is required to formulate the new doctrine, and carry it to manifold fruition; but a close examination always shows that the sprite was in the air before the Prospero came to catch him. It is very striking to notice, in the history of Algebra for instance, long periods in which great improvements were effected in the science, which cannot be traced to any individual, but seem to have been due merely to the working of the minds of scientific men generally upon the matter, one giving it this little turn, another that, in the main always for the better. Like every other thing that has the virtue of truth in it, science grows as it goes, not like the idle gossiping tale by the casual accretion of heterogeneous matter, but by the chemical combination of pure element with pure element in reasonable proportion.

I know of no greater advantage for science than the existence of an army of independent workers sufficiently enlightened for self-criticism, who shall test the results and theories of their day. Great and indispensable as are the uses of professional schools of scientific workmen, they are open to one great and insidious danger. The temptation there to swear by the word of the master is often irresistible. Not to speak of its being often the readiest avenue to fame and profit, it is the perfectly natural consequence of the contact of smaller mind with greater.

There are few things where the want of an enlightened scientific public strikes an expert more than the matter of scientific text-books. If the British public were educated as it ought to be, publishers would not be able to palm off upon them in this guise the ill-paid work of fifth-rate workmen so often as they do; nor would the scientific articles and reviews in popular journals and magazines so often be written by men so palpably ignorant of their subject.

We all have a great respect for the integrity of our British legislators, whatever doubts may haunt us occasionally as to their capacity in practical affairs. The ignorance of many of them regarding some of the most elementary facts that bear on every-day life is very surprising. Scientifically speaking, uneducated themselves, they seem to think that they will catch the echo of a fact or the solution of an arithmetical problem by putting their ears to the sounding-shell of uneducated public opinion. When I observe the process which many such people employ for arriving at what they consider truth, I often think of a story I once heard of an eccentric German student of chemistry. This gentleman was idle, but, like all his nation, systematic. When he had a precipitate to weigh, instead of resorting to his balance, he would go the round of the laboratory, hold up the test-tube before each of his fellow-students in turn, and ask him to guess the weight. He then set down all the replies, took the average, and entered the result in his analysis.

I will not take up your time in insisting upon the necessity of the diffusion of science among that large portion of the public who are, or ought to be, appliers of scientific knowledge to practical life. That part of my theme is so obvious, and has been of late so much dwelt upon, that I may pass it by, and draw your attention to another place in which the shoe pinches. All of you who have taken any practical interest in the organisation of our educational institutions must be aware of the great difficulty in securing the services of non-professional men of sufficient scientific knowledge to act on School Boards, and undertake the direction of our higher schools. It is no secret among those who carefully watch the course of the times in these matters that our present organisation is utterly insufficient; that it has not solved, and shows every day less likelihood of solving, the problems of higher education. This arises, to a great extent, from the fact that a scientifically educated public of the extent presupposed by the organisation really does not at present exist.

If the existence of a great scientific public be as important as I think I have shown it to be, it must be worth while to devote a few moments to the consideration of the means we adopt to produce it both in the rising and in the risen generation.

It would naturally be expected that we should look carefully to the scientific education of our youth, to see that the best men and the best means that could be had were devoted to it; that we should endeavour to make for them a broad straight road to the newest and best of our scientific ideas; that we should exercise them when young on the best work of the greatest masters; familiarise them early with the great men and the great feats of science, both of the past and of the present; that we should avoid retarding their progress by making the details and illustrations or particular rules and methods end in themselves. Granting that it is impossible to bring every learner within reach of the fullest scientific knowledge of his time, it would surely be reasonable to take care that the little way we lead him should not be along some devious by-path, but towards some eminence from which he might at least *see* the promised land. The end of all scientific training of the great public I take to be, to enable each member of it to look reason and nature in the face, and judge for himself what, considering the circumstances of his day, may be known, and not be deceived regarding what must to him remain unknown. If this be so, surely the ideal of scientific education which I have sketched is the right one: yet it is most certainly not the ideal of our present system of instruction. To attain conviction on that head it is sufficient to examine the text-books and examination papers of the day.

Let us confine ourselves for the present to the most elementary of all the exact sciences, viz., geometry and algebra. These two, although among the oldest, are, as Professor Cayley very justly reminded the Association last year, perhaps the most progressive and promising of all the sciences. Great names of antiquity are associated with them, and in modern times an army of men of genius have aided their advance. Moreover, it cannot be said that this advance concerns the higher parts of these sciences alone. On the contrary, the discoveries of Gauss, Lobatschewsky, and Riemann, and of Poncelet, Möbius, Steiner, Chasles, and Von Standt, in geometry, and the labours of De Morgan, Hamilton, and Grassman, not to mention many others, in algebra, have thrown a flood of light on the elements of both these subjects. What traces of all this do we find in our school books? To be sure *antiquity* is stamped upon our geometry, for we use the text-book of Euclid, which is some two thousand years old; but where can we point to the influence of *modern* progress in our geometrical teaching? For our teaching of algebra, I am afraid, we can claim neither the sanction of antiquity nor the light of modern times. Whether we look at the elementary, or at what is called the higher teaching of this subject, the result is unsatisfactory. With respect to the former, my experience justifies the criticism of Professor Henrici; and I have no doubt that the remedy he suggests would be effectual. In the higher teaching, which interests me most, I have to complain of the utter neglect of the all-important notion of algebraic form. I found, when I first tried to teach University students co-ordinate geometry, that I had to go back and teach them algebra over again. The fundamental idea of an integral function of a certain degree, having a certain form and so many coefficients, was to them as much an unknown quantity as the proverbial x. I found that their notion of higher algebra was the solution of harder and harder equations. The curious thing is that many examination candidates, who show great facility in reducing exceptional equations to quadratics, appear not to have the remotest idea beforehand of the number of solutions to be expected; and that they will very often produce for you by some fallacious mechanical process a solution which is none at all. In short, the logic of the subject, which, both educationally and scientifically speaking, is the most important part of it, is wholly neglected. The whole training consists in example grinding. What should have been merely the help to attain the end has become the end itself. The result is that algebra, as we teach it, is neither an art nor a science, but an ill-digested farrago of rules, whose object is the solution of examination problems.

The history of this matter of problems, as they are called, illustrates in a singularly instructive way the weak point of our English system of education. They originated, I fancy, in the Cambridge Mathematical Tripos Examination, as a reaction against the abuses of cramming bookwork, and they have spread into almost every branch of science teaching—witness test-tubing in chemistry. At first they may have been a good thing; at all events the tradition at Cambridge was strong in my day, that he that could work the most problems in three or two and a half hours was the ablest man, and, be he ever so ignorant of his subject in its width and breadth, could afford to despise those less gifted with this particular kind of superficial sharpness. But, in the end, came all to the same: we were prepared for problem-working in exactly the same way as for bookwork. We were directed to work through old problem papers, and study the style and peculiarities of the day and of the examiner. The day and the examiner had, in truth, much to do with it, and fashion reigned in problems as in everything else. The only difference I could ever see between problems and bookwork was the greater predominance of the inspiriting element of luck in the former. This advantage was more than compensated for by the peculiarly disjointed and, from a truly scientific point of view, worthless nature of the training which was employed to cultivate this species of mental athletics. The result, so far as problems worked in examinations go, is, after all, very miserable, as the reiterated complaints of examiners show; the effect on the examinee is a well-known enervation of mind, an almost incurable superficiality, which might be called Problematic Paralysis —a disease which unfits a man to follow an argument extending beyond the length of a printed octavo page. Another lamentable feature of the matter is that an enormous amount of valuable time is yearly wasted in this country in the production of these scientific trifles. Against the occasional working and propounding of problems as an aid to the comprehension of a subject, and to the starting of a new idea, no one objects, and it has always been noted as a praiseworthy feature of English methods, but the abuse to which it has run is most pernicious.

All men practically engaged in teaching who have learned enough, in spite of the defects of their own early training, to enable them to take a broad view of the matter, are agreed as to the canker which turns everything that is good in our educational practice to evil. It is the absurd prominence of written competitive examinations that works all this mischief. The end of all education nowadays is to fit the pupil to be examined; the end of every examination not to be an educational instrument, but to be an *examination* which a creditable number of men, however badly taught, shall pass. We reap, but we omit to sow. Consequently our examinations, to be what is called fair —that is, beyond criticism in the newspapers—must contain nothing that is not to be found in the most miserable text-book that any one can cite bearing on the subject. One of my students, for example, who was plucked in his M.A. examination, and justly so if ever man was, by the unanimous verdict of three examiners, wrote me an indignant letter because he believed, or was assured, that the paper set by the examiners could not have been answered out of Todhunter's Elementary Algebra. I have nothing to say, of course, against that or any other text-book, but who put it into the poor young man's head that the burden lay with me to prove that the examination in question ought to contain nothing but what is to be found in Todhunter's Elementary Algebra? The course of this kind of reasoning is plain enough, and is often developed in the newspapers with that charming simplicity which is peculiar to honest people who are, at the same time, very ignorant and very unthinking. First, it follows that lectures should contain nothing but what is to be found in every text-book; secondly, lectures are therefore useless, since it is all in the text-book; thirdly, the examination should allude to nothing that is not in the text-books, because that would be unfair; fourthly, which is the coach or crammer's deduction, there should be nothing in the text-book that is not likely to be set in the examination. The problem for the writer of a text-book has come now, in fact, to be this—to write a book so neatly trimmed and compacted that no coach, on looking through it, can mark a single passage which the candidate for a minimum pass can safely omit. Some of these text-books I have seen, where the scientific matter has been, like the lady's waist in the nursery song, compressed "so gent and sma'," that the thickness of it barely, if at all, surpasses what is devoted to the publisher's advertisements. We shall return, I verily believe, to the Compendium of Martianus Capella. The result of all this is that science, in the hands of specialists, soars higher and higher into the light of day, while educators and the educated are left more and more to wander in primeval darkness.

When our system sets such mean ends before the teacher, and encourages such unworthy conceptions of education, is it to be wondered at that the cry arises that pupils degenerate beneath even the contemptible standards of our examinations? These can hardly be made low enough to suit the popular taste. It is no merit of the system we pursue, but due simply to the better educated among our teachers—men, many of them, who work for little reward and less praise—that we have not come to a worse pass already. Some even of the much-abused crammers have conceptions of a teacher's duty far higher than the system-mongers of the day, whom it is their special business to outwit; and it is but fair to allow to such of these also as deserve it part of the credit of stemming the torrent of degeneration. We place our masters in positions such that their very bread depends upon their doing what many of them know and will acknowledge to be *wrong*. Their excuse is, "We do so and so because of the examination."

The cure for all this evil is simply to give effect to a higher ideal of education in general, and of scientific education in particular. Science cannot live among the people, and scientific education cannot be more than a wordy rehearsal of dead text-books, unless we have living contact with the working minds of living men. It takes the hand of God to make a great mind, but contact with a great mind will make a little mind greater. The most valuable instruction in any art or science is to sit at the feet of a master, and the next best to have contact with another who has himself been so instructed. No agency that I have ever seen at work can compare for efficiency with an intelligent teacher, who has thoroughly made his subject his own. It is by providing such, and not by sowing the dragon's teeth of examinations, that we can hope to raise up an intelligent generation of scientifically educated men, who shall help our race to keep its place in the struggle of nations. In the future we must look more to men and to ideas, and trust less to mere systems. Systems have had their trial. In particular, systems of examination have been tested and found wanting in nearly every civilised country on the face of the earth. Backward as we are here, we are stirring. The University of London, after rendering a great service to the country by forcing the older universities to give up the absurd practice of restricting their advantages to persons professing a particular shade of religious belief, has for many years pursued its career as a mere examining body. It has done so with rare advantages in the way of Government aid, efficient organisation, and an unsurpassed staff of examiners. Yet it has been a failure as an instrument for promoting the higher education—foredoomed to be so, because, as I have said, you must sow before you can reap. At the present time, with great wisdom, the managers of that institution have set about the task of really fitting it out for the great end that it professes to pursue. If they succeed in so doing, they will confer upon the higher education one of the greatest benefits it has yet received. They have an opportunity before them of dethroning the iron tyrant Examination which is truly enviable. This movement is only one of the signs of the times. Among the younger generation I find few or none that have any belief in the "learn when you can and we will examine you" theory; and small wonder, for they have tasted the bitterness of its fruit. *Laissez faire* as a method in the higher education no longer holds its place, except in the minds of inexperienced elderly people, who cling, not unnaturally, to the views and fashions which were young when they were so.

All the same, the task of reformation is not an easy one. Examinations have a strong hold upon us, for various reasons, some good, some bad, but all powerful. In the first place, they came in as an outlet from the system of patronage, which, with many obvious advantages, some of which are now sorely missed, had become unsuited to our social conditions. There is a certain advantage in examinations from the organiser's point of view, which any one who, like myself, has to deal with large quantities of pretty raw material, will readily understand. Again, there is an orderly bustle about the system that pleases the business-loving eye of the Briton. Yearly the printed sheets go forth in every corner of the land. The candidates meet and, in the solemn silence of the examination hall, the inspector, the local magnate, or the professor, sits, while for two or three busy hours the pens go scratching over the paper. A feeling of thankfulness comes over the important actor in this well-ordered scene, that the younger generation have such advantages that their fathers never knew. It is only when the answers are dissected in the examiner's study that the rottenness is revealed underlying the fair outward skin. But then the examiner must go by his standards; he must consider what is done elsewhere, and what is to be reasonably expected. Accordingly he takes his report and quickly writes so many per cent. passed. Then the chorus of reporting examiners lift up their voices in wonderful concordance; and all, perhaps even the examiners, are comforted. There is something attractive about the whole thing that I can only compare to the pleasure with which one listens to the hum of a busy factory or to the roaring of the forge and ringing of the anvil. But what avails the hum of the factory if the product be shoddy, and what the roar of the forge and the ring of the anvil if the metal we work be base?

In conclusion, let us consider for a moment what might be done for the risen generation, who are too old to go formally to school, and yet not too old to learn. In their education such bodies as the British Association might be very helpful. Indeed, in the past, the British Association has been very helpful in many ways. It can point to an admirable series of reports on the progress of science, for which every one who, like myself, has used them, is very grateful. It is much to be desired that these reports should be continued, and extended to many branches of science which they have not yet covered.

The Association has at present, I believe, a committee of inquiry into science-teaching generally. This is typical of a kind of activity which the Association might very profitably extend. This Association, with its long list of members bristling with the names of experts in every science, not drawn from any clique or particular centre, but indiscriminately from the whole land, might take upon itself to look into the question of scientific text-books and treatises. Even if it did not set up a censorship of the scientific press, which might be an experiment of doubtful wisdom, although some kind of interference seems really wanted now and then, it might set itself to the highly useful work of filling the gaps in our scientific literature. There is nothing from which the English student suffers so much as the want of good scientific manuals. The fact is that the expense of getting up such books in this country is so great, and the demand for them, though steady, yet so limited, that it will not pay publishers to issue them, let alone remunerate authors to write them. In my student-days the scarcity was even greater than it is now, and in fact then no one could hope to get even a reasonable acquaintance with the higher branches of exact science unless he had some familiarity with French or German at the very least—a familiarity which was rare among my fellow-students either in England or in Scotland. Might not the British Association now and then request some one fitted for the task to write a treatise on such and such a subject, and offer him reasonable remuneration for the time, labour, and skill required?

Another field in which the Association might profitably extend its labours appears to me to be the furnishing of reports, from time to time, on the teaching of science in other countries, and the drawing up of programmes of instruction for the guidance of schoolmasters and of those who are reading for their own instruction. There is no need to impose these programmes on any one. I would leave as much freedom to the teacher as I would to the private student. The programme drawn up by the Society for the Improvement of Geometrical Teaching, for example, has been very useful to me as a teacher, although I do not follow it or any other system exclusively. The great thing is not to fall asleep over any programme or system. For the matter of that, Euclid would do very well in the earlier stages of school instruction at least, provided he were modernised, and judiciously discarded at that part of the student's career where a lighter vehicle and more rapid progress becomes necessary. In such programmes as I contemplate the bearing of recent discovery on the elements of the various sciences could be pointed out, and the general public kept in this way from that gross ignorance into which they are at present allowed to fall.

The British Association has of late, I believe, given its attention to the encouragement of local scientific activity. There can be no doubt that much could be done in this way that is not done at present. The concentration of scientific activity in metropolitan centres is beginning to have a depressing effect in Great Britain. This is seen in the singularly unequal way in which Government aid is distributed over the country. Large sums are spent—sometimes we outsiders think not to the best purpose—through certain channels, simply because these channels happen to have a convenient opening in some Government office in London, or in some place in that important city which has easy access to the ruling powers; while applications on behalf of other objects not less worthy are met with a refusal which is sometimes barely courteous. The result is that local effort languishes, and men of energy, finding that nothing can be done apart from certain centres, naturally gravitate thither, leaving provincial desolation to become more desolate.

I think our great scientific societies—the Royal Societies of London and Edinburgh and the Royal Irish Academy—might do more than they do at present to prevent this languishing of local science, which is so prejudicial to the growth of a scientific public. Besides their all-important publishing function, these bodies have for a considerable time back been constituted into a species of examining and degree-conferring bodies for grown-up men. That is to say, their membership has been conferred upon a principle of *exclusion*. Instead of any one being *admitted* who is willing to do his best, by paying his subscription or otherwise, to advance science, every one is *excluded* who does not come up to the standard of a certain examining body. So far is this carried in the case of the Royal Society of London, that there is an actual competitive examination, on the result of which a certain number of successful candidates are annually chosen. Now, against this proceeding by itself I have nothing to say, except that it appears to belong to the pupillary age both of men and nations. It is not the honouring of the select few that I think evil, but the exclusion of the unhonoured many. The original intention in founding these societies was to promote the advancement of science. How that is done by excluding any one, be it the least gifted among us, who is honestly willing to contribute his mite towards the great end, fairly passes my comprehension. If it is thought necessary, for the proper cultivation of the scientific spirit among us, that the degree-conferring function should be continued, let there by all means be an inner court of the temple, a place for titular immortals; but let there be also a court of the Gentiles, where those whose fate or whose choice it is to serve science unadorned may find a modest reception. I believe that the adoption of this suggestion would enormously extend the usefulness of our great scientific societies, and give to their voice a weight which it never had before. At all events, if the trammels of tradition, or some better reason with which I am unacquainted, should prevent them from broadening their basis in the way I indicate, nothing prevents the British Association, with its more liberal constitution, from considering what may be done for the scientific plebeian.

There is one other function of the British Association in connection with which I wish to venture another suggestion. During the annual meeting, scientific men have an opportunity of making each other's acquaintance. Great men exchange ideas with great men; and, most important of all, young and little men have a chance, rarely otherwise afforded, of taking a nearer view of the great. What I would suggest for consideration is, whether it might not be possible to form an organisation which would in a certain sense carry this advantage through the whole year. I have already alluded more than once to the difficulties that the scientific public—and here I include professional men generally, in fact all but the leaders of science—have in keeping pace with recent advances. Would it not be possible to have an arrangement enabling at least every large centre of the higher education to have periodically the benefit of communion with and instruction from the high priests of the various branches of science? How glad we, the teachers of science in Edinburgh for example, would be to have a course of lectures once every three or four years from Professors Cayley, Sylvester, Stokes, Adams, Lord Rayleigh. In this way effect would be given to the principle which cannot be too much insisted upon, that the power of the spoken word far exceeds that of the written letter. Not only should we learn from the mouths of the prophets themselves the highest truths of science, but the present generation would thus come to know face to face, as living men, those whose work will be the glory of their time and a light for future ages. From the want of a proper circulating medium, the influence of great scientific men very often does not develop until they and the secrets of their insight have gone from among us. The object of what I propose is to make these men more of a living power in their own lifetime.

SECTION B

CHEMICAL SCIENCE

OPENING ADDRESS BY PROF. HENRY E. ARMSTRONG, PH.D., F.R.S., SEC. C.S., PRESIDENT OF THE SECTION

IN the Chemical Section of the British Association for the Advancement of Science the advancement of chemistry throughout the British Empire must be a subject of commanding interest. Signs of such advancement are not wanting:—the rapid establishment of science colleges in one after another of our large towns; the establishment of the Society of Chemical Industry, which now, only in the fifth year of its existence, numbers over 2,000 members; the granting of a Royal charter to the Institute of Chemistry; the changes introduced at the London University in the regulations for the D.Sc. degree; the report of the Royal Commission on Technical Education, in which the value to chemical manufacturers of advanced chemical knowledge is so fully recognised; the important conference on education held at the Health Exhibition last year; the recent agitation to found a teaching university in London with adequate provision for research—surely all these are signs that the value of higher education must and will, ere long, be generally recognised.

The neglect of chemical research in our British schools has often been forcibly commented upon—of late, especially, by an eminent past-President of this section, Dr. Perkin, whose opinion is of peculiar value, as he is not only world renowned as a chemist, but also as a manufacturer: indeed, as the founder of two distinct important chemical industries. There can be no doubt of the fact and of the dire consequences to our country of such neglect: how is it, then, that such pronounced complaints have been so coldly received; that hitherto they have produced comparatively so little effect; and that such slight encouragement is being given to those who, notwithstanding the many difficulties in their way, have steadfastly devoted themselves to research work? I question whether the value of such work has yet been brought home to teachers generally, let alone the public: the "*cui bono?*" cry is almost invariably met by pointing to some discovery of great pecuniary value as the outcome of research. This argument educationalists very properly refuse to recognise. Too little has been said as to the cause of the neglect so bitterly and properly complained of. Hence it is that I propose again to take up what many may regard as a somewhat threadbare theme.

Every one will agree with Prof. Sir Henry Roscoe, who in his address last year to this Section said "that those who are to become either scientific or industrial chemists should receive as sound and extensive a foundation in the theory and practice of chemical science as their time and abilities will allow, rather than they should be *forced prematurely*"—the italics are mine—"into the preparation of a new series of homologous compounds, or the investigation of some special reaction, or of some possible new colouring matter, though such work might doubtless lead to publication." We must also cordially agree with him that the aim should be, as he tells us his has been, "to prepare a young man by a careful and fairly complete general training to fill with intelligence and success a post either as teacher or industrial chemist, rather than to turn out mere specialists, who, placed under other conditions than those to which they have been accustomed, are unable to get out of the narrow groove in which they have been trained." If it were necessary to show that Sir Henry Roscoe is a believer in research in its proper place, ample proof would be afforded by his statement, "that, far from underrating the educational advantages of working at original subjects, he considers this sort of training of the highest and best kind, but only useful when founded upon a sound and general basis."

But I venture to think that something has to be added in order to completely define the position of those who deplore the slight amount of original work which is being done in British laboratories. We maintain that no one can really "*fill with intelligence and success* a post either as teacher or industrial chemist" who has not been trained in the methods of research; and that, owing to the neglect of research, the majority of students are of necessity trained in a narrow groove. The true teacher and the industrial chemist are daily called upon to exercise precisely those faculties which are developed in the course of original investigation, and which it is barely possible—many would say, perhaps with justice, it is impossible—to sufficiently cultivate in any other manner. In a works the *chemist* is scarcely required as long as all goes well. The quality of the materials used or produced can be controlled by purely routine processes of analysis by the works analyst, or by well-trained laboratory boys. But things never do go well for any long period of time: difficulties are always arising; obscure points have to be investigated; and, if the manufacturer understand his business, improvements have to be effected—which cannot be done unless the conditions under which he is working be understood, as well as the character of the changes which are taking place. Investigation is therefore necessary at every step. No amount of instruction, such as is ordinarily given, in the mere theory and practice of chemical science will confer the habits of mind, the acuteness of vision and resourcefulness required of an efficient chemist in a works, any more than the mere placing of the best tools in a workman's hands will make him a skilful operator.

Such being our position, we maintain that it is essential to make research an integral portion of the student's course in every college which pretends to *educate chemists*. It will not suffice occasionally to set a promising student to investigate, but a number of students, as well as the staff, must always be engaged in original work: in fact, *an atmosphere of research must pervade the college*. It cannot be too clearly recognised that it is this which characterises and distinguishes the German schools at the present time. The student does not learn so much from the one special piece of work with which he is occupied, but a number of his fellow-students being also similarly engaged, the spirit of inquiry is rife throughout the laboratory: original literature is freely consulted, and they thus become acquainted with the methods of the old masters; vigorous discussions take place, not only in the laboratory, but also at that most useful institution, the "Kneipe"; the appearance of each new number of the scientific periodicals is keenly welcomed;—in fact, a proper spirit of inquisitiveness is awakened and maintained, until it gradually becomes a habit. Probably there is less actual routine teaching done by the staff in the German schools than in our own. I am proud to own my indebtedness to one of them, and I can without hesitation say that I never truly realised what constituted the *science* of chemistry until I came under its influence.

But to realise the state which I have pictured—*to create an atmosphere of research in our science colleges in order that it may be possible for our students to obtain complete training in chemistry*, several things are required. In the first place, it will be necessary that the students come to them better prepared than they are at present: as a rule they are so ill-prepared that it is very difficult, if not impossible, in the time at disposal to give such preliminary instruction as is indispensable before higher work can be attempted. Their mathematical knowledge is so ill-digested that it is more often than not necessary to begin by teaching simple proportion, and they look aghast at a logarithm table. They cannot draw; so far have we advanced in our civilisation that the subject is more often than not an "extra" in our schools. They understand a little French; but German, which may almost be called the language of modern science, is indeed an unknown tongue to them. I do not complain of their want of knowledge of science subjects, but of the unscientific manner in which they have been trained at school, and especially of the manner in which their intellectual faculties have become deadened from want of exercise, instead of developed and sharpened. Too many have never acquired the habit of working steadily and seriously; they have not learnt to appreciate the holiness of work,[1] so that they render the office of teacher akin to that of slave-driver instead of to that of friend. What is perhaps worst is their marked inability, often amounting to downright refusal, either to take proper notice of what happens in an experiment or to draw any logical conclusion from an observation. Man is said to be a reasoning being, but my experience as an examiner and teacher would lead me to believe that this fact is altogether lost sight of by the average schoolmaster, who appears to confine himself almost exclusively to the teaching of hard dry facts, and makes no attempt to cultivate those very faculties which are supposed to characterise the human race; or he is so ill-prepared for his work that he fails to understand his duty. These are harsh words, but the evil is of such magnitude that it cannot be too plainly stated; those who, like myself, are brought full face to it fail in their duty if, when opportunity occurs, they do not take occasion to call attention to its existence.

Probably the only remedy—certainly the most effectual, and that which can be most easily applied—is the introduction of a *rational system* of practical science teaching into all our schools, whatever their grade; one effect would be that all the school subjects would of necessity soon be taught in a more scientific manner. I am not one of those who would eschew the teaching of classics, and I do not wish to see science teaching introduced into schools generally, in order that the students who come to me may already have gained some knowledge of science: under existing circumstances I prefer that they shall not; but I desire its introduction because the faculty of observing and of reasoning from observation, and also from experiment, is most readily

[1] In my experience, the behaviour of ordinary day male students is, in this respect, particularly striking in comparison with that of female and evening students: the evening students, who come with a desire to learn, and the female students are invariably most attentive, and make the fullest use of the opportunities afforded them.

developed by the study of experimental science: this faculty, which is of such enormous practical value throughout life, being, I believe—as I have said elsewhere—left uncultivated after the most careful mathematical and literary training. No one has stated this more clearly than Charles Kingsley. We are told that, speaking to the boys at Wellington College, he said: "The first thing for a boy to learn, after obedience and morality, is a habit of observation—a habit of using his eyes. It matters little what you use them on, provided you do use them. They say knowledge is power, and so it is—but only the knowledge which you get by observation. Many a man is very learned in books, and has read for years and years, and yet he is useless. He knows *about* all sorts of things, but he can't *do* them." This is precisely our complaint—the average schoolboy may know a good deal *about* things, but he can't *do* them. The ordinary school system of training does not, in fact, develop the "wits," to use a popular and expressive term for the observing and reasoning faculties; but it is certain that the wits require training. It is because the teaching of experimental science tends to develop the wits that those among us who know its power are so anxious for its introduction. This cannot be too clearly stated, the popular view—to judge from newspaper discussions—being apparently that science is to be classed with "extras": that it is good for those who can afford it, but can be dispensed with by those who cannot. This undoubtedly is true of the "science" which is taught the specialist, and I fear even of much of the "science" which is at present taught in schools: let us hope that ere long other views will prevail when the object which it is sought to gain by teaching science is made clear.

While blaming the schoolmaster for his neglect, it must not be forgotten that the teaching of sciences in schools meets with comparatively little encouragement at the hands of our examining bodies and the universities. Again, examinations are too often entrusted to those who have no educational experience, and with most unfortunate results: in no case, probably, is inexperience so inexcusable as in an examiner. Too often, also, the examinations are in the hands of pure specialists, who take too formal a view of their duty, and expect from boys and girls at school as much as from their own students, who are older and devote more time to the work. Such examiners are prone to discourage science by marking too severely; and as their questions govern the teaching, instruction is given in schools without due reference to educational requirements, and in a purely technical style: this, I fear, is the effect of some of the universities' local examinations.

I have it on good authority, that the recent changes in the scheme of the examinations for admission at Sandhurst have forced one large school, well known for the attention paid in it to the teaching of science, to cease to give instruction in science to those of its pupils who propose to compete at these examinations, at once on their deciding to do so. Then, not only are the science scholarships at the universities few in proportion, but the great majority of students pass through their university career without being called upon to gain the slightest knowledge of physical science: yet, more often than not, the teachers are chosen from these. A large proportion become clergymen, and considering the demands upon them and the unbounded opportunities which they have of imparting useful information, there cannot be a doubt that to no other class of the community is a knowledge of natural science likely to be of more value.[1] Let us hope that the time is near when our universities will no longer be open to this reproach.[2] Whatever steps they may elect to take, it is before all things important that it be not forgotten that their main purpose must be to influence the schools, so that experimental science may be used as an educational weapon at the most appropriate time, and not when the faculties to be fashioned by it have become atrophied through neglect, as I fear is too often the case, ere the university is reached.

We must carefully guard against being satisfied with the mere introduction of one or more science subjects into the school curriculum: some of those who strenuously advocate the introduction of science teaching perhaps do not sufficiently bear this in mind. Chemistry, physics, &c., may be—and I fear are, more often than not—taught in such a way that it were better had no attempt whatever been made to teach them. I hold that it is of no use merely to set lads to prepare oxygen, &c., or to make experiments which please them in proportion as they more nearly resemble fireworks; and it is not the duty of the schoolmaster to train his boys as though they were to become chemists, any more than it is his duty to fit them to enter any other particular profession or trade: the whole of the science teaching in a school should be subservient to the one object of developing certain faculties. Unfortunately, two great difficulties stand in the way at present—viz. the want of suitable books and of a rational system of teaching science from the point of view here advocated; and the requirements of the universities and other examining bodies. Both books and examinations are of too special a character: they may suit the specialist, but do not meet educational requirements. I have already somewhat fully expressed my views on this subject in a paper read at the Educational Conference in London last year. Although much more might be said, I will now only call attention to the important service which we may render in removing these difficulties.

The reform most urgently needed, in which, as members of the community, not merely as chemists, we are all most interested, is the introduction of some system which will insure a proper training for teachers. Engineers, lawyers, medical men, pharmacists, have severally associated themselves to found institutions which require those who desire to join the profession to obtain a certain qualification; even chemists are seeking to do this through the Institute of Chemistry. But schoolmasters, although members of what is probably the most responsible, onerous, useful, and honourable of any of the professions, have as yet neither made, nor shown any inclination to make, a united effort to insure that all those who join their profession shall be properly qualified. Surely the time has come when the subject must receive full public attention; the country cannot much longer remain content that the education of all but those of its sons and daughters who come within the province of the School Board should be carried on without any guarantee that it is being properly conducted.

Glaring as are the faults in the existing school system, and although it rests with the universities and other teaching and examining bodies—if the public do not intervene—to prescribe a proper course of instruction for potential schoolmasters and to enforce a rational system of training all the mental faculties, we science teachers may meanwhile do much by introducing more perfect methods into our own system of teaching. The students attending our courses belong to various classes: some will become chemists, and require the highest and most complete training; others will be teachers in colleges or schools; many will occupy themselves as consulting chemists or analysts; many others will have to take charge of manufacturing operations in which a knowledge of chemistry is of more or less direct importance and value; not a few will become medical men; and a large proportion, let us hope, will be those who have no direct use for chemistry, although the knowledge will be of great service to them in many ways: among such we may include architects and builders, engineers, farmers, and even country gentlemen. Have we sufficiently considered the several requirements of all these various classes? I submit, with all due deference, that we have not! Our attention has been too exclusively directed to the training up of the future analyst; the instruction has been of too technical a character.

I know it is rank heresy to say so, but I maintain that in future far less time must be devoted to the teaching of ordinary qualitative and quantitative analysis, and that *technical instruction* as now given in these subjects must find its place later in the course. Our main object in the first instance must be to fully develop the intellectual faculties of our students; to encourage their aspirations by inculcating broad and liberal views of our science, not an infinite number of petty details. We must not merely teach them the principles and main facts of our science, but we must show them how the knowledge of those facts and principles has been gained; and they must be so drilled as to have complete command of their knowledge. The great

[1] "I sometimes dream," said Kingsley, "of a day when it will be considered necessary that every candidate for ordination should be required to have passed creditably in at least one branch of physical science, if it be only to teach him the method of sound scientific thought."

[2] I learnt with the most lively satisfaction, but a few days ago, that Dr. Percival, the late head-master of Clifton College, speaking at a meeting of Convocation at Oxford last term, said: "If twenty years ago this university had said: from this time forward the elements of natural science shall take their place in responsions side by side with the elements of mathematics, and shall be equally obligatory, you would long ago have effected a revolution in school education." This remark elicited some warm expressions of approval. Dr. Percival has, I am sure, the approval of all science teachers, and he will earn their gratitude, and deserve that of the public at large, if he can succeed in inducing his university to take action in accordance with his enlightened views.

majority will not be required to perform *ordinary* analyses, either qualitative or quantitative; it will be sufficient for them to have gained such an amount of practical experience that they thoroughly understand the principles of analysis; that they shall have learnt to appreciate the sacredness of accuracy; and that they shall have acquired sufficient manipulative skill to be able when occasion requires to carry into execution the analytical process which their text-books tell them is applicable, and even, if necessary, to modify the process to suit circumstances.

Chemistry is no longer a purely descriptive science. The study of carbon compounds and Mendeljeff's generalisation have produced a complete revolution! The faults in our present system are precisely those which have characterised the teaching of geography and history, and which are now becoming so generally recognised and condemned; in fact, no better statement of the manner in which I conceive chemistry should be taught could be given them by broadly applying to the teaching of chemistry what was said by Professor Seeley at the International Conference on education last year, in an important paper on the teaching of history.

The necessity for some change must, I venture to think, be patent to all thoughtful teachers, and especially to those who are called upon to fulfil the painful duties of an examiner. The railway book-stalls have made us acquainted with "Confessions" of all sorts, but if the "Confessions of an Examiner" were to be written they would be far more heartrending than any. The examiner in chemistry, let him go where he will, scarcely dare to ask a question to which the answer cannot be directly read out from a text-book. He will be told "that such and such a compound is formed by the action of so and so upon so and so," but he will usually find blank ignorance of the phrase "by the action of," and as to the mode of performing the operation. The examiner would, however, be bound to agree with the teacher that it is almost impossible to induce students to seek information outside the lecture-room, and except in the ordinary cram text-books, and that it is hopeless to expect them to devote attention to anything unless it will pay in a subsequent examination—in fact that the old university spirit of acquiring knowledge for its own sake is almost unknown among our science students. Herein lies one of the teacher's most serious difficulties, as he is more often than not bound to teach in a particular way, or to teach certain subjects, in entire opposition to his own views, in order to qualify his students to pass a particular examination; for example, many of our colleges now distinctly state that their courses are intended to qualify students to pass the examinations of the London University, and hence they are governed by the requirements of that university, which vary more or less as the examiners are periodically changed. The examiner, on the other hand, is often placed in a difficult position: it is clear to him that the system under which the students he is called upon to examine have been taught is a bad one; yet he feels that he has no right to set questions such as he honestly believes should direct the teaching into proper channels, because he knows that the teacher is immovable, and it is not fair to make the examinees the victims of a system for which they are not responsible. Hence, perforce, the teacher goes on teaching badly and the examiner examining badly. Difficulties of this kind are bound to make themselves felt at a transition period like the present, and will only disappear if we recognise the grave responsibility which rests upon ourselves and improve our methods of teaching and our text-books: these, in too many instances, are unsuited to modern requirements, and are being made worse by stereotyping, and the practice which is gradually creeping in of merely changing the date on the title page and the numeral before the word "edition," thus engendering the belief that the information is given up to date.

Both in teaching and examining two important changes ought forthwith to be made: our students ought at the very beginning of their career to become familiar with the use of the balance; and the imaginary distinction between so-called inorganic and organic compounds should be altogether abandoned. I do not mean that students should be taught quantitative analysis as ordinarily understood, but that instead of endeavouring to make clear to them by explanation only the meaning of terms such as equivalent, for example, we should set them to perform a few simple quantitative exercises in determining equivalents, &c. It can easily be done, and terms which otherwise long remain mythical acquire a real meaning in the student's mind. That the elements of the chemistry of carbon compounds do not find a place at a very early period in the course of instruction is one of those riddles connected with our system which it is impossible to answer. Attention was once pithily directed to the fact in my hearing by a scientific friend—not a chemist—who said he had often felt astonished that, although he had learnt a good deal of chemistry, the chemistry of the breakfast-table was practically a sealed book to him, common salt being the one object of which he felt he knew something.

I may here urge that there is one great error which we *must* avoid in the future, that of overworking our students, in the sense of obliging them to pay attention to too many subjects at a time. This is done more or less, I believe, in all our science schools, and medical students are peculiarly unfortunate in this respect. It is to some extent necessitated by the deficient preliminary education of our students; but I believe that I am justified in stating that it is also partly, perhaps mainly, due to the fact that the curriculum is too often imposed by lecturers who are directly interested in the attendance of students at their lectures. This is one of the great difficulties in the way of higher education, and the continuance of the evil is probably in a measure due to inappreciation of what constitutes higher education and culture: neither consist in a smattering of knowledge of a variety of subjects such as is too often required at present.

The more general appreciation of the value of science undoubtedly depends to a considerable extent on improvements such as I have indicated being introduced. When such is the case, we may hope that a large number of students will enter our chemical schools, not with the intention of becoming chemists, but because it will be recognised that the training there given is of a high educational value, and that a knowledge of chemistry is of distinct service in very many avocations.

We may also hope that it will be possible ere long to teach chemistry properly to medical students. Seeing that the practice of medical men largely consists in pouring chemicals into that delicately organised vessel, the human body, and that the chemical changes which thereupon take place, or which normally and abnormally occur in it, are certainly not more simple than those which take place in ordinary inert vessels in our laboratories, the necessity for the medical man to have a knowledge of chemistry—and that no slight one—would appear to ordinary minds to stand to reason; that such is not generally acknowledged to be the case can only be accounted for by the fact that they never yet have been taught *chemistry*, and that the apology for chemistry which has been forced upon them has been found to be of next to no value. No proof is required that the student has ever performed a single quantitative exercise; and I have no hesitation in saying that the examinations in so-called practical chemistry, even at the London University, are beneath contempt: after more than a dozen years' experience as a teacher under the system, I can affirm that the knowledge gained is of no permanent value, and the educational discipline *nil*. Here the reform must be effected by the examining boards: it is for them to insist upon a satisfactory preliminary training, and they must so order their demands as to enforce a proper system of practical teaching; and if chemistry is to be of real service to medical men, more time must be devoted to its study. Physiological chemistry is taught nowhere in our country, either at the universities or at any of our great medical schools; let us hope that the publication of works like those of Gamgee and Lauder Brunton may have some effect in calling attention to this grievous neglect of so important a subject.

Having dealt with the educational aspect of the question, let me now briefly refer to some other difficulties which seriously hinder research. It has been more or less openly stated that the teachers in our chemical schools might themselves do far more. Is this the case? I do not think so; I believe it is not the staff, in most cases, who are primarily in fault. Under our peculiar system of placing the government of science schools in the hands of those who have little, if any, experience as educationalists, and little knowledge of or sympathy with science, the appointments are sometimes made without the slightest reference to capability of inciting and conducting original investigation, and without any proof having been given either of a desire to promote higher education in the only possible way—by research; nevertheless experience shows that, as a rule, fair use is made by teachers of their opportunities. The opportunities afforded us are indeed few. In the first place, the amount of actual routine teaching we are called upon to perform is very considerable, many of us having to conduct evening as well as day classes; and the work is often of the most harassing description, owing to the want of interest displayed by the students. The assistance provided is also too often inadequate, and much which should be done by assistants is therefore thrown upon the principals. Higher work under these conditions is practically out of the question, not so much because it is impossible to snatch at intervals a few hours per week, but because the attention is so much taken up in the preparation of lectures and laboratory and tutorial teaching that it is impossible to secure that freedom of mind and concentrated attention which are essential to the successful prosecution of research. Bad, however, as is often the position of the principals, that of the junior staff is usually far worse. During official hours they are entirely occupied in tutorial work, and what little energy remains must more often than not be devoted to coaching or literary work, to supplement the too modest income which the salary attached to their official position affords. Under these circumstances, it is remarkable that so much enthusiasm should prevail among them on the subject of research. The tradition which prevails in the German schools, that the junior staff are bound to find some time for original work, is almost unknown in this country, and too often difficulties are raised, rather than facilities afforded, when the desire is manifested: we do not, in fact, sufficiently honour the assistant as the potential professor. It has also often struck me as remarkable, and it must have struck others who understand the German system, that in this practical country we have not adopted that cheap luxury—the Privat-Docent, who costs nothing and exercises a most important function in promoting higher education. The explanation of this and many other anomalies lies in the fact that very few among us realise what a university is: a clear exposition of the Scotch and German systems would be of great value in these days of new universities and university colleges.

I believe that in most, if not all, of the German chemical schools a private research assistant is placed at the disposal of the professor. Will this ever be the case here? The want material assistance is not only felt in this respect, however: few of our chemical schools are really efficiently equipped; most of them are seriously in want of larger and more expensive apparatus, of suitable specimens, &c.; the annual grant barely suffices for the purchase of the ordinary chemicals and the payment of unavoidable current expenses, so that, as a rule, nothing remains to meet the expenses of research work—*i.e.*, of higher education. In point of fact, nearly all of those who are engaged in research are doing so at their own expense; important assistance, for which we cannot be too thankful, is indeed received from the various research funds, but the proportion which the grants bear to the total sum expended is not large. I am sure we all recognise that each one of us is bound, according to his abilities and the opportunities he has, to add to the stock of knowledge, and that the keenest intellectual pleasure is derived therefrom; but it must not be forgotten that the results we obtain are very rarely of immediate practical value, and that as a rule *we* reap no pecuniary advantage. I venture to think, in act, that it is remarkable that so much, not that so little, is done, and that reproach rests very lightly apon the profession in this matter. Whether our national pride will prevent our being much longer beholden to foreigners for by far the greater number of new facts in chemistry is a difficult question to answer, and must rest with the public!

The occasions on which we teachers of science subjects are able to bear witness in public are of necessity few. Deeply sensible, not only of the honour, but also of the responsibility of my position as President ot this Section, I felt that it was my duty to avail myself of this opportunity. Being a teacher who is interested in teaching; being convinced of the existence of most serious faults in our educational system; feeling that the present is a most critical period: I have not hesitated to speak very freely. Some of the difficulties to which I have referred might soon disappear if science teachers generally would agree to consider them together, and I believe that it would be a very great advantage if an association for the discussion of educational questions were formed of the staffs of our science colleges throughout the country. The special difficulties which surround our science colleges, and prevent them from exercising their full share of influence upon the advancement of our national prosperity might also be removed at no distant date; but I see only one way of accomplishing this, and I fear it will hardly find favour: it is by their all becoming vested in the State. In this country we like to do things in our own way, and the objection will at once be raised that this would deprive all the colleges of their individuality, and would tend to crush originality and to stereotype teaching. If I thought so I should never make the suggestion. But it would not, provided that complete academic freedom were secured to the staff, and each college were left to adjust itself to local requirements; efficiency would be maintained by the competition of the various colleges. Local enterprise, which has hitherto been trusted to, is clearly breaking down under the tremendous strain of modern educational requirements: some change must ere long be made.

(*To be continued.*)

SECTION C

GEOLOGY

Opening Address by Prof. J. W. Judd, F.R.S., Sec. G.S., President of the Section.

As this city is the only place within the limits of the Scottish Highlands where our Association holds its annual gatherings, it is fitting that the attention of those who meet in this section should, on the present occasion, be specially directed to the grand problems of Highland geology. Six-and-twenty years have passed since the members of this section assembled here, under the presidency of my dear friend, my revered master, Charles Lyell. Few now present can have actually listened to the stormy discussions of that memorable occasion, but all are familiar with the nature of the problems which in the year 1859 were here so keenly debated. It is true that the fires of these controversies have now almost died out, and from their ashes have arisen the new problems which confront us to-day; but it will not, I think, be without profit to direct your attention for a few minutes to those two subjects which constituted the "burning questions" of that day—the age of the Crystalline Rocks of the Highlands, and the geological position of the Reptiliferous Sandstone of Elgin.

With respect to the first of these questions, there are especial reasons why I should briefly review the discussions which have taken place in connection with it. It was in the meetings of this section of the British Association that the successive stages of the controversy were gradually developed. It was at a former meeting of the Association in this city that James Nicol submitted to the scientific world that splendid solution of a difficult problem, which is now universally admitted to have been the correct one. This university was, during the last twenty-seven years of his active, useful, and honoured life, the scene and centre of the labours of that profound but modest thinker to whom we owe so much. Lest it should seem presumption on my part to speak on the question, I may add that for some years before his death it was my good fortune to enjoy the friendship and confidence of the late Prof. Nicol, with whom I had several opportunities of discussing the great questions at issue between himself and Murchison. Seeing, as I do to-day, his own great claims too often forgotten or ignored, I feel that, should I, on this occasion, hold my peace—"the very stones would cry out." It will indeed be an unfortunate day for our republic of science when the palm of recognition—withheld from him whom modesty and self-respect restrain from clamorous self-assertion—is permitted to be snatched away by the bold and noisy advertiser of his own claims.

Nearly seventy years ago, John Macculloch—that distinguished pioneer in Scottish geology—was able to prove that in our Western Highlands there exists a grand formation, made up of red sandstones and quartzite, both exhibiting unmistakable evidence of a sedimentary origin. He also pointed out that, associated with these red sandstones and quartzites, are beds of limestone, which are often altogether destitute of crystalline characters, and are sometimes bituminous, while they occasionally contain fossils.

Macculloch strongly insisted that this great system of strata, which covers large areas in Sutherland and Ross, extending also into some of the Western Isles, is distinct alike from the Old- and the New-Red Sandstone; he asserted that it belongs to a far older period than either of those formations, and, employing the phraseology of the early geologists, he gave to it the name of the "*Primary* Red Sandstone" (*Trans.* Geol. Soc. ser. 1, vol. ii. p. 450, &c. "Western Isles of Scotland" (1819), vol. ii. p. 89, &c. "System of Geology" (1831).

Macculloch showed clearly that the strata of his "Primary Red Sandstone Formation" are often found resting unconformably upon the gneissose and schistose rocks of the Highlands;

but that in other places they appear to be overlain conformably by, and even to alternate with, crystalline schists and gneisses. He was further able to state that the quartzites of his "Primary Red Sandstone Formation" contain organic remains, some of which he correctly identified as the burrows of marine worms, while others he recognised as *Orthoceratites* ("Western Isles of Scotland" (1819), vol. ii. pp. 512, 513). It is almost painful to have to add that his want of appreciation of the value of palæontological evidence, a weakness which Macculloch shared with so many of the early Scottish geologists, prevented any attempt on his part at the correlation of this "Primary Red Sandstone" with the rocks of other districts; and thus for more than forty years this important discovery remained almost entirely fruitless.

The next step in the history of our knowledge of these Highland strata which we have to record, was unfortunately a retrograde one. Sedgwick and Murchison, who visited the district in 1827, maintained that Macculloch had fallen into grievous error, and that his "Primary Red Sandstone Formation" was in fact no other than an outlying part of the Old Red Sandstone (*Trans.* Geol. Soc. ser. 2, vol. iii. p. 155).

This view was strongly protested against by Hay Cunningham, who, writing in 1839, after a careful survey of Sutherland, demonstrated the justice of Macculloch's conclusions, and even went beyond that geologist in showing the very intimate connection between the quartzite and limestone. He clearly illustrated by numerous sections the unconformity of the "Primary Red Sandstone Formation," consisting of red sandstone, quartzite, and limestone, upon the gneissose rocks, and the apparently conformable superposition to it of other schists and gneisses ("On the Geognosy of Sutherlandshire," by R. J. H. Cunningham, M.W.S.; *Transactions* of the Highland and Agricultural Society of Scotland, vol. xiii. (1839).

Such was the state of geological opinion when, in the winter of 1854, the attention of geologists was recalled to this ancient formation of Macculloch by the discovery in it of fossils by one who fully recognised their value and importance—Mr. Charles Peach. These fossils, though imperfect, were sufficient to prove that the strata containing them must be of *Palæozoic* age.

Three of the leaders of geological science at that day appear to have been deeply impressed with the importance of this discovery of Mr. Peach's; but for a time, at least, the fruits of that discovery were missed, through the unfortunate retrograde teachings of Sedgwick and Murchison in 1827.

Hugh Miller, whose splendid researches in the Old Red Sandstone had made him ready to welcome any extension of its boundaries, suggested that the fossils of Durness might belong to the marine Devonian.

Roderick Murchison, who in his younger days had worthily conquered a kingdom in Siluria, and by successive annexations in his later years had sought to convert this kingdom into an empire—one which should embrace all the Lower Palæozoic rocks of the globe—was not unwilling to claim his native Highlands as part of this ever-growing realm.

James Nicol, who had been the first to discover graptolites in the rocks of the Scottish Borderland, and had thus demonstrated their Silurian age, was so struck by the resemblance of some of the slaty rocks of the Highlands to the fossiliferous shales of his native district, that, ten years before Peach made his important discovery, he had suggested the probability of the Highland schists and gneisses being simply the Borderland shales and greywackes in an altered state ("Guide to the Geology of Scotland" [1844]). Hence Nicol, equally with Murchison, was prepared to accept the Silurian age of the Durness limestone, and of the rocks associated with it.

Murchison, still full of his old enthusiasm for discovery, determined to lose no time in putting to the test the truth of the suggestion made by his old friend Nicol and himself; and accordingly, shortly before the meeting of the British Association, which was fixed to take place in the year 1855 at Glasgow, we find the two friends making their way into the wild district of North-west Sutherland.

Unfortunately the time was too short and the weather too unpropitious for the task they had set before themselves.

When this Geological Section assembled at Glasgow, Murchison declared his conviction that the limestone of Durness, which had yielded the fossils to Mr. Peach, was of Silurian—that is, as he employed the term—of Lower Palæozoic age. But he, at the same time, maintained the truth of his old views, that the red sandstones of Applecross and Gareloch are in reality nothing but Old Red Sandstone ("Brit. Ass. Rep." 1855); *Trans.* of Sec. p. 87), and in this latter contention he received the warm support of Sedgwick, who was also present at the meeting (Geikie's "Memoir of Sir Roderick Murchison" (1875), vol. ii. p. 207).

Nicol, on the other hand, appears to have been greatly dissatisfied with the results of this hasty and inauspicious journey to Sutherland. While, however, withholding his judgment as to the age of the several rock-masses, he insisted, in opposition to the views of Murchison and Sedgwick, that the whole of the vast series of Red Sandstones in Applecross and Torridon is, as Macculloch showed, inferior to the quartzite and limestone (see Nicol's "Geology of the North of Scotland" (1866), Appendix, p. 96).

In the summer of the next year, 1856, Nicol, so soon as he was released from his teaching work in this university, hastened back to the Western Highlands to try and resolve some of the doubts which troubled him concerning the age and succession of the strata. This summer's labour was productive of great and important discoveries. In the first place, he was able to completely confirm the conclusions of Macculloch and Hay Cunningham, that *all* the Red Sandstone of the Western Islands, with the exception of some small patches of "New Red," belong to an old formation underlying the quartzite and limestone. But his researches also enabled him to show that Macculloch's "Primary Red Sandstone" in reality consists of *two* formations, the lower—to which he subsequently gave the name of the "Torridon Sandstone"—lying unconformably on the gneiss, and the upper (consisting of quarzite and limestone, containing fossils) resting everywhere unconformably upon, and overlapping, the sandstones.[1] It is a very noteworthy circumstance that while Nicol admitted the accuracy of the descriptions of Macculloch and Hay Cunningham which seemed to point to a conformable superposition of beds of gneiss to the quartzite and limestone, the results of this first summer's work had already raised serious misgivings in his mind as to the correctness of this conclusion, for he wrote as follows:—"The fact of the overlying gneiss having been metamorphosed *in situ*, and not pushed up over the quartzite, is one requiring further investigation" (*Quart. Journ. Geol. Soc.* vol. xiii., 1857, p. 35). It is not surprising, however, to find that Nicol was so staggered by the magnitude of the faults which would be required to bring about such a result, that for more than a year he hesitated to accept this, which we now know to be the true, explanation of the phenomena.

There was a suggestion—and it was nothing more than a suggestion—made by Nicol at this time, which has often been very unfairly quoted to his disadvantage. Convinced that Macculloch was right as to the infraposition of the Torridon Sandstone to the quartzite and limestone, and strongly inclined to accept Murchison's confident assertion that this Torridon Sandstone was simply the "Old Red," Nicol pointed out that the only possible way of harmonising these two views was to suppose that the quartzites and limestones were of Carboniferous age; and he showed that the imperfect fossils which had been up to that time obtained at Durness were not sufficient to negative such a supposition (*Quart. Jour. Geol. Soc.* vol. xiii., 1857, p. 36).

But during the summers of 1857 and 1858, Nicol continued his labours in the Western Highlands, with the result of clearing away many of his difficulties and perplexities. Murchison, too, had revisited the district, and seen that his idea of the "Old-Red" age of the Torridon Sandstone would have to be finally abandoned, and that Macculloch's views, as amended by Nicol, concerning the relations of the Highland rock-masses must be accepted. Salter, too, examining more perfect specimens of fossils which had in the meanwhile been obtained from the Durness limestone by the indefatigable Mr. Charles Peach, showed that they were certainly of *lower* Palæozoic age (Silurian of Murchison).

The position taken up by Murchison, and on which he made his final stand, was simply arrived at by combining the stratigraphical conclusions of Macculloch and Nicol with the palæontological results of Peach and Salter.

Murchison attended the meetings of this Association at Dublin in 1857, and at Leeds in 1858, on both occasions making use of the opportunity for explaining in detail his ideas concerning the age and succession of the Highland rocks. On the latter

[1] Colonel Sir Henry James is said to have made similar observations during the same season, the summer of 1856, and to have communicated them to Sir Roderick Murchison by letter. But there can be no doubt that Nicol's discovery was made quite independently, and he was the first to publish it.

occasion, he challenged his old friend Nicol to meet him at the forthcoming meeting at Aberdeen to discuss the question, and the challenge was accepted.

When Murchison arrived at this city, in September 1859, he brought with him a redoubtable champion in the person of Prof. (now Sir Andrew) Ramsay, the director of the Geological Survey, who had been conducted to Assynt and shown the section there. It may perhaps serve as a caution against hasty generalisations, drawn from a single section imperfectly examined, to remember that so excellent a field-geologist as Ramsay undoubtedly was not only failed to see the weakness of Murchison's position, but threw all the weight of his great authority into the scale against Nicol in this memorable controversy.

Nicol, however, laid before this meeting a paper which, afterwards published in detail in the *Journal* of the Geological Society,[1] must be admitted to have really established the main facts concerning the geology of the Highlands as accepted by all geologists at the present day; though his views, as is not uncommonly the case with great and original discoveries, were met for a long time with nothing but bitter opposition or cold neglect. Permit me to state, as briefly as possible, the conclusions which Nicol, as the result of three years of patient work in the Western Highlands, was able to announce in this place, just twenty-six years ago.

1. He maintained with Macculloch and Hay Cunningham, and in opposition to the views originally propounded by Sedgwick and Murchison, that there exists in the Western Highlands an enormously thick series of red sandstones, quartzites, and limestones, which rest unconformably upon the ancient gneisses and schists, and belong to a far older geological period than the Old Red Sandstone.

2. He showed that this series of strata really constitutes *two* distinct formations, and that the older of these, the Torridon Sandstone, consists of red sandstones and conglomerates, in which no organic remains could be detected.

3. The younger of these formations was shown by him to lie unconformably upon the Torridon Sandstone, and to consist of three members, which Nicol named the Quartzite, the Fucoid Beds, and the Limestone (*Quart. Journ. Geol. Soc.* vol. xvii., 1861, p. 92, &c.). It is this formation which has yielded the interesting fossils of Lower Palæozoic age.

4. The apparent repetition of beds of quartzite and limestone, which was insisted upon by Murchison, was shown to be due to faulting and overthrow, and thus the "Upper Quartzite" and the "Upper Limestone" of that author were proved to have no real existence (*Quart. Journ. Geol. Soc.* vol. xvii., 1861, pp. 98, 108, 109, &c.).

5. What so many authors had taken for a conformable upward succession of this older Palæozoic formation into overlying schist and gneiss, was asserted by Nicol to be an altogether fallacious appearance, due to the thrusting of the crystalline rocks over the sedimentary ones by great overthrow-faults.

6. The relations between these crystalline and sedimentary strata in the Scottish Highlands were shown to be precisely similar to those which are constantly produced by lateral pressure in all great mountain-chains, and consist of sharp foldings, inversions, and faulting on the very grandest scale. Examples of overthrow-faults, similar to those of the Scottish Highlands, were instanced by Nicol as occurring in the Alps (*Quart. Journ. Geol. Soc.* vol. xvii., 1861, pp. 108, 109, 110).

We cannot perhaps better illustrate the position maintained by Nicol in this remarkable paper than by quoting the following passage: "Until some rational theory is produced of the mode in which an overlying formation, hundreds of square miles in extent and thousands of feet in thickness, can have been metamorphosed, whilst the underlying formation of equal thickness and scarcely less in extent has escaped, we shall be justified in admitting inversions and extrusions" (*i.e.*, of older masses on younger, as he explains his meaning to be) "equal to those of the Alps" (*Quart. Journ. Geol. Soc.* vol. xvii., 1861, p. 110).

The only serious error into which Nicol fell—and after all it is a very inconsiderable one judged in comparison with his undoubtedly great achievements—was that of attaching too much importance to the influence of igneous intrusions in connection with the tremendous inversions and overthrow-faults to which he so clearly showed that these Highland rocks have been subjected. We now know that many of these supposed intrusive masses, though really of igneous origin in all probability, were of *older* date than the Palæozoic rocks in the midst of which they lie; and that they were brought into their present positions, not by intrusion in a liquid state, but by complicated faulting. It must be remembered that these "granulites," as Nicol very justly called them (*Quart. Journ. Geol. Soc.* vol. xvii., 1861, p. 89) for they present a wonderful analogy with the typical rocks of Saxony which are known by that name, have long been regarded by geologists as among the most difficult and perplexing of rocks to explain the origin of, though the recent researches of Dr. Lehmann have now done something towards the solution of the problem.

Calmly reviewing, in the light of our present knowledge, the grand work accomplished single-handed by Nicol, I have no hesitation in asserting that when this Association met here twenty-six years ago, he had already mastered the great Highland problem in all its essential details, and that his results were distinctly proclaimed during the meetings of this section.

If, then, Nicol had so fully solved this great problem of Highland geology twenty-six years ago, how is it, may not unreasonably be asked, that we have waited so long for the justice of these views to be admitted?

A variety of circumstances have contributed to bring about this unfortunate result. Murchison was at the time too old and infirm to examine in careful detail the wild districts where those rock-masses are exhibited. Hence Nicol's oft-repeated invitations to view the sections in his company remained unheeded, and we find the great geologist of Aberdeen writing in 1866 his concluding plaintive words in this memorable discussion: "I must express my most sincere regret that my illustrious opponent—from whom only the most thorough conviction that my views are well founded, and that the question was one on which it became a teacher of geology in Scotland to give no uncertain utterances, could have compelled me to differ—has never found it convenient to meet me again in the North. I am convinced that we agree in so many essential points, that a few hours together in the field would bring us nearer in opinion than whole volumes of controversy." ("Geology of the North of Scotland, p. 96.")

The phalanx of eminent geological authorities opposed to the views of Nicol, including Professors Harkness, Ramsay, Archibald Geikie, and Hull, for a long time carried all before them; but it is now admitted that each of these excellent observers was deceived by having seen only portions of the evidence, and that they based their conclusions on imperfect data. Nicol, though during the later years of his life he declined unavailing controversy, still continued to study the Highlands year by year, re-examining every joint in his armour and satisfying himself of its soundness.

In the year 1877 I had an opportunity of visiting for the first time the interesting sections of Assynt and Loch Broom, in company with Dr. Taylor Smith, F.G.S., and Mr. Richard D. Oldham, now of the Geological Survey of India. Although I entered upon this task with the strongest prepossessions in favour of the Murchisonian hypothesis, yet what I saw there during several weeks of work convinced me that the theory of an "Upper Quartzite" and an "Upper Limestone" was altogether untenable, and that, so far as these two sections were concerned, Nicol's interpretation was undoubtedly the correct one. I was greatly impressed with the proofs of enormous folding and faulting among these Highland rocks, and when, shortly afterwards, I had an opportunity of meeting Prof. Nicol in this place, and of hearing from his lips many details of his later work, I strongly urged him to republish his conclusions with the fuller illustrations and arguments which he was then so well able to supply. To all my pleadings he made but one reply: important as he knew these discoveries to be, yet in his advancing years he thought but little of the glory of them compared to their painful consequences to himself—the breach of the old friendly relations with one he, to the end, so greatly loved and honoured. He strongly deprecated at that time the reopening of a controversy associated for him with such bitter memories; but he expressed his full conviction that when sufficiently accurate topographical maps were in existence, and the whole district should be surveyed by competent geologists, the truth of all the essential parts of his teaching would be established.[1]

[1] *Quart. Journ. Geol. Soc.* vol. xvii., 1861, pp. 85-113. This paper was read on December 5, 1860; although its title is slightly different, the whole course of the argument is the same with that of the paper read here in the September of the previous year.

[1] In my two earlier papers "On the Secondary Rocks of Scotland," published in 1873 and 1874 respectively, I had employed the Murchisonian nomenclature for the older rocks of the Highlands whenever I had occasion

Most completely have these anticipations of Nicol been fulfilled. During the last seven years many of the sections of the Western Highlands have been visited by different geologists, Dr. Hicks leading the way, and not a few papers have been published embodying the results of these new studies of some of the disputed points. Such an able review of this recent work has been lately drawn up by my friend, Prof. Bonney, in his Anniversary Address to the Geological Society, that I need not go over the ground again, but will content myself by referring to that address and to two exhaustive papers read by Dr. Hicks before the Geologists' Association for full details concerning this later work. It will be seen that while new methods of study have enabled them to improve or correct Nicol's petrological nomenclature, the principal conclusions of nearly all these writers concerning the relations of the several rock-masses entirely support his views on the subject.

But very recently Nicol's work has been tested in the way which he himself so earnestly desired. Prof. Lapworth, who, like Nicol, was especially prepared for the task by long and patient study of the crumpled Silurian rocks of the Borderland, taking advantage of the newly published Ordnance maps of Sutherland, proceeded in the summer of 1882 to Eriboll, bent on the task of unravelling the complicated rocks and of mapping them upon the large scale of 6 inches to the mile. Prof. Lapworth's detailed maps and sections were exhibited to the Geological Society on May 9, 1883, during the reading of a paper by Dr. Callaway, in which the views of Nicol also received a considerable amount of valuable support.

In the same year, 1883, a detachment of the Geological Survey of Scotland, under the superintendence of Messrs. B. N. Peach and J. Horne, commenced the detailed mapping of the Durness-Eriboll district. How admirably these gentlemen have performed their task we all know, and I hope that some interesting information concerning their conclusions will be laid before the present meeting. In offering them—as I am sure that I am empowered by you to do—the hearty congratulations of the Geological Section of the British Association upon the auspicious commencement of this great undertaking, I cannot refrain from reminding you that, of the leaders in this important enterprise, one is the son of the discoverer of the Durness fossils, the veteran Mr. Charles Peach to whom we owe so much, while the other is a very active and efficient local secretary of this Section.

Nor should I do justice to my own sentiments on the subject if I failed to bear tribute to the judgment displayed by the present chief of the Geological Survey in his choice of a base from which to attack this difficult problem, to his loyalty in accepting results so entirely opposed to his published opinions, and to his promptitude in making his fellow-workers in geology acquainted with these important discoveries. Unfortunately called upon while still young, and with but little of that ripe experience which he has since gained, to grapple with the most intricate of problems—problems which the most practised of field-geologists might be forgiven for failing to solve—his own judgment yielded, though not without serious misgivings (see "Memoirs of Sir Roderick Murchison" (1875), vol. ii. p. 238) when opposed to the ardent confidence of a companion and friend whose reputation in the scientific world commanded his respect, and whose previous achievements had won his complete reliance. If, like your own Randolph at Bannockburn, he has "lost a rose from his chaplet" at the commencement of this great Highland campaign, we are well assured that the error will be worthily repaired in its subsequent stages.

The conclusions arrived at by Nicol, by Professor Lapworth, and by the officers of the Geological Survey, are, in all their main features, absolutely identical; and the Murchisonian theory of Highland succession is now, by universal consent, abandoned.

In the second of the great controversies to which we have alluded as having occupied the attention of this Geological Section in 1859—that concerning the age and relations of the Reptiliferous Sandstone of Elgin—the combatants were found ranged in quite a different order. Nicol is seen battling shoulder to shoulder with Murchison, Ramsay, and Harkness, in favour of the *Palæozoic* age of the beds in question; while Lyell, supported by Symonds of Pendock and Moore of Bath, is as stoutly maintaining their *Secondary* age.

The finding by Mr. Patrick Duff, in the year 1852, of the little fossil lizard called *Telerpeton*, and the determination of its true nature by Mantell and Owen, constitute a discovery comparable in importance and fruitfulness to Mr. Peach's detection of the fossiliferous character of the limestone of Durness; up to that time no doubt had ever been entertained as to the "Old Red" age of the yellow sandstone of Elgin. For bringing together the remarkable fossils of these rocks, geologists are indebted to the untiring labours of Dr. Gordon of Birnie—whom, full of years and honours, and the object of such universal respect and love as indeed make grey hairs a "crown of glory," we rejoice to have still in our midst. Studying Dr. Gordon's important collections, Professor Huxley was able, shortly before the previous meeting of the Association in this city, to announce that a crocodilian (*Stagonolepis*), and a second lizard of Triassic affinities (*Hyperodapedon*), existed at the period when these beds were deposited, so that even in 1859 the palæontological evidence in favour of the Mesozoic age of these rocks was admitted to be almost overwhelming.

But this evidence has been very greatly strengthened since that date; for Professor Huxley has shown that the genus *Hyperodapedon* is represented in the Trias of Warwickshire, of Devonshire, and of India. In the same reptiliferous sandstone, with its abundant footprints, the teeth of *Ceratodus*, a fish unknown in the Palæozoic rocks, have been found, together with the remains of a reptile which Professor Huxley permits me to state is, in his opinion, probably *Dinosaurian*. I am sure that you will all join with me in the hope that the health of the President of the Royal Society may soon be so far restored that he may be able to return to the examination of these fossil reptiles of Elgin, in the study of which some of the earliest of his great palæontological discoveries were achieved.

The manner in which the yellow sandstones, which have yielded these reptilian remains, are at many different points found associated with beds containing *Holoptychius* and other Old Red Sandstone fish, appeared to many geologists altogether inexplicable on any other hypothesis than that the strata are all of the same geological age.

In spite, however, of these appearances, and the interesting observations of Dr. Gordon and Dr. Joass on the rocks of the Tarbet peninsula, which seemed to support the hypothesis just referred to, I am able to announce that proof of the most clear and convincing character now exists of the distinction between the fish-bearing "Old Red" and the reptiliferous "New Red" of the neighbourhood of Elgin. In the year 1873 I showed that rocks, identical in character with the reptiliferous sandstone of Elgin, and the overlying calcareous and cherty rock of Stotfield, exist on the northern side of the Moray Firth, in the county of Sutherland, and that they there conformably underlie Rhætic and Liassic strata. Very recently Dr. Gordon has added a crowning discovery to his long list of previous ones, by detecting in the same quarry the rocks containing the reptilian and fish remains respectively. I find, however, that while the two series of beds present well-marked differences in their mineral characters, the yellow sandstones with fish remains clearly overlie the undoubted Upper Old Red, and are separated from it by a well-marked bed of conglomerate. In other quarries in the district, the manner in which these two series of strata have been thrown side by side by the action of great faults is very clearly exhibited. I hope that full details of the evidence on this interesting subject will be laid before you during the present meeting.

The facts relied upon by the Palæontologist and the Stratigraphist respectively are thus found to be no longer opposed to one another. By a complicated series of parallel faults, the Devonian and Triassic sandstones, which happen to have a general resemblance in their mineral characters, are found again and again thrown side by side with one another in the Elgin district, so that the error into which geologists fell before the discovery of the distinctive fossils of the two sets of rocks, was a very pardonable one.

A retrospect of these two controversies, now so happily laid at rest, is not, I think, without its uses for the student of Highland geology, for it may serve to furnish him with some useful warnings which are in great danger of being overlooked at the present time.

The discovery of a few fossil remains in strata where they were previously unknown, has completely revolutionised our ideas concerning the age of rock-masses of enormous extent and

to refer to them; but in the third of this series of papers, published in 1878 (*Quart. Journ. Geol. Soc.* vol. xxxiv. p. 660), I had no hesitation in abandoning this terminology for that of Nicol.

thickness. Resemblances in mineral character have been proved not only to have been, at their best, very unsafe guides indeed, but to have actually betrayed those who trusted in them into the most serious errors. But for the discoveries of Charles Peach on the one hand, and of Patrick Duff and Dr. Gordon on the other, geologists would probably still continue to class the sandstones of Torridon and Elgin respectively with the "Old Red."

But perhaps the consideration of greatest importance which is impressed upon us by this retrospect is, that in these Highland districts we must be always prepared to meet with rock-masses of very different geological ages, thrown into puzzling juxtaposition by the gigantic movements to which this part of the earth's crust has been subjected. He who enters on the study of Highland geology without being prepared to encounter at every step complicated foldings, vast dislocations, and stupendous inversions of the strata, can scarcely fail to be betrayed into the most disastrous and fatal errors.

The early history of Scotland is inextricably interwoven with that of Scandinavia. This proposition, true as it is of the insignificant periods of which human history takes cognizance, applies with even greater force to the vast epochs that fall within the ken of the geologist. To us the separation of Scotland and Scandinavia is an event of very recent date indeed; it is not only an accident, but an uncompleted accident! The Scottish Highlands, with the Hebrides and Donegal on the one hand, with Orkney and Shetland on the other, must be regarded—to use a technical phrase—as mere "outliers" of the Scandinavian Peninsula.

We must acknowledge, at the outset, that the study of the geological history of this Scandinavian peninsula and its outliers is a task bristling with difficulties. The problems presented to us in our Scottish Highlands are vast, complicated, and at times seemingly insoluble. But they are precisely the same problems that confront our brother geologists in Scandinavia. And if our tasks, our doubts, our perplexities are the same, we equally share in the advantages and triumphs of discovery.

The geologists of Scandinavia—and right worthy sons of Thor they are—have the advantage of possessing a territory almost limitless in its vastness, and seemingly infinite in its variety. But the very extent of their splendid country, with its sparse population and restricted means of communication, increases the difficulties of their task. "The harvest truly is plenteous, but the labourers are few!" With our smaller area, if we cannot expect so much variety, we may hope to gain something from the number of our students and the greater accessibility of our fields of labour.

Nor would I undervalue, in this connection, the importance of the union of this country with England. I allude, of course, not to events of yesterday, like the Accession of James VI. to the English throne and the Parliamentary Act of Union, but to operations that preceded these by many millions of years! It is no small advantage that a country like Scotland, in which the rock-formations are found hopelessly crushed and crumpled together, or broken into a thousand illfitting fragments that seem to defy all attempts to reduce them to order, should be united to one like England, where, by comparison, all is orderly and simple, the strata lying in regular sequence like well-arranged volumes in a library, and only await the touch of the geologist's hammer to display the wealth of their fossil contents.

The great Scandinavian *massif*, with its outlying fragments, constitutes the "basal-wreck"—to employ Darwin's expressive term—of a great Alpine chain. On other occasions I have endeavoured to show how much our study of the nature and products of volcanic action is facilitated by the existence of similar "basal-wrecks" of volcanic mountains, like those which exist in your beautiful Western Isles. In the same way, I believe we may learn more by the study of this dissected mountain-chain, concerning the operations by which these grand features of our globe have originated, than by the most prolonged examination of the superficial characters of the Alps or the Himalayas.

Here the scalpel of denudation has laid bare the innermost recesses of the mountain-masses, and what we can only guess at in the Alps and the Himalayas, here stands in our own Highlands clearly revealed to view.

It is a well ascertained fact that all the existing lofty mountain-chains have been formed at a very recent geological period. The reason of this it is not difficult to divine. In the higher regions of the atmosphere, the forces of denudation work so rapidly that within a very short period—geologically speaking—the vastest mountain-chain is razed to its very foundations—

> "They melt like mists, the solid lands,
> Like clouds they shape themselves, and go!"

It is not surprising then to find Powell and Gilbert, fresh from the study of the grand mountain-masses of the American Continent, giving expression to these thoughts in the following words: "All large mountains are young mountains, and, from the point of view of the uniformitarian, it is equally evident that all large mountains must be growing mountains; for if the process of growth is continuous, and if a high mountain melts with exceptional rapidity before the play of the elements, it is illogical to suppose that the uprising of any mountain, which to-day is lofty, has to-day ceased."

The Scandinavian Alps were a living and a growing mountain-chain in the far distant Palæozoic period. Now it is not only dead, but stretched on the dissecting table of the geologist—its outer integuments and softer tissues stripped away, and its very skeleton bared to our view—a splendid "subject" for the student of mountain anatomy.

One of the first to recognise this value of our Scottish Highlands to the student of Orographic Geology was the late Daniel Sharpe. He had made himself familiar with many of the characteristic details of Alpine architecture—so far as it was then understood—and was able to show that the foliated masses of our Highland districts exhibit precisely those relations which would be seen if the contorted and fan-like masses of the Alps were planed away by denudation. Nor in suggestions of this kind, as we have seen, was James Nicol far behind Sharpe; but at that time many of the most important features of mountain-structure were unrecognised or misinterpreted, and the conclusions of these geological pioneers were little more than guesses—though very valuable and suggestive guesses—after truth.

It is to our geological brethren over the Atlantic that we are especially indebted, not only for many important discoveries in the mechanics of mountain-formation, but for clearing away many of the clouds of error in which the subject had become involved. To Henry Darwin Rogers, who, after a career of valuable geological work in his native State of Pennsylvania, accepted the hospitality of this country, and spent the last decade of his useful life as Professor of Natural History and Geology in the sister university of Glasgow, must be assigned the foremost place in that school of orographic geologists which has grown up in America.

The first sketch of the important theory of mountain-building to which Rogers and his fellow-geologists were led by the study of the Appalachian chain, was published in 1842, but it was not till 1858 that the complete evidence on which this theory was founded could be published.

The conclusion at which Rogers arrived was, briefly expressed, as follows:—The Appalachian mountains were carved by denudation out of an enormously thick mass of stratified deposits, thrown into a series of parallel wave-like folds. To the westward of the mountain range "the crust-waves flatten out, recede from one another, and vanish into general horizontality;" but towards the heart of the mountain-mass the same flexed strata become greatly crowded together, their "axis-planes," become more and more inclined, till at last their folds, yielding at their apices to the tremendous lateral thrust, fractures twenty to eighty miles in length, and attended with a displacement of 20,000 feet or more, were produced.

Unfortunately Rogers accompanied these just views of mountain structure with certain crude speculations and untenable hypotheses concerning the methods by which they were produced. But in the minds of other American geologists, among whom may especially be mentioned Dana, Le Conte, and Vose—the fruitful ideas of Rogers have undergone development and expansion, while they have received abundant illustration through the labours of that active band of pioneers—the United States Geological Survey—including Clarence King, Powell, Emmons, Hague, Dutton, Gilbert, and many others.

Nor have the brilliant results attained by these investigators in the New World been without their effect on the geologists of Europe. Lory, Suess, Heim, Baltzer, and others have shown that the clue to the right understanding of the structure of the Alps, which had been so diligently sought and so long missed by Von Buch and De Beaumont, by Studer and Favre, was now placed in our hands by the researches of the American geologists.

In Northern Europe, Kjerulf, Dahll, Brögger, Reusch, and other geologists have ably illustrated the same peculiarities of structure in the denuded mountain-chain near the southern extremity of which we are now assembled; and in a recent valuable and suggestive essay "On the Secret of the Highlands" Professor Lapworth has shown how perfectly these structures are exemplified in the western district of Sutherland.

In offering a few remarks on some of the still unsolved problems of Highland geology I shall not hesitate to treat, as belonging to the same geological district, both Scandinavia and Scotland. Not only is the succession of geological deposits in the two areas almost completely identical, but the characters of the several formations and their relations to one another in the one country are almost the exact counterpart of what they are in the other.

The problems which await solution in Scotland are the same which confront our brethren in Scandinavia; their difficulties are our difficulties, their successes our successes; if they share the benefits of our discoveries, we equally partake with them in the fruits of their achievements. Important links in the chain of geological evidence, absolutely wanting in the one area, may perchance be found in the other. Every advance, therefore, which is made in the knowledge of the rocks of the one country, must necessarily re-act upon the opinions and theories which prevail among geologists in the other.

At the base, and forming the foundation of this greatly denuded mountain-chain, there exist enormous masses of highly foliated, crystalline rocks. These, in great part at least, underlie the oldest known, fossiliferous strata, and are therefore of pre-Cambrian or Archæan age. In spite of the labours of Kjerulf, Dahll, Brögger, Reusch, Tornebõhm, and many others in Scandinavia, and of Macculloch, Nicol, and their successors in this country, much still remains to be done in studying the petrographical characters and the geognostic relations of these widespread formations.

Some thirty years ago it was suggested by Sir Roderick Murchison that among these Archæan rocks there exists a "fundamental gneiss," a formation which is the counterpart and contemporary of the rocks in Canada, to which Sir William Logan gave the name of "Laurentian." Since that time other similar attempts have been made to identify portions of these Archæan rocks in the Highlands and Scandinavia with crystalline rock-masses in different parts of the New and Old World.

I confess that, speaking for myself, I am not sanguine as to the success of such endeavours. The miserable failures which we have seen to have attended similar attempts, in the case even of far less altered rocks, where identifications have been based on mineralogical resemblances only (and in connection with which definite palæontological or stratigraphical evidence has been subsequently obtained) ought surely to teach us caution in generalising from such uncertain data. It has been argued that, where palæontological evidence is wholly wanting, and stratigraphical relations are doubtful or obscure, then we may be allowed to avail ourselves of the only data remaining to us—those derived from mineralogical resemblances. But surely, in such cases, it is wiser to admit the insufficiency of the evidence, and to say "We do not know!" rather than to construct for ourselves a "fool's paradise," with a tree of pseudo-knowledge bearing the Dead-Sea fruit of a barren terminology! The impatient student may learn with the blind poet that

They also serve, who only stand and wait.

It is thought by some that the application of the microscope to the study of rock-masses may reveal peculiarities of structure that will serve as a substitute for palæontological evidence concerning the age of a rock when the latter is wanting. Greatly as I value the insight afforded to us by the microscope when it is applied to the study of the rocks, and highly as I esteem the opinions of some of those who hold these views, yet I fail to see that any such connection between the minute structure and the geological age of a rock has as yet been established.

Although the bold generalisation which sought to sweep all the crystalline rocks of our central Highlands into the great Silurian net has admittedly broken down, yet it by no means follows that the whole of these rock-masses are of Archæan age. Nicol always held that among the complicated foldings of the Highland rocks many portions of the older Palæozoic formations, in a highly altered condition, were included (see *Quart. Journ. Geol. Soc.* vol. xix. (1864), p. 184, and "Geology and Scenery of the North of Scotland," 1866). The same view has been persistently maintained by Dr. Hicks, to whose researches among the more ancient rock-masses of the British Isles geologists are so greatly indebted, and also by Prof. Lapworth.

To the settlement of this very important question we may feel sure that the effort of the officers of the Geological Survey will be especially directed. The geological surveyors of Scandinavia have been so fortunate as to detect, in rocks of an extremely altered character, a number of fossils sufficiently well preserved for generic and sometimes even for specific identification. Failing the occurrence of such a fortunate accident, I confess that it has always appeared to me that the disturbances to which these Highland rocks have been subjected are so extreme, and the difficulty of making out the original planes of bedding so great, that but little can be hoped for from general sections constructed to show the relations of the rocks of the Central and Southern Grampians to the fossiliferous deposits of the North-West of Sutherland.

Lying unconformably upon these Archæan crystalline rocks in our North-West Highlands we find great masses of arkose or felspathic grit, with some conglomerates, the whole of these well-stratified deposits attaining a thickness of several thousands of feet. These rocks, in their characters and their relations, so greatly resemble the "Sparagmite Formation" of Scandinavia. that it is impossible to refrain from drawing comparisons between them. The Scandinavian formation, however, includes calcareous and slaty deposits, which are wanting in its Scottish analogue. The "Sparagmites" of Scandinavia, as a whole, appear to underlie strata containing Cambrian (Primordial) fossils, but in the very highest portion of the "Upper Sparagmite Formation" of Southern Norway there have been found, according to Kjerulf, specimens of *Paradoxides*.

The Scottish formation has, on the other hand, yielded no undoubted organic remains. Murchison, on the ground of its unconformable infraposition to his Silurian strata, and its resemblance to certain beds in Wales which he called Cambrian, referred it in his later years to that system. Although an identification, based on such grounds, must be admitted to be of small value indeed, yet the discovery of "Primordial" fossils in the very similar rocks of Scandinavia may be admitted to lend it some slight support. In the present state of our knowledge, however, it is surely wiser to admit that the question of the age of these beds is still an open one, and to call it by the name suggested by Nicol—"The Torridon Sandstone." Kjerulf believes there is evidence that the Scandinavian Sparagmite, in places, passes horizontally into true gneiss, and similar appearances are not wanting in the case of our Torridon Sandstone.

(*To be continued.*)

NOTES FOR THE OPENING OF A DISCUSSION ON ELECTROLYSIS, TO BE HELD IN SECTION B, AT THE BRITISH ASSOCIATION IN ABERDEEN, SEPT., 1885, BY PROFESSOR OLIVER LODGE

I. *WHAT is an Electrolyte?* The question has two distinct meanings:

(*a*) Is a given substance an electrolyte at all; *i.e.* when alone.

(*b*) Is it the electrolyte in any particular case; *i.e.* when mixed with other substances.

In answering (*a*) remember that the fact of bad conductivity does not imply that what there is is non-electrolytic. An electrolyte is one whose conduction is wholly electrolytic. Distinction between metallic and electrolytic conduction. Obedience to Ohm's law shown by electrolytes.

Tests of Electrolytic conduction.
1. Visible decomposition.
2. Polarisation.
3. Non-agreement with Volta's series-law.
4. Transparency.

In answering (*b*) the fact of bad conductivity gives a decided negative, but substances which almost insulate when alone may conduct when mixed; *e.g.* $H_2O + HCl$.

To the question, What is the real conductor when a salt (or acid) is dissolved in water? there are four possible answers:

(1) The salt only,
(2) The water only,
(3) Both the salt and the water,
(4) A hydrate of the salt.

(1) is to be held by those who regard the water as unchanged by the addition of salt

(2) is to be held by those who suppose the water-molecules to be dissociated, or mechanically knocked asunder, by the massive salt-atoms

(3) and (4) are mere modifications of one another, not easily to be distinguished.

In deciding this question (*b*) we really decide what are the primary and what are the secondary products of electrolysis.

Discussion of experimental evidence bearing on the point.

Hittorf's and Buff's experiments on mixed Electrolytes.

Magnus and others on the effect of current-intensity. (With intense currents you are more likely to get the real ions liberated because secondary actions have hardly time to occur).

Direct experiment suggested by observing the place of appearance of free acid; and preliminary reply in favour of (3) or (4).

Valid objection suggested by Smee to regarding any of these experiments as crucial; but possible means of evading the objection.

Experiments of Hisinger, Berzelius and Davy on electrolytes in series sometimes throw light on the question, which are the real ions.

II. *Questions about the "migration of ions." Do ions in salt-solutions travel at different rates? And, in any case, at what rate do they travel?*

Distinction between fused and dissolved compounds.

There being simple experimental evidence that solutions often concentrate near anode and weaken near cathode, or perhaps occasionally *vice versâ*: what is the explanation?

Several possible hypotheses:

(1) Hittorf's that the salt is primarily decomposed and that its ions travel at different speeds.

(2) Hittorf's resort in exceptional cases, that per-salts are electrolysed into sub-salts and radical.

(3) Burgoin's, that a hydrate of the salt is electrolysed and that the water travels mostly with the cation.

(4) D'Almeida's, that a free acid envelop is formed around anode and is electrolysed in series with the salt.

(5) Quincke's, that opposite ions have charges differing in magnitude as well as in sign, and are therefore urged with different forces.

(6) Wiedemann's, that the entire salt molecules electrify themselves by contact with the water and are thus urged bodily either with or against the current.

(7) Kohlrausch's, that every ion has its own definite rate of propagation in a given fluid when urged by a given force; and that this rate is calculable from conductivity, concentration, and migration, data.

(8) Suggested, that opposite corresponding ions must always travel at equal opposite rates, but that in solutions the water may conduct more or less of the current.

Mode in which this hypothesis (8) can explain migration; and limitation to its explanation.

Easy calculation of total or resultant velocity of ions, but difficulty in apportioning the right fraction of this velocity to each ion in accordance with Kohlrausch's theory.

Reasons for supposing it necessary that opposite ions must travel at the same pace.

Wiedemann's, Quincke's, and Helmholtz's theories of electric *Endosmose*, and proof by Wiedemann that it is independent of "migration" phenomena.

Bearing of experiments with electrolytes in series on the question of relative migration velocities; and other suggested migration experiments.

III. *Quantitative Laws of Electrolysis.*

(*a*) Ohm's law of electrolytic conduction.
(*b*) Faraday's two laws,
(1) The voltametric law.
(2) The law of electro-chemical equivalence.

And (*c*) dependence of decomposition EMF on chemical combination-energy.

Nature of experimental evidence in favour of these laws.

Question whether Ohm's law will be exactly obeyed for violent currents. Very important consequences of the law, if exact for feeble currents.

Physical consequences of Faraday's two laws; to be asserted of all substances for which they are accurately true.

Law (1) asserts that no such electrolyte possesses a trace of metallic conduction; *i.e.* that electrolytic conduction and chemical decomposition are precisely correlative. In Helmholtz's words, "Through each section of an electrolytic conductor we have always equivalent electrical and chemical motion." Or again, in other words, with a spice of natural hypothesis (first due perhaps to Ampère), Electrolysis is a kind of electrical *convection* rather than conduction, each atom carrying a charge with it; and the charge conveyed by every atom of a given substance is the same.

Law (2) extends this last important statement to all electrolytes, and enables us to conclude that a definite quantity of electricity belongs to each unit of affinity of every atom of whatever kind, and that fractional portions of such atomic charges are, in electrolysis at least, unknown.

This last is a most astounding statement, for it suggests that electricity may be "atomic" as well as matter.

Calculation of magnitude of this atomic charge; enormous value of it in proportion to size of atoms (10^{-11} electrostatic units, probably, per monad atom).

IV. *Questions concerning Polarisation; and the EMF needed to send a current through an electrolyte.*

The chemical changes which go on in a circuit wholly electrolytic, or in any homogeneous portion of a circuit, are decomposition and identical recomposition, and consume no energy: accordingly no finite EMF is needed to send a current through an electrolyte *when the force is really applied to it*, and Ohm's law is obeyed by electrolytes exactly as by metals.

But at junctions of metals with electrolytes, or of electrolytes with one another, permanent chemical changes may occur, and at these places a finite EMF may be situated; and this may be either negative, when it is called polarisation, or positive, when the whole arrangement is called a battery.

Calculation of such EMFs from thermo-chemical data.

Joule's proof that the heat of chemical action is a secondary result—electric currents being the primary. The EMF (whether positive or negative) of any arrangement is obtained in volts, if the total heat produced by the chemical changes per dyad gramme-equivalent be divided by 46,000.

Total polarisation may be regarded as the sum of two kinds:

(*a*) Temporary polarisation, existing during continuance of current.

(*b*) Residual polarisation, existing afterwards.

(*b*) is caused by a more or less permanent alteration of the surface of the electrodes by the clinging or combined ions.

(*a*) is caused, according to Helmholtz's theory, by a Leyden jar action of the charged atoms straining across molecular distance of the surface of each electrode, and unwilling to part with their charges. When the ions are able to combine with the electrode, or otherwise retain their charges, this (*a*) portion is very small.

Effect of secondary actions in destroying polarisation, and rendering possible a permanent current even when apparently insufficiently propelled. Helmholtz's air-free cell.

Intense currents diminish the amount of secondary action; and also modify maximum polarisation values, raising them above their customary amounts.

V. *Mechanism of Electrolytic Conduction.*

Electrolytic conduction is certainly a convection of Electricity by atoms of matter; but concerning the mode in which the atoms make their way through the fluid there are several hypotheses:

(1) The molecular chain of Grotthus; modified and accepted by Faraday and many others, modified further by Hittorf to explain migration.

(2) The dissociation hypothesis of Clausius and Williamson; virtually accepted by Maxwell, modified by Quincke to explain migration, and shewn by Kohlrausch to explain the facts of conductivity.

(3) The electrostatic hypothesis of Helmholtz.

Because Ohm's law is obeyed, it is certain that no polarisation can exist inside a homogeneous electrolyte: in other words, there is no *chemical cling* of the atoms there, but only a frictional rub. Wiedemann's view that conductivity is inversely proportional to ordinary viscosity.

Probable independence of conductivity and tenacity of combination. Such facts as these, if well established, render necessary *some form* of dissociation hypothesis.

A Grotthus chain of quite *equidistant* atoms might serve, instead of actual dissociation, or a momentary dissociation would be sufficient; but no hypothesis which involves a tearing asunder of molecules in the *interior* of a homogeneous electrolyte can be permitted.

Herein lies the great distinction between electrolytes and dielectrics.

Hypotheses (1) and (2) may be held in either of two forms:

(*a*) The electrical influence of the electrodes may be supposed to reach every molecule of the fluid. This was Grotthus's form of (1), and is Quincke's form of (2).

(*b*) The electrical influence of each electrode may only extend within molecular distance of its surface, while the adjustments occurring in the main body of the fluid are effected by ordinary diffusion. This was probably Faraday's form of (1) and it is Maxwell's form of (2).

Helmholtz's hypothesis (3) emphasises the (*b*) aspect of the matter by appealing to electrostatic interactions of the atoms to maintain uniformity of composition. And within a range of 10^{-8} centimetres of each electrode there is supposed to exist an ordinary electrostatic strain, like that in an ordinary dielectric condenser plate.

The great magnitude of the atomic charges explains the feebleness of the difference of potential required to effect decomposition on electrostatic principles. And the same thing suggests a mainly electrical theory of chemical affinity.

To separate an atom from its charge requires expenditure of work, hence Helmholtz's theory of a specific attraction between matter and electricity, which he uses to explain Volta's "contact force," the charge of atoms in a molecule, frictional electricity, and many other phenomena.

VI. *Addenda.*

Calculation of EMF needed to effect decomposition—
(*a*) of a dielectric,
(*b*) of an electrolyte,
on electrostatic principles.

Suggested theory of disruptive discharge.

Possible distinction between chemical compounds and molecular aggregates.

Discussion of various phenomena from the point of view of a possible "atomic" theory of electricity.

NOTES

SINCE our last issue Dr. Harting, of the Dorpat Observatory, has announced an apparent variation in the great nebula of Andromeda, which has caused some excitement in the astronomical world. As represented in all our drawings, and, still better, in a photograph which Mr. Common was fortunate enough to obtain last year, the centre of the nebula appeared to be only moderately condensed. There was no star or stellar point. Now, on the contrary, there is a most unmistakable star of the eighth or ninth magnitude. The question is, is this a *stella nova* in the line of sight of the nebula, or has the phenomenon been produced by a new condensation in the centre of the nebula itself? Opinion inclines to the latter view, as, according to some accounts, other accompanying changes have been seen with large instruments, &c. But, on the other hand, spectroscopic evidence that the apparent nebula is not a very distant cluster is absent. By our next issue we may hope for a large harvest of telescopic and spectroscopic observations of this new object.

THE International Congress of Schoolmasters was opened in the Grand Theatre at Havre on the afternoon of the 6th instant, Mr. Goblet, the Minister of Public Instruction, presiding.

THE Severn tunnel has now been completed, and on Saturday last a train containing officials and their friends passed through it from end to end.

A CASE of Asiatic cholera has occurred at Cardiff. A labourer, loading a vessel which had recently arrived from Barcelona, drank water which had been put into a cask at that port, and which was described by the medical inspector as totally unfit to drink, having the appearance of discoloured milk, and being putrid. The man died in a few hours of Asiatic cholera.

ON August 25 and subsequent days was held in Turin the International Congress of Alpine Clubs. The principal topic of discussion was the better management of refuges erected in different parts of the Alps, new regulations for guides, and pensions to be granted to them. The honorary president was the King of Italy, His Majesty being represented by M. Loyi; the acting president was Prof. Ferrati. The readings of minimum and maximum thermometers were also collected and discussed. Several excursions took place at the close of the session.

THE German Meteorological Society met for its third congress at Munich last month. Prof. Bezold, of Munich, who delivered the address of the meeting, took for his subject "The Advances of Meteorology during the last Ten Years," dwelling mainly on the alterations made by the introduction of the synoptical method in connection with telegraphy.

THE eleventh *Bulletin* of the United States Geological Survey is a paper on the quaternary and recent mollusca of the Great Basin, with descriptions of new forms, by Mr. R. Ellsworth Call, with an introduction containing a sketch of the quaternary lakes of the Great Basin, by Mr. G. K. Gilbert.

REPEATED severe shocks of earthquake have occurred in the south-east of Lower Austria and in the north of Styria, and have been followed by further shocks in Bonia, described as moving from east to west.

WE have received Prof. Holden's account of the progress of astronomy in 1884, and Prof. Rockwood's account of vulcanology and seismology for the years 1883 and 1884, reprinted from the Smithsonian Report for 1884; also Mr. Albert Williams's report on placer mines, and mining districts, from the report of the tenth census of the United States on the statistics and technology of the precious metals.

THE programme of the technological examinations of the City and Guilds of London Institute for the Advancement of Technical Education for the session 1885-86 has been published. It contains a detailed syllabus of the examinations for the different grades on each subject, and copies of recent examination papers. It is to be obtained at the offices at Gresham College, and at Exhibition Road.

MR. G. J. SYMONS, who has examined the trees recently damaged by lightning in Richmond Park, has communicated the results of his observations to the *Times*. They are two of a group of oaks in the eastern part of the park, slightly south-west of, but very near, the White Lodge. They were fine trees, their girth at 3 feet being 11 and 12 feet respectively; the trunks are 23 feet apart, and one is nearly due north of the other. There are three other trees quite close to them (within 40 feet), which are uninjured, except by the branches which were thrown upon them. The injury to one tree, though fatal to it, is unimportant, but the other tree affords a tremendous instance of disruptive power. It appears to have been cut through horizontally at about 3 feet above the ground; the upper portion shows comparatively little injury, but the lower part is not merely stripped of its bark, but burst open in a very intense way; spikes of the stem, several inches thick and 10 to 15 feet long, stand out from the trunk somewhat like the ribs of an umbrella before it is fully opened, and grip between themselves and the centre of the trunk branches which fell from the upper part before they had time to reclose, while the ground for perhaps 200 feet around is strewn with the bark and fragments of the trunk, from scraps like lucifer-matches to pieces which some men could not lift. From this state of facts Mr. Symons suggests some problems: Why one tree rather than another should be struck if it be not the tallest? why, as in this case, the wreck of one tree is greater than that of the other 23 feet away? what produces this disruptive force? &c. A curious question is, Why oaks and elms are especially liable to be struck? It was stated in 1787 that the elm, chestnut, oak, and pine were the trees most often struck in America; in 1860 Mr. Symons himself stated, in a paper read to the British Association, that the elm, oak, ash, and poplar were the most frequently struck in this country. The last number of *Das Wetter* of Magdeburg contains an abstract of ten years' records of trees injured; 265 are reported, and of these 165 were oaks; the only other trees of which the number was more than trifling were: Scotch firs, 34; pines, 22; and beeches, 20. It has been suggested that the frequency with which oaks are struck is due to the presence of iron in the wood.

It is strange to contrast the weather which we have had during the summer in England, and indeed in Western Europe, with that prevailing in China, Japan, and the rest of Eastern Asia. While here it has been exceedingly dry, with as a rule a hot sun during the day, in Japan it rained almost without intermission throughout June and July, and the sun was rarely seen. It has been in fact a season of unusually heavy rainfall; while with us the reverse has been the case. When the latest mails left, landslips and inundations were of daily occurrence. Between Yokohama and Tokio the railway line was blocked in several places by masses of earth which had fallen, a great part of the country was under water; and the same reports come from Osaka in the south of the main island. Here the water invaded the line, washing away the ballast, and rendering passage impossible; the inundations had rendered many people homeless, and great distress prevailed in many places. The same story comes from China. In the south, in the Kwangtung province, the rivers which debouche at Canton had become swollen with the constant rains, overflowed their banks, and spread desolation far and wide. Whether there is any connection between the extreme dryness here and the extraordinary rains in the far East, and whether either, as has been suggested, has any connection with the unusual seismic activity prevailing at present, must be left to meteorologists to determine; but as this activity, whether, as volcanic eruptions or as earthquakes, appears impartially distributed all over the globe, from Hungary to South America, from the Eastern Archipelago and Japan to Cashmere, it is not easy *primâ facie* to see how it could be the cause of, or have any connection with, such strikingly different phenomena in different parts of the Old World.

THE *Auk* (vol. ii. Nos. 2, 3), published at Boston for the American Ornithologists' Union by Messrs. Estes and Lauriat, continues to furnish evidence of the great activity with which ornithology is prosecuted in North America, though the students of that branch of science still affect rather the particular than the general, much as did most British ornithologists some thirty years ago, and as many do now. This perhaps is only to be expected, and since the avifauna of North America is so enormously larger than that of the British Islands, the condition may very likely last longer there than here. Nearly every paper in these two numbers (for April and July of the present year)—reviews of books apart—refers only to the birds of the Nearctic Region or Sub-region; but most of them seem to the eye of a European to be good of their kind. It looks as if the nomenclatural paroxysm, which lately afflicted our esteemed brethren in the United States, were gradually passing away, and we trust that they will then have time to apply their energies to more important subjects. Dr. Stejneger, however, has a fifth series of his "Analecta Ornithologica." His views are in the main so entirely in accordance with what has generally been held in England to be orthodox, that we cannot object to his labours, whatever be the trouble they may cause; and we greatly regret the rare occasions in which we think him mistaken. One of them is in his present paper (pp. 183, 184), where he strives, and we consider fails, to make out that the generally accepted name of *Scops* for a genus of Owls ought to be dropped. Because Brünnich in 1762 turned Brisson's *Scopus* into *Scops*, the latter term was obviously not thereby established; and the former being, as Brisson tells us (*Ornithologie*, v. p. 503), his own coinage from the Greek σκιά (*umbra*) properly a shadow, but taken by him to mean also the colour umber—a signification it seems never to have possessed—it is a wholly different thing from the classical σκώψ, which has always meant an Owl of some sort. Thus the two words are absolutely distinct, and Brünnich can be only regarded as having made a misdirected attempt at grammatical emendation. We therefore hold that even the ornithologists of America, who recognise Brünnich's generic names (which the ornithologists of Europe in general do not), will be fully justified in retaining the name *Scops* in the sense in which Savigny used it. Dr. Merriam has a notice (p. 312) headed "The eggs of the Knot (*Tringa canutus*) found at last!" but we must beg leave to remind him that sixty-five years ago this bird was found to breed abundantly on the Parry Islands, and, though admittedly no eggs are now forthcoming in collections, it has always been understood that specimens were then brought thence. It does not now appear that Lieut. Greely brought home any, though we trust he may have done so; but if he did not we are much in the same position as before in regard to that oological *desideratissimum*. Mr. Ernest E. T. Seton has a letter (p. 316), admirable for its common sense, on "The popular names of Birds," which in a new country, inhabited by English-speaking men and women, is by no means a matter to be neglected. We have to congratulate Mr. Allen on his promotion to the Curatorship of the Central Park Museum in New York City, and Mr. Brewster on succeeding to the appointment at Harvard University thereby vacated. Both these gentlemen are so well known by name to English ornithologists, that it is quite unnecessary to point out their eminent qualifications for the posts they now respectively hold, and we hope will long continue to enjoy. The name of Dr. Coues does not appear as a contributor in either of these numbers, which fact is, we suppose, attributable to his departure westward, where we trust he will continue those field-observations for which he became distinguished so long ago. We miss also any important communication from Dr. Shufeldt. Migh we venture to suggest that the quantity of small type used in this excellent journal is rather trying to some eyes? It unfortunately happens that even ornithologists are not exempt from some of the bodily inconveniences of advancing years, however young they may continue mentally; and at present the volume of the *Auk* is not so obese but that it might wax fatter without losing its volant powers.

COL. YOLLAND, C.B., F.R.S., one of the Inspectors of Railways under the Board of Trade, died on Friday last at Baddesley Vicarage, Atherstone, Warwickshire. He was born in 1810, was admitted into the Royal Military Academy, and obtained his commission in the Royal Engineers in 1828. He rose by regular promotion until he became lieutenant-colonel in 1855, and a brevet colonel in the army in 1858. After being employed in Canada till 1835, he was employed successively at the Ordnance Survey at the Tower of London, at Southampton, Dublin, and Enniskillen. During this interval he superintended the publication of astronomical observations, first those made with Ramsden's zenith sector, and afterwards with Airy's, the latter observations being for the purpose of determining the latitudes of various trigonometrical stations in Great Britain and

Ireland. He also compiled an account of the measurement of the Loch Foyle base, which was made during the years 1827–29. The article on geodesy, which forms part of the mathematical text-book used at the Royal Military College, was written by Col. Yolland. In 1854 Col. Yolland was appointed one of the Inspectors of Railways under the Board of Trade. In 1856 he was selected as the engineer member of the Commission appointed by the Secretary of State for War to consider the best mode of reorganising the system of training officers of the scientific corps, with the special intention of abolishing patronage and opening the commissions in those corps to competition. The Commissioners, the other two of whom were Col. W. J. Smith, R.A., and the Rev. W. C. Lake, visited France, Prussia, Austria, and Sardinia, and, after studying the methods of appointment in use in those countries, drew up a report, which was printed by order of the House of Commons.

DR. SCHOMBURGK's Report on the Progress and Condition of the Botanic Garden and Government Plantations in South Australia for the year 1884, which is dated from the Botanic Garden, Adelaide, in March last, gives, as usual, a good deal of interesting matter on the cultivation of useful plants. The co-operation, which has of late years been so much extended between the botanic gardens in all our colonial and foreign possessions, has been the means of inciting the several directors to increased energy in the development of new resources and the interchange of valuable plants, so that matter of a similar character, or treating of the same plants, often appears in reports from gardens widely separated geographically from each other. Thus we find in the report before us notes on the suitability or otherwise for Australian culture of many plants that have been similarly reported on from other parts of the world. Amongst those reported upon by Dr. Schomburgk may be mentioned mustard, rape, sesamum, ground nut, tobacco, hops, canary seed, chicory, capers, esparto, &c., &c. Speaking of esparto grass (*Macrochloa tenacissima*), which is a native of Spain, Portugal, and North Africa, and is, we are reminded, exported into England alone to the amount of 140,000 to 150,000 tons a year, so that it is becoming scarcer every day, and consequently fetching higher prices, Dr. Schomburgk says: "Considering the similarity of our climate with that of Spain, I endeavoured to introduce this valuable grass into the Colony, which, after many difficulties, I succeeded in accomplishing, and I have not been disappointed in its acclimatisation in South Australia. The grass which I have now cultivated for the last five years grows admirably with us, notwithstanding the most severe droughts we have to contend with. It is propagated by seed. The question will naturally be asked, 'Suppose we succeed in growing the grass here, where shall we find a market for it?' Our enterprising and go-ahead neighbours in Victoria have already established two paper mills, and I understand Sydney also possesses one, so that, if we succeed, the market for the grass is close at hand, and I think it would even pay to export the grass to England, as by means of hydraulic pressure the bulk would be considerably reduced." Another industry which seems to promise well in South Australia is the production of sumac, which consists of the powdered leaves and twigs of *Rhus coriaria* and *Rhus cotinus*, shrubs of the Mediterranean region, and grown largely in Southern Europe for the sake of the leaves. Dr. Schomburgk says both plants grow in the Adelaide Botanic Garden, and the climate seems to suit them; he recommends, however, that trials should be made to ascertain whether they would thrive in poor or sandy soil. On this subject the British Consul at Palermo, in the neighbourhood of which the best sumac is grown, says the soil best adapted for the plant is that of a sandy nature. It is propagated by cuttings. The bulk of the sumac is shipped from Palermo to various countries, but principally to the United States. A catalogue of plants added during 1884 to the collection under cultivation at the Botanic Garden is given in the form of an appendix.

IT was hardly to be expected that the season should pass without the appearance of the sea-serpent somewhere, and if we are to believe the information forwarded to us from a correspondent in Norway, it has just visited the coast of Nordland. Three Sundays ago some lads were returning to the Island of Röd from the church at Melö, in the middle of the day, when they saw far out in the fjord a streak in the sea, which they believed to be a flock of wild ducks swimming. On proceeding further, however, they heard the whizzing as of a rushing fountain, and in a few moments perceived a great sea-monster with great velocity making straight for the boat. It appeared to be serpentine in shape, with a flat, scaly head, and the lads counted seventeen coils on the surface of the water just as it passed the stern of the boat so closely that they could have thrown a boat-hook into it. By subsequent measurements on land the length of the animal was estimated at about 200 feet. It pursued its course on the surface of the sea until close behind the boat, when it went down with a tremendous noise, but reappeared a little after, shaping its course for the Melö, where it disappeared from view. Naturally the lads were greatly frightened. The weather at the time was hot, calm, and sunny. Our informer states that the lads are intelligent and truthful, and that there is no reason to discredit their unanimous statement, made, as it were, in a terribly frightened condition. It might be added that the waters in which the animal was seen are some of the deepest on the Norwegian coast, and that it is not the first time fishermen have averred having seen the sea-serpent here. The existence of the sea-serpent is fully believed in along the coast of Norway.

WE have received the *Journal* and *Proceedings* (vol. xviii.) of the Royal Society of New South Wales for 1884. Besides the President's address, it contains several papers, reports of the various meetings, an abstract of the meteorological observations at the Sydney Observatory, and a rainfall map. Amongst the papers we find one on the removal of bars from the mouths of rivers, by Mr. Shellsbear; on some New South Wales minerals, by Prof. Liversidge; on the oven-mounds of the aborigines of Victoria, by Mr. MacPherson; on a new form of actinometer, by Mr. Russell; on the water supply of the interior of New South Wales; and shorter papers on gold, on the trochoided plane, on doryanthes, &c., Mr. Caldwell's paper on the embryology of the marsupiala, monotremata, and ceratodus.

WE have to acknowledge a copy of the English translation of the paper read by Messrs. Thorell and Lindström to the Royal Swedish Academy of Sciences, on the Silurian scorpion found in Gothland (NATURE, vol. xxxi. p. 295). It is published by Norstedt and Sons, Stockholm.

THE ceremony of the Chevreul centennial has been postponed until January 1, 1886. To give more solemnity to the celebration all the Paris students will be present at the *fête;* now most of them are in the provinces or abroad. The health of M. Chevreul continues excellent, and the delay is not likely to prove an obstacle to the ceremony.

PROF. DOOLITTLE, of the Lehigh University, Pennsylvania, has published a treatise on practical astronomy, as applied to geodesy and navigation (New York: Wiley; London: Trübner). It is intended as a text-book for universities and technical schools, and as a manual for the field astronomer. The object has been to present in a systematic form the most approved methods in use at the present time, and these are illustrated by complete numerical examples. In the introduction the method of least squares is developed with special reference to the requirements of this particular class of work.

NEARLY all the ironworks at Pittsburgh, besides some forty iron firms within a radius of thirty miles, are now using the natural gas of the district, as are also most of the glass factories, distilleries, breweries, &c. This is creating an entire revolution in the labour market there. The output of iron and steel at Pittsburgh is about 750,000 tons per annum, and as it takes some 50 bushels of coal to make one ton of iron, it follows that at least 38,250,000 bushels of coal will be dispensed with in the yearly consumption, throwing out of employment an enormous number of miners, firemen, ashmen, roadmen, and other *employés* of the collieries. The cause of this great change being entirely one of nature's arrangement renders it an impossibility for trade unions and labour agitators to deal with the matter.

WE have received the *Report* and *Proceedings* of the Bristol Naturalists' Society for the year ending April 30 last. The principal paper is a long one, with illustrations, by Prof. Lloyd Morgan, on sub-aërial denudation and the Avon gorge, in which he has worked out in detail the subject of the influence of geological structure on the scenery of the Avon, more particularly of that section of the Avon basin lying between Bristol and the Channel. There are also papers on the mapping of the millstone grit at Long Ashton near Bristol by the same writer, on a common fin whale stranded in the Bristol Channel by Mr. Wilson, and on the newly-discovered phenomenon of apospory in ferns by Mr. Druery. There are also papers on the rainfall at Clifton in 1884, and meteorological observations with regard to temperature during the same year. Finally Mr. Bucknall prints the eighth part of his fungi of the Bristol district, and Mr. White additions to his *flora* of the Bristol coal-field. The report shows that only a portion of the papers read are printed. Perhaps it is right to add in conclusion that the society is in a flourishing financial condition, for it has not only a comfortable balance on the right side of its current accounts, but has actually a capital to the amount of 17*l*. 10*s*. invested in securities.

A REPORT from the Government Astronomer in the *Hong Kong Government Gazette* upon the progressive motion of typhoons gives the following average velocities. The course of the typhoon is here followed from its commencement on the east coast of Luzon, the cradle of the typhoons of the China seas, into the Sea of Japan, beyond which they are dissipated and lost in the North Pacific :—

	Nautical miles an hour
East of Luzon	7
China Seas between 12° and 18° N.	6
China Seas between Hong Kong, Luzon, and Southern Formosa	11
About Hainan	13
East of Formosa	10
In Southern China: Kwangtung, Fokien, and Kiangsi	10
In the Formosa Straits	12
About Shanghai	12
In Northern China	23
About Japan	19
In the Sea of Japan	30

DR. NICKERSON, of New York, has published as a pamphlet the memorial address by him on Joseph Henry and the magnetic telegraph, delivered at Princeton College. It is printed at the request of the President and members of the College, and is published by Charles Scribner and Sons, of New York.

WE have to acknowledge Mr. G. J. Symons's "British Rainfall" for 1884. The issue for 1860, in four pages, is reprinted and bound with the volume, and is interesting as the beginning of the elaborate work which Mr. Symons now publishes every year. The present volume differs from its predecessors, inasmuch as it contains no articles from observers upon experimental or other branches of rainfall work; but their place has been supplied by notes by the editor scattered throughout the book. He has invited observers to report any facts within their knowledge bearing on the effect produced upon the level of water in wells, &c., by the small rainfall of the year. Consequently observers' accounts occupy a considerable space. Mr. Symons has added a full account of the drought.

WE have received the report of the *Verein für Naturkunde* of Mannheim for the fiftieth and fifty-first years of its existence. The report contains the jubilee address, and also a lecture delivered by the late Dr. Schimper in the year 1834, on the classification and succession of organisms, together with a brief biography of the author and a bibliography of his writings.

THE additions to the Zoological Society's Gardens during the past week include a Purple-faced Monkey (*Semnopithecus leucoprymnus*) from Ceylon, presented by Mr. Ernest Greathead; a Weeper Capuchin (*Cebus capucinus* ♂) from South America, presented by Mrs. A. Sinclair; a Ring-tailed Coati (*Nasua rufa* ♂) from South America, presented by Master J. C. Robinson; a Yellow-footed Rock Kangaroo (*Petrogale xanthopus* ♀) from South Australia, presented by Mr. C. W. Holden; a Levaillant's Cynictis (*Cynictis penicellata* ♀), a Suricate (*Suricata tetradactyla* ♀) from South Africa, presented by Mr. John Constable; four Black Water Voles (*Arvicola amphibius*) from Scotland, presented by Mr. W. Arkwright, F.Z.S.; a White-backed Piping Crow (*Gymnorhina leuconota*) from South Australia, presented by Miss A. Charsley; a Poë Honey-eater (*Prosthemadera Novæ-Zealandiæ*) from New Zealand, presented by Mr. Charles Clifton, F.Z.S.; a Humboldt's Lagothrix (*Lagothrix Humboldti*) from the Upper Amazons, a Glutton (*Gulo luscus*) North European, deposited; a Jaguar (*Felis onça*) from America, deposited; two Long-fronted Gerbilles (*Gerbillus longifrons*), two Snow Birds (*Junco hyemalis*), five Common Vipers (*Vipera berus*), thirty Striped Snakes (*Tropidonotus sirtalis*) bred in the Gardens).

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, SEPTEMBER 13–19

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on Sept. 13

Sun rises, 5h. 34m.; souths, 11h. 55m. 44·2s.; sets, 18h. 18m.; decl. on meridian, 3° 38′ N.: Sidereal Time at Sunset, 17h. 50m.

Moon (at First Quarter on Sept. 16) rises, 10h. 52m.; souths, 15h. 50m.; sets, 20h. 42m.; decl. on meridian, 13° 54′ S.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	4 6	10 56	17 46	9 5 N.
Venus	8 49	14 3	19 17	9 52 S.
Mars	0 27	8 30	16 33	21 31 N.
Jupiter	5 10	11 45	18 18	5 56 N.
Saturn	22 53*	7 1	15 9	22 22 N.

* Indicates that the rising is that of the preceding day.

Occultations of Stars by the Moon

Sept.	Star	Mag.	Disap. h. m.	Reap. h. m.	Corresponding angles from vertex to right for inverted image ° °
19	13 Capricorni	6	20 4	21 23	122 272
19	14 Capricorni	5	21 33	22 41	151 273

The Occultations of Stars are such as are visible at Greenwich.

Sept. h.
18 ... 19 ... Mercury at greatest elongation from the Sun, 18° west.

ASTRONOMICAL NOTES

NEW COMET.—A new comet, discovered by Mr. Brooks, has been observed by Mr. Wendell, of Harvard College Observatory, and Mr. Ainslie Common, of Ealing. On Friday night its approximate position was R.A. 13h. 53m., and N.P.D. 52° 20′. Its R.A. is increasing and N.P.D. decreasing; diameter, 9 minutes of arc, and getting brighter.

NEW MINOR PLANET.—On the evening of the 3rd inst. Herr Palisa, of Vienna, discovered a minor planet, thus bringing the number of these bodies to 250. The following are the particulars of the discovery:—September 3, 9h. 53s. (Greenwich mean time); right ascension, 23h. 34m. 44s.; north polar distance, 106° 9′ 35″; daily motion in right ascension, 48s. decreasing, in polar distance 3′ increasing; magnitude, 11th.

GEOGRAPHICAL NOTES

THE Caroline Islands, which are attracting so much political attention now, are described at some length in the *Gazette Géographique*. It is generally acknowledged that they were discovered by a Portuguese navigator in 1526, and during the rest of the sixteenth century they were frequently visited by Spanish and Portuguese explorers. They were called the Carolines about 1686 by a pilot named Lezcano, who saw many islets there, but could not tell to what group they belonged, or indicate their exact position. The name was given to them after Charles II.; they have also been called the New Philippines, but this has never prevailed. Towards the end of the seventeenth century the Spaniards in the Philippines and Mariannes learned something of the Carolines, and in 1705 an imperfect map of the group was sent to Pope Clement XI., and then the Jesuits of the mission at Manila resolved to establish a branch in the Carolines. In 1710 the missionaries and a few soldiers set sail, but on arriving at the Pelews were all massacred. Up to 1817 the Carolines were visited by navigators of all nations, but the number of the islands, their exact position, and the hydrography of the seas in which they were situated, was totally unknown. In that year Kotzebue, and subsequently Freycinet, Duperrey, Dumont d'Urville, and others, visited the whole of the Archipelago, and from them we got our first accurate accounts of the Carolines and their inhabitants. The Caroline archipelago forms part of Micronesia, and is situated to the south of the Ladrones, to the west of the Marshalls, and to the north of New Guinea. It consists of about 500 islands, of which the greater number are only *atolls*. The number of real islands is only forty-eight, but as each of these is surrounded by a certain number of islets, it may be said that the archipelago consists of forty-eight groups; forty-three of these are low coral islands, while five are composed of basalt with coral at the base. The superficial area over which the archipelago is spread is about forty-five square leagues. Geographically it may be divided into three main groups, separated by two large channels: the eastern group, of which the principal island is Ascension or Ponape; the central group, and the western group, the principal island being Eap or Jap, of which much is being heard just now. Ponape is between 50 and 60 miles round, and has a peak in the centre which rises to a height of 2860 feet. At one part of its coast there are curious ruins which are still a problem for ethnologists; they are apparently the remains of a large building constructed of huge blocks of basalt. The archipelago, although close to the equator, enjoys a temperate climate; there are two rainy seasons—one in January, the other in August. The islands are of astonishing fertility; the principal productions are the bread-fruit, cocoa-nut, the palm, bamboo, orange, and clove tree, sugar-cane, beetle, sweet potato, &c. The population is generally estimated at 18,000 to 20,000, and belongs ethnologically to the Micronesian family. The principal elements are Malay and Maori; but there is also a mixture of Negrito and Papuan, to which in later times was added a Chinese and Japanese element. The language is as mixed as the race; the grammatical constructions are the same as those of the Maori, but Malay influence is also evident. In some of the islands there are two languages, as in Java—the vulgar and polished. They have no religion properly so-called; they believe in spirits, which are the souls of their deceased ancestors, and they have a great respect, a kind of cult for their dead, whom they preserve till the body falls to pieces. As in all the islands of the Pacific, *tabu* is practised. Each group of islands is governed by a chief or king. His power in time of peace is purely nominal, but he enjoys the respect of all; but in the frequent bloody wars his authority is unbounded, and all submit blindly to his will.

THE Pelews or Palaos Islands are quite distinct from the Carolines; they are the most western islands of Micronesia, and are situated about 600 miles east of the Philippines. The archipelago consists of ten principal islands and a number of islets. The principal one, called Babelthuap, is 30 miles long, the southern part being very mountainous. All the islands are covered by thick forests, the trees of which are used by the natives to construct their large canoes. Besides the yam and the cocoa-nut there are also bananas, oranges, and a large number of nutritious roots. The population is about 3500 souls, belonging to a race which is quite distinct from the Caroline Islanders. They present all the characteristics of the Malay and Papuan races, and are probably the result of the mixture of a superior Malay tribe with an inferior aboriginal people. Old travellers speak very well of these natives: they are said to be in every way superior to the inhabitants of the Caroline Islands. Here also there are two languages: one for addressing superiors, the other inferiors; possibly it would be more correct to say that there is only one language, with copious honorific forms. The king has instituted an order, which he gives or withdraws at his pleasure: the insignia is the first cervical vertebra of the fish *dugong*.

THE *Rundschau für Geographie und Statistik* for September reproduces a forgotten discourse of Alexander von Humboldt. It was never published, although it was privately printed for the use of the members of the Society before whom it was delivered. It deals with the primitive peoples of America and the monuments which they have left behind them, and was delivered before the Philomatic Society of Berlin in January, 1806; that is a few months after his return from his travels. It had grown to be a bibliographical curiosity; part of its contents was afterwards reproduced in his "Ansichten der Natur" and "Vues des Cordillères," and later investigations have materially altered some positions taken up; but the discourse is otherwise very interesting, especially after its disappearance for nearly eighty years.

THE NEW STAR IN ANDROMEDA

We have received the following important communications from Lord Rosse and Dr. Huggins relating to the new star. Whether the star be connected with the nebula or not, during the last week evidence has been brought forward that it has changed both its brilliancy and position with regard to the nucleus. This question of change of position is of the highest importance, for arguments were advanced in this journal (NATURE, vol. xvi. p. 413) on the occasion of the outburst of the stella nova in 1866, which suggested that a body which reduced its lustre so rapidly could have no very great mass, and that therefore it might not be so very remote.

Dr. Huggins is able to decide between the different statements which have been published as to the spectrum of the star: he has little doubt as to the existence of bright lines between D and *b*. This endorses Lord Rosse's observation which we printed last week.

SINCE my communication of September 8 our books have been searched for information on the past history of the nucleus of the Andromeda nebula. I subjoin in full the entries bearing upon the question whether the "new star" is now seen for the first time, or is a variable now shining out with abnormal brilliancy. The latter would appear to be the case. The nebula was frequently observed in past years with the 6-foot reflector and measures made. These measures being too few in number for a proper survey of the nebula, publication was postponed in 1878, and the details of configuration of the nebulosity have not appeared such as to merit a monograph. ROSSE

September 12

The Great Nebula in Andromeda as observed at Birr Castle with the 6-foot Reflector

1848, December 13.—Three new stars seen near nucleus. Others stars at moments suspected in large nucleus.

1848, December 15.—Confirmed previous night's observations about the three stars *n n f* of nucleus.

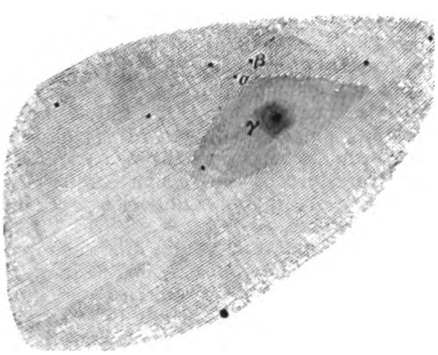
1851, October 25.—[On a rough sketch accompanying micrometrical measurements the nucleus is indicated by a point].

1852, September 16.—Nucleus looked very sharp. Had suspicion of a point in centre of nucleus of large nebula which formed one angle of a quadrilateral of which the other three are small stars to the left.

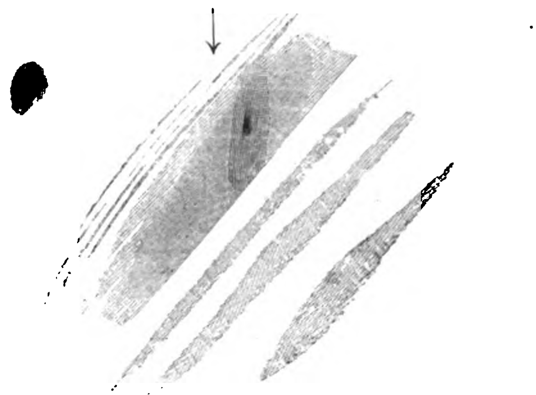
1855, October 15.—With higher power several stars become visible about the nucleus. Nucleus itself suspected at moments to be resolvable.

1856, October 28.—I observed the nucleus attentively for a long time, and I thought I could at times see stars along its north edge, but I am not very confident about it.

1857, October 16.—The higher power of single lens brings out a great many very faint stars around the nucleus. α seen steadily, β seen by glimpses and I suspect a star in the neighbourhood of γ. The sketch represents the central portion of the nebula. [A point is indicated in the centre of the nucleus.]



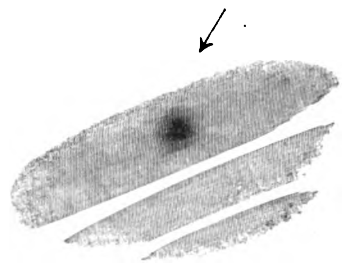
1860, October 19.—I think the nucleus is extended as in accompanying sketch.



1860, November 13.—[A sketch was carefully made, which is almost identical with the sketch of 1860, October 19, showing the extension of the nucleus very plainly. No point is indicated in the centre of the nucleus.]

[In 1861 and 1862 numerous micrometrical measures were taken, accompanied by rough sketches, showing the nucleus as a diffused nebulous patch, either round or slightly extended as on 1860, October 19.]

1871, October 7.—A rough sketch was made [showing the nucleus round and rather distinct.]



1872, August 7.—Nucleus very distinct on ground of nebula.

1877, November 2.—Nucleus extends in same direction as nebula; immediately following the nucleus the nebulosity decreases quickly in brightness, more so than on preceding side.

THE star was observed here first on the night of the 3rd inst. It presented the appearance of an orange-coloured star of from the 8th to the 9th magnitude. With a spectroscope of low dispersive power a continuous spectrum was seen from about C in the red to a little beyond F. There was an apparent condensation of light from about D to *b*, which might be due to bright lines in that part of the spectrum. This supposition was strengthened by the employment of a more powerful spectroscope, but I was not able to be certain on this point.

On the 9th the star, which was then distinctly on one side of the principal point of condensation in the nebula, appeared to me to have a less decided orange tint. It presented an appearance in the spectroscope similar to that which it had on the 3rd, with the exception that the light was less strong about D. I was so far confirmed in my suspicion of bright lines that I have little doubt that from three to five bright lines were present between D and *b*.

On the 3rd inst. the star did not appear clearly defined in the refractor of 15 inches aperture, but the state of the sky was not good enough to enable me to be sure that the star was truly nebulous. On the 9th the star was certainly free from nebulosity. WILLIAM HUGGINS

Upper Tulse Hill, S.W.

ON September 8 the new star in the nebula (Messier 31) in Andromeda was examined in my 10-inch reflector. The *nova* shines with a yellowish tint and looks like an ordinary star of about $7\frac{1}{2}$ mag., being a perfectly sharp and well-defined stellar point situated near the central region of the nebula. It is quite free from any blurred appearance or any aspect of indefiniteness other than that introduced by the nebula on which it is projected.

On later nights the star seemed to have slightly decreased; its light was feebler and less sparkling, but I made no exact comparisons for tracing the decline of brilliancy, if any.

During many years the naked eye appearance of this conspicuous nebula has been familiar to me, and I have been accustomed to notice it particularly while engaged in prolonged watches for shooting stars. No sharply-defined nucleus was ever perceptible, but now the involved star is distinctly visible by slightly averting the vision. When the air is very clear the glowing out of the star now and then is very obvious, and I mention the fact in proof that the variation of the nebula by this new phenomenon is sufficiently great to affect its naked-eye aspect. LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Red Rays after Sunset

THERE have lately been seen here some remarkable examples of rose-coloured streamers radiating from the sun at an interval of from 20 to 30 minutes after sunset, particularly on the 3rd, 5th, and 6th of this month. On the 3rd the appearance was especially striking, the contrast of colour between one very broad, vertical ray and the greenish-gray sky which separated it from its neighbours being most marked.

That these rose-coloured rays are essentially identical with the diffused rose-tint observed on other occasions is evident, not only from the similarity of colour and of interval after sunset at which they appear, but also from the occurrence of intermediate examples, in which the rays are so far and so broad that the radiate character is almost lost.

It is, however, by no means so clear why the coloured tract of sky should be sometimes split into rays, and it is with a view to ventilate this question that I desire to call attention to the subject.

I believe it is generally supposed that the dark spaces between the rays are due to masses of cloud intercepting the sun's light, but there are difficulties in the way of this explanation which I have never seen met.

It need hardly be pointed out that the matter (whatever it be) which reflects the red light must be at an altitude far above any such masses of cloud as could intercept the sun's rays; it could not otherwise receive and reflect those rays half an hour after the sun had set to the observer. But although above the level of the clouds, the reflecting matter would still be subject to interception of the sun's rays by cloud at sunset, and in order to judge whether the phenomenon can be so accounted for it is necessary to consider what kind of horizon that would be behind which the sun would set to an observer at the altitude supposed. My impression is that the horizon as seen from such a height would be so distant that whatever the irregularities of cloud-surface forming it, it would be practically a level line, and that the most mountainous masses of cumulus-cloud would be insufficient to cast at that distance the enormous shadows which would be necessary to account for the rifts between the rays.

Clifton, September 8 GEORGE F. BURDER

Fireball

A LARGE fireball was visible at Bristol and other places on September 11, at about 9h. 25m. p.m. It was described to me by several observers who approximately assigned its path as from *Altair* towards the western horizon. The sky was much clouded here at the time, with only 1st magnitude stars visible, but the light of the meteor appears to have been something astonishing.

Mr. G. T. Davis, of Theale, near Reading, writes me that, when first seen there, the meteor was near β Ophiuchi, and seemed to describe a slightly curved path to the horizon, which it touched apparently under β Serpentis. It exhibited a greenish tinted disk with bright, white aureole around it, and left no train. The aureole was at least 16′ in diameter.

It will be desirable to collect further accounts of this fine meteor. The direction of its path suggests that it may belong to the same system as that of the detonating fireball of September 14, 1875, which had a radiant point at α 348°, δ 0° ± (Tupman). During the past fortnight I have observed a considerable number of shooting-stars, and one of the best radiant points is at α 346, δ 0° ±, or 2° W. of that of Col. Tupman's fireball of September 14, 1875. W. F. DENNING

Bristol, September 13

Pulsation in the Veins

IF Mr. Hippisley will refer to Landois' text-book, vol. i. p. 196, he will find it there stated, on the authority of Quincke, that a venous pulse occurs on rare occasions, normally, in the veins on the back of the hand and foot, when the peripheral ends of the arteries become dilated and relaxed. But it is to be remembered that the very same phenomenon may obtain *abnormally*, owing to some pathological condition of the heart, as stenosis of the mitral orifice, or insufficiency in action of the mitral valve. Mr. Hippisley does not state in his letter whether the heart was in a healthy condition, or whether any lesion of that organ was present in those on whom his experiment was tried. J. W. WILLIAMS

Middlesex Hospital

"Furculum" or "Furcula"

Is there any authority for the use of furc*ulum* for the *os furculatorium* of birds? I am told by a contributor to the *Proceedings* of this Society, whose phraseology I have ventured to interfere with, that "furc*ulum*" has been employed by Balfour, Huxley, and Rolleston. Such may be the case, but it is possible that even these great anatomical writers may have erred in the use of a Latin termination. No dictionary that I have been able to refer to contains the word "furculum."

The Zoological Society of London P. L. SCLATER

THE BRITISH ASSOCIATION

Aberdeen, Monday

THERE have been few meetings of the British Association so crowded with papers in nearly all the sections. On Saturday several sections met which, unless under the greatest pressure, never meet on that day. Section D has been compelled to split up into three subsections, and probably most of the sections will have to meet on Wednesday morning. The social distractions have been much more numerous than usual, and we suspect have somewhat seriously interfered with the legitimate work of the meeting. As might be expected, the Music Hall was crowded on Wednesday evening last to hear the President's address, which seems to have produced a great impression on the audience.

It is being more and more strongly recognised that such pre-arrangements as those of Sections A and B ought to become general throughout the sections. The discussions in the two great sections, of which the programmes have appeared in NATURE, have certainly excited great interest among real workers in physics and chemistry. It is to be hoped that a full abstract of these discussions will be placed on record, as otherwise they cannot have any great permanent results. Perhaps the most popular feature in the regular sectional work has been the reading of Sir John Lubbock's paper on ants, in Section D, on Friday.

The number of entertainments, afternoon parties, excursions, and *conversaziones* is almost without precedent. The *conversazione* in the Art Galleries on Thursday last was in every way successful, though the place was overcrowded. The flower and fruit show and the illuminations outside reminded many of the South Kensington displays. It was satisfactory to notice that, thanks to

Prof. Traill, the nucleus of a valuable local natural history collection has been formed. Prof. Osborne Reynolds's illustrations of compression of solids was one of the most attractive features of the evening. The collection of pictures was large and highly creditable, while the precious collections of old manuscripts and books lent by the Earl of Crawford had many admirers. One of the most successful afternoon parties was given the same day at Tollshill Wood by Mr. David Stewart. Of course, of the numerous Saturday excursions, that to Balmoral was the most popular. In spite of the wretched weather 200 people must have left Aberdeen for Ballater at 1 p.m. and happily by the time the end of the railway journey was reached the weather greatly improved. The drive from Ballater to Balmoral evidently gave great enjoyment to the occupants of the long cavalcade of miscellaneous "machines" which wound along the banks of the Dee, and no less, we may be sure, did the sumptuous five o'clock dinner ("lunch," it was called) which was provided in the ball-room of Balmoral. Gen. Gairdner presided at the table, and, after proposing the Queen's health, drank, by command of Her Majesty, prosperity to the British Association. Under the guidance of Dr. Profeit the guests made a round of the fine grounds of Balmoral, and on driving back to Ballater, passed Her Majesty on her return from a day's outing. The excursion to Dunecht was also a great success, the arrangements at Lord Crawford's observatory exciting much interest.

A deputation from Birmingham is here to make arrangements for the visit to that town next year. It is evident that the Birmingham people mean to make the 1886 meeting a success, though, so far as social arrangements go, it will be difficult to surpass that of Aberdeen. It is expected that Manchester will be the place of meeting in 1887, and for 1888 or 1889 several enterprising members hope to secure the selection of London, in order to have a meeting in common with the American Association. Against this choice, however, there will probably be a strong protest, though of course the American Association will be sure to receive an enthusiastic welcome whenever it chooses to visit the old country.

Prof. Adams's lecture on Friday attracted a large audience, and on Saturday evening the Music Hall was filled with an enthusiastic audience of genuine working men to listen to Mr. H. B. Dixon's lecture and admire his experiments. Mr. Murray's lecture to-night will certainly be of popular interest, but, summing up as it does the present position of oceanography, it will also be of the highest scientific value. The diagrams are very striking, and certainly original. A full report will no doubt appear in NATURE.

The regret at the resignation of the secretaryship of the Association by Prof. Bonney is universal, though it is confidently expected that Mr. Atchison will be a thoroughly competent successor.

The additional arrivals up to this morning will bring the total number present at the meeting up to 2500.

SECTION B

CHEMICAL SCIENCE

OPENING ADDRESS BY PROF. HENRY E. ARMSTRONG, PH.D., F.R.S., SEC. C.S., PRESIDENT OF THE SECTION [1]

I NOW pass to the consideration of a subject of special interest in this section, which I think requires the immediate earnest attention of chemists and physicists combined—that of *Chemical Action*. In his Presidential Address to the Association last year Prof. Lord Rayleigh made only a brief reference to chemistry, but many of us must have felt that his few remarks were pregnant with meaning, especially his reference to the importance of the principle of the dissipation of energy in relation to chemical change. A year's reflection has led me to think them of peculiar weightiness and full of prophecy. I would especially draw attention to the closing paragraph of this portion of his address: "From the further study of electrolysis we may expect to gain improved views as to the nature of the chemical reactions, and of the forces concerned in bringing them about. I am not qualified—I wish I were—to speak to you on recent progress in general chemistry. Perhaps my feelings towards a first love may blind me, but I cannot help thinking that the next great advance, of which we have already some fore-shadowing, will come on this side. And if I might, without presumption, venture a word of recommendation, it would be in favour of a more minute study of the simpler chemical phenomena."

[1] Continued from p. 453.

Chemical action may be defined as being any action of which the consequence is an alteration in molecular constitution or composition; the action may concern molecules which are of only one kind—cases of mere decomposition, of isomeric change and of polymerisation; or it may take place between dissimilar molecules—cases of combination and of interchange. Hitherto it appears to have been commonly assumed and almost universally taught *by chemists* that action takes place directly between A and B, producing AB, or between AB and CD, producing AC and BD, for example. This, at all events, is the impression which the ordinary average student gains. Our text-books do not, in fact, as a rule, deign to notice observations of such fundamental importance as those of De La Rive on the behaviour of nearly pure zinc with dilute sulphuric acid, or the later ones of Faraday ("Exp. Researches," Series vii., 1834, 863, *et seq.*) on the insolubility of amalgamated zinc in this acid. Belief in the equation $Zn + H_2SO_4 = H_4 + ZnSO_4$ hence becomes a part of the chemist's creed, and it is generally interpreted to mean that zinc *will* dissolve in sulphuric acid, forming zinc sulphate, not, as should be the case, that *when* zinc dissolves in sulphuric acid it produces zinc sulphate, &c. In studying the chemistry of carbon compounds we become acquainted with a large number of instances in which a more or less minute quantity of a substance is capable of inducing change in the body or bodies with which it is associated without apparently itself being altered. The polymerisation of a number of cyanogen compounds and of aldehydes, the "condensation" of ketonic compounds and the hydrolysis of carbohydrates are cases in point; but so little has been done to ascertain the nature of the influence of the contact-substance, or *catalyst*, as I would term it, the main object in view being the study of the product of the reaction, that the importance of the catalyst is not duly appreciated. Recent discoveries, however—more particularly Mr. H. B. Dixon's invaluable investigation on conditions of chemical change in gases, and the experiments of Mr. Cowper with chlorine and various metals, and of Mr. Baker on the combustion of carbon and phosphorus—must have given a rude shock, from which it can never recover, to the belief in the assumed simplicity of chemical change. The inference which I think may fairly be drawn from Mr. Baker's observations—that *pure* carbon and phosphorus are incombustible in *pure* oxygen—is indeed startling, and his experiments must do much to favour that "more minute study of the simpler chemical phenomena" so pertinently advocated by Lord Rayleigh.

But if it be a logical conclusion from the cases now known to us that chemical action is not possible between any two substances other than elementary atoms, and that the presence of a third is necessary, what is the function of the third body—the catalyst—and what must be its character with reference to one or both of the two primary agents? In the discussion which took place at the Chemical Society after the reading of Mr. Baker's paper, I ventured to define chemical action as *reversed electrolysis*, stating that in any case in which chemical action was to take place it was essential that the system operated upon should contain a material of the nature of an electrolyte (Chem. Soc. *Proc.*, 1885, p. 40). In short, I believe that the conditions which obtain in any voltaic element are those which must be fulfilled in every case of chemical action. There is nothing new in this; in fact, it practically was stated by Faraday in 1834 ("Experimental Researches in Electricity," series vii. §§ 858, 859[1]); and had due heed been given to Faraday's teachings we

[1] "Those bodies which, being interposed between the metals of the voltaic pile, render it active, *are all of them electrolytes*, and it cannot but press upon the attention of every one engaged in considering this subject, that in those bodies (so essential to the pile) decomposition and the transmission of a current are so intimately connected that one cannot happen without the other. If, then, a voltaic trough have its extremities connected by a body capable of being decomposed, as water, we shall have a continuous current through the apparatus; and whilst it remains in this state we may look at the part where the acid is acting upon the plates and that where the current

should scarcely now be so ignorant as we are of the conditions of chemical change.

The questions—What is Electrolysis? What is an Electrolyte? are all-important to the chemist, if my contention be accepted. Moreover, the consideration of chemical action from this point of view almost of necessity obliges us also to consider what it is that constitutes chemical affinity. I will not presume to offer any opinion on this subject; but I would recall attention to the prominence which so great an authority as Helmholtz gave in the last Faraday Lecture (Chem. Soc. *Trans.*, 1881, 277) to the view held by Faraday, and which is so definitely stated in a passage in his "Experimental Researches"[1] (series viii. 918, also 850 and 869).

Helmholtz used the words: "I think the facts leave no doubt that the very mightiest among the chemical forces are of electric origin. The atoms cling to their electric charges, and opposite electric charges cling to each other; but I do not suppose that other molecular forces are excluded, working directly from atom to atom." In the passages which immediately follow, this physicist then makes several statements of extreme importance, which directly bear upon the subject I desire to discuss, and which, therefore, I quote.[2]

The interpretation of Faraday's law of electrolysis, which Helmholtz has brought under the notice of chemists, is of the most definite and far-reaching character. Does it, however, at all events in the form in which he has put it forward, accord sufficiently with the facts as these present themselves to the chemist's mind? All will recognise that the chemical changes effected by a current in a series of electrolytic cells are equivalent to those which take place within the voltaic cells wherein the current is generated; but in neither case is the action of a simple character: in both a variety of chemical changes takes place, the precise character of which is but imperfectly understood, and we are unable to assign numerical values, either in terms of heat or electrical units, to most of the *separate* changes. Moreover, many compounds are not electrolytes, while others which are regarded by the chemist as their analogues are very readily decomposed by a current of low E.M.F., although no great difference is to be observed in their "heats of formation;" liquid hydrogen chloride on the one hand, and fused silver chloride on the other, may be cited as examples. Again, how are we to interpret on this theory such changes as that involved in the conversion of stannic into stannous chloride? The former, I suppose, is to be regarded as consisting of an atom of quadrivalent tin charged with four units of, say, positive electricity, and of four atoms of univalent chlorine, each carrying a unit charge of negative electricity; on withdrawal of two of the chlorine atoms, the residual $SnCl_2$ will have two free unit charges of positive electricity. We know that when the temperature is sufficiently lowered two such residues unite, forming Sn_2Cl_4, and it is not improbable that crystalline stannous chloride represents a still later stage of condensation. Is this compatible with the theory? That cases of this kind are contemplated would appear from the reference to "unsaturated compounds with an even number of unconnected units of affinity," which we are told may be charged with equal equivalents of opposite electricity; and also from the allusion to the existence of molecules of elementary substances composed of two atoms. It is more than probable that these anomalies would disappear on fuller statement of his views by the author of the theory: I have ventured to call attention to them in the hope of eliciting such statement.

Helmholtz tells us that electrolytes belong to the class of typical compounds, the constituents of which are united by "atomic affinities," not to the class of "molecular aggregates." Is this the fact? Before chemists can accept this conclusion many difficulties must be removed which appear to surround the question. In the first place, it is in the highest degree remarkable that, with the one single exception of *liquefied* ammonia, *no known binary hydride is in the liquid state an electrolyte*: liquid hydrogen chloride, bromide and iodide, for example, withstanding an E.M.F. of over 8,000 volts (8,040 De la Rue cells: Bleekrode). Water, again, according to Kohlrausch's most recent determinations, has an almost infinite resistance. Yet a mixture of hydrogen chloride and water readily conducts, and is electrolysed; an aqueous solution of sulphuric acid behaves similarly, although the acid itself has a very high resistance.[1] Very many similar examples might be quoted, but it is well known that aqueous solutions generally conduct more or less perfectly, and are electrolysed.[2]

The current belief among physicists would appear to be that the dissolved electrolyte—the acid or the salt—is almost exclusively primarily decomposed (Wiedemann, "Elektricität," 1883, ii. 924). We are commonly told that sulphuric acid is added to water to *make it conduct*, but the chemist desires to know why the solution becomes conducting. It may be that in all cases the "typical compound" is the actual electrolyte—*i.e.* the body decomposed by the electric current—*but the action only takes place when the typical compounds are conjoined and form the molecular aggregate*, for it is an undoubted fact that HCl and H_2SO_4 dissolve in water, forming "hydrates." This production of an "electrolytical system" from dielectrics is, I venture to think, *the* important question for chemists to consider. I do not

is acting upon the water as the reciprocals of each other In both parts we have the two conditions, *inseparable in such bodies as these*, namely, the passing of a current and decomposition; *and this is as true of the cells in the battery as of the water-cell*; for no voltaic battery has as yet been constructed in which the chemical action is only that of combination: *decomposition is always included*, and is, I believe, an essential chemical part

"But the difference in the two parts of the connected battery—that is, the decomposition or acting cells—is simply this: in the former we urge the current through, but it, apparently of necessity, is accompanied by decomposition; in the latter we cause decompositions by ordinary chemical actions (*which are, however, themselves electrical*), and, as a consequence, have the electrical current; and as the decomposition dependent upon the current is definite in the former case, so is the current associated with the decomposition also definite in the latter."

[1] "All the facts show us that that power commonly called chemical affinity can be communicated to a distance through the metals and certain forms of carbon; that the electric current is only another form of the forces of chemical affinity; that its power is in proportion to the chemical affinities producing it; that when it is deficient in force it may be helped by calling in chemical aid, the want in the former being made up by an equivalent of the latter; that, in other words, *the forces termed chemical affinity and electricity are one and the same*."

[2] "Several of our leading chemists have lately begun to distinguish two classes of compounds—viz. molecular aggregates and typical compounds, the latter being united by atomic affinities, the former not. Electrolytes belong to the latter class. If we conclude from the facts that every unit of affinity is charged with one equivalent, either of positive or of negative electricity, they can form compounds, being electrically neutral, only if every unit charged positively unites under the influence of a mighty electric attraction with another unit charged negatively. You see that this ought to produce compounds in which every unit of affinity of every atom is connected with one, and only one, other unit of another atom. This, as you will see immediately, is the modern chemical theory of quantivalence, comprising all the saturated compounds. The fact that even elementary substances, with few exceptions, have molecules composed of two atoms makes it probable that even in these cases electric neutralisation is produced by the combination of two atoms, each charged with its full electric equivalent, not by neutralisation of every single unit of affinity. Unsaturated compounds with an even number of unconnected units of affinity offer no objection to such an hypothesis: they may be charged with equal equivalents of opposite electricity. Unsaturated compounds with one unconnected unit, existing only at high temperatures, may be explained as dissociated by intense molecular motion of heat, in spite of their electric attractions. But there remains one single instance of a compound which, according to the law of Avogadro, must be considered as unsaturated even at the lowest temperature—namely, nitric oxide (NO), a substance offering several very uncommon peculiarities, the behaviour of which will be perhaps explained by future researches." The popular mistake is here made of assuming that elementary substances, with few exceptions, have molecules composed of two atoms. We now know considerably over seventy elements, but of these the molecular weights in the *gaseous* state of only thirteen have been satisfactorily determined. The gaseous elements hydrogen, oxygen, nitrogen and chlorine, and also bromine, iodine and tellurium, have diatomic molecules; phosphorus and arsenic have tetratomic molecules; those of sulphur are hexatomic, and selenium molecules are probably of similar constitution, but more readily broken down than those of sulphur; lastly, cadmium and mercury molecules are monatomic It is more than probable that carbon, and also silicon and boron, form highly complex molecules. Of the remaining undetermined elements, the greater number are metals, and it is not unreasonable to assume that many of these will be found to resemble cadmium and mercury in molecular composition. It is clear, however, that at present we have no right to say that the elementary molecules are, as a rule, diatomic. It would assist in removing this error if chemists would consistently place *after* the symbol the numeral indicating the "atomicity" of the elementary molecule—thus, Hg_1, Cd_1, O_2; and if in all cases when a numeral is absent, or is placed *before* the symbol, it were understood that advisedly no indication of the molecular state is afforded.

[1] It is more than probable that the most nearly pure sulphuric acid which can be obtained is not homogeneous, but is at least a mixture of H_2SO_4, $H_2S_2O_7$ and "hydrated compounds" in proportions depending on the temperature, and hence that (pure) sulphuric acid, H_2SO_4, like water, would behave as a dielectric.

[2] On the other hand, it is remarkable that, whereas liquefied ammonia may be electrolysed, an aqueous solution of ammonia is a most imperfect conductor (Faraday, F. Kohlrausch), although solutions of ammonium salts compare favourably in conductivity with corresponding sodium and potassium salts. This fact serves *somewhat* to allay the suspicion that Bleekrode did not take sufficient precautions to dry the ammonia; but his result cannot, I think, be accepted as final, on account of the relatively high E.M.F. required, and the repetition of the experiment with every precaution to ensure purity of the gas is most important. Faraday regarded the decomposition of ammonia on electrolysis of its solution as merely the result of secondary action.

believe that we shall be able to state the exact conditions under which chemical change will take place until a satisfactory solution has been found.

F. Kohlrausch (*Pogg. Ann.* 1876, 159, 233) has shown that, on adding sulphuric acid to water, the electric conductivity increases very rapidly until when about 30 per cent. of acid is present a maximum (6,914) is attained; conductivity then diminishes almost as rapidly, and a minimum (913) is reached when the concentration corresponds with that of a monohydrate (H_2SO_4,OH_2); from this point conductivity increases somewhat (to 1,031 at 92·1 per cent. H_2SO_4), and then again falls, and is probably zero for the pure acid; on adding sulphuric anhydride to the acid conductivity again increases. Solutions of other acids and of a number of salts—chiefly deliquescent and very soluble salts—also exhibit maximum conductivity at particular degrees of concentration. In no other case has the existence of two maxima, such as are observed in solutions of sulphuric acid, been established; but probably this is because the experiments either have not been, or cannot well be, carried out with pure substances or very concentrated solutions. Solutions of less soluble salts increase in conductivity as the amount of salt dissolved increases.

Kohlrausch has suggested, as an explanation of the influence of the "solvent" on the conductivity of an "electrolyte," that in a solution the ions which are being transferred electrolytically come less frequently into collision than would be the case in the pure substance. There is therefore less opportunity for the formation of new molecules, and the ions are able to travel farther before entering into combination.

Regarding the question from a chemist's point of view, however, I cannot help thinking that this explanation is scarcely satisfactory or sufficient; but I cannot resist the feeling that the production of electrolytically conducting solutions from dielectrics is in some measure dependent upon the occurrence of chemical action. If the composition of the solutions of maximum conductivity be calculated,[1] it will be seen that they contain but a limited number of water molecules; thus the solution of sulphuric acid of maximum conductivity (at 18°) contains 30·4 per cent. of acid, and therefore has the composition $H_2SO_4 : 12{\cdot}4\ H_2O$ (approximately); for nitric acid the ratio is 1 : 8; for acetic acid it is about 1 : 17. Now, it is highly remarkable that the solutions of maximum electric conductivity are also very nearly those in the formation of which nearly the maximum amount of heat is developed; this will at once be obvious on comparison of the curves given by Thomsen ("Thermochemische Untersuchungen," vol. iii.) and by Kohlrausch. In the chemist's experience, the point of maximum heat development is usually near to the point of maximum chemical change, and I think, therefore, that we are justified in concluding that, even if electrical conductivity be not a maximum at a particular concentration on account of the presence of a particular hydrate (belonging to the class of molecular aggregates) in maximum amount, at all events the "structure" of the system is especially favourable, and the "chemical influence" exerted by the one set of molecules upon the other is at a maximum at the point of maximum conductivity. The fact that the amount of sulphuric acid required to form a solution of maximum conductivity increases with temperature—

Temp.	0°	10°	20°	30°	40°	50°	60°	70°
Per cent.	30·2	30·9	30·7	32·5	33·5	34·1	34·5	35·4

and also the fact that the maxima and minima of conductivity tend to become obliterated with rise of temperature (Kohlrausch), are both in accordance with the view that conductivity is in some way dependent upon chemical composition, as the effect of rise of temperature would be to cause the dissociation of hydrates such as I have referred to. The increase in conductivity of aqueous solutions with rise of temperature would appear to be against the view here put forward; but it is probable that this may be largely due to diminution in viscosity and increase in the rate of diffusion.

Our knowledge of the binary metallic compounds, which are generally admitted to be electrolytes *per se*, also affords evidence, I think, of an intimate relation between chemical constitution and "electrolysability." It has been pointed out (comp. L. Meyer, "Theorien d. mod. Chemie," 4th ed. p. 554) that, whereas all the metallic chlorides and analogous compounds which cannot be electrolysed are easily-volatile bodies, the electrolysable metallic chlorides, &c., are fusible only at high temperatures. A careful discussion of the various known cases does not, however, justify the conclusion that decomposition takes place, or not, according as the temperature at which the body assumes the liquid state—and at which, therefore, there is full opportunity given for electrolysis to take place—is high or low, especially as recent observations show that electrolysis may take place prior to fusion. But it is especially noteworthy that many of the chlorides, &c., which are electrolytes undoubtedly contain more than a single atom of metal in their molecules; indeed, after careful consideration of the evidence, I am inclined to go so far as to put forward the hypothesis *that among metallic compounds only those are electrolytes which contain more than a single atom of metal in their molecules.* No difficulty will be felt in granting this of cuprous and stannous chlorides, and even of cadmium, lead, silver, and zinc chlorides; but opinions will differ as regards the metals of the alkalies and the alkaline earths.[1] Assuming the constitution of metallic electrolytes to be such as I have suggested it is not improbable that on electrolysis a part only of the metal is determined to the one pole, the remainder being transferred along with the negative radical to the opposite pole. Hittorf, indeed, has already put forward this view in explanation of the remarkable results he obtained on determining the extent of transfer of the ions in aqueous and alcoholic solutions of the chloride and iodide of cadmium and zinc.

Again, an argument in favour of a connection between chemical constitution and electrical conductivity is the fact that carbon, sulphur, selenium and *phosphorus* each exist in conducting and non-conducting modifications, as it can scarcely be doubted that the so-called allotropic modifications of these elements are differently constituted.

It appears, as I have already said, to be the current belief that when aqueous solutions are submitted to electrolysis, as a rule the dissolved substance, and not the water, is the actual electrolyte. Without reference to the question I have raised as to the constitution of an electrolyte, it appears at least doubtful whether this view can be justified by appeal to known facts; at all events, I have failed to find satisfactory evidence that such is the case. Moreover, as sulphuric anhydride dissolves in water with considerable development of heat, it would appear that more work has to be done to separate hydrogen from sulphuric acid than to separate it from water; on this account we might expect that the water rather than the acid would be decomposed. Are not perhaps both affected according to the proportions in which they are present? The marked variation in the extent to which the negative ion is transferred to the positive pole, as observed by Hittorf, when solutions of different degrees of concentration are electrolysed, would appear to support this view. The difference in the products, according as dilute or very concentrated solutions of sulphuric acid are used, may also be cited as an argument that the chemical changes effected vary with the concentration; but, on the other hand, it is quite possible that the observed differences may result from the occurrence of purely secondary changes. Ostwald has recently put forward the view that one *or more* of the hydrogen atoms of certain acids are split off according to the concentration of the solution.

I call attention to this because I conceive that it has a most

[1]

Formula	Formula weight	Per cent. in solution of max. cond.	Composition in approximate mol. ratios	Conductivity
HNO_3	63	29·7	1 : 8	7330
HCl	36·4	18·3	1 : 9	7174
H_2SO_4	98	30·4	1 : 12·4	6914
H_3PO_4	98	46·8	1 : 6	1962
$C_2H_4O_2$	60	16·6	1 : 17	15·2
KOH	56	28·1	1 : 8	5995
$NaOH$	40	15·2	1 : 12·7	3276

[1] We may regard as evidence in support of this explanation the fact that neither beryllium chloride, which fuses at 600°, nor mercuric chloride, is an electrolyte, as both of these, at temperatures not far removed from their boiling-points, exhibit the simplest possible molecular composition. It should be pointed out, however, that Nilson and Patterson found it possible to determine the density of beryllium and chloride gas at a temperature 100°—150° below the melting-point found by Carnelly; but they were not able to say that fusion took place. Clarke's recent interesting observations on mercuric chloride and iodide do not, I think, suffice to prove that these compounds are electrolytes; it is more than probable that electrolysis is preceded by the formation of mercurous compounds. Even an aqueous solution of mercuric chloride does not conduct appreciably better than water (Buff). I should perhaps add that the mere presence of more than a single atom of metal in the molecule does not, I believe, alone constitute the compound an electrolyte; much depends probably both on the nature of the metal and on the structure of the molecule.

important bearing on the discussion of the nature of the chemical changes which occur during the dissolution of metals. Formerly it was said that when zinc acts upon dilute sulphuric acid, the zinc displaces the hydrogen of the water and the resulting zinc oxide dissolves in the acid, forming zinc sulphate; the modern explanation advocated by most chemists has been that the metal directly displaces the hydrogen of the acid: in fact, that this is the nature of the change whenever an acid is acted upon by a metal. If in a solution of sulphuric acid, of whatever strength, the acid be the actual electrolyte, I imagine that we are right in accepting this modern view; but if the water be the electrolyte, we must, to be consistent, return to the view that the oxide—more probably in most cases the hydroxide—is the primary product. And if it can be shown that during electrolysis both water and acid, according to circumstances—concentration, E. M. F., &c.—undergo change, it will be necessary to teach that in a similar manner the action of metals on acids is no less complex. Our views on the action of metals on concentrated sulphuric acid, and on solutions of nitric acid of various strength, must also materially depend on the interpretation of the behaviour of these acids on electrolysis with varying electromotive forces.

Having thus fully explained why I venture to think that Helmholtz's definition that "electrolytes belong to the class of typical compounds, not to that of molecular aggregates," is somewhat open to question, it now becomes necessary to make some slight reference to the constitution of these so-called molecular aggregates. Although opinions differ widely as to the definition to be given of a typical or atomic compound, and of a molecular compound or aggregate, the majority of chemists appear to agree that we must recognise the existence of two distinct classes of compounds. Prof. Williamson, in his address to this Section at the York meeting (1881), entered at length into the discussion of this question, and in very forcible terms objected to the recognition of molecular combinations as something different from atomic combinations; in this I, in the main, agree most fully with him. He further said that he had been led to doubt whether we have any grounds for assigning any limits whatever to atomic values, and he adduced a number of cases which, in his opinion, afforded illustration of a capability of elements to assume greater atomic values by combining with both negative and positive atoms than with atoms of one kind only; for example, he cited the compounds K_2CuCl_4 and K_2HgCl_4 as proof that copper and mercury may assume hexad functions; the compound K_2AgI_3 as an illustration that silver may act as a pentad; and the compounds $KAsF_6$ and K_2AsF_7 were regarded by him as evidence of the heptadicity and nonadicity of arsenic.

I have long been of opinion that the experimental investigation of this question is of great importance, and I believe that it must ere long attract the attention it deserves. The problem will be solved, not by discussions on the fertile theme of valency, but by determining the structure—the constitution—of bodies such as were referred to by Prof. Williamson.

My own view on the question is a very decided one. So far as the mere definition of valency is concerned, I entirely agree with Lossen; and, as I have said, I hold with Prof. Williamson that in all compounds the constituents are held together by atomic affinities, and atomic affinities only, but I believe that the formation of so-called molecular compounds is mainly due to peculiarities inherent more especially in the negative elements—*i.e.* the non-metals and metalloids and not in the positive elements—the metals; in other words, to the fact that, as was first pointed out, I believe, by Lothar Meyer, the negative elements tend to exhibit a higher valency towards each other than towards positive elements. The view I take, then, is, that in the majority of so-called molecular compounds the parent molecules are preserved intact in the sense in which a hydrocarbon radical, such as ethyl, is preserved intact in an ethyl compound, being held together by the "surplus affinity" of the negative elements. Thus I would represent the compounds K_2CuCl_4 and K_2HgCl_4 as containing copper and mercury of the same valency as the metal in the parent chloride, and regard them as compounds of the radicals $(CuCl_2)$, $(HgCl_2)$ and (KCl); a view which may be expressed by the formulæ

$$Cu{Cl . ClK \atop Cl . ClK} \qquad Hg{Cl . ClK \atop Cl . ClK}$$

The arsenic compounds referred to may be similarly represented

$$F_4AsF . FK \qquad F_3As{F . FK \atop F . FK}$$

We do not hesitate to attribute to the so-called double cyanides this order of structure, without in any way supposing that the metal changes in valency. Evidence that the "constituent radicals exist unchanged in molecular compounds" is afforded by facts such as that ferrous and potassium chlorides, for example, form a compound which obviously is still ferrous, being of a green colour, which would hardly be the case if the valency of the iron were increased; and that in like manner the compounds formed from stannous chloride manifest all the properties of stannous derivatives.

Whatever be the nature of chemical affinity, it is difficult to resist the conclusion that the "charge" of a negative radical especially is rarely, if ever, given up all at once, that its affinity is at once exhausted. It would also appear that the amount of residual charge—of surplus affinity—possessed by a radical after combination with others depends both on its own nature and that of the radical or radicals with which it becomes associated. Differences such as are observed in the composition and stability of the hydrates of the salts of an acid—the sulphates, for example—clearly point to this. Other illustrations are afforded by the manner in which chlorhydric acid yield chlorhydrates of some metals and chlorides of others.[1]

It is noteworthy, however, that often those elements which from the ordinary point of view are regarded as possessed of feeble affinities are those which manifest the greatest tendency to form molecular compounds. Thus it is commonly held that, of the three elements, chlorine, bromine and iodine, chlorine has the highest and iodine the lowest affinity, and this views accords well with the recent observations of V. Meyer on the relative stability of their diatomic molecules at high temperatures; but nevertheless we find that the compound which HI forms with PH_3 is far more stable than that of HBr or HCl with this gas; and it is well known that mercuric *iodide* has a much greater affinity for other iodides than have mercuric bromide and chloride for the corresponding bromides and chlorides.[2]

The recognition of the peculiarity in the negative elements to which I would attribute the formation of molecular compounds must, I think, exercise an important influence in stimulating and directing the investigation of these compounds and of compounds other than those of carbon; in the near future the determination of the structure of such compounds should occupy an important share of the chemist's attention. It will perhaps afford a clue in not a few cases which are not altogether satisfactorily interpreted in accordance with the popular view of valency. I may instance the formation of (?) polymeric metaphosphates, of complex series of silicates and tungstates, and of compounds of hydrocarbons with trinitrophenol. It may even serve to explain some of the peculiarities of the more complex carbohydrates.

It is one of the most clearly established of the "laws of substitution" in carbon compounds that negative radicals tend to accumulate: numerous instances are afforded by the behaviour of paraffinoid compounds with chlorine, bromine and oxidising agents, and by that of unsaturated paraffinoid compounds when combining with hydrogen bromide and iodine. The special affinity of negative elements for negative is not improbably the cause of this accumulation. A similar explanation may perhaps be given of some of the peculiarities which are manifested by benzenoid compounds.

I would even venture to suggest that in electrolysing solutions the friction arising from the attraction of the ions for each other is perhaps diminished, not by the mere mechanical interposition of the *neutral* molecules of the solvent—in the manner suggested by Kohlrausch—but by the actual attraction exercised by these molecules upon the negative ion in virtue of the affinities of the negative radicals.

One result of increased attention being paid to the investigation

[1] The name chlorhydric acid is here applied to the compound $HCl(OH_2)_x$—probably x = 1—which, according to Thomsen, is present in an aqueous solution of hydrogen chloride. It would be an advantage if we ceased to speak of HF, HCl, HBr, HI, as acids, and always termed them hydrogen fluoride, chloride, bromide and iodide respectively. The names hydric chloride, bromide, &c., might with equal advantage be altogether abandoned; hydrochloric acid is objectionable, as suggesting a relation to chloric acid. The names fluor-, chlor-, brom-, and iodhydric, as applied to the *acids* present in aqueous solutions of the hydrides, are especially appropriate as indicating that they are compounds containing the radical water—that they are hydrates: indeed, it would be well to restrict the use of hydric and hydro- to bodies of this kind, and to speak of hydrides as hydri-, not as hydro-, derivatives. It would then be possible to give comparatively simple names even to complex hydrates.

[2] Thomsen gives the values in heat units as—

$$HGCl_2,2KClAq = 1380$$
$$HgBr_2,2KBrAq = 1640$$
$$HgI_2,2KIAq = 3450$$
$$HgCy_2,2KCyAq = 8830$$

of problems such as I have indicated will probably be that we shall be called upon to abandon some even of our most cherished notions. I would suggest, for example, that it may become necessary to regard nitrogen peroxide not as a mixed anhydride of nitrous and nitric acids, but as a compound of two NO_2 groups; its conversion into nitrite and nitrate affords no proof of its constitution, as chlorine peroxide, ClO_2, which exhibits no tendency whatever to combine with itself, also yields both chlorite and chlorate. A greater shock may result from a conviction arising that not only carbon dioxide, but sulphur dioxide, and perhaps even sulphur trioxide, dissolve in water, forming *hydrates*—$SO_2{\cdot}OH_2$, $SO_3{\cdot}OH_2$—not *hydroxides*. In recent times, in discussing questions of this kind, we have perhaps often been led to attach too much importance to the argument from analogy; it is not improbable that, especially in the case of compounds other than those of carbon, chemical change involves change in structure more frequently than we are apt to believe.

It is possible that a precise estimate of what, for want of a better name, I have spoken of as residual affinity, may sooner or later be obtained, if the view Prof. Lodge has propounded in his paper "On the Seat of the Electromotive Forces in a Voltaic Cell" be correct, that the cause of the volta effect is the *tendency to chemical action* between the bodies in contact; that, for example, chemical strain at the air-contacts is the real cause of the apparent contact-force at the junction of two metals in air. Prof. Lodge, if I understand his argument, appears to assume that the air effects are in some way dependent on the presence of "dissociated oxygen atoms." I think this is probably an entirely unnecessary assumption: of late years, no doubt, it has been the fashion to attribute the occurrence of changes of various kinds to the presence of products of dissociation, but probably to a very unnecessary extent. Recent investigations to which I have alluded show that there are other factors of extreme importance: for example, that water must be present in order to render a mixture of carbonic oxide and oxygen explosive. Again, the observations of V. Meyer and Langer have shown that, whereas chlorine *violently attacks* platinum at low temperatures, it is *without action* upon it at temperatures between about 300° and 1300°, but then *again begins to act* upon it, the action becoming violent at 1600° to 1700°. I have little doubt that the action at low temperatures is dependent upon the presence of moisture; if it were due to dissociated chlorine atoms, the action should increase with rise of temperature without break. In short, I see no reason to assume that oxygen at ordinary temperatures consists of other than diatomic molecules.[1] Assuming Prof. Lodge's view to be correct, the strain exists in virtue of the attraction which the oxygen molecules exert upon the metal molecules. On this assumption I can well understand that the method of calculation followed by Prof. Lodge will not uniformly lead to satisfactory results. The "heat of combination" is not necessarily a measure of "affinity." The values are in all cases algebraic sums of a series of values, scarcely one of which is known, and, as I have already pointed out, the affinities of the molecules are by no means always of the same order as the affinities of the constituent atoms; for example, in all probability, oxygen stuff has a higher absolute affinity than sulphur stuff; chlorine stuff a higher absolute affinity than iodine stuff; yet iodine and sulphur compounds, more often than not, seem to exhibit more residual affinity than chlorine and oxygen compounds. So that, from Prof. Lodge's point of view, chlorine would have the higher and iodine the lower contact values; whereas from my point of view the reverse might often be the case. I point this out because it appears to me that we here have an opportunity of testing the question experimentally, and seeing that it is possible practically to prevent chlorine from attacking metals by excluding moisture, I do not take the hopeless view that Prof. Lodge and others seem to hold regarding the possibility of settling the important question of pure contact *versus* chemical action by appeal to experiment. I may also point out that according to my hypothesis it is possible that the metals may exert a considerable attraction for each other, especially those having monatomic molecules:[2] many alloys are undoubtedly compounds; possibly not a few are compounds of the "molecular aggregate" class.[1]

To return now for but a few moments to the subject of chemical change and its intimate connection with electrical phenomena. One application I would make of the views here put forward would be to explain the superior activity of bodies in the *nascent state*, and in particular of nascent hydrogen. Briefly stated, I believe it to consist in the fact that nascent hydrogen is hydrogen in circuit—hydrogen in electrical contact with the substance to be acted upon. The experiments of Faraday and of Grove afford the clearest evidence that in order to bring about action between hydrogen and oxygen at ordinary temperatures it is merely necessary to make them elements in a voltaic circuit. The difference in the effects produced by "nascent hydrogen" from different sources is, I imagine, attributable to the variations in E.M.F., which necessarily attend variations in the constituent elements of the circuit.

It is not so easy, however, as yet to explain some of the changes which take place at high temperatures. Mr. Dixon's experiments have proved that a mixture of carbonic oxide and oxygen is non-explosive, but that explosion takes place if moisture be present, the velocity of the explosive wave depending upon the amount of water present. When the mixture of the two gases is "sparked," change takes place, but only in the path of the discharge. Mr. Dixon considers "that the carbonic oxide becomes oxidised at the expense of the water, the hydrogen *set free* then becoming reoxidised. M. Traube, who in a series of papers has called attention to the importance of water in promoting oxidation, has suggested that the oxygen and carbonic oxide together act on the water, forming hydrogen peroxide and carbonic acid: $CO + 2OH_2 + O_2 = CO(OH)_2 + H_2O_2$; and that the peroxide then reacts with carbonic oxide to form carbonic acid: $CO + O_2H_2 = CO(OH)_2$. The carbonic acid, of course, is resolved into carbon dioxide and water (*Berichte*, 1885, p. 1890). Traube actually shows that traces of hydrogen peroxide are formed during the combustion. It appears to me that the water may exercise the same kind of action as it (or rather dilute sulphuric acid) exercises in a Grove's gas battery, and that its hydrogen does not become free in any ordinary sense. The production of hydrogen peroxide is not improbably due to a secondary simultaneous change.

Unlike a mixture of carbonic oxide and oxygen, a mixture of hydrogen and oxygen is violently explosive. If we assume that in both cases the reacting molecules are electrolysed by the very high E.M.F. employed, and that the atoms then combine, it is difficult to explain the difference in the results. Does it arise from the fact that hydrogen is an altogether peculiar element? Or are we to attribute it to an influence which water itself exercises upon the formation of water from hydrogen and oxygen—as in the Grove gas battery? It is noteworthy that the velocity of the explosive wave in electrolytic gas, according to Berthelot and Vielle, is a close approximation to the mean velocity of translation of the molecules in the gaseous products of combustion calculated from the formula of Clausius (H. B. Dixon, *Phil. Trans.*, 1884, p. 636). And this is also true of mixtures of carbonic oxide and oxygen, and of nitrous oxide and oxygen with hydrogen. May we therefore assume, as the velocity corresponds with that of the products, that the water exercises the important office of inducing change throughout the mass, and not that the hydrogen is peculiar? I am tempted here to suggest that perhaps the "induction" observed by Bunsen and Roscoe in a mixture of chlorine and hydrogen is due to the occurrence of a change in which a something is produced which then promotes reaction between the two gases. I here assume that there would be no action between the pure gases.

If I have allowed myself to flounder in among these difficult questions, it is not because I feel that I am justified in speaking

[1] This conclusion would also lead me to disbelieve entirely in the explanation which Clausius has given of electrolysis.

[2] Assuming that the heat absorbed in raising the temperature of a solid is mainly expended in overcoming intermolecular attraction, the high "atomic heat" of metals may be regarded as evidence that their molecules powerfully attract each other, and hence that their molecular composition is relatively simple; and on this view the "atomic heat" of carbon and of a number of other non-metals and of some metalloids is low owing to the extent to which the "affinity" of the atoms is, as it were, exhausted in the formation of their molecules. Comparison of the "molecular heats" of chlorides and similar compounds with those of the oxides lends much support to this view, as we have reason to believe that the chlorides—which have high "molecular heats"—are of relatively simple molecular composition, and that the oxides—which have low "molecular heats"—are of relatively complex molecular composition.

[1] The study of alloys from this point of view will probably furnish interesting results. It is noteworthy that the contact difference of potential of brass is less than that of copper, and much less than that of zinc, with the same solution, in all the cases quoted by Ayrton and Perry; thus—

	Zinc	Copper	Brass
Alum ...	− ·536 volt.	− ·127	− ·014
Sea salt	− ·565 ,,	− ·475	− ·435
Sal ammoniac	− ·637 ,,	− ·596	− ·348

It is especially important to examine the copper-tin alloys, which vary in electrical conductivity in so remarkable a manner.

with authority, but in the hope that I may be the "fool," and that the "angels" who are well able to discuss them will be led to do so without delay: for chemists are anxiously awaiting guidance on matters such as I have referred to.

Attention must, however, be directed to the study of electrical phenomena by the recent publications of Arrhenius and of Ostwald (*Journal für praktische Chemie*," 1884, 30, 93, 225; 1885, 31, 219, 433), and especially by the statement put forward by the latter that the rate of change under the influence of acids (in hydrolytic changes) is strictly proportional to the electrical conductivities of the acids. There cannot be a doubt that these investigations are of the very highest importance.

I trust that in the discussions which we are to have on molecular weights of liquids and solids, and on electrolysis, there may be a free exchange of opinion on some of the points here raised. My reason for selecting these subjects for discussion in this Section will have been made sufficiently clear, I imagine. Last year in the Physical Section the idea assumed shape which had long been latent in the minds of many members of the Association, that it is unadvisable, as a rule, to encourage the reading of abstract papers, which rarely are, or can be, discussed. Two important discussions were *introduced* by Profs. Lodge and Schuster. We must all cordially agree with Prof. Lodge's remarks on the importance of discussing subjects of general interest at these meetings. It appears to me, however, that even a more important work may often be accomplished if the discussion consist of a series of papers which together form a monograph of the subject. I have endeavoured to carry this idea into practice on the present occasion, and a number of friends have most kindly consented to assist. Unexpected difficulties have arisen, and probably we shall none o us succeed in doing all we might wish. I trust, however, that the Section will approve of this first attempt sufficiently to justify my successors in this chair in adopting a similar course.

I much regret that it is impossible for me to attempt any review of recent work in chemistry. Not a few really important discoveries might be chronicled, and the patient industry of many who have toiled long to win results apparently insignificant should have been mentioned with high approval. A few remarks I will crave permission for, as regarding the general character of the work being done by chemists, and regarding that which has to be done.

Complaints are not unfrequently made in this country that a large proportion of the published work is of little value, and that chemists are devoting themselves too exclusively to the study of carbon compounds, and especially of synthetical chemistry. We are told that investigation is running too much in a few grooves, and it is said that we are gross worshippers of formulæ. Most of these outbursts are attributable to that pardonable selfishness which consists in assigning a higher value to the particular class of work with which one happens to be engaged or interested in than to any other line of investigation; too frequently they result from want of sympathy with, if not absolute ignorance of, the scope and character of the work complained of. It must not be forgotten that chemical investigation, like other investigation, is to a large extent the work of genius; the rank and file must necessarily follow in the order of their abilities and opportunities; hence it is that we work in grooves. The attention paid to the study of carbon compounds may be more than justified both by reference to the results obtained and to the nature of the work before us: the inorganic kingdom refuses any longer to yield up her secrets—new elements—except after severe compulsion; the organic kingdom, both animal and vegetable, stands ever ready before us; little wonder, then, if problems directly bearing upon life prove the more attractive to the living. The physiologist complains that probably 95 per cent. of the solid matters of living structures are pure unknowns to us, and that the fundamental chemical changes which occur during life are entirely enshrouded in mystery. It is in order that this may no longer be the case that the study of carbon compounds is being so vigorously prosecuted: our weapons—the knowledge of synthetical processes and of chemical function—are now rapidly being sharpened, but we are yet far from ready for the attack. As to the value of this work, I believe that every fact honestly recorded is of value; an infinite number of examples might be quoted to prove this. No unprejudiced reader can but be struck also with the improvement in quality which is manifest in the majority of the investigations now published; at no time was more attention given to the discovery of all the products of the reactions studied, and to the determination of the influence of changes in the conditions. As regards our formulæ, those who look upon the outward visible form without proper knowledge of the facts symbolised, and who take no pains to appreciate the spirit in which they are conceived, are undoubtedly misled by them. The great outcome of the labours of carbon-chemists has been, however, the establishment of the doctrine of structure;[1] that doctrine has received the most powerful support from the investigation of physical properties, and it may almost, without exaggeration, be said to have been rendered visible in Abney and Festing's infra-red spectrum photographs. Some of us look forward to the extension of the doctrine of structure not only to compounds generally, but even to the "elements." The relationships between these are in so many cases so exactly similar to those which obtain between carbon compounds, which we are persuaded differ merely in structure, that it is almost impossible to avoid such a conclusion, even in the absence of all laboratory evidence.[2]

As the field of view opens out before us, so does the vastness of the work to be accomplished become more and more apparent; and Faraday's words of 1834 may be quoted as even more appropriate than half a century ago.

"Indeed, it is the great beauty of our science, Chemistry, that advancement in it, whether in a degree great or small, instead of exhausting the subjects of research, opens the door to further and more abundant knowledge, overflowing with beauty and utility, to those who will be at the easy personal pains of undertaking its experimental investigation.

SECTION C

GEOLOGY

OPENING ADDRESS BY PROF. J. W. JUDD, F.R.S., SEC. G.S., PRESIDENT OF THE SECTION [3]

CONCERNING the overlying formation of quartzites and limestones, much yet remains to be made out. Nicol, Lapworth, and the officers of the Geological Survey, have shown it to be made up of three principal members—the identity of which cannot be mistaken although different names have been assigned to them. While Nicol estimated the total thickness of this formation at from 300 to 800 feet, however, and Lapworth places it at the smaller of these amounts, the officers of the Survey believe it to be no less than 2,000 feet thick.

Even greater uncertainty still exists as to the exact geological age of this important formation. Murchison, who in his later years made "Silurian" a mere synonym for Lower Palæozoic, was no doubt right in regarding these rocks as being of that age. I have no intention of attempting to flog that dead horse—the controversy concerning the names which should be applied to the great systems containing the three faunas which Barrande so well showed to be present in the Lower Palæozoic rocks. That controversy, commencing, it must be confessed, with some tragic elements, has long since passed into the sphere of comedy, and now bids fair, if still persisted in, to degenerate into farce. Little, if anything, has been added to the work of Salter in connection with these fossils of the Durness limestone. With their abundance of that remarkable and aberrant mollusc, *Maclurea*, they can be paralleled with no other British or even European deposit, unless it be the Stinchar limestone of the Girvan district. Salter thought that this remarkable Scotch formation had its nearest analogues in the Calciferous sandstone and the Chazy limestone of North America. As those rocks contain "Primordial" forms of Trilobites, they must probably be regarded as either of Cambrian age, or as constituting a link between the rocks containing Barrande's first and second faunas respectively. Under these circumstances, it is a piece of welcome intelligence that the officers of the Geological Survey have succeeded in obtaining a rich and varied collection of organic remains from the beds of Sutherland; and the results of the examination and discussion of these fossils will be awaited by all geologists with the greatest interest.

Whether, as in the case of Scandinavia, other fossiliferous

[1] I venture here to direct attention to an extension of the acknowledged theory of structure suggested (by myself, I may say) at the close of the discussion of the van 't Hoff-Le Bel hypothesis of isomerism in Miller's "Chemistry," vol. iii., 1880 edition, p. 993. The same view was soon afterwards independently put forward by Dr. Perkin

[2] F. Exner, in a recent paper (*Monatshefte für Chemie*, 1885, p. 249). "On a New Method of Determining the Size of Molecules," actually puts forward an hypothesis as to the structure of elements.

[3] Continued from p. 458.

deposits of Silurian age will be found to be represented in a highly metamorphosed condition in our Scottish Highlands, remains to be discovered. There is such a perfect parallelism between the several members of the Silurian in Scania and in the Scottish Borderland, so well shown by the researches of Linnarson and Lapworth, that, as Nicol always anticipated, we may not improbably find a portion of the rocks of the Highlands to be altered forms of those of the Borderland.

Since the last meeting of the British Association in the Highlands, much progress has been made in the study of that pre-eminently British formation—the Old Red Sandstone. Dr. Archibald Geikie has thrown much new light, by his valuable researches, on the relations of the several members of the vast series of deposits which go by that name; while Dr. Traquair, bringing to bear on the subject great anatomical knowledge, has re-examined the collections of fossil-fish made by that indefatigable explorer, Hugh Miller. The Old Red Sandstone is the only great system of strata which we possess, while it is either wholly absent, or very imperfectly represented, in Scandinavia.

In the year 1876, I was able to announce that a vestige—a small but highly interesting vestige—of the great Carboniferous system exists within the limits of the Scottish Highlands. Well do I recall the deep, the ineffaceable impression made upon my mind when, standing at the Innimore of Ardtornish, I beheld for the first time this relic of a great formation, preserved by such a wonderful series of accidents. What the inscribed stone of Rosetta or the papyri of Herculaneum are to the archæologist, this little patch of sandstone is to the geologist. Overwhelmed by successive lava-streams that were piled upon one another to the depth of many hundreds of feet, and then carried down by a fault which buried it at least two thousand feet in the bowels of the earth, this fragment has remained while every other trace of the formation has been swept from the Highlands by the besom of denudation.

Highly interesting and important in these northern areas are the Mesozoic deposits, which in places attain a vertical thickness of several miles, and which must have originally covered enormous tracts of country. Now, judged by that very fallacious test, the space which they cover upon our geological maps, they appear in the Scottish Highlands to be absolutely insignificant.

The correspondence in characters between the several Secondary formations on the two sides of the North Sea is of a most striking kind. I have had the good fortune to study the Secondary rocks of Scania under the guidance and with the assistance of Professor Lundgren, of the University of Lund, who has made so many important discoveries in connection with them. While doing so, I have again and again felt almost constrained to pause and rub my eyes, to convince myself that I was not back again in Scotland—so complete is the correspondence between the mineral characters, the fossils, and the geognostic relations of these strata in the two areas.

The Triassic rocks of Scandinavia, consisting of variegated sandstones and conglomerates, containing much calcareous material, are absolutely undistinguishable from those of the Western Highlands. In both countries the thickness of the deposits of this age varies within very short distances, their development being local and inconstant. The formation which in places exceeds a thousand feet in thickness, at other points is reduced to an insignificant band of conglomerate. On the eastern flank of our Highlands, yellow sandstones belonging to this formation have yielded to Mr. Duff, Dr. Gordon, Mr. Grant, and others that interesting series of reptilian remains which, in the hands of Professor Huxley, have been made to throw such important light on the forms of life which existed at that remote geological period. In the very similar deposits which occur in Scandinavia, however, reptilian remains have not as yet been obtained. The abundance and variety in form and size of the footprints which occur in our Scottish rocks of this age indicate the richness of the vertebrate fauna which must have existed at that distant epoch.

On both sides of the North Sea, the Triassic rocks are found passing up insensibly into the great formation known as the Rhætic and Infralias—a formation imperfectly represented in England and Central Europe by a few thin and insignificant strata, but in our Highland districts attaining a vast thickness and exhibiting a magnificent development. This system of strata consists of alternation of marine and estuarine deposits, the latter containing in both areas thin seams of coal. In Scania, the working of the coal and fire-clays of these deposits has brought to light vast numbers of fossil plants, which have been so well described by Nathorst. Several very distinct floras, occurring at different horizons, have been made out, and the relations of the beds containing these floras to one another, and to the marine strata with which they are intercalated, have been clearly demonstrated by the researches of Hébert, Erdmann, and Lundgren. That similar rich stores of fossil plants would reward a search as skilful and persevering as that made by our Scandinavian brethren, if carried on in the equivalent strata of Scotland, there can be little doubt.

The whole of the vast Jurassic system in these northern latitudes, attaining a thickness of 3,000 or 4,000 feet, appears to be similarly made up of alternations of marine and estuarine strata. Time would fail me to indicate even in the briefest manner the numerous problems of the highest interest suggested by the study of these vast deposits. At many different horizons, beds of coal and the relics of a rich terrestrial vegetation abound. Most of these await careful study and description. So far as they are yet known, the Ferns, the Cycads, and the Conifers of the Jurassic rocks of the Highlands present wonderful resemblances with those described by Heer from strata of the same age in Norway, in Russia, in Siberia, and even far away in the Arctic regions. The marine forms occurring in the associated strata seem to indicate that they belong to an ancient life-province, distinct from those in which the Jurassic rocks of Central and of Southern Europe were deposited. In the Upper Jurassic, so well represented in Sutherland by strata not less than 1,000 feet in thickness, we find evidence of the existence of mighty rivers, the banks of which, though clothed with tree ferns, Cycads, and gigantic pines, yet at certain seasons must have borne down ice-buoyed blocks of vast dimensions.

That the succeeding Neocomian period was for Scandinavia and Scotland an epoch of elevation and of the prevalence of terrestrial conditions is indicated by the total absence of any trace of marine deposits of this age, no less than by the enormous denudation which can be shown to have followed the Jurassic and preceded the Cretaceous period. Our now ruined mountain-chain then probably formed the lofty watershed of a great continent, through which flowed the mighty rivers that formed the deltas known as the English and German Wealdens.

How powerful and prolonged were the agencies of sub-aërial waste during this period is shown by the fact that the relics of the Cretaceous formation are found resting in turn on every member of the Jurassic, the Rhætic, the Trias, and all the different Palæozoic and Archæan rocks. A great portion, indeed, of the thick and widespread Rhætic and Jurassic strata seems to have been removed by denudation before the commencement of the Cretaceous period.

That thick strata of chalk once covered large areas of the Scottish Highlands and of Scandinavia we have the clearest proofs. In Scania and the adjoining parts of Denmark deposits of this age are found let down by tremendous faults, and these include even younger members of the series than are anywhere found in England. In the West of Scotland I have shown that thin deposits of Cretaceous age, preserved to us by a wonderful series of accidents, still survive the tremendous denudation of the Tertiary periods. It is true that in Scandinavia and Scotland alike, the chalk alternates with sandstones and even with strata of estuarine origin, but the pure foraminiferal rock that occurs in both areas could have been formed in no very shallow sea. That before the commencement of the great Tertiary denudation large areas, in Scandinavia and Scotland alike, must have been swathed in winding sheets of chalky rock there cannot be the smallest doubt. That considerable portions of these winding-sheets remained to so late a period as the glacial is shown by the fact that the indestructible flints of the chalk with the rocks and fossils of the upper greensand abound in your boulder-clays of Aberdeenshire and Banffshire.

Of the vast periods of the Tertiary we have left to us, either in the Highlands or Scandinavia, but few and insignificant relics in the form of stratified deposits. In our beautiful Western Isles and in Antrim the lava poured out in successive streams, during enormous periods of time, from the lofty volcanic cones of the earlier Tertiary epoch, has here and there buried patches of lake-mud, or river-gravel, or ancient soils. But everywhere, alike in the Highlands and in Scandinavia, we behold the most impressive evidences of the sub-aërial waste, and of the elevation that promoted this waste during the Tertiary epoch. Among such evidences we may reckon the circumstance that all traces of the vast deposits of the Secondary periods have been relentlessly stripped away from the country, except where buried deeply by gigantic earth-throes, or sealed up under massive lava-streams.

Down to post-glacial times Scotland, and what are now its outlying islands, remained united with Scandinavia. I need not remind you how, during the glacial period, they were the scene of a similar succession of events; while from their then far more elevated mountain summits streams of glacier-ice flowed down and relieved the mantle of snow which enveloped them.

But at a very recent geological period, and indeed since the appearance of man in this part of our globe, the separation of the two areas, so long united, was brought about. In the district now constituting the North Sea, which separates the two countries, great faults, originating in the Tertiary epoch, appear to have let down wide tracts of the softer Secondary strata among the harder crystalline rock-masses. The numerous changes of level, of which we find such abundant evidence around the shores of this sea, facilitated the wearing away of the whole of these softer Secondary deposits, except the slight fringes that remain along the shores of Sutherland, Ross, and Cromarty, on the one hand, and the isolated patches forming Scania, Jutland, and the surrounding islands on the other. Little could the Vikings, as they sailed over this shallow sea, have imagined that their predecessors in these regions were able to roam on foot from Norroway to Suderey!

It is almost impossible to over-estimate the effects produced by the several denudations to which Scandinavia and the Scottish Highlands have been successively subjected. In that which occurred during the later Tertiary periods, almost every portion of the non-crystalline rocks that rose above the sea-level was either entirely removed or converted into level plains, which, covered with drift deposits, now form districts like Scania and Denmark. Where, as in the great central valley of Scotland, hard volcanic masses are associated with the softer sedimentary rocks, the former are left rising as picturesque crags, standing boldly up above the general level, while the latter are worn down and buried under drift. In the west of Scotland a chain of volcanic mountains, with summits towering to the height of from ten to fifteen thousand feet, have been reduced by this same denudation to basal-wrecks, the highest portions of which attain to but little more than 3,000 feet above the sea-level!

During the great elevation and denudation which marked the Neocomian period, thousands of feet of strata must have been removed over wide areas, as is proved by the wonderful overlap of the Cretaceous beds on all the older strata.

Of the enormous sub-aërial waste which went on in these Northern Alps during the Newer Palæozoic periods we have impressive evidence in the vast masses of the Old Red Sandstone and Carboniferous rocks—themselves only a series of fragments that have survived the later denudations—for these rocks are built up of the materials derived from our Northern Alps.

The Torridon Sandstone is the monument, and a very striking monument too, of another and still earlier period of enormous denudation. The thousands of feet of conglomerate and sandstone of which it is made up consist of the disintegrated crystals of granites and gneisses that have been swept away.

When we penetrate towards the axis of this eroded mountain-chain, the proofs of the magnitude of these denudations become even more striking and impressive. Here we see, towering aloft, the ruined buttresses of vast rocky arches, that when complete must have risen miles above the present surface; there we find, lying side by side, rock-masses that could only have been brought together by displacements of tens of thousands of feet; yet so complete has been the planing down of the surface since, that it requires the most careful study even to detect the almost obliterated traces of these grand movements. The Alps and the Himalayas, during their elevation, have suffered enormous waste and denudation; but if the elevation were to cease and the waste to go on till these magnificent mountain-chains were reduced to masses of diminutive peaks, ranging from 2,000 to 8,000 feet in height, we should then have the counterpart of this stupendous ruin of the mountain-chain of the north.

The history of the series of successive movements to which the rock-masses of our Highlands have been subjected is one well worthy of the most attentive study. When the evidence bearing upon the subject is carefully sifted and weighed, we become convinced of the fact that many of these movements—including some on a prodigious scale—must have taken place during what we are commonly accustomed to regard as comparatively recent geological periods.

On the eastern coast of Sutherland, a mass of Secondary rocks, including several thousands of feet of Triassic, Rhætic, and Jurassic strata, has been let down by a gigantic fault, so as to be placed in juxtaposition with the Old Red Sandstone and the crystalline rocks. Now, taking the very lowest estimates of the thicknesses of the several strata affected, the vertical "throw" of this fault must have exceeded a mile! It may not improbably, indeed, have been at least double or treble that amount! Yet this great dislocation was certainly produced at a later date than the Upper-Jurassic period, for rocks of that age are found to be affected by it.

Along the coasts of the Black Isle, strata of Middle and Upper Jurassic age are similarly found faulted against the "Old Red" and the crystalline rocks.

On the other side of the North Sea, in Andö, one of the Lofoten Isles, a patch of Lower-Oolite strata, consisting of marine and estuarine strata, and including beds of coal like that of Brora, is found let down by gigantic faults into the very heart of the crystalline rocks of the district. In Scania, the whole of the Secondary rock-masses owe their preservation in the same way to a plexus of tremendous faults, by which they have been entangled among the harder rocks. These faults have affected not only the Jurassic strata, but even the very youngest members of the Cretaceous series.

Nor are we without evidence that some of the great faults are of post-Cretaceous age, in this country, for in the Western Highlands displacements of several thousands of feet have been detected, which affect not only the Upper Cretaceous, but also the Older Tertiary rocks.

The effects produced by these great dislocations, which have a generally parallel direction in our Highlands, from north-east to south-west, are of the most startling character. Great strips of Triassic and Old Red Sandstone strata, like those of Elgin, and Turriff, and Tomintoul, and of the line of the Caledonian Canal, are found let down among the crystalline rocks by these gigantic faults.

The great central valley of Scotland itself consists of masses of Newer Palæozoic strata, faulted down between the harder Archæan and Lower Palæozoic rocks, which form the Highlands on the one hand, and the Borderland on the other.

The evidences of the existence of these great faults were collected by many of the older Scottish geologists, like Landale, Bald, Chalmers, Milne-Hoem, and Nicol; and the accurate mapping of the country by the officers of the Geological Survey has, on the whole, tended to confirm their results. With regard to the age of these great dislocations of Central Scotland, it can only be *certainly* affirmed that they are of more recent date than the youngest Carboniferous strata; but I have long believed that, like many similar dislocations both in our own Highlands and in Scandinavia, they are really post-Cretaceous.

Less difficulty perhaps will be found in accepting this apparently startling conclusion, when we remember that a complicated series of fractures injected by the lavas of the Great Tertiary volcanic foci of the West, extend right across the Highlands, the central valley, and the Borderlands of Scotland, and even traverse the whole series of the Secondary rocks in the North of England.

The indications of the tremendous manifestations of subterranean energy, to which these great dislocations owe their origin, are sometimes of a very striking kind. For hundreds of yards on either side of the faults, the two sets of strata are found bent and crumpled, and not unfrequently crushed into the finest dust ("fault-rock"). In the case of the great Sutherland-fault, to which I have previously alluded, we have a beautiful illustration of the way in which mineral veins may originate along such lines of fissure, for in the interstices of the granite of the Ord, where it has been broken up along this certainly post-Jurassic, and probably Tertiary fault, fluor-spar and pyrites have been deposited in large quantities.

It is impossible to study the tremendous movements and dislocations, and the enormous amount of denudation which have taken place in the Highlands and surrounding districts during Tertiary times, without being convinced that all the existing surface-features of the country must date from a comparatively recent period. The vast movements which have placed soft and hard masses in opposition along certain parallel lines—generally ranging in a north-east and south-west direction—and the denudation which has worn away the former, while it has left the latter standing in relief, must, I believe, both be referred to the Tertiary period; though the disposition of rock-masses brought about by earlier movements would of course exercise a certain though subordinate influence in producing the existing forms of the surface of the country.

At the close of the Jurassic period, and before the commencement of the Cretaceous, during the vast epoch marked by the deposition of the Neocomian of Southern Europe, a series of disturbances similar to those of the Tertiary, and scarcely inferior in their consequences, can be shown to have taken place.

If the movements of the Scandinavian and Scottish rock-masses which took place in the Tertiary and Mesozoic periods respectively were so startling in their magnitude and so vast in their effects, what shall we say concerning those far greater disturbances which affected the same area towards the close of the Older Palæozoic and the beginning of the Newer Palæozoic, when this Northern Alps was still a living and growing mountain-chain?

These movements, in which both the Archæan and the Older-Palæozoic rocks are found to be involved, have resulted in the production, through enormous lateral pressure, of those reversed faults, caused by the disruption along their axial planes of greatly inclined and compressed folds, as so well described by Rogers.

Dr. Archibald Geikie assures us that the studies of the geological surveyors in North-West Sutherland led to the conclusion that certain masses of rock have thus been carried almost horizontally over others, along these "thrust-planes" for a distance of at least ten miles. As the result of these tremendous lateral compressions, thin beds of limestone and quartzite, which have sufficiently definite characters to permit of their recognition, may be seen in Assynt, and in other parts of the Western Highlands, to be so repeated again and again by crumpling and faulting, that they have been regarded as deposits of enormous thickness; while, on the other hand, massive formations have been crushed and rolled out, thereby acquiring a laminated structure like so much pie-crust. Great portions of rock-masses, which, like the much-discussed "Logan-rock," have been nipped between gigantic faults, show evidence under the microscope of having been crushed to powder and subsequently reconsolidated, while the surfaces of the "thrust-planes" sometimes exhibit the phenomena known as "slickensides" on the most gigantic scale.

As we pass away from the central axis of this old mountain-chain, however, these complicated puckerings and dislocations pass gradually into more ordinary folds and faults, just as is the case with the Appalachians. The oft-repeated undulations of the Lower Palæozoic strata of the Borderland, so admirably described by Professor Lapworth, bear the same relation to the far more involved disturbances of rocks of the same age in the Highlands, which the foldings of the strata in the Jura do to the intense crumplings of those of the Alps; and these in turn pass insensibly into the slightly undulating or horizontal strata of the southern half of this island.

We may perhaps add another comparison between the existing mountain-chain of Southern Europe and the "basal wreck" of Northern Europe, one which I find has been already suggested by Professor Bonney. The Miocene Conglomerates, which in the Rigi and other flanking mountain masses of the Alpine chain are found piled to the depth of many thousands of feet, seem to be exactly represented in its prototype by the vast masses of the "Old-Red" Conglomerate.

Vast as were the three series of movements to which I have been referring, I believe that the Scandinavian and Highland rocks bear the impress of a still grander series of di turbances than either of these—one at the same time of older date and far more universal in its effects.

Many writers have treated of the great divisional planes, almost everywhere conspicuous in the Highland rock-masses, as being necessarily coincident with planes of sedimentation. It is manifest, indeed, that the tracing of sequences and unconformities among such rocks must proceed upon the assumption that the planes of foliation and stratification *are* coincident. Murchison and Geikie so fully recognised the fact that this proposition lay at the very root of their arguments concerning a Highland succession, that they added a supplement to their paper to illustrate and enforce it.

It must not be forgotten, however, that the truth of this proposition has not only been doubted, but has been stoutly contested by many of the most profound thinkers on geological questions.

As long ago as 1822, Professor Henslow, in a very remarkable paper, showed that the rocks of Anglesea are traversed by a system of divisional planes, which intersect the bedding at a very high angle, and must have been produced long subsequently to the latter; and in 1835 Professor Sedgwick extended the observations and enforced the arguments of Henslow.

At an even earlier date, Poulett Scrope had shown, by his study of viscous lavas, that the planes along which crystalline action takes place are determined by pressure and strain; and he insisted that the foliation of metamorphic masses was a phenomenon strictly analogous to the banding of rhyolitic lavas.

Charles Darwin, the pupil of Henslow and the friend of Poulett Scrope—whose labours in the geological field would perhaps have met with fuller recognition had they not been overshadowed by his still greater achievements in the world of biological thought—strongly maintained the truth of these views. He added the important observation that, in the South American continent, the planes of foliation are seen everywhere, over enormous areas, to be parallel to those of cleavage; and that these latter are of secondary origin and due to lateral pressure, the observations of Sharpe and the experiments of Sorby have convincingly demonstrated.

That the schists and gneisses of our Highlands and of Scandinavia have resulted from crystallising forces, acting upon strata of sandstone, clay, and limestone, or upon igneous materials constituting lava-currents, or intrusive sheets, dykes, and bosses, I see every reason for believing. That these re-crystallised and highly-foliated masses in the great majority of cases maintain their original positions and relations, or indeed anything approaching their original positions and relations, I greatly doubt; and my doubt on this point has increased the more I have studied the Highland rocks.

Thin bands of quartzite may be the rolled-out representatives of massive beds of sandstone or conglomerate; wide-spreading schists may consist of the crystallised materials of clays and shales, crumpled, pleated, and kneaded together in endless convolutions; vast sheets of gneiss may have originally been intrusive bosses of granite or thick strata of arkose. How, then, are we to apply the ordinary principles that regulate questions concerning dip and strike, and unconformity in the case of sedimentary deposits, to highly altered rocks like these?

The observations of Jukes, Allport, and Phillips on some of the simpler and more easily explicable examples of the production of foliation in rocks require to be cautiously extended, by patient study in the field and in the laboratory, to cases of a more complex and difficult character. Especially in this connection do we welcome such contributions to our knowledge as that made by Mr. Teall in his description of the remarkable foliated dyke of Scourie.

Very significant indeed is the fact that the phenomena of foliation appears to be confined to regions which have been the scene of the most violent subterranean movement and disturbance. That solid rock-masses, subjected to the tremendous earth-strains to which they are liable during mountain-making, are capable of internal movement and flow—like the ice of a glacier—we have the clearest evidence. Many illustrations might be adduced in support of the view that crystallisation is influenced and controlled by mechanical forces—pressures, stresses, and strains. May it not also be true, as long ago suggested by Vose, that the heat which must be generated in the great shearing movements taking place in rocks have also had much to do in giving rise to that re-crystallisation which is the essence of foliation? Rock-masses, in the throes of mountain-birth, have, like glaciers, behaved substantially as viscous bodies; may not the former have undergone molecular changes analogous to regelation in the latter?

That many of the stupendous earth-movements which produced the foliation of the rocks of Scandinavia and the Scottish Highlands must be referred to Archæan times, there is not the smallest room for doubt. That similar effects have resulted from the same agencies during subsequent periods, our fellow-geologists in Scandinavia believe they have found incontrovertible proof. For my own part I look forward confidently to the establishment of the same conclusion from the study of our own Highland rocks.

But here I am conscious that I am venturing on topics upon which great and allowable differences of opinion still exist. The debates in this Geological Section during the first meeting of the British Association in Aberdeen ought, I think, to have marked the practical close of one great series of controversies. The discussions of the present meeting will, I trust, result in the recognition and clear statement of a number of other equally important problems of Highland geology which still await solution. And I am sanguine enough to hope that when this Association next gathers here, my successor in this chair will have to congratulate his audience upon a very brilliant retrospect of work actually accomplished in the interval.

I am encouraged in this optimism by the fact that in the period which has elapsed since our last meeting here, great and important improvements have been made in the methods of geological investigation. We have seen how the discovery of a few fragmentary shells in the limestone of Durness, and of sundry casts of bones in the sandstone of Elgin, have been the means of profoundly modifying our ideas concerning the age of vast tracts of rock in the Highlands. The development of modern methods of petrographical research is destined, I believe, to lead to a similar revolutionising of our views concerning the wonderful series of changes which have taken place within rock-masses, subsequently to their original accumulation.

Especially does the application of the microscope to the study of rocks, when employed in due subordination to, and illustration of, work done in the field, promise to be the source of valuable and fruitful discoveries in the field of Highland geology.

In connection with this subject, I cannot refrain from reminding you that while the initiative in the application of the palæontological method of research was taken by an English land-surveyor, we are indebted to a Scotchman in an equally lowly station of life, for overcoming some of the first difficulties in connection with petrographical study. Many microscopists had employed their instruments, and sometimes with useful results, in the study of the powders and the polished surfaces of rocks; but it is to William Nicol, of Edinburgh, the inventor of the well-known polarising prism which bears his name, that we owe the discovery of the method of preparing transparent sections of fossils, crystals, and rocks, whereby their internal structure may be examined by transmitted light. Nicol bequeathed his preparations to his friend Alexander Bryson, and some of them are now preserved in the British Museum. It is interesting, too, to recall the circumstance that it was a thin section of the granite of Aberdeen in the collection of Bryson which exhibited to Sorby that wondrous assemblage of minute cavities containing liquids, and led him, shortly before our previous meeting here, to write his paper "On the Microscopical study of Crystals, indicating the origin of Minerals and Rocks"—a paper which has indeed proved epoch-making in the history of geology.

Before concluding the remarks which by your kindness I have been permitted to offer you to-day, I cannot forbear from indulging in a pleasant reminiscence of a personal character. Nearly fifteen years have passed away since I first visited the Highlands for the purpose of geological study; it was at that time I first found myself at liberty to put into practice a scheme cherished by me from boyhood, that of studying those Secondary rocks and fossils of the Highlands among which such valuable pioneer work had been done by John Macculloch, Roderick Murchison, and Hugh Miller. I had endeavoured to prepare myself for a somewhat difficult task, by a training partly unofficial and partly official—I will not employ the terms "amateur" and "professional," for of late they have been so sadly misused—but when I came a stranger among you, I could not have deserved, and I certainly did not anticipate, that cordial welcome, that kindly aid and that generous appreciation, of which I accept my position here to-day as the crowning manifestation.

While I continue to occupy myself with the glorious problems of Highland geology—and hitherto I have found that each difficulty surmounted has resulted, like the sown teeth of the slaughtered dragon, in a plentiful crop of new ones—the many acts of kindness of my numerous friends here can never cease to be present in my mind. For not only am I indebted to those who, like your own Dr. Gordon, of Birnie, and Dr. Joass, of Golspie, have been able out of stores of their knowledge to furnish me with "things new and old," and who have been unfailing in their aid and sympathy, but to those also who have pitied, but nevertheless helped, the "daft callant that speers after the chucky stanes."

I know of no higher pleasure than that which the geologist experiences in visiting regions of great scientific interest which are new to him, and of grasping the hands of fellow-workers, whose labours and teachings he has learned to admire and to appreciate. Whatever may be my lot in this way in future years, however rich the country visited may be in objects of profound instructiveness or of surpassing interest, I can anticipate or desire nothing more valuable than the lessons, or kinder than the reception which I have met with here.

"I'll ask na mair, when I get there,
Than just a *Hielan* welcome."

SECTION D

BIOLOGY

OPENING ADDRESS BY PROF. W. C. MCINTOSH, M.D., LL.D., F.R.SS.L. & E., F.L.S., COR. M.Z.S., PRESIDENT OF THE SECTION

I HAVE selected the subject of the phosphorescence of marine animals for a few remarks on the present occasion—the theme, perhaps, being the more appropriate from its congenial local surroundings; for, like St. Andrews, Aberdeen is an

"Old University town
Looking out on the cold North Sea."

A phenomenon so striking as the emission of light by marine organisms could not fail to have attracted notice from very early times, both in the case of navigators and those who gave their attention in a more systematic manner to the study of nature. Accordingly we find that the literature of the subject is both varied and extensive—so much so, indeed, that it is impossible on the present occasion to give more than a very brief outline of its leading features. This is a subject of less moment, however, since the great microscopist, Ehrenberg, in his treatise, "Das Leuchten des Meeres," published by the Berlin Academy in 1835, has given a very full account of the early literature on phosphorescence, both in marine and terrestrial animals, no less than 436 authors being quoted. The limitation just mentioned is therefore sufficiently warranted.

Though it is in the warmer seas of the globe that phosphorescence is observed in its most remarkable forms—as for instance the sheets of white light caused by *Noctiluca*, and the vividly luminous bars of *Pyrosoma*—yet it is a feature which the British zoologist need not leave his native waters to see both in beauty and perfection. Many luminous animals occur between tide-marks, and even the stunted sea-weeds near the line of high water everywhere sparkle with a multitude of brilliant points. As a ship or boat passes through the calm surface of the sea in summer and autumn, the wavelets gleam with phosphorescent points, or are crested with light; while the observer, leaning over the stern, can watch the long trail of luminous water behind the ship, from the brightly sparkling and seething mass at the screw, to the faint glimmer in the distance. On the southern and western shores, again, every stroke of the oar causes a luminous eddy, and some of the smaller forms are lifted by the blade and scintillate brightly as they roll into the water. The dredge and trawl likewise produce, both in the shallower and deeper parts of our seas, many luminous types of great interest and beauty.

I shall, in the first instance, glance at the various groups of marine animals which possess the property of phosphorescence, and thereafter make some general remarks on the subject. It is found then that this feature is possessed by certain members of the Protozoa, and by the following groups of the Metozoa,—viz. Cœlenterates, Echinoderms, Worms, Rotifers, Crustaceans, Molluscoids, Mollusks, and Fishes.

About the middle of last century Baster found that at least three species of what he called microscopic animalcula ("Opuscula Subseciva," vol. i. p. 31, table 4, Fig. 1), apparently infusoria, were phosphorescent; and fully half a century later, Pfaff noticed that the luminosity of the sea at Kiel was due to certain members of the group just mentioned. Subsequently both Michaelis and Ehrenberg met with phosphorescent infusoria in the Baltic, the latter describing them as species of *Peridinium* (now *Ceratium*) and *Prorocentrum*. The same fact, associated with the absence of *Noctiluca* at Kiel, has again more recently been brought forward by Stein. In our own seas I have been especially struck with this feature in July and August, the whole surface of the sea along the eastern shores of England and Scotland teeming with *Ceratium* and *Peridinium*, besides other Infusoria, which form a greenish scum on the interior of tow-nets in inshore water, and for many miles seaward. As the waves curl from the sides of the boat in quiet water, the crest of each sparkles with multitudes of luminous points, which gleam for a moment as the ripple stretches outward, and then disappear; or, still more vividly, when the plunging vessel sends the sparkling spray all around the bow. If, on removing the tow-net from such water at night it is suddenly jerked, the whole interior is beautifully lit up with a luminous lining, which glows brightly for a few seconds and then fades. I have been unable, nevertheless, to satisfy myself as to the phosphorescence of isolated examples of *Ceratium*, and Mr. Murray (who is inclined to follow Klebs in considering them algæ), tells me that he has not been more successful.

The most conspicuous member of the first group (viz. the Protozoa), however, is *Noctiluca*, which for a long time has been associated with luminosity in many seas. The minute size of this little transparent gelatinous sphere, which ranges from ⅙ to ¼ of a millimetre, probably gave origin to some of the ancient views that the phosphorescence of the sea originated from the water, and not from any visible organisms. Amongst the first who clearly made known the relationship of this minute body to the phenomenon we are examining was M. Rigaut, a French naval surgeon, who examined it off various parts of the French coasts as well as off the Antilles, and pointed out in a memoir communicated to the Academy that the luminosity of the sea was caused by an immense number of what he termed little spherical polyps, about a quarter of a line in diameter (*Journal des Savants*, tome xliii., February, 1770, pp. 554–61). The observations of this acute French surgeon were followed up by many subsequent authors, amongst whom may be mentioned Baker, Martin Slabber, Abbé Dicquemare, Suriray, Macartney, and Baird; while in more recent times Verhaege, De Quatrefages, and Giglioli have specially studied the phosphorescence of the sea caused by *Noctiluca*. The light given out by this form is occasionally spread over a large area, and is often evident along the margin of the beach, where the broad belts of Noctilucæ gleam in the broken water. It is not uncommon in summer on the southern shores of Britain, while it is rare in the northern; but it stretches into most of the great oceans, and is the cause of that diffused and silvery phosphorescence so well known to voyagers in the warmer seas. At Ostend, Verhaege found the maximum number in a given quantity of water in the warm months, few or none appearing in the winter. The observations of De Quatrefages ("Observations sur les Noctiluques," *Ann. des Sc. Nat.*, 3e Série, Zool., tom. xiv. p. 226) were made on the shores of France as well as those of Sicily, for he accompanied the distinguished Prof. Henri Milne-Edwards (whose loss science has had so recently to deplore), on his celebrated "Voyage en Sicile," and they were more extensive than those of the previous author. He attributes the emission of the clear bluish light in quiet water, or the white light with greenish or bluish touches in broken water, to any physical agent which produces contraction, the scintillations arising from the rupture and rapid contraction of the protoplasmic filaments in the interior. Thus, like Verhaege and others, he found no special luminous organ. Moreover, Ehrenberg and De Quatrefages observed that the light emitted by *Noctiluca*, though apparently uniform under a lens, was broken up into a number of minute scintillations when highly magnified. Mr. Sorby, in examining the light of this form, has been unable to obtain satisfactory spectroscopic results, apparently from its feebleness.

Besides *Noctiluca*, which was chiefly met with in inshore water, Mr. Murray, of the *Challenger*, describes various species of *Pyrocystis* (*Proc. Roy. Soc.*, vol. xxiv., p. 553, pl. xxi.; and *Narrative*, Zool., vols. i. and ii., pp. 935–38), a closely-allied form, and indeed some of which have been thought to be identical with the former. They abound in the open sea, and are the chief causes of its phosphorescence in the tropical and subtropical oceans. The light is stated to proceed from the nucleus, and in this respect diverges from that observed by De Quatrefages in *Noctiluca*. When shaken in a glass they give out, Sir Wyville Thomson observes ("Atlantic," vol. ii. p. 87), the uniform soft light of an illuminated ground-glass globe.

Dr. Giglioli, during the voyage of the Italian frigate *Magenta*, mentions (*Atti della R. Accad. delle Sc. di Torino*, vol. v., 1869-70, p. 492) that another group of the Protozoa, viz. the Radiolaria, show phosphorescent properties. In the Pacific the genera *Thalassicolla*, *Collozoum*, and *Sphærozoum* shone with an intermittent greenish light. It is possible that Dr. Baird (Loudon's *Mag. Nat. Hist.*, vol. iii. p. 312, Fig. 81, *c*, *d*), in his earlier paper, refers to the same group when describing an unknown phosphorescent pelagic organism.

No group of marine animals is more prominent in regard to phosphorescence than the Cælenterates. The Hydroida are familiar examples (even after many days and in impure water some of these retain this property, a shock to the stem sending off a crowd of luminous points from the trophosome), and, as Mr. Hincks observes, none excels the common *Obelia geniculata*, which forms pigmy forests on the broad blades of Laminariæ all around our shores. In the fresh specimen a touch during summer causes a large number of luminous points to appear on the zoophytes, the stems most irritated emitting beautiful flashes, which glitter like faintly-dotted lines of fire, the points not being harshly separated, but blending into each other, while the shock imparted by the instrument detaches the minute medusoids, which scintillate upward from the parent stem to the summit of the water. Mere blowing on the surface in July, where Laminariæ abound, suffices to produce the emission of light from the pelagic buds. Moreover, these minute bodies, along with the various species of *Ceratium* and minute larval forms of diverse kinds, are sometimes swept by the gales landward, and cause phosphorescence where least expected. In the same manner Vaughan Thompson ("Zoological Researches," vol. i. part i. mem. iii. p. 48, 1829) found luminous patches on the masts and windward yardarms on board ship, and they gradually mounted upward as the gale increased. Many of the free gonosomes of the Hydroids are as luminous as the polypites, and indeed have been described by some of the older naturalists as one of the main causes of the luminosity of the ocean. The light in these (*e.g. Thaumantias*) gleams around the margin and along the four radii.

The Ascraspedote Medusæ have also been signalised as factors in producing the phosphorescence of the sea, such forms as *Pelagia noctiluca* and *Pelagia cyanella* being especially prominent. Spallanzani, indeed, made an elaborate series of experiments on the luminosity of the Medusæ in his voyage to the Two Sicilies. Some of these, as *Dactylometra* (*Pelagia*) *quinquecirra*, Agass., are nocturnal in their habits. They are only occasionally found floating at the surface during the day, while at night, in the same localities, the bottom swarms with these large masses of dull phosphorescence, moving about with the greatest rapidity (Agassiz, "North American Acalephæ," p. 49, Cambridge, 1865). Species of *Rhizostoma* were likewise observed by Giglioli to have a pale bluish luminosity. The two most abundant Medusæ of our eastern shores, viz. *Aurelia aurita* and *Cyanea capillata* (both in its young purple and adult brown condition), so far as I can make out, exhibit no luminosity. This agrees with the views expressed long ago by Ehrenberg.

The oceanic Hydrozoa (*Siphonophora*) are likewise characterised by their phosphorescence. Thus Giglioli met with luminosity in *Abyla*, *Diphyes*, *Eudoxia*, *Praya* and *Aglaismoides*. Dr. Bennett ("Gatherings of a Naturalist," p. 69, 1860) has also observed luminosity amongst the Coralligenous Actinozoa, the grazing of a boat on a coral reef causing a vivid stream of phosphoric light. Similar observations were made on Madrepores by Giglioli (*Atti della R. Accad. d. Sc. di Torino*, vol. v. p. 502), the light in this case being bright greenish and enduring some minutes.

Amongst the Alcyonarians the luminosity of the common Sea-Pen (*Pennatula phosphorea*) has been long known, and was studied by Gesner, Bartholin, Adler, and others. In the earlier part of this century Grant made the well-known and oft-quoted description (*Brewster's Edin. Journ.* vol. vii. p. 330, 1827), in which he pictures a *Pennatula* "with all its delicate transparent polypi expanded and emitting their usual brilliant phosphorescent light, sailing through the still and dark abysses by the regular and synchronous pulsations of the minute fringed arms of the whole polypi." But it ought to be balanced by his concluding statement, that the sea-pens are probably stationary, or "lie at the bottom, and move languidly like Spatangi, Asteriæ or Actiniæ" (certainly the specimens in the St. Andrew's Marine Laboratory were very helpless). Edward Forbes again observed that the light proceeded from the irritated point to the extremity of the polypiferous portion, and never in the opposite direction. As Dr. George Johnston tells us, Forbes induced Dr. George Wilson to test, along with Professor Swan, the polyps during phosphorescence by a delicate galvanometer, but without result. He thought the luminosity was due to a spontaneously inflammable substance.

More recently a series of interesting observations were made by Panceri on the structure and physiology of the luminous organs of this form. His conclusions are (1) that the light emanates from the polyps and zoids; (2) that the phosphorescent organs are the eight white cords adhering to the outer surface of the stomach, and that these are chiefly composed of cells containing a substance of a fatty nature, the oxidation of which causes the light. Panceri's conclusions further considerably modify Forbes's views about the direction of the waves or points of light. He supposes that the elements which stand in the place of nerves are capable of producing in the luminous batteries of the polyps a momentary oxidation—more rapid and more intense—accompanied by phosphorescence. Like those examined by Professor Milnes Marshall ("Report on the Oban Pennatulidæ," p. 49, Birmingham, 1882), the specimens at St. Andrews, after irritation, show a series of brilliant coruscations which flash along the rows of polyps in a somewhat irregular manner.

Two other Alcyonarians, *Funiculina* and *Umbellularia*, are equally phosphorescent. Though the former is familiar enough to some of the long liners of the outer Hebrides and west coast, it is rare that either is procured for scientific investigation. *Funiculina quadrangularis*, according to Forbes (Johnston's *Brit. Zooph.* vol. i. p. 166), gives out a vivid bluish light, which comes from the bases of the polyps, and appears to be connected with the reproductive system. Wyville Thomson ("Depths of the Sea," p. 149) describes the specimens procured in the *Porcupine* as resplendent with a steady pale lilac phosphorescence like the flame of cyanogen; and always sufficiently bright to make every portion of a stem caught in the tangles distinctly visible. The same zoologist mentions that the stem and polyps of *Umbellularia* are so brightly phosphorescent, that Captain Maclear found it easy to determine the character of the light by the spectroscope. It gave a restricted spectrum sharply included between the lines *b* and D ("Atlantic," vol. i. p. 151).

Besides the foregoing Alcyonarians, *Isis* and *Gorgonia* have been indicated as likewise phosphorescent. Dr. Merle Norman and Dr. Gwyn Jeffreys (whose death since the last meeting of the British Association is a serious loss to science) mention a beautifully luminous *Isis* on board the French ship *Le Travailleur*; and Sir Wyville Thomson ("Atlantic," vol. i. p. 119), with the facile and genial pen which characterised the lamented naturalist, gives a fascinating picture of a long, delicate, simple Gorgonian which came up in immense numbers in the trawl from 600 fathoms off the Spanish coast. He conjures up this Gorgonian forest as an animated cornfield waving gently in the slow tidal current, and glowing with a soft diffused phosphorescence, scintillating and sparkling on the slightest touch, and now and again breaking into long avenues of vivid light, indicating the paths of fishes or other wandering denizens of these enchanted regions. Prof. Moseley thinks that this brilliant phosphorescence of the Alcyonarians may be regarded as an accidental production, but that it may be of occasional service. Further, that the deep sea is at any rate lighted up by these Alcyonarians, which would thus form luminous oases round which animals with eyes might possibly congregate ("Notes of a Naturalist on the *Challenger*," p. 590).

The last group of the Cœlenterates, the *Ctenophora*, are even more conspicuous than the foregoing in regard to luminosity. It is indeed long since the Abbé Dicquemare descanted on *Cydippe* (*Pleurobrachia*) and Suriray on *Beroë*, while subsequent authors have made it clear that the majority of this group are phosphorescent. In our own seas, as Prof. Allman observes, *Beroë* at various stages is one of the most prominent luminous forms during certain seasons. Their enormous numbers make their effects more striking, though the intensity of the phosphorescence is less than that of the Medusæ. Quiet seas like Bressay Sound and the Firth of Forth are occasionally covered by a dense layer of these animals. Prof. Allman found that *Beroë* did not phosphoresce if suddenly taken from light into darkness, but that after they had remained about twenty minutes in obscurity they became luminous. Considerable variety exists in this respect at St. Andrews, some emitting light at once, others showing none. It is probable that this uncertainty is connected with the hygienic condition of the individuals.

In foreign seas many brightly luminous species are met with. Thus Prof. A. Agassiz ("North American Acalephæ," p. 20, Cambridge, 1865) describes *Mnemiopsis Leidyi* as "exceedingly phosphorescent, and when passing through shoals of these Medusæ, varying in size from a pin's head to several inches in length, the whole water becomes so brilliantly luminous that an oar dipped up to the handle can plainly be seen on dark nights by the light so produced; the seat of the phosphorescence is confined to the locomotive rows, and so exceedingly sensitive are they that the slightest shock is sufficient to make them plainly visible by the light emitted from the eight phosphorescent ambulacra." The same author (*Op. cit.* p. 24) mentions that *Lesueuria* has a very peculiar bluish light of an exceedingly pale steel colour, but very intense. Giglioli, again, found that the beautiful riband-like *Cestus* shone with a reddish yellow light, but in *Eucharis* the latter was intensely blue (*Op. cit.* p. 495, 496).

While many of the preceding group are pelagic at all periods of their existence, the luminous star-fishes are in their adult condition members of the bottom fauna. The larval stages of the brittle-stars, however, are passed at the surface of the water, where it is probable they add their quota to swell the ranks of the phosphorescent types. Amongst the first to note this property in the brittle-stars was Prof. Viviani, who found on the shores of Genoa a little brittle-star which he termed *Asterias noctiluca*,[1] and which probably is identical with the *Amphiura elegans* of Leach. Péron likewise mentions the phosphorescence of his *Ophiura phosphorea*. Sir Wyville Thomson observed in the *Porcupine* that the light from *Ophiacantha spinulosa* was of a brilliant green, coruscating from the centre of the disk along the rays and illuminating the whole outline of the starfish ("Depths of the Sea," p. 98). More recently Prof. Panceri of Naples has re-examined the phosphorescence of the species described by Viviani, and he finds that though with the first momentary glow the whole ray is lit up with a greenish light, that the luminous points correspond with the bases of the pedicels and are ranged in pairs along the arms (*Atti della R. Accad. d. Sc. Fisiche e Mathem. di Napoli*, 1875, p. 17, pl. iv. figs. 1, 3). In deep water (between twenty and forty fathoms) off our eastern shores, *Ophiothrix* gleams all over the trawl-net with a pale greenish light; but the adults of the same form between tide-marks give no trace of luminosity.

The older authors were familiar with certain luminous annelids which they termed *Nereides*, such as *Nereis phosphorans*. Ehrenberg paid considerable attention to this group, specially referring to *Polynoë fulgurans* from the North Sea, *Nereis noctiluca*[2] and *Nereis* (*Photocharis*) *cirrigera*, the latter species having a photogenic structure in its cirri like the electric organ of the Torpedo. The latter form is probably related to the ubiquitous *Eusyllis*, which, under various names, has been noticed by many observers. Thus it is very likely the same species that is mentioned by Harmer, in Baker's "Employment for the Microscope," p. 400, as having been found on oyster shells; and also by Vianelli, who describes it as a caterpillar-like form amongst seaweeds. Indeed the Syllideans have been conspicuous in the literature of phosphorescence from the time of De la Voie (1665, *fide* Panceri), and Vianelli ("Nuove Scoperte intorno le Luci dell' Acqua Marina," Venezia, 1749), to the recent period of Claparède ("Glanures Zootomiques," p. 95) and Panceri (*Op. cit.* p. 8). The structure of the cirri of the phosphorescent forms, however, gives no support to the opinion of Ehrenberg that they possess a special photogenic structure.

The luminous annelids group themselves under five families, viz. the Polynoidæ, Syllidæ, Chætopteridæ, Terebellidæ, and Tomopteridæ, and the number may yet be extended to include other pelagic types.

In the first family one of the most abundant is *Harmothoë imbricata*, which lives both between tide-marks and deep water, and is cosmopolitan in geographical distribution. It discharges bright greenish scintillations from the point of attachment of each dorsal scale; and thus, under irritation, the flashes are arranged in pairs along the body, or in a double moniliform line. If severely pinched the worm wriggles through the water, emitting sparks of green light from the bases of the feet. The separated scales also continue to gleam for some time, chiefly at the surfaces of attachment (scars), near which, in each, a ganglion exists. The same phenomenon is readily produced in a fragment either of the anterior or posterior end of the body. No mucous secretion is emitted, but the light is clearly produced by the will of the animal, and by the agency of its nervous system. A recent writer, Dr. Jourdan (*Zoologischer Anzeiger*, March, 2 1885, No. 189, p. 133), has endeavoured to prove that this luminosity in another member of the Polynoidæ (viz., *Polynoë torquata*) is produced by cells secreting a phosphorescent mucus, but this view is by no means applicable in all cases.

Besides the species mentioned, various other forms in this family are equally luminous, such as *Polynoë scolopendrina*, *Achloë astericola*, *Polynoë lunulata*, and a Zetlandic *Eunoa*.

[1] "Phosphorescentia Maris," Genoa, 1805, p. 5, tab. i. figs. 1, 2. He observes: "Species hæc radiatæ instar stellæ scintillas in marinis aquis excitasse, quas electrico fluido adscripserunt, admodum probabile est."

[2] Supposed by some to refer to *Noctiluca miliaris*.

As an example of the Syllidæ, the common *Eusyllis*, so often mentioned by previous authors, may be taken. Under irritation a fine green light is emitted from the ventral aspect of each foot, and the scintillations seem to issue from many points at each space, flash along both sides of the worm posterior to the point of stimulation, and then disappear. Under severe irritation the animal remains luminous behind the injured part for nearly half a minute, while the surface of granular light on each segment is larger than usual, and in some instances those of opposite sides are connected on the ventral aspect by a few phosphorescent points. The body behind the irritated region has a paler pinkish hue immediately after the emission of light showing that the luminosity is diffused.

In the Chætopteridæ the phosphorescence is remarkably beautiful, bright flashes being emitted from the posterior feet; but the most vivid luminosity is at a point on the dorsum between the lateral wings of the tenth segment. Here the abundant mucus exuded by the animal can be drawn out as bluish-purple fire of great intensity, which, besides, now and then gleams along the edges of the wing-like processes, and illuminates the surrounding water. A very characteristic odour, somewhat resembling that produced by phosphorus in combustion, is given out by the animal during such experiments. In this connection it may be observed that Quoy and Gaimard mention that an odour similar to that around an electric machine is given out by luminous marine annelids.

Amongst the Terebellidæ, as first shown by Grube none excel the genus *Polycirrus* in the brightness of the phosphorescence and the ease with which it is elicited. Mere blowing on the water of the dissecting-trough suffices to cause in the British *Polycirrus* the most vivid pale bluish luminosity, which gleams for a moment along every one of the independent mobile tentacles. Long before Grube, however, had discovered the phosphorescence of *Polycirrus*, our patient and laborious countryman, Sir J. Graham Dalyell, had noticed it in the group ("Powers of the Creator," vol. ii. p. 210), for he mentions that when irritated *Terebella figulus* gave out the most copious blue refulgence, intermingled with a reddish flame. Another member of this family, viz. *Thelepus*, is only faintly phosphorescent in life, but when decomposition has made progress it gleams in the vessel with a pale lambent light, somewhat like phosphorus in air.

In the pelagic Tomopteridæ certain peculiar structures on the parapodia, formerly supposed by some to be eyes, and by others simply glandular organs, were lately found by Professor Greeff (*Zoologischer Anzeiger*, 1882, p. 384—87) to be luminous organs, which, though glandular, have a considerable nervous supply, including a ganglion.

Panceri's observations on the luminous annelids of Naples, and the peculiar type *Balanoglossus* (Enteropneusta) have recently added considerably to our knowledge of the subject. He specially describes, in *Chætopterus*, the structure of the phosphorescent glands in the great pinnules and other parts, which produce the luminous mucus. With some reason he concludes that two kinds of phosphorescence are present in annelids, viz., one which is the result of purely nervous action, and another which is due to this *plus* a luminous secretion.

A Turbellarian, viz., *Planaria retusa*, was mentioned by Viviani (*Op. cit.* p. 13) as luminous, but this feature appears to be rare in the group; and the same may be observed of phosphorescent Rotifers, one of which (*Synchæta baltica*) was described by Ehrenberg (*Op. cit.* p. 128). Giglioli (*Op. cit.* p. 498) again, records a *Sagitta* which showed a feeble luminosity in the posterior region of the body.

The minute forms amongst the Crustacea (chiefly Copepoda) were recognised as phosphorescent by Athanasius Kircher in 1640, and have been mentioned by most authors who have alluded to the subject since that date. Thus Viviani gives seven species from the shores of Genoa, and Tilesius no less than nineteen luminous crustaceans from Krusenstern's voyage. Dr. Baird describes the light given out by those met with in his cruises as brilliant in the extreme, and Vaughan Thompson added considerably to our knowledge of *Sapphirina* and of the luminous schizopods, an example of which had been discovered by Sir Joseph Banks, and described by Macartney (*Phil. Trans.* 1810, as "Cancer fulgens"). Most authors agree that the minute forms, such as the Copepods, give a sparkling appearance to the surface of the water. The light in these, according to Lesson, proceeds from glands placed on the sides of the thorax; while Giglioli found the luminous organ of the cosmopolitan *Sapphirina* in the anterior part of the thorax. On the other hand, Captain Chimmo (*Euplectella*, &c., 1878) thought it was decomposing food in the stomach, and Prof. Moseley (*Op. cit.* p. 574.—Naturalist on the *Challenger*) in certain cases entertained a similar opinion. The phosphorescence of the Euphausiidæ was a prominent feature in the voyage of the *Challenger*, brilliant flashes being emitted on capture from a series of spots along the trunk and tail. Mr. Murray also met with a diffused light in the Faröe channel when dredging in the *Triton*, and he attributed this to the phosphorescent organs of *Nyctiphanes norvegica*, M. Sars, one of the same group. Prof. G. O. Sars describes these organs as composed of a series of coloured globules, the lens-like body of which acts as a condenser, and thus enables the animal to produce at will a bright flash of light in a given direction ("*Challenger* Narrative," Zoology, I. part ii. pp. 740—43).

Marine phosphorescence has some of its most striking examples amongst the Tunicates. One of the best known instances is that of *Pyrosoma*, the light from which has been so graphically described by M. Péron, Prof. Huxley, and other naturalists who have had an opportunity of observing it. It proceeds in each member of the compound organism from two small patches of cells at the base of each inhalent tube. These cells contain a substance resembling fat. *Salpa* has frequently been mentioned as a luminous form by many authors, but Delle Chiaje found that in the Mediterranean *Salpa pinnata* was not phosphorescent; and amongst the multitudes of Salpæ which for some weeks abounded at Lochmaddy in North Uist, neither the former nor the *Salpa spinosa* of Otto exhibited this property, though a spark was occasionally seen in the nucleus in some specimens, probably from the food. Giglioli likewise is doubtful concerning them, but in one instance a brilliant rose-coloured light appeared in the nucleus. *Doliolum*, on the other hand, shone with a greenish tint, while examples of *Appendicularia* which he encountered in various seas were chameleon-like in their luminosity, and often gleamed with great brightness.

Various mollusks exhibit the property of phosphorescence. Fabricius ab Aquapendente mentions *Sepia*, Panceri *Eledone*, Adler *Chama* and "*Dactylus*." The best known, however, is *Pholas dactylus*, which possesses two wavy bands and triangular organs of ciliated epithelium on the inner surface of the mantle. These secrete a luminous substance, soluble in ether and alcohol, which light up the excurrent water. The light is also maintained for a long time during putrefaction, as in the case of *Thelepus*. Panceri found that carbonic acid extinguished the light, but that air re-illuminated it, just as Johannes Müller had previously observed in a vacuum and in air. The light is monochromatic, the bands having a constant place in connection with the solar spectrum (from line E to line F).

Several Pteropods likewise contribute to the phosphorescence of the sea. Thus Giglioli noticed that a *Cleodora* gave out a very reddish light, while a *Criseis* and a *Hyalæa* were luminous at the base of the shell. He mentions also a large unknown Heteropod (*Op. cit.* p. 497) in the Indian Ocean, which glowed with a reddish phosphorescence. Amongst the Dermatobranchs, *Phyllirrhoë* has the same property, Giglioli further found that *Loligo sagittatus* and a small *Octopus* gleamed all over with a whitish luminosity.

Phosphorescence in living fishes appears to have been accurately observed within a comparatively recent date, though the luminosity of dead fishes has been known from very early times, and has been the subject of many interesting experiments such as those of Robert Boyle on dead whitings (*Phil. Trans.* 1667, pp. 591-93), and Dr. Hulme on herrings (*Phil. Trans.* 1800, p. 161). I do not mean to say that the literature of the so-called phosphorescent fishes is scanty, for it extends from the days of Aristotle and Pliny to modern times, but that the writers have had little reliable evidence in regard to living fishes to bring forward. Thus of upwards of fifty fishes entered by Ehrenberg in his list it is hard to say that one is really luminous during life. In many cases it is probable that the supposed phosphorescence of large forms, such as sword-fishes and sharks, has arisen from the presence of multitudes of minute phosphorescent animals in the water, just as the herring causes a gleam when it darts from the side of a ship. Prof. Moseley, for instance, observed in the *Challenger* that when large fishes, porpoises, and penguins dashed through phosphorescent water, that it was brilliantly lit up, and their track marked by a trail of light. The same feature is observed in hooked fishes, and it is known that fishermen are doubtful of success when the sea is very phosphorescent, for the presence of the net in the water excites the luminosity and scares the herring.

One of the most striking instances of phosphorescence in living fishes is that of the luminous shark (*Squalus fulgens*) found by Dr. Bennett. This is a small dark-coloured shark, which was captured on two or three occasions at the surface of the sea. It emitted without irritation a vivid greenish luminosity as it swam about at night, and it shone for some hours after death. The phosphorescence appears to be due to a peculiar secretion of the skin. The eyes of the shark were more prominent than usual in such forms. (The Danish naturalist Reinwardt describes a phosphorescent fish (*Hemiramphus lucens*) from the Moluccas. *Fide* Giglioli, *Op. cit.* p. 503.) Little is known with regard to the luminosity of the "Pearl-sides" (*Maurolicus pennantii*, Cuv. and Val.) of our own shores, though from its wide distribution this lack of information seems to be remediable.

In recent times phosphorescence has generally been associated with deep-sea fishes. Thus in a narrative of the early part of the voyage of the *Challenger* (NATURE, August 28, 1873) Sir Wyville Thomson mentions ranges of spots or glands producing a phosphorescent secretion on the body of a fish pertaining to the Sternoptychidæ, a species of which is included by Dr. F. Day in the British list. Of a new *Echiostoma* (one of the Stomiatidæ) it is also noted that the two rows of probably phosphorescent dots along the body were red, surrounded by a circle of pale violet ("*Challenger* Narrative, Zoology," I. vol. ii. p. 42). Dr. Günther ("*Challenger* Narrative, Zoology, I. part ii. p. 905) observes that many deep-sea fishes have round, shining, mother-of-pearl bodies embedded in the skin. These are supposed to be producers of light, and they have been observed to be phosphorescent in two species of Sternoptychidæ. He further states that the whole muciferous system is dilated in deep-sea fishes, that is, fishes inhabiting 1000 fathoms or more, and that the entire body seems to be covered with a layer of mucus, the physiological use of which is unknown; it has been noticed to have phosphorescent properties in perfectly fresh specimens.

Having thus briefly reviewed the leading features of phosphorescence in marine animals, a glance may now be taken at the supposed causes and purposes of this provision.

I do not deem it necessary to go into detail with regard to the numerous views which have been advanced to account for the phosphorescence of marine organisms, for these range over a very wide area—from its production by electricity, the constant agitation of the water, by putrefaction, by luminous imbibition, to its manifestation as a vital action in the animals, or a secretion of a phosphorescent substance. Ehrenberg considered it a vital act similar to the development of electricity, and sometimes accompanied by the secretion of a mucilaginous humour which is diffused around; while others, such as Meyen, thought it only a superficial oxidation of the mucous coat, or a luminour secretion from certain glands. Some believed that a liquid containing phosphorus was secreted, and that this underwent slow combustion; while others explained that it was a nervous fluid modified by certain organs to appear as light. Coldstream thought it was due to an imponderable agent, and that phosphorus or an analogous substance might enter into the organs producing it. De Quatrefages, again, clearly affirms that it is produced in two ways: (1) by the secretion of a peculiar substance exuding from the entire body or a special organ; and (2) by a vital action independent of all material secretion. Panceri was strongly impressed with the importance of fatty matter in the forms he examined—such as *Pennatula*, the Medusæ, Beroïdes, Pholades, *Chætopteri*, and *Noctilucæ*—the phosphorescence arising from the slow oxidation of this substance; the nervous system of the living animal, however, being capable of producing a momentary oxidation more rapid and more intense, accompanied by light.

It will be observed that in the Protozoa the structure of the minute but often very abundant animals which furnish the luminosity clearly proves that the presence of a well-defined nervous system is not required for its manifestation, the protoplasm of their bodies alone sufficing for its development. There are neither glands for secreting it, and in some apparently no fatty matter for slow combustion. In the Cœlenterates the phenomena appear to be more nearly related to nervous manifestations, though in certain cases the luminous matter possesses inherent properties of its own. While in some annelids, such as *Chætopterus* and *Polyirrus*, there are glands which may be charged with the secretion of a luminous substance, it is otherwise with certain Polynoidæ, in which the emission of light appears to be an inherent property of the nervous system. The irritability in the phosphorescent examples of the latter family, however, varies considerably, some, *e.g. Polynoë scolopendrina*, being sluggish, while others, like *Harmothoë*, are extremely irritable. In the Crustaceans the luminosity seems to have the nature of a secretion, probably under the control of the nervous system. In *Pyrosoma* and *Pholas dactylus* a luminous secretion is also a prominent feature, and in both the latter and the annelids decay excites its appearance, as also is the case, to a limited extent, in fishes.

It is evident, therefore, that the causation of phosphorescence is complex. In the one group of animals it is due to the production of a substance which can be left behind as a luminous trail. The ease, for instance, with which in *Pennatula* and other Cœlenterates the phosphorescence can be repeatedly produced by friction on a surface having a minute trace of the material, clearly points to other causes than nervous agency. The action, moreover, clearly affects the organic chemical affinities of the tissues engaged. On the other hand again, as in certain annelids, it is purely a nervous action, probably resembling that which gives rise to heat.

With the exception of such as Macartney, the older authors, who in some cases took an imaginative view of the question, connected the emission of light with the special economy of the deep sea. The speculations to this effect are fairly summarised in "Brewster's Edinburgh Encyclopædia," published in 1830 (Chiefly the views of Dr. Macculloch). Thus it is supposed that total darkness exists at the depth of 1000 feet, and that the phosphorescence of marine animals is a substitute for the light of the sun. Moreover, that by these lights the animals on the one hand are guided for attack, and on the other their power of extinguishing them enables them to escape destruction. Fishes are known to prey chiefly at night, and the writer supposes that the phosphorescence of their prey guides them; for, he says, this luminosity is particularly brilliant in those inferior animals which from their astonishing powers of reproduction, and from a state of feeling little superior to that of vegetables, appear to have been in a great measure created for the food of the more perfect kinds. Dr. Coldstream at a later period (1847) reproduced the same views in his article on animal luminosity (Todd's "Cyclop. of Anat. and Phys.").

The same notion was brought forward in the "Report of the Cruise of the *Porcupine*" (*Proc. Roy. Soc.*, No. 121, 1870, p. 432), and special reference was made to the young of certain starfishes, which are stated to be more luminous than the adults, that being part of the general plan which provides an excess of the young of many species, apparently as a supply of food, their wholesale destruction being necessary for the due restriction of the multiplication of the species, while the parent individuals, on the other hand, are provided with special appliances for escape or defence. Thus phosphorescence, it is further asserted ("Depths of the Sea," p. 149), in very young Ophiacanthæ just rid of their plutei, in a sea swarming with predaceous crustaceans, such as *Dorynchus* and *Munida*, with great bright eyes, must be a fatal gift. Some naturalists still appear to hold a similar, though perhaps modified view. Much caution, however, is necessary in theorising on this head.

In the first place, phosphorescent animals do not appear to be more abundant in the depths of the sea than between tide-marks or on the surface, the latter perhaps presenting the maximum development of those exhibiting this phenomenon. Very many of the young that have been indicated as so brilliantly luminous become surface-forms soon after leaving the egg, and thus at their several stages more or less affect the three regions—of surface, mid-water, and bottom.

A survey of the life-histories of the several phosphorescent groups affords at present no reliable data for the foundation of a theory as to the functions of luminosity, especially in relation to food. No phosphorescent form is more generally devoured by fishes or other animals than that which is not; and, on the other hand, the possessor of luminosity, if otherwise palatable, does not seem to escape capture. An examination of the stomachs of fishes makes this clear, except perhaps in the case of the herring, which, however, is chiefly a surface-fish. Further, it is not evident that such animals are luminous at all times, for it is only under stimulation that many exhibit the phenomenon.

Moreover, the irregularity of its occurrence in animals possessing the same structure and habits in every respect, strengthens the view just expressed. Thus, while *Pholas dactylus* has been known from the days of Pliny to be luminous, the common *Pholas crispata* is not so endowed. Two annelids abound between tide-marks (*Harmothoë imbricata* and *Polynoë floccosa*), and closely resemble each other in habits and appearance; yet one is brightly luminous, while the other shows no trace. Instead of luring animals for prey, or affording facilities for being easily preyed upon, the possessors of phosphorescence in the annelids are often the inhabitants of tubes, or are commensalistic on starfishes. Indeed, every variety of condition accompanies the presence of phosphorescence in the several groups, so that the greatest care is necessary in making deductions, especially if these are to have a wide application.

In the foregoing brief outline of the remarkable phenomenon of phosphorescence as it affects marine animals, it is apparent that, though a considerable increase in our knowledge has taken place during the last quarter of a century, much more yet remains to be done. I, however, confidently look forward for further advances, in this as well as in other departments, to the marine laboratories of the country—I mean such institutions as those now in working order at Granton, St. Andrews, and Tarbet, as well as the larger establishment proposed to be erected by the Biological Association at Plymouth. These laboratories, it is true, have been tardily instituted, but it is satisfactory to think that at last the zeal and methods of the workers have, and will have, a better field for their exercise than formerly, and that the zoology of the fisheries will obtain that attention which its importance to the country necessitates.

SECTION E.

GEOGRAPHY.

OPENING ADDRESS BY GENERAL J. T. WALKER, C.B., LL.D., F.R.S., F.R.G.S., PRESIDENT OF THE SECTION.

MY predecessors in this chair have claimed for geography a range of science which may be said to be practically unlimited; for it comprehends the history of the earth itself, and of all the life to be met with on the surface of the earth, from the first beginnings of things, and through their subsequent development onwards to their present conditional status; it is associated in a greater or less degree with every other department of knowledge and is a remarkable exemplification of the mutual interdependence and correlation of the physical sciences, for while all other branches of science are incomplete without some knowledge of geography, it is incomplete without some knowledge of each and all of them.

Such claims on behalf of geography would, not many years ago, have been considered extravagant and exaggerated; a popular encyclopædia which is still of some note defines geography to be simply the science which describes the surface of the earth, and somewhat querulously complains that geographical treatises contain matter not unfrequently taken from statistics, natural philosophy, and history which it declares to be irrelevant and not properly admissible into such treatises. And in a popular sense geography is still commonly suggestive only of such a knowledge of locality as may be acquired from maps and charts, with their graphical delineations of whatever exists on the surface of the earth, and of the various natural or artificial boundary lines of the peoples and states between whom the surface is divided. But the British Association and the Royal Geographical Society have successfully maintained that scientific geography is not restricted in its scope to a mere knowledge of locality—though that in itself is a very important factor in whatever appertains to the intercourse and mutual relations of mankind—but embraces all that relates to the structure and existing configuration of the earth, and takes cognisance of the varied conditions of all the life, both animal and vegetable, which is nurtured and supported by the earth; it studies the side lights which the general configuration of surface throws on the character of each locality as a home and support of life, and it examines with special interest the influence which that character has exerted on the social and political conditions of different races and peoples.

And geography does not merely devote its attention to the existing order of things as now displayed to our gaze; in alliance with geology it studies the history of a distant past, when the features of the earth's surface were not precisely as now, and lands which we see high above our horizon lay deep beneath the ocean, and life existed in other forms, whose mute records we possess in the fossils—the *Ilkha-kâni* or written stones as they are significantly called by the people of Afghanistan—which, after long lying entombed among the rocks, are presented to modern sight as revelations of life's early dawn; it investigates what Baron Richtofen describes as the reciprocal causal relations of the three kingdoms—land, water, and atmosphere; it seeks to determine the processes by which in some parts of the globe continents were built up with their varied sculpture of mountain and valley, of highly elevated plateau and low lying plain, of lakes and inland seas, and great river systems,—while in other parts land was depressed below the sea level, or broken up into the islands which are now dotting the surface of the ocean; and it endeavours to trace a process of continuous evolution of life from the primary and simplest types which perished in the early ages of the earth's history, to the latest and most highly developed types which are now flourishing around us. Going back still further it searches for evidence of the first beginnings of the material universe; it looks beyond the orbit of the most distant planet of the solar system, and scrutinises the boundless regions of stellar space to find, in the widely scattered particles of the nebulæ, the beginnings of new solar systems and new worlds such as ours; there it may be said to behold as in a mirror the formation of our own planet as a fluid igneous mass thrown off with great velocity from its sun, and rapidly revolving, and then becoming spheroidal, and slowly cooling and solidifying, and finally acquiring the crust which was to become an abode for life, the stage whereon man was to play out the drama of his planetary existence, and be held all the while fast imprisoned and out of touch with the surrounding universe.

More than this we would seek to know, but in vain; in passing from the early dawn of matter to that of life, science finds its career of wonderful achievement in the one direction exchanged for failure and disappointment in the other; it cannot discover the origin of life in any of its existing material forms, nor trace to its birthplace the spiritual life which exerts such an influence on what is material; it cannot ascertain whether man had a prior existence as different from his present existence as the first beginnings of his planet home differed from its present condition; it cannot gauge the truth of the poet's prescient conception that

> "Our birth is but a sleep and a forgetting;
> The soul that rises with us, our life's star,
> Hath had elsewhere its setting
> And cometh from afar."

It whispers faint suggestions regarding the possible future of the planet; but when questioned as to what is to follow the coming soul's setting of man, the planet's chief glory and dignity, it has nothing to reply, but is hopelessly dumb and inarticulate.

Scientific geography embraces a wide range of subjects, wider than can be claimed for any other department of science. Thus the President of this Section has a vast field from which to gather subjects for his opening address. I shall, however, restrict my address to the subject with which I am most familiar, and give you some account of the Survey of India, and more particularly of the labours of the trigonometrical or geodetic branch of that survey, in which the best years of my life have been passed.

I must begin by pointing out that the survey operations in India have been very varied in nature, and constitute a blending together of many diverse ingredients. Their origin was purely European, nothing in the shape of a general survey having been executed under the previous Asiatic Governments; lands had been measured in certain localities, but merely with a view to acquiring some idea of the relative areas of properties, in assessing on individuals the share of the revenue levied on a community; but other factors than area—such as richness or poverty of soil, and proximity or absence of water—influenced the assessment, and often in a greater degree, so that very exact measurements of area were not wanted for revenue purposes, and no other reason then suggested itself why lands should be accurately measured. The value of accurate maps of individual properties, with every boundary clearly and exactly laid down, was not thought of in India in those days, and indeed has only of late years begun to be recognised by even the British Government. The idea of a general geographical survey never suggested itself to the Asiatic mind. Thus when Englishmen came to settle in India, one of their first acts was to make surveys of the tracts of country over which their influence was extending; and as that influence increased, so the survey became developed from a rude and rapid primary delineation of the broad facts of general geography, to an elaborately executed and artistic delineation of the topography of the country, and in some provinces to the mapping of every field and individual property. Thus there have been three orders or classes of survey, and these may be respectively designated geographical, topographical, and cadastral; all three have frequently been carried on *pari passu*, but in different regions, demanding more or less elaborate survey according as they happened to be more or less under British influence. There is also the Great Trigonometrical or Geodetic Survey, by which the graphical surveys are controlled, collated, and co-ordinated, as I will presently explain.

Survey operations in India began along the coast-lines before the commencement of the seventeenth century, the sailors preceding the land surveyors by upwards of a century. The Directors of the East India Company, recognising the importance of correct geographical information for their mercantile enterprises, appointed Richard Hakluyt, Archdeacon of Westminster, their historiographer and custodian of the journals of East Indian voyages, in the year 1601, within a few weeks of the establishment of the company by Royal Charter. Hakluyt gave lectures to the students at Oxford, and is said by Fuller to have been the first to exhibit the old and imperfect maps and the new and revised maps for comparison in the common schools, "to the singular pleasure and great contentment of his auditory." The first general map of India was published in 1752 by the celebrated French geographer D'Anville, and was a meritorious compilation from the existing charts of coast-lines and itineraries of travellers. But the Father of Indian Geography, as he has been called, was Major Rennell, who landed in India as a midshipman of the Royal Navy in 1760, distinguished himself in the blockade of Pondicherry, was employed for a time in making surveys of the coast between the Paumben Passage and Calcutta, was appointed Surveyor of the East India Company's dominions in Bengal in 1764, was one of the first officers to receive a commission in the Bengal Engineers on its formation, and in 1767 was raised to the position of Surveyor-General. Bengal was not in those days the tranquil country we have known it for so many years, but was infested by numerous bands of brigands who professed to be religious devotees, and with whom Rennell came into collision in the course of one of his surveying expeditions, and was desperately wounded; he had to be taken 300 miles in an open boat for medical assistance, the natives meanwhile applying onions to his wounds as a cataplasm. His labours in the survey of Bengal lasted over a period of nineteen years, and embraced an area of about 300,000 square miles, extending from the eastern boundaries of Lower Bengal to Agra, and from the Himalayas to the borders of Bandelkand and Chota Nagpur. Ill-health then compelled him to retire from the service on a small pension and return to England; but not caring, as he said, to eat the bread of idleness, he immediately set himself to the utilisation of the large mass of geographical materials laid up and perishing in what was then called the India House; he published numerous charts and maps, and eventually brought out his great work on Indian Geography, the "Memoir of a map of Hindostan," which went through several editions; this was followed by his Geographical System of Herodotus, and various other works of interest and importance. His labours in England extended over a period of thirty-five years, and their great merits have been universally acknowledged.

Rennell's system of field-work in Bengal was a survey of routes checked and combined by astronomical determinations of the latitude and the longitude, and a similar system was adopted in all other parts of India until the commencement of the present century. But in course of time the astronomical basis was found to be inadequate to the requirements of a general survey of all India, as the errors in the astronomical observations were liable materially to exceed those of the survey, if executed with fairly good instruments and moderate care. Now this was no new discovery, for already early in the eighteenth century the French Jesuits who were making a survey of China—with the hope of securing the protection of the Emperor, which they considered necessary to favour the progress of Christianity—had deliberately abandoned the astronomical method and employed triangulation instead. Writing in the name of the missionaries who were associated with him in the survey, Père Regis enters fully into the relative advantages of the two methods, and gives the trigonometrical the preference, as best suited to enable the work to be executed in a manner worthy the trust reposed in them by a wise prince, who judged it of the greatest importance to his State. "Thus," he says, "we flatter ourselves we have followed the surest course, and even the only one practicable in prosecuting the greatest geographical work that was ever performed according to the rules of art."

What was true in those days is true still; points whose relative positions have been fixed by any triangulation of moderate accuracy present a more satisfactory and reliable basis for topographical survey than points fixed astronomically. Though the lunar theory has been greatly developed since those days by the labours of eminent mathematicians, and the accuracy of the lunar tables and star catalogues is much increased, absolute longitudes are still not susceptible of ready determination with great exactitude; moreover, all astronomical observations, whether of latitude or longitude, are liable to other than intrinsic errors, which arise from deflection of the plumb-line under the influence of local attractions, and which of themselves materially exceed the errors that would be generated in any fairly executed triangulation of a not excessive length, say not exceeding 500 miles.

Thus at the close of the last century Major Lambton, of the 33rd Regiment, drew up a project for a general triangulation of Southern India. It was strongly supported by his commanding officer—Colonel Wellesley, afterwards the Duke of Wellington—and was readily sanctioned by the Madras Government; for a large accession of territory in the centre of the peninsula had been recently acquired, as the result of the Mysore campaign, by which free communication had been opened between the east and west coasts of Coromandel and Malabar; and the proposed triangulation would not merely furnish a basis for new surveys, but connect together various isolated surveys which had already been completed or were then in progress. The Great Trigonometrical Survey of India owes its origin as such, and its simultaneous inception as a geodetic survey, to Major Lambton, who pointed out that the trigonometrical stations must needs have their latitudes and longitudes determined for future reference just as the discarded astronomical stations, not however by direct observation, but by processes of calculation requiring a knowledge of the earth's figure and dimensions. But at that time the elements of the earth's figure were not known with much exactitude, for all the best geodetic arcs had been measured in high latitudes, the single short and somewhat questionable arc of Peru being the only one situated in the vicinity of the equator. Thus additional arcs in low latitudes, as those of India, were greatly needed and might be furnished by Lambton. He took care to set this forth very distinctly in the programme which he drew up for the consideration of the Madras Government, remarking that there was thus something still left as a desideratum for the science of geodesy, which his operations might supply, and that he would rejoice indeed should it come within his province "to make observations tending to elucidate so sublime a subject."

Lambton commenced operations by measuring a base line and a small meridional arc near Madras, and then, casting a set of triangles over the southern peninsula, he converted the triangles on the central meridian into a portion of what is now known as the Great Arc of India, measuring its angles with extreme care, and checking the triangulation by base lines measured at distances of two to three degrees apart in latitude. His principal instruments were a steel measuring chain, a great theodolite, and a zenith sector, each of which had a history of its own before coming into his hands. The chain and zenith sector were sent from England with Lord Macartney's Embassy to the Emperor of China, as gifts for presentation to that potentate, who unfortunately did not appreciate their value and declined to accept them; they were then made over to Dr. Dinwiddie, the astronomer to the embassy, who took them to India for sale. The theodolite was constructed in England for Lambton, on the model of one in use on the Ordnance Survey; on its passage to India it was captured by the French frigate, the *Piemontaise*, and landed at Mauritius, but eventually it was forwarded to its destination by the chivalrous French Governor, De Caen, with a complimentary letter to the Governor of Madras.

Lambton was assisted for a short time by Captain Kater, whose name is now best known in connection with pendulum experiments and the employment of the seconds' pendulum as a standard of length; but for many years afterwards he had no officer to assist him. At first he met with much opposition from advocates of the discarded astronomical method, who insisted on its being sufficiently accurate and more economical than the trigonometrical. But he was warmly supported by Maskelyne, the Astronomer-Royal in England; and soon had an opportunity of demonstrating the astronomical method to be fallacious, for its determination of the breadth of the peninsula in the latitude of Madras was proved by the triangulation to be forty miles in error. Still, for several years he never received a word of sympathy, encouragement, or advice either from the Government or from the Royal Society. A foreign nation was the first to recognise the importance of his services to science, the French Institute electing him a corresponding member in 1817. After this, honours and applause quickly followed from his own countrymen. In 1818 the Governor-General of India—then the Marquis of Hastings—decided that the survey should be withdrawn from the supervision of a local Government and placed under the Supreme Government, with a view to its extension over all India, remarking at the same time that he was "not aware that with minds of a certain order he might lay himself open to the idle imputation of vainly seeking to partake the gale of public favour and applause which the labours of Colonel Lambton had recently attracted;" but as the survey had reached the northern limits of the Madras Presidency, its transfer to the Supreme Government, if it was to be further extended, had become a necessity. He directed the transfer to be made, and the survey to be called in future the Great Trigonometrical Survey of India. Noticing that the intense mental and bodily labour of conducting it was being performed by Lambton alone, that his rank and advancing age demanded some relief from such severe fatigue, and farther, that it was not right that an undertaking of such importance should hang on the life of a single individual, the Governor-General appointed two officers to assist him—Captain Everest, as chief assistant in the geodetic operations; and Dr. Voysey, as surgeon and geologist. Five years afterwards Lambton died, at the age of seventy. The happy possessor of an unusually robust and energetic constitution and a genial temperament, he seems to have scarcely known a day's illness, though he never spared himself nor shrank from subjecting himself to privations and exposure which even Everest thought reckless and unjustifiable. These he accepted as a matter of course, saying little about them, and devoting his life calmly and unostentatiously to the interests of science and the service of his country.

Everest's career in the survey commenced disastrously. He was deputed by Lambton to carry a triangulation from Hydrabad, in the Nizam's territory, eastwards to the coast, crossing the forest-clad and fever-haunted basin of the Godavery river, a region which he described as "a dreadful wilderness, than which no part of the earth was more dreary, desolate, and fatal." Indignant at being taken there, his escort, a detachment of the Nizam's troops, mutinied, and soon afterwards he and his assistants, and almost all the men of his native establishment, were stricken down by a malignant fever; many died on the spot, and the survivors had to be carried into Hydrabad, whence litters and vehicles of all descriptions, and the whole of the public elephants, were despatched to their succour. To recover his health Everest was compelled to leave India for a while and proceed to the Cape of Good Hope, where he remained for three years. He availed himself of the opportunity to inspect Lacaille's meridional arc, which, when compared with the arcs north of the equator, indicated that the opposite hemispheres of the globe were seemingly of different ellipticities. He succeeded in tracing this anomaly to an error in the astronomical amplitude of the arc, which had been caused by deflection of the plumb-line at the ends of the arc, under the influence of the attraction of neighbouring mountains. Thus he became aware of the necessity of placing the astronomical stations of the Indian arcs at points where the plumb-line would not be liable to material deflection by the attraction of neighbouring mountain ranges. Shortly after his return to India Lambton died, and Everest succeeded him, and immediately concentrated his energies on the extension of the Great Arc northwards. He soon came to the conclusion that his instrumental equipment, though good for the time when it was procured, and amply sufficient for ordinary geographical purposes, was inadequate for the requirements of geodesy, and generally inferior to the equipments of the geodetic surveys then in progress in Europe. He therefore proceeded to Europe to study the procedure of the English and French surveys, and also to obtain a supply of new instruments of the latest and most improved forms. The Court of Directors of the Honourable East India Company accorded a most liberal assent to all his proposals, and gave him *carte blanche* to provide himself with whatever he considered desirable to satisfy all the requirements of science.

Everest returned to India with his new instrumental equipment in 1830, a year that marks the transition of the character of the operations from an order of accuracy which was sufficient as a basis for the graphical delineation of a comparatively small portion of the earth's surface, to the higher precision and refinement which modern geodesists have deemed essentially necessary for the determination of the figure and dimensions of the earth as a whole. He immediately introduced an important modification of the general design of the principal triangulation, which up to that time had been thrown as a network over the country on either side of the Great Arc, as in the English survey and many others; but he abandoned this method, and, adopting that of the French survey instead, he devised a system of meridianal chains to be carried at intervals of about 1° apart, and tied together by longitudinal chains at intervals of about 5°, the whole forming, from its resemblance to the homely culinary utensil with which we are all familiar, what has been called the gridiron system in contradistinction to the network. The entire triangulation was to rest on base-lines to be measured with the new Colby apparatus of compensation bars and microscopes which had been constructed to supersede the measuring chain the Emperor of China had rejected; the base-lines were to be placed at the intersections of the longitudinal chains of triangles with the central meridional or axial chain, and also at the further angles of the gridirons on each side. Latitudes were to be measured at certain of the stations of the central chain, with new astronomical circles in place of the old zenith sector, to give the required meridional arcs of amplitude. Two radical improvements on all previous procedure were introduced in the measurement of the principal angles, one affecting the observations, the other the objects observed. The great theodolites were manipulated in such a manner as not merely to reduce the effects of accidental errors by numerous repetitions in the usual way, but absolutely to eliminate all periodic errors of graduation by systematic changes of the position of the azimuthal circle relatively to the telescope, in the course of the complete series of measures of every angle. The objects formerly observed had been cairns of stones or other opaque signals; for these Everest substituted luminous signals, lamps by night, and, by day, heliotropes which were manipulated to reflect the sun's rays through diaphragms of small aperture, in pencils appearing like bright stars, and capable of penetrating a dense atmosphere through which distant opaque objects could not be seen.

Everest's programme of procedure furnished the guiding principles on which the operations were carried out during the period of half a century which intervened between their commencement under his superintendence and the completion of the principal triangulation under myself. The external chains have necessarily been taken along the winding course of the frontier and coast lines instead of the direct and more symmetrical lines of the meridians and the parallels of latitude. The number of the internal meridional chains has latterly been diminished by widening the spaces between them, and in two instances a principal chain has been dispensed with because, before it could be taken in hand, a good secondary triangulation had been carried over the area for which it was intended to provide. But these are departures from the letter rather than the spirit of Everest's programme which has been faithfully followed throughout, first by his immediate successor, Sir Andrew Waugh, and afterwards by myself, thus affording an instance of the impress of a single mind on the work of half a century which is probably unique in the annals of India; for there, as is well known, changes of personal administration are frequent, and are not uncommonly followed by changes of procedure.

The physical features of a country necessarily exercise a considerable influence on the operations of any survey that may be carried over it, and more particularly on those of a geodetic survey, of which no portion is allowed to fall below a certain standard of precision. Every variety of feature, of scenery, and of climate that is to be met with anywhere on the earth's surface between the equator and the arctic regions has its analogue between the highlands of Central Asia and the ocean, which define the limits of the area covered by the Indian survey. Thus in some parts the operations were accomplished with ease, celerity, and enjoyment, while in others they were very difficult and slow of progress, always entailing great exposure, and at times very deadly. In an open country, dotted with hills and commanding eminences, they advanced as on velvet; in close country, forest-clad or covered with other obstacles to distant vision, they were greatly retarded, for there it became necessary either to raise the stations to a sufficient height to overlook all surrounding obstacles, or to render them mutually visible by clearing the lines between them; and both these processes are more or less tedious and costly. There are many tracts of forest and jungle which greatly impeded the operations, not merely because of the physical difficulties they presented, but because they teemed with malaria, and were very deadly during the greater portion of the year, and more particularly immediately after the rainy seasons, when the atmosphere is usually clearest and most favourable for distant observations. At first tracts of forest, covering extensive plains, were considered impracticable; thus Lambton carried his network over the open country, and stopped it whenever it reached a great plain covered with forest and devoid of hills; but Everest's system would not permit of any break of continuity, nor the abandonment of any chain which was required to complete a gridiron; it has been carried out in all its integrity, often with much sacrifice of life, but never with any shrinking on the part of the survey officers from carrying out what it had become a point of honour with them to accomplish, and the accomplishment of which the Government had come to regard as a matter of course. We have already seen how the progress of Everest's first chain of triangles was suddenly arrested because he and all his people were struck down by malaria in the pestilential regions of the Godavery basin. That chain remained untouched for fifty years; it was then resumed and completed, but with the loss of the executive officer, Mr. George Shelverton, who succumbed when he had not yet reached, but was within sight of, the east coast line, the goal towards which his labours were directed. Many regions, as the basin of the Mahanaddi, the valley of Assam, the hill ranges of Tipperah, Chittagong, Arracan, and Burma, and those to the east of Moulmein and Tennasserim, which form the boundary between the British and the Siamese territories, are covered with dense forest, up to the summits of the peaks which had to be adopted as the sites of the survey stations. As a rule the peaks were far from the nearest habitation, and they could not be reached until pathways to them had been cut through forests tangled with a dense undergrowth of tropical jungle; not unfrequently large areas had to be cleared on the summits to open out the view of the surrounding country. Here the physical difficulties to be overcome were very considerable, and they were increased by the necessity that arose, in almost every instance, of importing labourers from a great distance to perform the necessary clearances. But the broad belt of forest tract known as the Terai, which is situated in the plains at the feet of the Nepalese Himalayas, was the most formidable region of all, because the climate was very deadly for a great portion of the year, and more particularly during the season when the atmosphere was most favourable for the observations, though the physical difficulties were not so great as in the hill tracts just mentioned, and labour was more easily procurable. Lying on the British frontier, at the northern extremities of no less than ten of the meridional chains of triangles, it had necessarily to be operated in to some extent, and Everest wished to carry the several chains across it, on to the outer Himalayan range, and then to connect them together by a longitudinal chain running along the range from east to west, completing the gridiron in this quarter. But the range was a portion of the Nepalese territories, and all Europeans—excepting those attached to the British embassy at Khatmandu—were debarred from entering any part of Nepal, by treaty with the British Government. Everest hoped that the rulers of Nepal might make an exception in his favour for the prosecution of a scientific survey; and when he found they would not, he urged the Government to compel them to give his surveyors access, at least, to their outlying hills; but he urged in vain, for the Government would not run the risk of embarking in a war with Nepal for purely scientific purposes. Thus the connecting chain of triangles—now known as the N.E. Longitudinal Series—had to be carried through the whole length of the Terai, a distance of about 500 miles, which involved the construction of over 100 towers—raised to a height of about 30 feet to overlook the earth's curvature—and the clearance of about 2,000 miles of line through forest and jungle to render the towers mutually visible. It required no small courage on Everest's part to plunge his surveyors into this region; he endeavoured to minimise the risks as much as possible by taking up the longitudinal chain in sections, bit by bit, on the completion of the successive meridional chains, and thus apportioning it between several survey parties, each operating in the Terai for a short time, instead of assigning it to a single party to execute continuously from end to end, as all the other chains of triangles. But notwithstanding these precautions, the peril was great, and the mortality among both officers and men was very considerable; greater than in many a famous battle, says Mr. Clements Markham, in an eloquent passage in his Memoir of the Indian Surveys, in which he claims for the surveyors who were employed on these operations—with no hope of reward other than the favourable notice of their immediate chief and colleagues—merit for more perilous and honourable achievement than much of the military service which is plentifully rewarded by the praises of men and prizes of all kinds.

Everest retired in 1843, and was succeeded by Waugh, who applied himself energetically to the completion of the several chains of triangles exterior to the Great Arc, for which he obtained a substantial addition to the existing equipment of great theodolites. It was under him that the formidable longitudinal series through the Terai, which had been begun by Everest, was chiefly carried out. He personally initiated the determination of the positions and heights of the principal snow peaks of the Himalayan ranges; and he did much for the advancement of the general topography of India, which had somewhat languished under his predecessor, who had devoted himself chiefly to the geodetic operations. He retired in 1861, and I succeeded to the charge of the Great Trigonometrical Survey. The last chain of the principal triangulation was completed in 1882, shortly before my own retirement.

Of the general character of the operations, it may be asserted without hesitation that a degree of accuracy and precision has been attained which has been reached by few and surpassed by none of the great national surveys carried out in other parts of the world, and which leaves nothing to be desired even for the requirements of geodesy; a very considerable majority of the principal angles have been measured with the great 24-inch and 36-inch theodolite, and their theoretical probable error averages about a quarter of a second; of the linear measurements the probable error, so far as calculable, may be taken as not exceeding the two-millionth part of any measured length. And as regards the extent of the triangulation, if we ignore the primary network in Southern India, and all secondary triangulation, however valuable for geographical purposes, we still have a number of principal chains—meridional, longitudinal, and oblique—of which the aggregate length is 17,300 miles, which contain 9,230 first-class angles all observed, and rest on eleven base-lines measured with the Colby apparatus of compensation bars and microscopes. This prodigious amount of field-work furnishes an enormous mass of interdependent angular and linear measures; and each of these is fallible in some degree, for, great as was the accuracy and care with which they had severally been executed, perfect accuracy of measurement is as yet beyond human achievement; thus every circuit of triangles, every chain closing on a base-line, and even every single triangle, presented discrepancies the magnitude of which was greater or less according as derived from a combination of many, or only of a few, of the fallible facts of observation. Thus, when the field operations were approaching their termination, the question arose as to how these facts were to be harmonised and rendered consistent throughout, which was a very serious matter considering their great number. The strict application of mathematical theory to a problem of this nature requires the adjustment to be effected by the application of a correction to every fact of observation, not arbitrarily, but in such a manner as to give it its proper weight, neither more nor less, in the final investigation, and in this the whole of the facts must be treated simultaneously. That would have involved the simultaneous solution of upwards of 4,000 equations between 9,230 unknown quantities, by what is called the method of minimum squares, and I need scarcely say that it is practically impossible to solve such a number of equations between so many unknown quantities by any method at all. Thus a compromise had to be made between the theoretically desirable and the practically possible. It would be out of place here to attempt to describe the method of treatment which was eventually adopted, after much thought and deliberation; I will merely say that the bulk of the triangulation was divided into five sections, each of which was treated in succession with as close approximation to the mathematically rigorous method as was practically possible; but even then the mass of simultaneous interdependent calculation to be performed in each instance was enormous, I believe greatly exceeding anything of the kind as yet attempted in any other survey. But the happy result of all this labour was that the final corrections of the angles were for the most part very minute, less than the theoretical probable errors of the angles, and thus fairly applicable without taking any liberties with the facts of observation. If the attribute of beauty may ever be bestowed on such things as small numerical quantities, it may surely be accorded to these notable results of very laborious calculations, which, while in themselves so small, were so admirably effective in introducing harmony and precision throughout the entire triangulation.

If now we turn once more to what Lambton calls "the sublime science of geodesy," which was held in such high regard by both him and Everest, we shall find that the great meridional arc between Cape Comorin and the Himalayas, on which they laboured with so much energy and devotion, is not the only contribution to that science to which the Indian triangulation is subservient, but every chain of triangles—meridional, longitudinal, or oblique—may be made to throw light either on geodesy, the science of the figure of the earth, or on geognosy, the science of the earth's interior structure, when combined with corresponding astronomical arcs of amplitude. Thus each of the several meridional chains of triangles may be utilised in this way, as their prototype has been, by having latitude observations taken at certain of their stations to give meridional arcs; and the several longitudinal chains of triangles may also be utilised—in combination with the main lines of telegraph—by electro-telegraphic determinations of differential longitudes to give arcs of parallel. When the stations of the triangulation which are resorted to for the astronomical observations are situated in localities where the normal to the surface coincides fairly with the corresponding normal to the earth's figure, the result is valuable as a contribution to geodesy; when the normal to the surface is sensibly deflected by local attraction, the result gives a measure of the deflection which is valuable as a contribution to geognosy.

Having regard to these circumstances, I moved the Government to supply the Trigonometrical Survey with the necessary instruments for the measurement of the supplemental astronomical arcs; and as officers became available on the gradual completion of the successive chains of triangles, I employed some of them in the required determinations of latitude and differential longitude. It so happened that about the same time geodesists in Europe began to recognise the advantages to science to be acquired by connecting the triangulations of the different nationalities together, and supplementing them with arcs of amplitude. The "International Geodetic Association for the Measurement of Degrees in Europe" was formed in consequence, and it has been, and is still, actively employed in carrying out this object; in India, however, the triangulation was complete and connected throughout, so that only the astronomical amplitudes were wanting. They are still in progress, but already meridional chains, aggregating 1,840 miles in length, and lying to the west of the Great Arc, have been converted into meridional arcs; and the three longitudinal chains, from Madras to Mangalore, from Bombay to Vizagapatam, and from Kurrachee *via* Calcutta to Chittagong, of which the aggregate length is 2,600 miles, have been converted into arcs of parallel. In the former the operations follow the meridional course of the chains of triangles; in the latter they follow the principal lines of the electric telegraph, which sometimes diverge greatly from the direction of the longitudinal chains of triangles, the two only intersecting at occasional points; the astronomical stations are therefore placed at the trigonometrical points which may happen to be nearest the telegraph lines, whether on the meridional or on the longitudinal chains, and their positions are invariably so selected as to form self-verificatory circuits which are usually of a triangular form, presenting three differential arcs of longitude; each of these arcs is measured independently as regards the astronomical work—though for the third arc there is usually no independent telegraph line, but only a coupling of the lines for the first and second arcs—and this has been proved to give such an excellent check on the accuracy of the operations, that it is not too much to say that no telegraphic longitude operations are entirely reliable which have not been verified in some such manner.

Through the courtesy of Colonel Stotherd, Director-General of the Ordnance Survey, I am enabled to exhibit two charts, one of the triangulation of India, the other of that of Europe, which have recently been enlarged to the same scale in the Ordnance Survey Office at Southampton for purposes of comparison. The first is taken from the official chart of the Indian Survey, and shows the great meridional and longitudinal chains and Lambton's network of principal triangles, the positions of the base-lines measured with the Colby apparatus, the latitude and the differential longitude stations, the triangular circuits of the longitudinal arcs, the stations of the pendulum and the tidal operations which will be noticed presently, and the secondary triangulations to fix the peaks of the Himalayan and Sulimani ranges, and the positions of Bangkok in Siam and Kandahar in Afghanistan, the extreme eastern and western points yet reached. The chart of the European triangulation has been enlarged from one published by the International Geodetic Association of Europe; in it special prominence is given to the Russian meridional arc, which extends from the Danube to the Arctic Ocean, and is 25° 20′ in length, and to the combined English and French meridional arc, 22° 10′ in length, which extends from the Balearic Island of Formentera in the Mediterranean, to Saxavord in the Shetland Islands. The aggregate length of the meridional arcs already completed in India is about equal to that of the English, French, and Russian arcs combined; but the longest in India is about $1\frac{1}{2}°$ shorter than the Russian. As regards longitudinal arcs, I believe the two which were first measured in India, and were employed shortly afterwards by Colonel Clarke in his last investigation of the figure of the Earth, are the only ones which have as yet been deemed sufficiently accurate to be made use of in such investigations, though arcs of much greater length have been measured in Europe. It would be interesting, if time permitted, to set forth the salient points of divergence between the systems of the Indian and the European surveys; I will only mention that in the southern part of the Russian arc, for a space of about 8° from the Duna to the Dneister, a vast plain, covered with immense and almost impenetrable forests, presented great obstacles to the prosecution of the work; the difficulty was overcome by the erection of a large number of lofty stations of observation, wooden scaffoldings which were 120 and even as much as 146 feet high, to overlook the forests. In Indian forests, as the Terai on the borders between British and Nepalese territories, the stations were rarely raised to a greater height than 30 feet, or just sufficient to overtop the curvature, and all trees and other obstacles were cleared away on the lines between them; this was found the most expeditious and economical process. The stations were very substantial, with a central masonry pillar, for the support of a great theodolite, which was isolated from the surrounding platform for the support of the observer. The lofty Russian scaffoldings only sufficed for small theodolites, and they were so liable to shake and vibration, that the theodolites had to be fitted with two telescopes to be pointed simultaneously by two observers at the pair of stations, the angle between which was being measured.

All the modern geodetic data of the Indian survey that were available up to the year 1880 were utilised by Colonel A. R. Clarke, C.B., of the Ordnance Survey, in the last of the very valuable investigations of the Figure of the Earth which he has undertaken from time to time. It will be obvious that new data tend to modify in some degree the conclusions derived from previous data, for the figure of so large a globe as our earth is not to be exactly determined from measurements carried over a few narrow belts of its superficies. Thus thirty years ago it was inferred that the equator was sensibly elliptic—and not circular, as had been generally assumed—with its major axis in longitude 15° 34′ east of Greenwich; but later investigations indicate a far smaller ellipticity, and place the major axis in west longitude 8° 15′. More significant evidence of the influence of new facts of observation in modifying previous conclusions is furnished by the French national standard of length, the metre, which was fixed at the ten-millionth part of the length of the earth's meridional quadrant, as deduced from the best geodetic data available up to the end of the last century; but it is now found to be nearly $\frac{1}{5000}$th part less than the magnitude which it is supposed to represent, the difference being about a hundred times greater than what would now be considered an allowable error in an important national standard of measure.

The Indian survey has also made valuable contributions to geodesy and geognosy in an elaborate series of pendulum observations for determining variations of gravity, which throws light both on the grand variation from the poles to the equator that governs the ellipticity, and on the local and irregular variations depending on the constitution of the interior of the earth's crust. They were commenced in 1865 by Captain J. P. Basevi, on the recommendation of General Sabine and the Council of the Royal Society, with two pendulums, one of which the General had swung in his notable operations which extend from a little below the equator to within 10° of the pole. Captain Basevi had nearly completed the operations in India, and had taken swings at a number of the stations of the Great Arc and at various other points near mountain ranges and coast lines, when he died of exposure in 1871 at a station on the high table-lands of the Himalayas, while investigating the force of gravity under mountain ranges. Major Heaviside swung the pendulums at the remaining Indian stations, then at Aden and Ismailia on the way back to England, and finally at the base station, the Kew Observatory. Afterwards they and a third pendulum were swung at Kew and Greenwich by Lieutenant-Colonel Herschel, who took all three to America, swung them at Washington, and then handed them over to officers of the United States Coast Survey, by whom they have been swung at San Francisco, Auckland, Sydney, Singapore, and in Japan.

The pendulum operations in India have been successful in removing from the geodetic operations the reproach which had latterly been cast on them, that their value has become much diminished since the discovery that the attraction of the Himalayan mountains is so much greater than had previously been suspected, that it may have materially deflected the plumb-line at a large number of the astronomical stations of the Great Arc, and injuriously influenced the observations. Everest considered the effects of the Himalayan attraction to be immaterial at any distance exceeding sixty miles from the feet of the mountains; but in his days the full extent and elevation of the mountain masses was unknown, and their magnitude was greatly underestimated. Afterwards, when the magnitude became better known, Archdeacon Pratt of Calcutta, a mathematician of great eminence, calculated that they would materially attract the plumb-line at points many hundred miles distant; he also found that everywhere between the Himalayas and the ocean, the excess of density of the land of the continent as compared with the water of the ocean would combine with the Himalayan attraction and increase the deflection of the plumb-line northwards, towards the great mountain ranges, and that under the joint influence of the Himalayas and the ocean the level of the sea at Kurrachee would be raised 560 feet above the level at Cape Comorin.

But as a matter of fact the Indian arc gave a value of the earth's ellipticity which agreed sufficiently closely with the values derived from the arcs measured in all other quarters of the globe, to show that it could not have been largely distorted by deflections of the plumb-line; thus it appeared that whereas Everest might have slightly underestimated the Himalayan attraction, Pratt must have greatly overestimated it. His calculations were however based on reliable data, and were indubitably correct. For some time the contradiction remained unexplained, but eventually Sir George Airy put forward the hypothesis that the influence of the Himalayan masses must be counteracted by some compensatory disposition of the matter of the earth's crust immediately below them, and in which they are rooted; he suggested that the bases of the mountains had sunk to some depth into a fluid lava which he conceived to exist below the earth's crust, and that the sinking had caused a displacement of dense matter by lighter matter below, which would tend to compensate for the excess of matter above. Now Pratt's calculations had reference only to the visible mountain and oceanic masses, and their attractive influences—the former positive, the latter negative—in a horizontal direction; he had no data for investigating the density of the crust of the earth below either the mountains on the one hand, or the bed of the ocean on the other. The pendulum observations furnished the first direct measures of the vertical force of gravity in different localities which were obtained, and these measures revealed two broad facts regarding the disposition of the invisible matter below; first, that the force of gravity diminishes as the mountains are approached, and is very much less on the summit of the highly elevated Himalayan table-lands than can be accounted for otherwise than by a deficiency of matter below; secondly, that it increases as the ocean is approached, and is greater on islands than can be accounted for otherwise than by an excess of matter below. Assuming gravity to be normal on the coast lines, the mean observed increase at the island stations was such as to cause a seconds' pendulum to gain three seconds daily, and the mean observed decrease in the interior of the Continent would have caused the pendulum to lose $2\frac{1}{2}$ seconds daily at stations averaging 1,200 feet above the sea level, 5 seconds at 3,800 feet, and about 22 seconds at 15,400 feet—the highest elevation reached—in excess of the normal loss of rate due to height above the sea.

Pratt was strongly opposed to the hypothesis of a substratum, or magma, of fluid igneous rock beneath the mountains; he assumed the earth to be solid throughout, and regarded the mountains as an expansion of the invisible matter below, which thus becomes attenuated and lighter than it is under regions of less elevation, and more particularly in the depressions and contractions below the bed of the ocean. And certainly we seem to have more reason to conclude that the mountains emanate from the subjacent matter of the earth's crust than that they are as wholly independent of it as if they were formed of stuff shot from passing meteors and asteroids; any severance of continuity and association between the visible above and the invisible below appears, on the face of it, to be decidedly improbable.

The hypothesis of sub-continental attenuation and sub-oceanic condensation of matter is supported by the two arcs of longitude on the parallels of Madras and Bombay; for at the extreme points of these arcs, which are situated on the opposite coast lines, the horizontal attraction has been found to be not landwards, as might have been anticipated, but seawards, showing that the deficient density of the sea as compared with the land is more than compensated by the greater density of the matter under the ocean than of that under the land.

While on the subject of the constitution of the earth's crust, I may draw attention to the circumstance that the tidal observations which have been carried on at a number of points on the coasts of India, as a part of the operations of the Survey, tend to show that the earth is solid to its core, and that the geological hypothesis of a fluid interior is untenable. They have been analysed by Prof. G. H. Darwin, with a view to the determination of a numerical estimate of the rigidity of the earth, and he has ascertained that whilst there is some evidence of a tidal yielding of the earth's mass, that yielding is certainly small, and the effective rigidity is very considerable, not so great as that of steel, as was at first surmised, but sufficient to afford an important confirmation of the justice of Sir William Thomson's conclusion as to the great rigidity.

The Indian pendulum observations have been employed by Colonel Clarke, in combination with those taken in other parts of the globe, to determine the earth's ellipticity. Formerly there was wont to be a material difference between the ellipticities which were respectively derived from pendulum observations and direct geodetic measurements, the former being somewhat greater than $\frac{1}{290}$, the latter somewhat less than $\frac{1}{300}$; but as new and more exact data became available, the values derived from these two essentially independent sources became more and more accordant, and they now nearly agree in the value $\frac{1}{293}$.

As a part of the pendulum operations, a determination of the length of the seconds' pendulum was made at Kew by Major Heaviside, with the pendulum which had been employed for the same purpose by Kater early in the present century, when leading men of science in England believed that in the event of the national standard yard being destroyed or lost, the length might be reproduced at any time with the aid of a reversible pendulum. In consequence of this belief an Act of Parliament was passed in 1824 which defined the relations between the imperial and the seconds' pendulum, the length of the former being to that of the latter—swung in the latitude of London, in a vacuum and at the level of the sea—in the proportion of 36 inches to 39·1393 inches. Thus, while the French took for their unit of length the ten-millionth part of the earths' meridional quadrant, the English took the pendulum swinging seconds in the latitude of London. In case of loss the yard is obviously recoverable more readily and inexpensively by reference to the pendulum than the metre by reference to the quadrant; it is also recoverable with greater accuracy; still the accuracy is not nearly what would now be deemed indispensable for the determination of a national standard of length, and it is now generally admitted that every pendulum has certain latent defects, the influence of which cannot be exactly ascertained. Thus the instrument cannot be relied on as a suitable one for determinations of absolute length; but, on the other hand, so long as its condition remains unaltered, it is the most reliable instrument yet discovered for differential determinations of the variations of gravity. In truth, however, the pendulum is a very wearisome instrument to employ even for this purpose, for it has to be swung many days and with constant care and attention to give a single satisfactory determination; thus if such a thing can be invented and perfected as a good differential gravity meter, light and portable, with which satisfactory results can be obtained in a few hours, instead of many days, the boon to science will be very great.

The trigonometrical operations fix with extreme accuracy two of the co-ordinates—the latitude and longitude—which define the positions of the principal stations; but the third co-ordinate, the height, is not susceptible of being determined by such operations with anything like the same degree of accuracy, because of the variations of refraction to which rays of light passing through the lower strata of the atmosphere are liable, as the temperature of the surface of the ground changes in the course of the day. In the plains the apparent height of a station ten to twelve miles from the observer has been found to be upwards of 100 feet greater in the cool of the night than in the heat of the day, the refraction being always positive when the lower atmospheric strata are chilled and laden with dew, and negative when they are rarefied by the heat radiated from the surface of the ground. At hill stations the rays of light usually pass high above the surface of the ground, and the diurnal variations of refraction are comparatively immaterial, and very good results are obtained by the expedient of taking the vertical observations between reciprocating stations at the same hour of the day, and as nearly as possible at the time of minimum refraction; but in the plains this expedient does not usually suffice to give reliable results. The hill ranges of central and those of northern India are separated by a broad belt of plains, which embraces the greater portion of Sind, the Punjab, Rajputana, and the valley of the Ganges, and is crossed by a very large number of the principal chains of triangles, on the lines where the chart shows stretches of comparatively small triangles, which are in most instances of considerable length. Thus it became necessary to run lines of spirit levels over these plains, from sea to sea, to check the trigonometrical heights. The opportunity was taken advantage of to connect all the levels which had been executed for irrigation and other public works, and reduce them to a common datum; and eventually lines of level were carried along the coast and from sea to sea to connect the tidal stations. The aggregate length of the standard lines of level executed up to the present time is nearly 10,000 miles, and an extensive series of charts of the levels derived from other departments of the public service and reduced to the survey datum has already been published.

The survey datum which has been adopted for all heights, whether deduced trigonometrically or by spirit-levelling, is the mean sea level as determined, either for initiation or verification, by tidal observations at several points on the coast lines. At first the observations were restricted to what was necessary for the requirements of the survey, and their duration was limited to a lunar month at each station. In 1872 more exact determinations were called for, to ascertain whether gradual changes in the relative level of land and sea were taking place at the head of the Gulf of Cutch, as had been surmised by the geological surveyors, and observations were taken for over a year at three tidal stations on the coasts of the gulf, to be repeated hereafter when a sufficient period had elapsed to permit of a measurable change of level having taken place. Finally, in 1875, the Government intimated that as "the great scientific advantages of a systematic record of tidal observations on Indian coasts had been frequently urged and admitted," such observations should be taken at all the principal ports and at such points on the coast lines as were best suited for investigations of the laws of the tides. In accordance with these instructions, five years' observations have been made at several points, and new stations are taken up as the operations at the first ones are completed.

The initiation of the later and more elaborate operations is due in great measure to the recommendations of the Tidal Committee of the British Association, of which Sir William Thomson was President. The tidal observations have been treated by the method of harmonic analysis advocated by the Committee. The constants for amplitude and epoch are determined for every tidal component, both of long and of short periods, and with their aid tide-tables are now prepared and published annually for each of the principal ports; and further, it is with them that Prof. G. H. Darwin made the investigations of the effective rigidity of the earth, which I have already mentioned. The very remarkable waves which were caused by the earthquake on December 31, 1881, in the Bay of Bengal, and by the notable volcanic eruptions in the island of Krakatoa and the Straits of Sunda on August 27 and 28, 1883, were registered at several of the tidal stations, and thus valuable evidence has been furnished of the velocities of both the earth-wave and the ocean-wave which are generated by such disturbances of the ordinarily quiescent condition of the earth's crust.

I must not close this account of the non-graphical, or more purely scientific, operations of the great Trigonometrical Survey of India without saying something of the officers who were employed thereon, under the successive superintendence of Everest, Waugh, and myself. A considerable majority were military, from all branches of the army—the cavalry and infantry, as well as the corps of engineers and artillery; the remainder were civilians, mostly promoted from the subordinate grades. Prominent shares in the operations were taken by Lieutenant Renny, Bengal Engineers, afterwards well known in this neighbourhood as Colonel Renny Tailyour, of Borrowfield in Forfarshire, of whom and his contemporary, Lieutenant Waugh, Everest, retiring, reported in terms of the highest commendation; by Reginald Walker, of the Bengal Engineers, George Logan, George Shelverton, and Henry Beverley, all of whom fell victims to jungle fever; by Strange, F.R.S., of the Madras Cavalry, whose name is associated with the construction of the modern geodetic instruments of the Survey; by Jacob—afterwards Government Astronomer at Madras—Rivers and Haig, all of the Bombay Engineers; Tennant, C.I.E., F.R.S., Bengal Engineers, afterwards Master of the Mint in Calcutta; Montgomerie, F.R.S., of the Bengal Engineers, whose name is best remembered in connection with the Trans-Himalayan geographical operations; James Basevi, of the Bengal Engineers, who so sadly died of exposure while engaged on the pendulum operations in the higher Himalayas; Branfill, of the Bengal Cavalry; Thuillier, Carter, Campbell, Trotter, Heaviside, Rogers, Hill, and Baird, F.R.S., all engineer officers; also Hennessey, C.I.E., F.R.S., M.A., Herschel, F.R.S., and Cole, M.A., whose names are intimately associated with the collateral mathematical investigations and the final reduction of the principal triangulation.

The Trigonometrical Survey owes very much to the liberal and even generous support which it has invariably received from the Supreme Government, with the sanction and approval, first of the Directors of the East India Company, and afterwards of the Secretary of State for India. In times of war and financial embarrassment the scope of the operations has been curtailed, the establishments have been reduced, and some of the military officers sent to join the armies in the field; but whatever the crisis, the operations have never been wholly suspended. Even during the troubles of 1857-58, following the mutiny of the native army, they were carried on in some parts of the country, though arrested in others; and the then Viceroy, Lord Canning, on receiving the reports of the progress of the operations during that eventful period, immediately acknowledged them to the Surveyor-General, Colonel Waugh, in a letter from which the following extract is taken:

"I cannot resist telling you at once with how much satisfaction I have seen these papers. It is a pleasure to turn from the troubles and anxieties with which India is still beset, and to find that a gigantic work, of permanent peaceful usefulness, and one which will assuredly take the highest rank as a work of scientific labour and skill, has been steadily and rapidly progressing through all the turmoil of the last two years."

The operations have been uninfluenced by changes of *personnel* in the administration of the Indian Empire, as Governor-Generals and Viceroys succeeded each other, but have met with uniform and consistent support and encouragement. It may well be doubted whether any similar undertaking, in any other part of the world, has been equally favoured and as munificently maintained.

In conclusion I must state that I have purposely said nothing of the graphical operations executed in the Trigonometrical and other branches of the Survey of India, because they are more generally known, their results appear in maps which speak for themselves, and time would not permit of my attempting to describe them also. They comprise, *first*, the general topography of all India, mostly on the standard scale of 1 inch to the mile; *secondly*, geographical surveys and explorations of regions beyond the British frontier, notably such as are being carried on at the present time on the Russo-Afghan frontier, by Major Holdich and other officers of the Survey; *thirdly*, the so-called Revenue Survey of the British districts in the Bengal Presidency, which is simply a topographical survey on an enlarged scale—4 inches to the mile—showing the boundaries and areas of villages for fiscal requirements; and *fourthly*, the Cadastral Survey of certain of the British districts in the Bengal Presidency, showing fields and the boundaries of all properties, on scales of 16 to 32 inches to the mile. There are also certain large scale surveys of portions of British districts in the Madras and Bombay Presidencies, which, though undertaken originally for purely fiscal purposes by revenue and settlement officers working independently of the professional survey, have latterly been required to contribute their quota to the general topography of the country. And of late years a survey branch has been added to the Forest Department, to provide it with working maps constructed for its own requirements on a larger scale than the standard topographical scale, but on a trigonometrical basis, and in co-operation with the Survey Department. But this brief capitulation gives no sort of idea of the vast amount of valuable topographical and other work for the requirements of the local Administrations and the public at large—always toilsome, often perilous—which has been accomplished, quite apart from and in quantity far exceeding the non-graphical and more purely scientific work which I have been describing. Its magnitude and variety are such that a mere list of the officers who have taken prominent shares in it, from first to last, would be too long to read to you. Three names, however, I must mention: *first*, that of General Sir Henry Thuillier, who became Surveyor-General on the same day that I succeeded to the superintendence of the Great Trigonometrical Survey, and with whom I had the honour of co-operating for many years; under his administration a much larger amount of topography was executed than under any of his predecessors, and a great impetus was given to the lithographic, photographic, engraving and other offices in which the maps of the survey are published; *secondly*, that of Colonel Sconce, who became Deputy Surveyor-General soon after my accession in 1878 to the Survey-Generalship, and with whom I was associated for some years, much to my gratification and advantage, in various matters, but more particularly in the establishment of cadastral surveys on a professional basis at a moderate cost, to render them more generally feasible, which was a matter of the utmost importance for the administration of the more highly populated portions of the British provinces; and *thirdly*, that of Lieutenant-Colonel Waterhouse, who has for many years superintended the offices in which photography is employed, in combination with zincography and lithography, for the speedy reproduction *en masse* of the maps of the Survey, and has done much to develop the art of photogravure, whereby drawings in brushwork and mezzotint may be reproduced with a degree of excellence rivalling the best copperplate engraving, and almost as speedily and cheaply as drawings in pen and ink work are reproduced by photo-zincography.

Mr. Clements Markham's Memoir on the Indian Surveys gives the best account yet published of the several graphical surveys up to the year 1878. In that year the Trigonometrical, Topographical, and the Revenue branches, which up to that time had constituted three separate and almost independent departments, were amalgamated together into what is now officially designated "the Survey of India." In the same year the chronicle so well commenced by Mr. Markham came to an end on his retirement from the India office—unfortunately, for it is a work of excellence in object and in execution, and most encouraging to Indian surveyors, who find their labours recorded in it with intelligent appreciation and kindly recognition.

During the present meeting, several papers by officers of the Survey will be read—one by Colonel Barron, in person, on the cadastral surveys in the organisation of which he has taken a leading share; by Major Baird, on the work of spirit-levelling, which he superintends conjointly with the tidal observations; by Colonel Godwin Austen, on Lieutenant-Colonel Woodthorpe's recent journey from Upper Assam to the Irawadi river; by Colonel Branfill, on the physical geography of Southern India; and by Colonel Tanner, on portions of the Himalayas, and on recent explorations in Southern Tibet. Major Bailey will also read a paper on the forest surveys.

SECTION G

MECHANICAL SCIENCE

Opening Address by B. Baker, M.Inst.C.E., President of the Section

Two hundred and fifty-seven Presidential Addresses of one kind and another have been delivered at meetings of the British Association since the members last mustered at Aberdeen. I need hardly say that the candid friend who informed me of this interesting fact most effectually dispelled any illusion I may have previously entertained as to the possibility of preparing an address of sufficient novelty and suggestiveness to be worthy of your attention, and I can only hope that any shortcomings will be dealt with leniently by you. One compensating advantage obviously belongs to my late appearance in the field—I have 257 models of style upon which to frame my address. My distinguished predecessor, Sir Frederick Bramwell, has a style of his own, in which wit and wisdom are combined in palatable proportions; but were I to attempt this style I should doubtless incur the rebuke which a dramatic critic of Charles the Second's time administered to a too ambitious imitator of a popular favourite: "He's got his fiddle, but not his hands to play on't." I must search further back than last year, therefore, for a model of style, and the search reminds me that I labour under a double disadvantage: firstly, that only two addresses intervene between the present one and that of my partner, Mr. John Fowler, with whom I have so long had the honour of being associated, and whose professional experiences, as set forth in his address, are necessarily so largely identical with my own; and, secondly, that within the same period I have read before this Section two somewhat lengthy papers on the work which is at present chiefly engaging the attention of Mr. Fowler and myself—the great Forth Bridge.

Although, for the reasons aforesaid, I am conscious that my address may fail in novelty, I cannot honestly profess to feel a difficulty in preparing an address of some kind, for the subjects embraced under the head of "Mechanical Science" are so inexhaustible that even the youngest student might safely accept the responsibility of speaking for an hour on some of them. Prof. Rankine, addressing you thirty years ago, said it was well understood that questions of pure or abstract mechanics form no part of the subjects dealt with in this Section. With characteristic clearness of conception and precision of language he told you what the term "mechanical science" meant, and, after thirty years' interval, his words may be recalled with advantage to every one proposing to prepare an address or report for this Section. "Mechanical science," said Prof. Rankine, "enables its possessor to plan a structure or machine for a given purpose without the necessity of copying some existent example; to compute the theoretical limit of the strength and stability of a structure or the efficiency of a machine of a particular kind; to ascertain how far an actual structure or machine fails to attain that limit, and to discover the cause and the remedy of such shortcoming; to determine to what extent, in laying down principles for practical use, it is advantageous for the sake of simplicity to deviate from the exactness required by pure science; and to judge how far an existing practical rule is founded on reason, how far on custom, and how far on error." There is thus an ample text for many discourses; but, as I am not writing a treatise on engineering, but merely delivering a brief address, I will confine my attention at present to a particular case of the branch of mechanical science referred to in the last clause of Prof. Rankine's definition, and will ask you to consider how far the existing practical rules respecting the strength of metallic bridges are "founded on reason, how far on custom, and how far on error."

The first question obviously is, What are the rules adopted by engineers and Government departments at the present time?—and it is one not easily answered. I have for some time past been receiving communications from leading Continental and American engineers, asking me what is my practice as regards the admissible intensity of stress on iron and steel bridges, and in replying I have invited similar communications from themselves. As a result I am able to say that at the present time absolute chaos prevails. The old foundations are shaken, and engineers have not come to any agreement respecting the rebuilding of the structure. The variance in the strength of existing bridges is such as to be apparent to the educated eye without any calculation. If the wheels of a miniature brougham were fitted to a heavy cart the incident would excite the derision even of our street boys, and yet equal want of reason and method is to be found in hundreds of bridges in all countries. It is an open secret that nearly all the large railway companies are strengthening their bridges, and necessarily so, for I could cite cases where the working stress on the iron has exceeded by 250 per cent. that considered admissible by leading American and German bridge-builders in similar structures.

In the case of old bridges the variance in strength is often partly due to errors in hypothesis and miscalculation of stresses. In the present day engineers of all countries are in accord as to the principles of estimating the magnitude of the stresses on the different members of a structure, but not so in proportioning the members to resist those stresses. The practical result is that a bridge which would be passed by the English Board of Trade would require to be strengthened 5 per cent. in some parts and 60 per cent. in others before it would be accepted by the German Government or by any of the leading railway companies in America. This undesirable state of affairs arises from the fact that in our own and some other countries many engineers still persistently ignore the fact that a bar of iron may be broken in two ways—namely, by the single application of a heavy stress or by the repeated application of a comparatively light stress. An athlete's muscles have often been likened to a bar of iron, but, if "fatigue" be in question, the simile is very wide of the truth. Intermittent action—the alternative pull and thrust of the rower, or of the labourer turning a winch—is what the muscle likes and the bar of iron abhors. Troopers dismount to rest their horses, but to relieve a bar of iron temporarily of load only serves to fatigue it. Half a century ago Braithwaite correctly attributed the failure of some girders, carrying a large brewery vat, to the vessel being sometimes full and sometimes empty, the repeated deflection, although imperceptibly slow and wholly free from vibration, deteriorating the metal, until, in the course of years, the girders broke. These girders were of cast-iron; but it was equally well known that wrought-iron was similarly affected, for in 1842 Nasmyth called the attention of this Section to the fact that the "alternate strain" in axles rendered them weak and brittle, and suggested annealing as a remedy, he having found that an axle which would snap with one blow when worn would bear eighteen blows when new or after being annealed.

So important a matter as the action of intermittent stresses could not escape the attention of the Royal Commissioners appointed in 1849 to consider the application of iron to railway structures, and some significant and sufficiently conclusive experiments were made by Capt. Douglas Dalton and others. Cast-iron bars 3 inches square and 13 feet 6 inches span between the supports were deflected, both by the slow action of a cam and the percussive action of a swinging pendulum weight. When the deflection was that due to one-third of the breaking weight, about 50,000 successive bendings by the cam broke one of the bars, and about 1000 blows from the pendulum another. When the deflection was increased from one-third to one-half, about 500 applications of the cam, and 100 blows, sufficed to rupture two of the specimens. Slow-moving weights on bars and on a small wrought-iron box girder gave analogous results; and the deduction drawn by the experimenters at the time was that "iron bars scarcely bear the reiterated application of one-third the breaking weight without injury, hence the prudence of always making beams capable of bearing six times the greatest weight that could be laid upon them."

Although these experiments were entirely confirmatory of all previous experience, they would appear to have little influenced the practice of engineers, since Fairbairn, more than ten years later, in a communication to this Section, said that opinions were still much divided upon the question whether the continuous change of load which many wrought-iron structures undergo has any permanent effect upon their ultimate powers of resistance. To assist in settling the question he communicated to the Association the results of some experiments carried out by himself and Prof. Unwin on a little riveted girder 20 feet span and 16 inches deep. Once more the same important but disregarded facts were enforced on the attention of engineers. About 5000 applications of a load equal to four-tenths of the calculated breaking load fractured the beam with the small ultimate deflection of three-eighths of an inch, and subsequently, when repaired, the beam broke with one-third of the load and a deflection of but a quarter of an inch, which sufficiently indicated how small a margin the factor of safety of four, when currently adopted, allowed for defective manufacture, inferior material, and errors in calculation. Still nothing was done, and the general practice of engineers and the Board of Trade regulations continued unaltered.

Soon after the introduction of wrought-iron bridges on railways, the testimony of practical working was added to that of experiments. In 1848 several girder bridges of unduly light proportions were erected in America, and one of 66 feet span broke down under the action of the rolling load in the same manner as Fairbairn's little experimental girder. Again, in early American timber bridges the vertical tie-rods were often subject to stresses oscillating between 1 ton and 10 tons per square inch and upwards. Many of these broke, as did also the suspension bolts in platforms subjected to similar stresses. In my own experience, dozens of broken flange-plates and angle-bars, and hundreds of sheared rivets, have been the silent witnesses of the destructive action of a live load. Like evidence was afforded by early constructed iron ships deficient in girder strength. Under the alternating stresses due to the action of the waves weaknesses not at first apparent would, in the course of time be developed, and additional strength, in the way of stringers and otherwise, become imperative.

If none of the preceding evidence had been forthcoming, the results of the historical series of experiments carried out by Wöhler for the Prussian Ministry of Commerce would alone be conclusive. For the first time a truly scientific method of investigation was followed, and an attempt was made to determine the laws governing the already proved destructive action of intermittent stresses. In previous experiments the bar or girder was alternately fully loaded and wholly relieved of load. Wöhler was not satisfied with this, but tested also the result of a partial relief of load. The striking fact was soon evidenced on testing specimens under varying tensions, that the amount of the variation was as necessary to be considered as that of the maximum stress. Thus, an iron bar having a tensile strength of 24 tons per square inch broke with about 100,000 applications of a stress varying from *nil* to 21 tons, but resisted 4,000,000 applications of the 21 tons when the minimum stress was varied from *nil* to 11½ tons. The alternations of stress in the case of some test pieces numbered no less than 132,000,000; and too much credit cannot be bestowed by engineers upon Wöhler for the ingenuity and patience which characterised his researches. As a result, it is proved beyond all further question that any bar or beam of cast iron, wrought iron, or steel may be fractured by the continued repetition of comparatively small stresses, and that, as the differences of stress increase, the maximum stress capable of being sustained diminishes.

Various formulæ based upon the preceding experiments have been proposed for the determination of the proper sectional area of the members of metallic structures. These formulæ differ in some essential respects, and doubtless many experiments are still required before any universally accepted rules can be laid down. Probably at the present time the engineers who have given the most attention to the subject are fairly in accord in holding that the admissible stress per square inch in a wrought-iron girder subject to a steady dead load would be one and a half times as great as that in a girder subject to a wholly live load, and three times that allowable in members subject to alternate tensile and compressive stresses of equal intensity, such as the piston-rod of a steam-engine or the central web-bracing of a lattice girder. If the alternations of stress to be guarded against are not assumably infinite in number, but only occasional —as in wind bracing for hurricane pressures, or in a vessel amongst exceptionally high waves—then the aforesaid ratio of 3, 2, and 1 would not apply, but would more nearly approach the ratios 6, 5, and 4.

Hundreds of existing railway bridges which carry twenty trains a day with perfect safety would break down quickly under twenty trains per hour. This fact was forced on my attention nearly twenty years ago by the fracture of a number of iron girders of ordinary strength under a five-minute train service. Similarly, when in New York last year I noticed, in the case of some hundreds of girders on the "Elevated Railway," that the alternate thrust and pull on the central diagonals from trains passing every two or three minutes had developed weaknesses which necessitated the bars being replaced by stronger ones after a very short service. Somewhat the same thing had to be done recently in this country with a bridge over the Trent, but the train service being small the life of the bars was measured by years instead of months. If ships were always amongst great waves the number going to the bottom would be largely increased, for, according to Mr. John, late of Lloyd's, "many large merchant steamers afloat are so deficient in longitudinal strength that they are liable under certain conditions of sea to be strained in the upper works to a tension of from 8 to 9 tons per square inch, and to a compression of from 6 to 7 tons—stresses which the experiments already referred to proved would cause failure after a definite number of repetitions. Similarly, on taking ground or being dry-docked with a heavy cargo on board, it has been shown that vessels are liable to stresses of over 11 tons per square inch on the reverse frames, but no permanent injury results from such high stresses, because the number of repetitions is necessarily very limited.

It appears natural enough to every one that a piece even of the toughest wire should be quickly broken if bent backward and forward to a sharp angle; but, perhaps, only to locomotive and marine engineers does it appear equally natural that the same result would follow in time if the bending were so small as to be quite imperceptible to the eye. A locomotive crank axle bends but 1-34th of an inch, and a straight driving axle the still smaller amount of 1-64th of an inch under the heaviest bending stresses to which they are subject, and yet their life is limited. During the year 1883 one iron axle in fifty broke in running, and one in fifteen was renewed in consequence of defects. Taking iron and steel axles together, the number then in use on the railways of the United Kingdom was 14,848, and of these, 911 required renewal during the year. Similarly, during the past three years no less than 228 ocean steamers were disabled by broken shafts, the average safe life of which is said to be about three or four years. In other words, experience has proved that a very moderate stress alternating from tension to compression, if repeated about one hundred million times, will cause fracture as surely as a sharp bending to an angle repeated perhaps only ten times.

I have myself made many experiments with a view to elucidate the laws affecting the strength of iron- and steel-work subject to frequent alternations of stress. Perhaps the most suggestive series was one in which I subjected flat steel bars about 3 feet long, in pairs, to repeated bendings until one bar broke, and then testing the surviving bar under direct tensile and compressive stresses to ascertain to what extent the metal had deteriorated. It had come under my notice, as a practical engineer, that if the compression members of a structure were unduly weak the fact became quickly evident, perhaps under the test load; but if, on the other hand, the tension members were weak, no evidence might appear of the fact until frequent repetition of stresses during several years had caused them to fracture without any measurable elongation of the metal. In the case of crank-shafts, also, the fracture is invariably due to a tearing and not a crushing action. It appeared to me, therefore, eminently probable that repetition of stresses might be far more prejudicial to tension than to compression members, and, if so, the fact ought to be taken account of in proportioning a structure.

This proved to be the case in my experiments. For example, the companion bars to those which had broken with 18,000 reversals of a stress less than half the original breaking weight behaved, when tested as columns thirty diameters in length, precisely the same as similar bars which had done no work at all, whereas when tested in tension the elongation was reduced from the original 25 per cent. to 2·5 per cent., and the fracture appeared to indicate that the bars had been made of three different kinds of steel imperfectly welded together. With a stress reduced by one-fourth the number of bendings required to break the bars was increased to 1,200,000. In this instance the calculated maximum working stress on the extreme fibres was 43 per cent. of the direct ultimate tensile resistance of the steel, and about 30 per cent. of the stress the bar was capable of sustaining as a beam under the single application of a load. Of course, the bars failed by tension, and the extreme fibres had thus deteriorated as regards tensile stresses to the extent indicated by the above percentages. Tested as a column, however, the injury the bar had received from the 1,200,000 bendings was inappreciable. The ductility was of course very largely reduced, but ductility is a quality of comparatively little importance when a material is in compression. There is no ductility in the slender Gothic stone columns of our cathedrals, which, though heavily stressed, have carried their loads for centuries. As I found repeated bendings raised the limit of elasticity, I rather anticipated finding an increased resistance from this cause in long columns. This did not prove to be the case, nor did I find any difference in short columns four diameters in length.

In addition to the preceding experiments with rectangular bars, I have tested the endurance of many revolving shafts of cast iron, wrought iron, and steel, with similar results. About 5000 reversals of a stress equal to one-half the static breaking weight sufficed generally to cause the snapping of a shaft of any of the above materials. When the stress was reduced and the number of applications increased, I found the relative endurance of solid beams to be more nearly proportional to the tensile strength of the metal than to the breaking weight of the beam, a distinction of great importance where axles, springs, and similar things are concerned. Many of my experiments were singularly suggestive. Thus, it was instructive to see a bar of cast iron loaded with a weight which, according to Fairbairn's experiments, it should have carried for a long series of years, broken in two minutes when set gently rotating. Also to find a bar of the finest mild steel so changed in constitution by some months of rotation as to offer no advantages either in strength or toughness over a new cast-iron bar of the same section.

Although, as already stated, many more experiments are required before universally acceptable rules can be laid down, I have thoroughly convinced myself that, where stresses of varying intensity occur, tension and compression members should be treated on an entirely different basis. If, in the case of a tension member, the sectional area be increased 50 per cent. because the stress, instead of being constant, ranges from *nil* to the maximum, then I think 20 per cent. increase would be a liberal allowance in the case of a compression member. I have also satisfied myself that if a metallic railway bridge is to be built at a minimum first cost, and be free from all future charges for structural maintenance, it is essential to vary the working stress upon the metal within very wide limits, regard being had not merely to the effect of intermittent stresses, but also to the relative limits of elasticity in tension and compression members even under a steady load.

Why an originally strong and ductile metal should become weak and brittle under the frequent repetition of a moderate stress has not yet been explained. Lord Bacon touched upon the subject two or three centuries ago, but you may consider his explanation not wholly satisfactory. He said, "Of bodies, some are fragile, and some are tough and not fragile. Of fragility, the cause is an impotency to be extended, and the cause of this inaptness is the small quantity of spirits." I am sorry to have no better explanation to offer, but whatever may be the immediate cause of fragility, no doubt exists that it is induced in metals by frequent bendings, such as a railway bridge undergoes. This fact, however, is not recognised in our Board of Trade Regulations, which remain as they were in the dark ages, as do those of the Ministry of Public Works of France and other countries. With us it is simply provided that the stress on an iron bridge must not exceed 5 tons per square inch on the effective section of the metal. In France it is still worse, as the limiting stress of rather under 4 tons per square inch is estimated upon the gross section, regardless of the extent to which the plates may be perforated by rivet holes. In neither case is any regard had in the rules to intermittent stresses or the flexure of compression members. In Austria the regulations make a small provision for these elements; and American specifications make a large one, the limiting stresses, instead of being constant at 5 tons, as with us, ranging from about 2½ tons to 6¾ tons per square inch, according to circumstances. It is hardly necessary that I should say more to justify my statement that, as regards the admissible intensity of stress on metallic bridges, absolute chaos prevails.

Engineers must remember that if satisfactory rules are to be framed, they, and not Governmental departments, must take the initiative. In former days the British Association did much to direct the attention of engineers to this important matter, but, so far as I know, the subject has been dropped for the past twenty years, and I have ventured, therefore, to bring it before you again in some detail. We are here avowedly for the advancement of science, and I have not been deterred by the dryness of the subject from soliciting your attention to a branch of science which is sadly in need of advancement.

Had I been addressing a less scientific audience I might have been tempted rather to boast of the achievements of engineers than to point out their shortcomings. The progress in many branches of mechanical science during the past fifty years has exceeded the anticipation of the most far-seeing. Fifty years ago the chairman of the Stockton and Darlington Railway, when asked by a Parliamentary committee if he thought any further improvements would be possible on railways, replied that he understood in future all new railways would have a high earthwork bank on each side to prevent engines toppling over the embankments, and to arrest hot ashes, which continually set fire to neighbouring stacks, but in other respects he appeared to think perfection was attained. Shortly before the introduction of locomotives it was also thought perfection was attained when low trucks were attached to the trains to carry the horses over the portions of the line where descending grades prevailed, and all the newspapers announced, with a great flourish of trumpets, that a year's experience showed the saving in horseflesh to be fully 33 per cent.

Although these views seem childlike enough from our present standpoint, I have no doubt that as able and enterprising engineers existed prior to the age of steam and steel as exist now, and their work was as beneficial to mankind, though different in direction. In the important matter of water supply to towns, indeed, I doubt whether, having reference to facility of execution, even greater works were not done 2000 years ago than now. Herodotus speaks of a tunnel 8 feet square, and nearly a mile long, driven through a mountain in order to supply the city of Samos with water; and his statement, though long doubted, was verified in 1882 through the abbot of a neighbouring cloister accidentally unearthing some stone slabs. The German Archæological Society sent out Ernst Fabricius to make a complete survey of the work, and the record reads like that of a modern engineering undertaking. Thus, from a covered reservoir in the hills proceeded an arched conduit about 1000 yards long, partly driven as a tunnel and partly executed on the "cut and cover" system adopted on the London underground railway. The tunnel proper, more than 1100 yards in length, was hewn by hammer and chisel through the solid limestone rock. It was driven from the two ends like the great Alpine tunnels, without intermediate shafts, and the engineers of 2400 years ago might well be congratulated for getting only some dozen feet out of level and little more out of line. From the lower end of the tunnel branches were constructed to supply the city mains and fountains, and the explorers found ventilating shafts and side entrances, earthenware socket-pipes with cement joints, and other interesting details connected with the water-supply of towns.

In the matter of masonry bridges, also, as great works were undertaken some centuries ago as in recent times. Sir John Rennie stated, in his presidential address at the Institute of Civil Engineers, that the bridge across the Dee at Chester was the "largest stone arch on record." That is not so. The Dee Bridge consists of a single segmental arch 200 feet span and 42 feet rise; but across the Adda, in Northern Italy, was built, in the year 1377—more than 500 years ago—a similar segmental arch bridge of no less than 237 feet span and 68 feet rise. Ferario not long since published an account of this, for the period, colossal work, from which it would appear that its life was but thirty-nine years, the bridge having been destroyed for military reasons on December 21, 1416. I believe our American cousins claim to have built the biggest existing stone arch bridge in the world—that across the Cabin Johns Creek; but the span, after all, is only 215 feet, or 10 per cent. smaller than the 500-year-old bridge. In timber bridges, doubtless, the Americans will ever head the list, for the bridge of 340 feet span built across the Schuylkill three-quarters of a century ago will probably never be surpassed. Our ancestors were splendid workers in stone and timber, and, if they had been in possession of an unlimited supply of iron and steel I fear there would have been little left for modern bridge-builders to originate.

The labours of the present generation of engineers are lightened beyond all estimate by labour-saving appliances. To prove how much the world is indebted to students of this branch of mechanical science, and how rapid is the development of a really good mechanical notion, it is only necessary to refer to the numerous hydraulic appliances of the kind first introduced forty years ago by a distinguished past-President, Sir W. G. Armstrong. Addressing you in 1854, Sir William Armstrong explained that the object he had in view from the first was "to provide, in substitution of manual labour, a method of working a multiplicity of machines, intermittent in their action and extending over a large area, by means of transmitted power, produced by a steam-engine and accumulated at one central point." The number of cases in which this method of working is a desideratum, or even indispensable, would appear to be limitless. I should be sorry, indeed, to have anything to do with building the Forth Bridge if hydraulic appliances were not at hand to do a giant's work. Let me shortly describe to you what we are doing there at the present time. More than 42,000 tons of steel plates and bars have to be bent, planed, drilled, and riveted together before or after erection, and hydraulic appliances are used throughout. The plates are handled in the shops by numerous little hydraulic cranes of special design, without any complication of multiplying sheaves, the whole arm being raised with the load by a 4-inch direct-acting ram of 6 feet stroke. A total length of no less than 60 miles of steel plates, ranging in thickness from 1¼ inches to ⅜ inch, have to be bent to radii of from 6 feet to 9 inches, which is done in heavy cast-iron dies squeezed together by four rams of 24 inches in diameter, and the same stroke. With the ordinary working pressure of 1000 lbs. per square inch, the power of the press is thus about 1750 tons. Some 3000 pieces, shaped like the lid of a box, 15 inches by 12 inches wide, with a 3-inch deep rim all round, were required to be made of ½-inch steel plate, and this was easily effected in two heats by a couple of strokes of a 14-inch ram. In numberless other instances steady hydraulic pressure has been substituted by Mr. Arrol, our able contractor, for the usual cutting and welding under the blacksmith's hammer.

Hydraulic appliances are also an indispensable part of the scheme for erecting the great 1700 feet spans. Massive girders will be put together at a low level, and be hoisted as high as the top of St. Paul's Cathedral by hydraulic power. Continuous girders, nearly a third of a mile in length, will be similarly raised. Not only the girders, but workmen, their sheds, cranes, and appliances will be carried up steadily and imperceptibly as the work of erection proceeds, on platforms weighing in some instances more than 1000 tons. It is hardly necessary to say that every rivet in the bridge will be closed up by hydraulic power, the machines being in many instances of novel design, specially adapted to the work. Thus the bed-plates, which in ordinary bridges are simple castings, in the Forth Bridge are necessarily built up of numerous steel plates, the size of each bed-plate being 37 feet long by 17 feet 6 inches wide. To grip together the 47 separate plates into a solid mass, 3800 rivets 1⅛ inches in diameter with countersunk heads on both sides are required, and, remembering that the least dimension of the bed-plate is 17 feet 6 inches, it will be seen that the ordinary "gap"-riveter would not be applicable. A special machine was therefore designed by Mr. Arrol, consisting of a pair of girders and a pair of rams, between which the bed-plate to be riveted together lies. A double ram machine had for like reasons to be devised for riveting up the great tubular struts of the bridge.

Not merely in the superstructure, but in the construction of the foundations, were hydraulic appliances of a novel character indispensable at the Forth Bridge. Huge wrought-iron caissons or cylinders, 70 feet diameter and 72 feet high, were taken up and set down as readily as a man would handle a bucket. In sinking these caissons through the mud and clay of the Forth compressed air was used. When the boulder-clay was reached the labour of excavating the extremely hard and tenacious material in the compressed-air chamber proved too exhausting, pick-axes were of little avail, and the Italian labourers who were chiefly employed lost heart over the job altogether. But a giant power was at hand, and only required tools fit for the work. Spades with hydraulic rams in the hollow handles were made, and, with the roof of the compressed air-chamber to thrust against, the workmen had merely to hold the handle vertically, turn a little tap, and down went the spade with a force of three tons into the hitherto impracticable clay as sweetly as a knife into butter. Probably, when addressing you thirty years ago, Sir William Armstrong never anticipated that a number of hydraulic spades would be digging away in an electrically lighted chamber or diving-bell, 70 feet diameter and 7 feet high, 90 feet below the waves of the sea; but still the spades come strictly within the definition of the class of machines, intermittent in their action and extending over a large area, which it was his aim to introduce. It would be possible, indeed, with the appliances at the Forth Bridge, to arrange that the simple opening of a valve should start digging at the bottom of the sea, riveting at a height of nearly 400 feet above the sea, and all the multifarious operations of bending, forging, and hoisting, extending over a site a mile and a half in length.

It would not only be impossible to build a Forth Bridge, but it would be equally impossible to fight a modern ironclad without the aid of hydraulic appliances. Most of the Presidents of this Section have referred in the course of their addresses to our navy, and certainly the subject is a tempting one, for the progress of mechanical science in recent years could not be better illustrated than by a description of the innumerable appliances which go to the making and working of a modern ironclad. Let me quote a single passage from a pamphlet by a naval officer, which caused a great stir a few years before the Crimean war, that I may recall to your minds what was the speed and what the armament of our fleet at that comparatively recent period. "Conceive," said Capt. Plunkett, R.N., "a British and French fleet issuing simultaneously from Spithead and

Cherbourg; seven hours' steaming at the rate of six miles an hour will bring them together. A single glance at the heavy and well-appointed tiers of a line-of-battle ship's guns will satisfy any one that they are no toys to be placed in the hands of novices. Formidable batteries of the heaviest ordnance are there—not a gun under a 32-pounder, and many 68-pounder shell guns." In little more than a quarter of a century engineers have changed all that, and advanced to 20-knot vessels and 120-ton guns. Archæologists tell us that our predecessors in mechanical science of the Stone Age were apparently a thousand or more years in finding out that the best way of fitting an axe was to slip the handle through the axe and not the axe through the handle. Engineers of the present day may be excused, therefore, for occasionally illustrating the rapidity of the advance of their science by contrasting the ships of thirty years ago with our modern ironclads.

The latest type of battle-ship weighs, fully equipped, about 10,000 tons. There are about 3400 tons of steel in her hull, apart from armour, which, with its backing, will weigh a further 2800 tons. The machinery, largely of steel, is about 1400 tons; the armament, including ammunition, 1100 tons; the coals, 1100 tons; and general equipment, 270 tons. A detailed description bristles with the word "steel," and enthusiastic newspaper reporters sent down to Chatham Dockyard can no more "spin out their copy" with Cowper's oft-quoted lines on the "Launch of a First-Rate":—

"Giant oaks of bold expansion
O'er seven hundred acres fell,
All to build thy noble mansion,
Where our hearts of oak do dwell."

A latter-day poet might boast of 700 acres being exhausted by a single vessel, but it would be a coal-field and not a forest. Accepting Prof. Phillips's estimate of the average rate of formation of coal, it may be shown that a hard-worked American liner during her lifetime burns as much coal as would be produced on the area of 700 acres in a period of 2000 years. We are thus with our steel ships using up our primeval forests at a far more extravagant rate than that at which our immediate forefathers cleared the oak forests. Coal is the great stimulant of the modern engineer. Pope Pius the Second has left on record an expression of the astonishment he felt when visiting Scotland, in the fifteenth century, on seeing poor people in rags begging at church doors, and receiving for alms pieces of black stone, with which they went away contented. To such early familiarity with coal may, however, be due the fact that Scotland has ever led the way in the development of the steam-engine, and that at the date of the battle of Waterloo she had built and registered seven steam-vessels, whilst England could boast of none.

Probably none but a poet or a painter would wish for a return to our old oak sailing ships. Some few people still entertain the illusion that the picturesque old tubs were better sea-boats than our razor-ended steamers; but, speaking of them in 1846, Admiral Napier said: "The ships look very charming in harbour, but to judge of them properly you should see them in a gale of wind, when it would be found they would roll 45° leeward and 43° windward." Even our first ironclads were not so bad as that, for although, according to the *Times*, when the squadron was on trial in the Bay of Biscay, the ships rocked wildly to the rising swell and the sea broke in great hills of surf, yet the maximum roll signalled by the worst roller of the lot—the *Lord Warden*—was but 35° leeward and 27° windward—a total range of 62° as compared with 88° in the old line-of-battle ships.

We have heard much about the state of the navy during the past twelve months. A dip into the publications of the British Association—which in this, as in other respects, afford a fair indication of what is uppermost in people's minds—will show that similar discussions have recurred periodically, at any rate since 1830. If we consult Hansard, as I had occasion to do recently, we find the same remark applies to periods long antecedent to 1830.

It amounts almost to a religious conviction in the mind of a Briton that Providence will not be on his side unless his fleet is at least equal to that of France and Russia united. What would be said now of a Minister who met an attack on the administration of the navy by demonstrating that we had *half* as many line-of-battle ships as Russia: and yet that was literally done less than fifty years ago. Speaking in the House of Commons on March 4, 1839, the Secretary of the Admiralty said: "For the last six months unceasing attacks have been made upon our naval administration, describing our navy as in a state of the utmost decrepitude, and Tory papers say that shameful reductions have been made in the navy by the present Government. It will be a consolation to my honourable friends to be assured that we have for years lived unharmed through dangers as great as that to which we are now exposed. In 1817 we had 15 sail-of-the-line in commission, and Russia had 30; in 1823 we had 12, and Russia 37; in 1832 we had 11, and Russia 36; and now we have 20, and the Russians 43, having raised our ships to nearly half the number of those of Russia.

Now as to our guns. The past twelve months is by no means the first occasion on which the armament of our navy has been attacked. Three years subsequent to the speech of the Secretary of the Admiralty just referred to, Sir Charles Napier made a statement from his place in Parliament of so extraordinary a character that I make no apology for quoting his exact words, as a reminder of the past and a warning for the future: "At the end of the last war the guns were in such a bad state that, when fired, they would scarcely hit an enemy, and during the latter period of the American war a secret order was issued that British ships of war should not engage American frigates, because the former were in such an inefficient state." As for himself, said the plain-spoken old admiral, when he got the order he put it in "the only place fit to receive it, the quarter-galley."

Happily, from our insular position, the change which the progress of mechanical science has wrought in military operations has not been brought home to the people of this country in the same vivid manner that it has to the people of the continents of Europe and America. In the American war, the Franco-German war, and the Russo-Turkish war the construction and equipment of railway works by engineers was an essential part of all great movements. The Russians, in 1877, constructed a railway from Bender to Galatz, 180 miles in length, in fifty-eight working days, or at the rate or more than three miles per day. Altogether, in the three latter months of that year they laid out and built about 240 miles of railway, and purchased and stocked the line with 110 locomotives and 2200 waggons. They also built numerous trestle bridges, together with an opening bridge and a ferry across the Danube.

We have had recent experience of the slowness of primitive modes of transport in the tedious advance of Lord Wolseley's handful of men in whale-boats up the Nile. It was the intention of the late Khedive, partly from military and partly from commercial considerations, to construct a railway exactly on the line of advance subsequently followed by Wolseley. My partner, Mr. Fowler, had the railway sent out in 1873, and the works were shortly after commenced. The total length was 550 miles, and the estimated cost, including rolling-stock and repairing-shops, 4,000,000*l*. Owing to financial difficulties the works were abandoned, but the 64 miles constructed by Mr. Fowler, and the recent extensions of the same by the military, proved of great service to the expedition, even some of the steam-launches being taken by railway to save delays at the cataracts.

During the siege of Paris the German forces were dependent upon supplies drawn from their base, and the army requirements were fully met by one line of railway running twelve to fourteen trains per day. Military authorities state that a train load of about 250 tons is equal to two days' rations and corn for an army corps of 37,000 men and 10,000 horses. The military operations in Egypt have proved that, even in the heart of Africa, railways, steamboats, electric lights, machine guns, and other offspring of mechanical science, are essential ingredients of success.

Members of this Section who visited the United States last year not for the first time could hardly have failed to notice that American and European engineering practice are gradually presenting fewer points of difference. Early American iron railway bridges were little more than the ordinary type of timber bridge done into iron, and the characteristic features, therefore, were great depth of truss, forged links, pins, screw-bolts, round or rectangular struts, cast-iron junction pieces, and, in brief, an assemblage of a number of independent members more or less securely bolted together, and not, as in European bridges, a solidly riveted mass of plates and angle-bars. At the present moment the typical American bridge is distinctly derived from the grafting of German practice on the original parent stock. Pin connections are still generally used in bridges of any size, but the top members and connections are more European than

American in construction, whilst for girders of moderate span, such as those on the many miles of elevated railway in New York, riveted girders of purely European type are admittedly the cheapest and most durable. From my conversations with leading American bridge builders, I am satisfied that their future practice and our own will approach still more nearly. We should never think of building another Victoria tubular bridge across the St. Lawrence, or repeat the design of the fallen Tay Bridge, nor would they again imitate in iron an old timber bridge, or repeat the design of the fallen Ashtabula bridge. In one respect the practice in America tends to the production of better and cheaper bridges than does our own practice, and it is this: each of the great bridge-building firms adopts by preference a particular type design, and the works are laid out to produce bridges of this kind. It is an old adage that practice makes perfect, and by adhering to one type, and not vaguely wandering over the whole field of design, details are perfected and a really good bridge is the result. Engineers in America therefore need only specify the span of their bridge, and the rolling load to be provided for, with certain limiting stresses, and they can make sure of obtaining a number of tenders from different makers of bridges, varying somewhat in design, but complying with all the requirements. With us, on the other hand, it is too often the privilege of a pupil to try his 'prentice hand on the design for a bridge, and it is no wonder, therefore, that many curious bits of detail meet the eye of an observant foreigner inspecting our railways.

The magnificent steel wire rope suspension bridge of 1600 feet span built by Roebling across the East River at New York well marks the advanced state of mechanical science in America as regards bridge-building. It is worthy of note that, at the second meeting of the British Association, held so long back as 1832, there was a paper on suspension bridges, and the author entreated the attention of the scientific world, and particularly of civil engineers, to the serious consideration of the question: "How far ought iron to be hereafter used for suspension bridges, since a steel bridge of equal strength and superior durability could be built at much less cost?" "I earnestly call upon the ironmasters of the United Kingdom," said he, "to lose no time in endeavouring to solve this question." In this, as in many other engineering matters, America has given us a lead. America, is indeed, the paradise of mechanics. When the British Association was inaugurated, years ago, there was, I believe, no intention to have a section for the discussion of mechanical science. Possibly it may have been considered too mean a branch. Even the usually generous Shakespeare speaks contemptuously of "mechanic slaves, with greasy aprons, rules, and hammers;" and our old friend Dr. Johnson's definition of "mechanical" is "mean, servile." We have lived down this feeling of contempt, and the world admits that the "greasy apron" is as honourable a badge as the priest's cassock or the warrior's coat of mail, and has played as important a part in the great work of civilising humanity and turning bloodthirsty savages into law-abiding citizens.

As I have had occasion to refer to Canada and America in the course of my remarks, I cannot refrain from expressing the high appreciation which I am sure every member of this Section entertains of the cordiality and warmth of our reception on the other side of the Atlantic last year. Such incidents make us forget that differences have ever existed between the two countries. I was amused the other day, on reading in Dr. Doran's "Annals of the Stage," that, in the year 1777, the theatrical company from Edinburgh was captured on its voyage to Aberdeen by an American privateer, and taken off Heaven knows where, for it did not turn up again. This, you will say, was a long time ago; but, if you glance through the speeches of our present gracious Sovereign, you will find one in which her Majesty speaks with "deep concern" of insurrection in Lower Canada, and of hostile incursions into Upper Canada by certain "lawless inhabitants" of the United States of North America.

This is strange reading, after our last year's experience. Gentlemen, I may not have carried you with me in some things I have said, but I think you will all agree with me in this: that the statesman who should suffer any slight difference of opinion to develope into a serious breach between ourselves and our brethren in Canada and cousins in America would, to quote the words of Burke, "far from being qualified to be directors of the great movements of this empire, be not fit even to turn a wheel in the machine."

NOTES

THE new gallery of fishes at the Natural History Museum is now open to the public, and an addition has been made to the Osteological Gallery by throwing open the pavilion at the west end, in which are exhibited skeletons and skulls of elephants, the giraffe, &c.

A REPORT is current in Rome that the members of the Italian Expedition to Central Africa, under the leadership of Signor Alfredo Massari, have been massacred.

THE natural history collections made by the late Dr. Nachtigal, in the course of his tour of annexation on the west coast of Africa, have arrived at Berlin in twenty cases, and the greater part of their contents will be assigned to the new ethnological museum.

AN astronomical-mathematical section, under the presidency of Profs. Reye and Christoffel, of Strassburg, has been formed in the Scientific Congress at Strassburg.

M. BOUQUET, a mathematician of some eminence and a Sorbonne professor, died on the 10th instant at the age of sixty-six.

THE death is announced of Mr. W. A. Guy, M.B., F.R.S., on the 10th inst., in the seventy-sixth year of his age. He was for a number of years Dean of the Medical Department in King's College, and Professor of Hygiene. He was admitted a Fellow of the Royal College of Physicians in 1844, held office as censor in 1855, 1856, and 1866, and as examiner in 1861–3, and in 1861, 1868, and 1875 was appointed Croonian, Lumleian, and Harveian lecturer. Mr. Guy also held a number of other appointments, among which were—honorary secretary to the Statistical Society in 1845, and President in 1873, examiner in forensic medicine at the University of London in 1862, Swiney Prizeman, 1869, and Vice-President of the Royal Society in 1876-7. Mr. Guy devoted much attention for many years to questions of sanitary reform and social science, and in 1878 was appointed one of the Royal Commissioners to inquire into the working of the Penal Servitude Acts; also in 1879 a member of the Criminal Lunatic Commission. He was the author of many essays on physiology and kindred subjects, and also of works of a more general character. Among his principal publications may be mentioned "Principles of Forensic Medicine," "Public Health," "The Factors of the Unsound Mind," "John Howard's Winter's Journey," and his last work, "The Claims of Science on Public Recognition and Support." It may be added that Mr. Guy was likewise editor of Hooper's "Physician's Vade-Mecum."

COL. PRJEVALSKY has sent the following message, dated July 1, from his camp in Chinese Turkestan:—"It is impossible to penetrate into Tibet by the Keria Mountains, the passes through them being impracticable for our beasts of burden, and the Chinese having obstructed the paths with rocks, and having also destroyed the bridges. The native population has given us everywhere a good reception, and, despite the interference of the Chinese, their sympathies with the Russians are openly pronounced. We shall pass the present month among the snow-covered mountains between the rivers of Keria and Khoten. About the middle of August we shall go to Khoten, and then by the course of the river of the same name to Aksu. All is well."

THE inaugural address at the commencement of the medical session 1885-86 will be delivered at St. Thomas's Hospital on October 1, at 3 p.m., by A. O. MacKellar, M.Ch., F.R.C.S., in the theatre of the hospital.

AT the request of the Batavian Society of Arts and Sciences, the Government of the Netherlands' Indies has taken a step which might be imitated by other Governments with advantage. It has distributed fifty copies of Prof. de Hollander's "Handleiding bij de Beoefening der Land- en Volkenkunde von Neder. Oost Indië" to its officials in all parts of its colonies, and has instructed them to compare their own observations with the statements in the work, and to report the result.

THE German Government has despatched a mission under Baron Pring to the Cheshire salt districts, charged with an investigation of the local industry, and especially of the phenomenon of land subsidence through brine pumping, Prince Bismarck being about to propose certain legislation affecting similar landslips in Germany.

WITH reference to Mr. G. J. Symons's letter last week on the subject of the trees in Richmond Park struck by lightning, Mr. Percy Smith writes to the *Times* that "the most probable cause of the liability of certain trees to be struck by lightning is that they are bad conductors of electricity. The suggestion that oak trees are struck because they contain iron is both erroneous and absurd. If oak did contain iron it would in all probability increase its conducting power and act as a preservative. If oak contained an estimable quantity of that metal the wood would turn black on exposure to air, on account of the tannin which is present. This blackening may be seen surrounding the iron nails in any oak fence. The contour of the ground, nature of the soil, and the presence or absence of water has more influence in deciding the locality of an electric discharge than the height of a tree. Add to this the difference in conductibility between various woods and we have at once an explanation of the apparent peculiarity of tall trees escaping unharmed while shorter trees are destroyed."

ONE of the proofs commonly advanced for the theory that the cold in northern regions has increased in historic times is that there is an increase of ice on the eastern shores of Greenland; another is that barley, which was successfully grown in Iceland from its first settlement in 870 down to the middle of the fifteenth century, is no longer cultivated there. It is, therefore, of much interest to learn from *Globus* that the Icelandic Government lately attempted to grow barley in the island on a considerable scale, and that the results were very favourable. Norwegian barley from Altenfjord, which is on the extreme north of the barley-growing zone, was planted and was fit for cutting down in eighty-nine days. The decline in the cultivation of barley in Iceland was really due, not to an increase in the cold, but to the fact that cattle-breeding paid better. Attempts are being made to grow other plants: at Reikjavik a botanical garden has been established, and the seeds of 382 kinds of plants which occur around Christiania have been planted there. It is probable, therefore, that the scanty garden flora of Iceland will be increased in the near future.

AT the recent meeting of the French Association at Grenoble, M. de Mortillet read a paper on Tertiary man before the anthropological section. The question, he said, was not to know whether man already existed in the Tertiary epoch as he exists at the present day. Animals varied from one geological stratum to another, and the higher the animals the greater was the variation. It was to be inferred, therefore, that man would vary more rapidly than the other mammals. The problem was to discover in the Tertiary period an ancestral form of man, a predecessor of the man of historical times. M. de Mortillet affirmed that there were unquestionably in the Tertiary strata objects which implied the existence of an intelligent being. These objects have, in fact, been found at two different stages of the Tertiary epoch—in the lower Tertiary at Thenay, and in the Upper Tertiary at Otta, in Portugal, and at Puy Courny, in Cantal. These objects proved that at these two distant epochs there existed in Europe animals acquainted with the use of fires and able more or less to cut stone. During the Tertiary period, then, there lived animals less intelligent than existing man, but much more intelligent than existing apes. M. de Mortillet gives the name of *anthropitheque*, or ape-man, to the species, which, he maintains, was an ancestral form of historic man, whose skeleton has not yet been discovered, but who has made himself known to us in the clearest manner by his works. A number of flints were exhibited from the strata in question, which had been intentionally chipped and exposed to fire. The general opinion of the *savants* assembled at Grenoble was that there can be no longer any doubt of the existence in the Tertiary period of an ancestral form of man.

AN ingenious instrument for ascertaining the distances of accessible and inaccessible points from the observer and from each other has been invented by Dr. Luigi Cerebotani, a Professor of the University of Verona. This apparatus consists mainly of a pair of telescopes mounted on a stand and fixed on a tripod for use. The telescopes are both brought to bear on the object, and a reading is then taken from a graduated scale on the instrument, which, compared with a set of printed tables, gives the distance. By this means the inventor obviates the necessity for the base line, which has hitherto had to be laid down in these operations, and he dispenses with all trigonometrical calculations. Distances can be measured between far-off objects, and, by means of a sheet of paper fixed on a drawing-board, a rough plan of the country under measurement can be sketched. In the same way the distances of ships at sea or of moving objects on land can be determined. The apparatus appears to be well adapted for land-surveying, and particularly for military purposes. In fact, it is stated to have been already adopted in the German army in the latter connection, and it is about to be tried by the authorities of our own War Department. A practical trial was made with this instrument on the Thames Embankment on the 11th inst., when its varied usefulness was demonstrated.

WE have received from the Director of the Batavia Observatory a volume containing statistics of the rainfall in the East Indian Archipelago for the year 1884. Rainfall observations were made during the year at 145 stations without interruption, although at the end of the year there were 172 stations, 94 of which were on the islands of Java and Madura.

IT is stated that the Physical and Mathematical Society of Tokio has decided in future to print its official proceedings in Japanese written in Roman letters instead of Chinese characters, although the authors of papers may employ any style or language they please. A similar step is in contemplation by the Japanese Chemical Society.

IN a note in a late issue of the *Bulletin* of the United States Fish Commission, Prof. Verrill discusses the question how long oysters will live out of water. In a fishmonger's in New Haven his attention was drawn to a large cluster of oysters attached to an old boot which hung in the window from about December 10 to February 25, when he found several of the larger oysters still alive. Most of the smaller and many of the larger ones were dead and dried up; in the case of the latter the edges of the shells had been broken or chipped. Those that were alive had all been hung up with the front edge of the shell downward and the hinge upward. They had been hanging in the show window, attached to a gas burner, freely exposed to the air and light. The place was doubtless cool, but the air must have been dry, and temperature variable. The remarkable duration of the lives of these oysters he attributes to two causes: first, the perfect condition of the edges of the shells, which allowed them to close up very tightly; secondly, the position—suspended as they were with the front edge downward—is the most favourable one possible for the retention of water within the gill-cavity, for in this position the edges of the mantle would closely pack against the inner edges of the shell, effectually closing any small leaks, and the retained water would also be in the most favourable position to moisten the gills, even after part had evaporated. It is also possible that when in this position the oyster instinctively keeps the shell tightly closed, to prevent the loss of water. This incident, says Prof. Verrill, may give hint of the best mode of transporting oysters and clams long distances. Perfect shells should be selected, and they should be packed with the front edge downward, and kept moderately cool, in a crate or some such receptacle which will allow a free circulation of air. Under such favourable conditions selected oysters can doubtless be kept from eight to twelve weeks out of water. Mr. Ryder, of Washington, adds that he has had oysters live in the shell for two weeks, where the temperature ranged from 30° to over 80° F., lying on shelves in the cases in his work-room, exposed the whole time to the air, without showing the slightest tendency to decompose.

THE schooner *Rosario*, at New York, reports than on June 23, in lat. 29° 14′ N. and long. 133° 25′ W., at 11 a.m., two heavy shocks of submarine earthquake were experienced. These were about one minute apart, and the last was much heavier than the first, causing the vessel to tremble violently. The sky was overcast, and the sea remarkably smooth.

THE Russian Geographical Society is said by the St. Petersburgh journals to contemplate sending a scientific expedition to the Amour for the purpose of studying the surrounding region with regard to its geographical, historical, and commercial features, as well as its mineral resources.

IT is announced in Brussels that the German Lieutenant Weissmann, who is in the service of the African Association, has discovered that the River Kassaï, which was always believed to join the Congo above the equator station, forms a curve and falls into Lake Leopold II.

ON the night of August 31 to September 1 temperature fell to a lower point in several districts than is known to have ever before happened so early in the season. Over upper and middle Strathspey in particular the frost was very severe. At Kingussie the protected thermometer fell to 24°·9 and the exposed to 18°·0, while at Grantown the exposed thermometer fell to 15°·0, these being all compared instruments and in good order. At Kingussie ice an inch thick was found on the water supplying the hygrometer. In this large district the potato crop is completely destroyed, not only in low-lying situations but also on the high-lying slopes. On the other hand, on crossing from Inverness-shire into Perthshire, the potato crop is safe, the tops being only slightly blackened. At the Ben Nevis Observatory on the same night, with a sky equally clear and cloudless as was over Strathspey, the protected thermometer fell only to 32°·9 and the exposed thermometer to 24°·6, being respectively 8°·0 and 6°·6 higher than occurred at Kingussie on the same night.

THE additions to the Zoological Society's Gardens during the past week include a Barbary Ape (*Macacus inuus*) from North Africa, presented by Miss Bedford; at Bank Vole (*Arvicola pratensis*) from Essex, presented by Mr. E. Rosling; a Common Hedgehog (*Erinaceus europæus*), British, presented by Master C. Hanrott; a Common Polecat (*Mustela putorius*), British, presented by Mr. W. Buckley; an Undulated Grass Parrakeet (*Melopsittacus undulatus*) from Australia, presented by Mdlle. de Nujac; a Smooth Snake (*Coronella lævis*) from Dorsetshire, presented by the Rev. O. P. Cambridge, C.M.Z.S.; two Douglass's Horned Lizards (*Phrynosoma douglassi*) from New Mexico, presented by Dr. R. W. Shufeldt; two Common Chameleons (*Chamæleon vulgaris*) from North Africa, presented by Mr. F. Bland.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, SEPTEMBER 20-26

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on September 20

Sun rises, 5h. 44m.; souths, 11h. 53m. 16·2s.; sets, 18h. 2m.; decl. on meridian, 0° 56′ N.: Sidereal Time at Sunset, 18h. 1m.

Moon (Full on Sept. 24) rises, 16h. 21m.; souths, 21h. 21m.; sets, 2h. 27m.*; decl. on meridian, 12° 12′ S.

Planet	Rises	Souths	Sets	Decl. on meridian
	h. m.	h. m.	h. m.	° ′
Mercury	4 1	10 50	17 39	8 51 N.
Venus	9 12	14 7	19 2	13 11 S.
Mars	0 23	8 21	16 19	20 42 N.
Jupiter	4 52	11 23	17 54	5 21 N.
Saturn	22 27*	6 35	14 44	22 20 N.

* Indicates that the rising is that of the preceding and the setting that of the following day.

Occultations of Stars by the Moon

Sept.	Star	Mag.	Disap.	Reap.	Corresponding angles from vertex to right for inverted image
			h. m.	h. m.	° °
20	18 Aquarii	6	18 47	19 55	49 305
21	B.A.C. 7774	6	22 8	23 22	136 283
24	B.A.C. 8365	6½	5 12	6 5	124 350
25	μ Piscium	5	20 12	21 9	94 233
26	B.A.C. 741	6½	21 19	22 3	26 299

The Occultations of Stars are such as are visible at Greenwich.

Sept.	h.	
20	8	Mercury at least distance from the Sun.
22	–	Sun in equator.
24	–	Partial eclipse of the Moon, but the Moon will set at Greenwich at about sunrise whilst partly obscured by the penumbra and before entering the shadow.

SCIENTIFIC SERIALS

The Proceedings of the Royal Society of Queensland, 1884, vol. i. parts 2, 3, 4.—We are glad to see that this new Society in one of our leading colonies is advancing rapidly. In the parts before us Mr. Tryon describes certain rock-drawings of the aborigines of Queensland, of a class hitherto undescribed (with plates). Mr. C. W. de Vis, who is one of the most indefatigable contributors, writes on new Australian lizards; on a new form of the genus Therapon; on new Queensland lizards; on a new species of Hoplocephalus; on an apparently new species of Halmaturus; on a new species of Hyla; a description of new snakes with a synopsis of the genus Hoplocephalus; on the fauna of the Gulf of Carpentaria, and a conspect of the genus Heteropus. Mr. Bailey gives instalments of his contributions to Queensland Flora. Mr. Broadbent writes on the migrations of birds at the Cape York peninsula, which is a peculiarly favourite spot for observing the migrations of birds from and to New Guinea, for the passage is shortest here. Ethnology is well represented in the numbers before us, for, besides the paper by Mr. Tryon mentioned above, we have one by Dr. Bancroft on the food of the aborigines of Central Australia, and one by Mr. Duffield on the inhabitants of New Ireland and its archipelago, their fine and industrial arts, customs, and language, especially their tattooing. Mr. Knight describes a new species of Parmelia, and Baron von Müller, the *Dendrobium cincinnatum*, sp. nov. Mr. Bernays describes exotic fruits new to Queensland. Mr. Pink pleads for the practice of hybridisation of plants; and Dr. Bancroft describes experiments with Indian wheats in Queensland. There are numerous other minor contributions.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, August 31.—M. Bouley, President, in the chair.—On the cyclonic character of the solar spots, in reply to M. Tacchini's objection, by M. Faye. In their normal state the spots, like terrestrial cyclones, are described as of circular form, with funnel-shaped penumbra, concentric circumferences, and vertical axis, varying in size from almost imperceptible pores to abysses large enough to engulph the earth. The mechanical identity of the two phenomena is thus established, while the absence of this special disposition in the penumbra of certain spots proves nothing against the author's theory, which accounts both for the development and occasional disappearance of the cyclonic form.—Note respecting M. Bochefontaine's experiment on the origin of cholera, by M. Trécul. A pill containing the comma bacillus having been swallowed by M. Bochefontaine with impunity, the author infers that Koch's germ may not after all be the active principle of cholera. In any case he protests against the ridicule cast upon the experimenter, whose courageous act is worthy rather of admiration and reward.—On the part played by the bacilli in the ravages of the vine attributed to *Phylloxera vastatrix*, by M. Luiz de Andrade Corvo. From his experiments the author concludes that the disease, to which he gives the name of "tuberculosis," is quite distinct from, and independent of, Phylloxera, that it is constitutional and hereditary, and may also be transmitted by contagion, the insect merely playing a secondary part in its propagation.—Octahedrons of sulphur with square base, which is physically a rhombus, by M. Ch. Brame.—On certain points in the physiological action of tanguin, the poison used at ordeals in Madagascar, by M. Ch. E. Quinquand.—Influence of the sun on the vegetation, the vegetable functions and virulence of the cultivated virus of *Bacillus anthracis*, by M. S. Arloing.—A letter was read by the Perpetual Secretary from King Oscar of Sweden, to the effect that on attaining his sixtieth year, in 1889, he proposes offering a prize of 2500 francs, with a gold medal valued at 1000 francs, to the author of the most important contribution to mathematical science. The already nominated judges are a German, a Swiss, and M. Hermite of the Academy. —Experiments with various kinds of wheat, with a view to ascertain the most productive variety under normal conditions, by M. P. P. Dehérain. Five varieties yielded the following returns per hectare (2½ acres):—

	Corn		Straw
	Quintals	Hectolitres	(Tons)
Scholey ...	40·7	49·8	7·323
Scotch red	40·2	48·7	7·687
Berwick	37·7	44·8	6·281
Bordeaux	32·3	39·8	5·630
Noé Blue	29·6	35·6	5·491

—Account of a meteor observed at Fontainebleau, by M. E. P. Mounier. This meteor was noticed at 7.20 a.m. in a clear sky, describing a parabolic curve from north to south at a velocity much inferior to that of a shooting star. It emitted an intensely white light like that produced by a magnesium wire in combustion. Before disappearing it broke into three fragments, which for an instant flared with a still more vivid light, and then suddenly became extinguished.

Berlin

Physiological Society, July 3.—Prof. Waldeyer reported on an investigation carried out in his institute by Herr Pischelis into the development of the thyroid gland. The oldest observers, Remak, Kölliker, and, quite recently, His, had found that the thyroid gland was developed medianly from the stomodærum, a thickening of the wall and then a buttonlike eminence arising thereon, which afterwards became hollow and got transformed into the gland. Seeing the gland was composed of two lateral lobes united by an intermediate piece, Herr His assumed that two protrusions arose from the anterior wall of the stomodærum, coalescing towards the middle. Herren Stieda and Wölfler had afterwards given an entirely different description of the development of this organ. According to them the thyroid gland was developed from two lateral buds emanating from the branchial cleft, probably from the fourth fissure. In view of this contradiction of authors Herr Born had quite recently resumed this investigation, and had come to the highly surprising conclusion that the thyroid gland originated both medianly and laterally, the middle part of the gland originating from the uppermost part of the stomodærum, the lateral portions from the branchial clefts. This fact having no analogy in embryology, Herr Pischelis had scrutinisingly traced the development of the thyroid gland, not only in swine, which had been examined by Herr Born, but also in rabbits and birds. The result was the complete confirmation of Herr Born's conclusions. Thus was all the ground taken from under the feet of phylogenetic speculators regarding the derivation of the thyroid gland. This organ, which was a complete riddle both physiologically and histologically, remained inexplicable phylogenetically as well. In the discussion which followed, the effects of the excision of the thyroid gland in men and animals were copiously enlarged on.—Prof. Eulenburg spoke on a communication concerning the influence of the cortex of the cerebrum on the temperature of the body, which had been lately laid before the Society by Dr. Raudnitz, and sought to refute the arguments which had been brought forward by the latter in opposition to the conclusions at which, in conjunction with Herr Landois, he (Prof. Eulenburg) had arrived. The speaker maintained both the exactness of his thermo-electric measurements and the accuracy of his statements in reference to phenomena he had observed regarding the influence of certain parts of the cortex cerebri on the temperature of the part of the body lying opposite. His statements were supported not only by experiments on animals by means of stimulation and cutting, but likewise by a large number of clinical experiences. —Dr. Müllenhoff spoke of the different methods of investigating the locomotion of animals, and discussed the advantages afforded in this study by the photographic representation of a large number of individual moments on the part of animals in the act of movement. A rather large series of photographs prepared by Herr Anschütz in Lissa were shown. They reproduced the movements of men and horses, of storks dropping into their nests, lying there, and issuing from them, and of pigeons.—Dr. Salomon next exhibited some beautiful preparations of paraxanthine crystals which he had obtained from urine, and set forth some further qualities and reactions of this xanthine body discovered by him a year ago in the urine. Paraxanthine occurred very sparely; one thousand litres of urine contained but one grain of paraxanthine. In just as small quantity was another xanthine body present in urine, a body which he had now discovered and had called provisionally "heteroxanthine." This body was precipitated amorphously in the form of powder or in the shape of poppy-seeds, and with soda formed beautiful crystals. Certain reactions served to discriminate it from paraxanthine and to range it under the head of xanthine bodies. Of quite peculiar interest was its chemical composition. So far as the elementary analysis had yet gone, heteroxanthine was a methylxanthine, while paraxanthine was a dimethylxanthine, isomeric with theobromine. Seeing, as was known, that coffeine was a trimethylxanthine, by the discovery of the simply methylated xanthine the gap in the series of methylxanthines was filled up. We had now xanthine, methylxanthine = heteroxanthine, dimethylxanthine = paraxanthine and theobromine, trimethylxanthine = coffeine.

THURSDAY, SEPTEMBER 24, 1885

PUBLIC OPINION AND STATE AID TO SCIENCE

ALTHOUGH Sir Lyon Playfair's address was probably listened to by a large number of members of the British Association as that of a man of science, there can be no doubt that to the vast majority of people outside it came as the utterance of a practical statesman. It was the Chairman of Committees of the House of Commons, the member of Parliament, the man of affairs who spoke, and the address was largely in keeping with these characters, for, as one writer has expressed it, it smells not so much of the laboratory as of the House of Commons. The subject of the endowment of research, of State aid to science, has been before the public for many years, and has been discussed under various circumstances, but it has never attracted at any one time the same earnest and general attention that it has since Sir Lyon Playfair's address. This is due not less to the pedestal on which the speaker was placed, than to the character and career of the speaker himself. The result has been that the guides and instructors of public opinion all over the country have felt it necessary to address themselves to the subject, and it is therefore possible now to gain some idea of the general drift of the public mind on the question of the claims of science on the State, and of the manner in which these claims should be met. Happily it is a question which men of all shades of opinion can consider without having their vision obscured by party passion and prejudice. As we go on it will be seen that the advocates of the doctrine of *laissez faire* are not absent; but, on the whole, those who have for so long maintained that the country, for the sake of its own happiness and prosperity and in order to maintain its place amongst other nations, must bring the teachings of science to its aid, have every ground for satisfaction.

To gauge public opinion on this question, in some measure, we have taken many of the leading journals of the metropolis, and propose to state briefly their views on this particular part of the Presidential Address. As will be seen, all shades of opinion are represented.

The *Times* acknowledges the reproach that countries less wealthy than our own make efforts to encourage science, by the side of which the encouragement afforded in England to science by the State sinks into insignificance; but it urges that, after all, the State is very much what the individuals who compose it choose to make it. Until public opinion exists in an organised and effective shape, the demand for the encouragement of science by the State will be addressed, for the most part, to a faithless and unbelieving generation. It points, as do a large number of other writers, to our ancient endowments for the benefit of education, and says that, although it may be conceded that they are still largely misapplied, they could be almost indefinitely increased, without direct assistance from the State, if vested interests and lack of intelligent initiative did not so often stand in the way. Until these obstacles are removed by the pressure of an active and enlightened public opinion, the State itself can hardly be expected to do much more than it does. The *Times*, therefore, acknowledges the need, and suggests that it should be met by the proper application of our existing educational endowments.

The *Standard* is as anxious as the President to see our Universities fully, and even lavishly, equipped for the prosecution of research; but it will not allow that they are so miserably starved as he would lead us to believe:—

"Sir Lyon Playfair falls into the vulgar error of reckoning as national expenditure on a given object only the outlay provided from taxation. Our Universities have resources which ought to be set against the State provision made in other countries for the same purposes. We are not, therefore, disposed to join in the outcry against the results of our English system. We believe that private benefactions and private enterprise have done much and are capable of doing more, and doing it better, than the State can do. We are not ashamed of the condition of scientific studies in England, and we claim for our countrymen a leading place among those who have built up the fabric of knowledge and promoted the well-being of man."

The *Daily Telegraph* likewise refers to private munificence which in the past has done in this country what State aid has to do at present in Continental countries, and it urges that scientific people should set before themselves, as their proper aim, to convince public opinion that the teaching of a far greater amount of science is necessary in our schools which are richly enough endowed.

The *Morning Post* maintains that Sir Lyon Playfair has conclusively demonstrated that we do not in respect to scientific education keep abreast of other countries, and in the same proportion as we allow ourselves to be distanced do we deny ourselves the means and the opportunities of developing our industrial and physical resources The money laid out in the manner indicated by Dr. Playfair, it says, would be well expended, and would in time be returned a hundredfold to the Imperial Exchequer.

The *Daily News* regards the address as singularly interesting and practical. It is a powerful and, as many will think, a conclusive plea for giving science a larger and a better place in modern life. Sir Lyon Playfair is a practical statesman, and suggests only practical measures. We must not only greatly enlarge our educational machinery, but must at the same time modernise it and bring it into direct relation to modern needs.

The *Morning Advertiser* eulogises the address because every word of it is directed to the one moral, "Educate, educate, educate." Never has the cause of scientific education been urged in a manner which commends itself more to common sense and conviction than in the singularly well-reasoned monologue wherein Sir Lyon Playfair, from the platform of the British Association, hits a national danger at the same time that he shows the means of correcting it.

The *Pall Mall Gazette* pronounces a verdict in favour of Sir Lyon Playfair as clearly and decidedly as the *Morning Post*. It says:—

"No one will be surprised that Sir Lyon Playfair should have selected for the subject of his address the 'Relation of Science to the State,' and when that is once explained it goes without saying that he made a very cogent plea for an establishment and endowment of science. This plea, it is perfectly certain, cannot be much longer refused. The Laissez-faire Society must add a new section to it betimes, for it is inevitable that the liberty of ignorance, which is impoverishing the life of the country at home and letting its trade slip through its fingers abroad, should soon be very rudely interfered with by the State. At present it is a case in this matter of Great Britain *contra mundum*. Every other civilised country has come to the conclusion by this time that the competition of the world is now a competition of intellect, and has taken steps accordingly. Either we or they must be wrong; and that it is we is now being brought home to us by the conclusive 'argument to the pocket.' John Bull's one ambition, according to Mr. *Punch*, is to 'guard his pudding;' but then he is beginning to find out that he can only fill his stomach by first filling his head. From the recognition of the vital importance of science to its establishment by the State—in a much less half-hearted fashion than at present—is in these days a short and inevitable step. The same considerations by which State interference has been justified elsewhere—its greater certainty, its ampler resources, its wider range—are all equally applicable here, and will come to be equally applied."

The *Globe* says the "argument" of the address may be conceded. Science deserves from the State all that the State can do for her. Minerva is a sort of alien deity in our intellectual Pantheon, and it is certain that the tendency and pressure of modern conditions impose upon all civilised States, an increasing obligation to learn or to lag. But it questions whether we really are in the evil plight depicted by the President, and points to "the magnificent private endowments of our insular foundations"—a source of revenue comparatively non-existent abroad, which, it states, Sir Lyon Playfair strangely ignores.

The *St. James's Gazette* thinks that reformers might bend some of their energies to seeing that more technical science and more arts likely to be useful to the craftsman and the mechanic, were brought within the curriculum of the Board Schools. For them we could easily spare some of the literary subjects:—

"With the moral of Sir Lyon Playfair's scientific sermon, and the journalistic lectures based on it, most people will agree. This is an age of science, and you can do nothing effectual in the practical way, from building ironclads to catching mussels, without a knowledge of what are called 'the laws of nature.' If you do not want your ironclads to be sunk by those of other navies, or your mussel trade to be ruined by foreign competition, you will do well to see that the 'laws of nature' are properly studied in your schools and colleges. That technical education in this country is not so good as it might be, and as it possibly is elsewhere, may be admitted."

But it does not think that this is due to superabundance of classics in our system of middle and higher-class education.

The *Guardian*, at the conclusion of a lengthy article devoted to the address, sums up its conclusions on the subject of the relations of the State to science thus:—

"On the whole we are inclined to think that the best service the State can render to education is to continue to help it in the unsystematic and irregular way which has hitherto proved so useful, considering each case as it arises, and adapting its measures to the particular needs which are brought before it. Much more may, no doubt, be done for Science, but it may be done in the same way as before, by grants for special purposes, by expeditions fitted out for costly investigations, perhaps by the foundation of professorships and scholarships. But it would be a misfortune if the free action of individual thought were repressed by being obliged to conform to the rules of a State-imposed system, or if individual exertion and private munificence were discouraged by the habit, already growing upon us too much, of looking to the State rather than to ourselves for the removal of every difficulty and the promotion of every useful end."

The *Athenæum*, refers to what has been done by the State for science since the last meeting of the British Association at Aberdeen twenty years ago, and instances the Science and Art Department, the Natural History Museum, grants to the Royal Society, &c., proceeds:—

"All this—and much more might be added—shows that British statecraft is not altogether disposed to frown coldly upon science and its devotees. And yet, after all, how little—how miserably little—has been officially done for the promotion of science compared with the magnitude of our scientific interests and the wealth of our country! It is only by looking abroad and observing what has been accomplished in other lands that we realise our own shortcomings. Germany and France, Switzerland, and some of the other small continental States, have displayed a zeal for scientific progress and a liberal recognition of science which strikingly contrast with our own parsimony. Even when we have undertaken a good work our heart has often failed us in carrying it through with dignity and liberality. As a striking and recent example we may refer to the *Challenger* expedition. Here was an expedition splendidly equipped for scientific work at the expense of the nation; and yet, when the results of the expedition come to be published as voluminous reports, they are distributed with so sparing a hand, and are published at so high a price, as to be practically inaccessible to most men of science."

The *Saturday Review* says that Sir Lyon Playfair's words are tempered by the consciousness that he may some day be called upon to make them good, and this adds the greater force to the adverse verdict which he is compelled to give, the censure which he cannot help pronouncing on the action of the State towards science in England. The reply to the question, What has the State done directly for science? the answer is, But little compared with the need, and that little often in the wrong way. As the pocket is said to be the most sensitive part of our race, it is to be hoped that when the British Association next meets in Aberdeen its future president will not be forced to repeat Sir Lyon Playfair's assertion: "English Governments alone fail to grasp the fact that the competition of the world has become a competition in intellect."

The *Spectator* speaks of the address as like a sermon preached by a popular clergyman on behalf of science, and wants to know why this branch of thought needs help so much more than art, literature, or pursuits like archæology, or the study of the historic past. It doubts whether in science, as in an army, honourable poverty does not conduce to the highest efforts; and whether richly endowed schools will produce the most successful professors, even in the inferior domain of applied science Wheatstone was great, and was paid? but how much a year, it asks, did Friar Bacon get? or did any body ever pay that early expert in natural science who discovered fire?

"And remembering what the history of thought has been, we cannot but deprecate that spirit of sordidness in which for some years past the claims of science have been pressed—the desire for salaries which has been so conspicuous whenever professors have descanted on the merits of research. We have not the slightest objection to scientific departments, and quite agree with Sir Lyon Playfair that if the State wants fishes it could learn how to get them better by inquiring of the fishes—who, at least, tell no lies—than of the fishermen, who often do; but still the picture he draws of the United States Government, with its dozen departments of inquiry into geology, palæontology, ichthyology, chemistry, and the rest, does not inspire us with enthusiasm. It is all very excellent, no doubt; but it was all consistent with slavery. France may be handed over to Paul Berts and its judges still take bribes."

The *Glasgow Herald* pronounces Sir Lyon Playfair's address a signal success. Those pedantic persons who fail to see the uses of science might find in the address an admirable lesson against the perpetual sneering at what they are pleased to term the abstractions of scientific teaching. Sir Lyon, in a word, has emphasised the teaching that the safety and the progress of every country are one with scientific advance and the growth of scientific precision.

On the whole, then, it may be pronounced that the movement in favour of State aid to science, in the interest of the State itself rather than of any particular branch of human knowledge, has advanced and has taken a hold of the public mind. The need is universally acknowledged; in many quarters it is proposed to meet it by the application of endowments, ancient and modern, to the changed requirements of the present day; in others—and these amongst the influential—it is boldly declared that the State must link itself, at whatever cost, with science if this country is to hold its high place amongst nations. "The same considerations by which State interference has been justified elsewhere—its greater certainty, its ampler resources, its wider range—are all equally applicable here, and will come to be equally applied."

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The New Star in Andromeda

On seeing the report in yesterday's *Standard* of the remarkable change in the nucleus of the nebula of Andromeda, I decided to write to you to mention that, accidentally noticing the nebula on Sunday evening, the 6th, I was struck by its conspicuousness, and set wondering how the ancients came to overlook an object so prominent. As frequent watching for meteors has made that region very familiar to me, it seems likely that an increase in general brightness has occurred, and made me specially notice its appearance.

What is of far more interest, however, I have learnt this morning that one of our scholars, Lawrence Richardson, noted and *recorded* an apparent change in the nebula, as he saw it in our 4¼ inch Cooke's refractor, about 9 p.m. September 1. I append a *verbatim* copy from his diary of what is perhaps the first English observation of this remarkable phenomenon.

J. Edmund Clark

Friends' School, Bootham, York, September 9

(Copy) "Sept. 1 . . . As a beginning [of the season's work] looked at Polaris, ϵ Lyræ and the great nebula of Andromeda. Noticed a small star in the centre of the latter which I do not remember having seen before, and which is not down in a small drawing I made on September 15, 1884.

Norwegian Testimony to the Aurora-Sound

How widespread in our days is the belief in the sound of the Aurora in Norway, the following may show. In March, 1885, I despatched some thousand circulars to all parts of the country containing different queries regarding the aurora, and amongst these also the following:—Have you or your acquaintances ever heard any sound during aurora, and, in this case, when and in what manner? Up to this date I have received answers to these queries from 144 persons in different parts of the country. Of these there are not less than 92, or 64 per cent., who believe in the existence of the aurora-sound, and 53 (36 per cent.) of these again state they have heard it themselves, whilst the other 39 cite testimonials from other people; only 21 (15 per cent.) declare they never have heard the sound or know anything about it, and the other 31 (22 per cent.) have not noticed the query at all. There are thus 92 affirmations against 21 negations.

The sound is described in these answers in the following manner:—

Sizzling (3)
Creaking or sizzling
An intermediate sound between sizzling and whizzing, sometimes as if a piece of paper were torn
A kind of sound as when you tear silk
Sizzling, th—ss
Soft whizzing, alternative with sizzling
Soft crackling, sizzling
Hissing and crackling
Partly hissing, partly as a kind of rushing whiz
Whispering and glistering
Strong whiz (3)
Whiz or whispering
Whiz, or distant, soft, continuous whizzing
A rather heavy rush, as from a distant waterfall
Quiet whizzing, hissing
Hissing, or hoy! hoy! hoy!
Whiz (2)
Rush, as from a stream
Soft but distant crackling, as from a lighted match-cord
Whizzing (5)
Whizzing in the air
Rush, as when sheep are chased
Soft whiz or hissing
Soft whiz
Soft hissing, soft whiz
Whizzing or whistling
Rippling
Crackling (4)
Hissing
Hissing noise in the air
Crack in the air
Din in the air
Continuous sounding, rolling din in the air
Clashing
Flapping, as a flag before the wind
Partly as rustling or flapping of sails hanging loose fore the wind, partly as hissing from fire
Like the noise from a distant, before the wind-flapping flag, which now and then sends out a creaking sound
Like the sound from sails of a ship hanging loose in stormy weather
Monotonous whizzing and creaking, as when a sheet flaps before the wind
Like burning juniper-boughs
Brustling or crackling as if burning juniper
As from a feeble burning flame
Like burning dried juniper
As from the flames of a conflagration
Cutting, hissing as from flames
Crackling and creaking, a noise as from a large fire-flame—as, for instance, burning dried boughs
Like the sound from a flight of birds
Noise as when a bird flaps in the air
Strong flapping noise, as when a bird passes very near you
Crackling from fire and flapping from wings
As of a bird flying through the air with great velocity
Whizzing noise, as when striking the air with a whip
Noise as from the dart of an arrow
Like the buzzing of a bee
Roaring noise, as when strong gushes of wind dart through the tree-tops of the wood
Creaking sound as from the blowing of the wind
Distant roar, as from a storm
Roaring as from a storm
Roaring as from a whirlwind
As from a soft-blowing wind
Soft breeze
Like the soft breeze through a wood
Whipping with whisk-brooms
Fanning
Soft noise, as when fanning with a piece of paper from a distance
Soft flapping with a piece of cloth
Roaring of the sea
Heavy, hollow roar from the sea
Sweeping sound, as when dry snow is sweeping over an ice-field
As when one holds a cloth by two corners and flaps with it

Creaking, at other times, as when a sail strikes against the mast or flaps before the wind	As when a thunder-clap passed over us from west to east
Partly whizzing, partly as when a sail flaps before the wind	Soft crackling, as from electric sparks from an electrical machine
As when a sail flaps before the wind	As when stroking a cat's back against the hairs

Christiania, September 16 SOPHUS TROMHOLT

A White Swallow

DURING our walk to-day on the Kendal Road, near Heversham, my brother and I were very much surprised to see a white swallow amongst a number of the ordinary kind. The bird's plumage was entirely white, except the lower part of the breast, which was greyish.

We are quite sure of its identity, as it flew around us several times.

Can you tell us whether a white swallow is really an uncommon sight? MARY BRIGGS

Sandside, near Milnethorpe, Westmoreland, September 4

THE HUME COLLECTION OF ASIATIC BIRDS

FOR some time past the interest of ornithologists has been aroused by the rumour that Mr. A. O. Hume, of Simla, had offered, or intended to give, his celebrated collection of Asiatic Birds to the Trustees of the British Museum; and I am glad to be able to inform the readers of NATURE that the whole of this collection is now safely housed in the Natural History Museum, the second half having been delivered by the P. and O. Company on the 18th of last month.

Those of our readers who are not ornithologists may wish to learn something in the first place about the collection itself and its generous donor.

Mr. A. O. Hume, C.B., occupied formerly a high position in the Bengal Civil Service, and devoted for many years his leisure hours to the study of ornithology, and especially of the birds of India. His aim was to form a collection of birds of every part of the British Asian Empire, in which every species should be represented by a complete series of specimens illustrating its range and its variations of colour according to age, season, or locality. For this purpose he organised a system under which a great number of local observers and collectors (in some years numbering nearly 100) worked for and with him. He fitted out expeditions with a staff of collectors and taxidermists, under his own leadership or that of his able former curator, Mr. Davison, into Scinde, Coorg, Manipur, the Malayan Peninsula, Tennasserim, and the Andaman and Nicobar Islands; he acquired by purchase or donation the Mandelli collection from Sikkim and Tibet, Brook's beautiful series from North-Western and Central India, Adam's Sambhur birds, Bingham's collections from Delhi and Tennasserim, Scully's collection from Turkestan. The expense incurred in forming this collection was in proportion to the enthusiasm with which Mr. Hume worked. He had built at Simla a museum for the reception of the collection which should finally form the basis for the preparation of a comprehensive work on the avifauna of the vast region which he was exploring. But whilst thus engaged Mr. Hume, with his wonderful activity and ready pen, which had rendered him *facile princeps* in all matters regarding Indian ornithology, published numerous papers in an ornithological periodical, *Stray Feathers*, which he founded and conducted for ten or eleven years, as well as several separate works — viz. "Notes on the Indian Raptores," "Nests and Eggs of Indian Birds," "List of the Birds of India," "Game Birds of India, Burmah, and Ceylon," and others.

However, during the last few years naturalists, to their great regret, became aware that Mr. Hume's interest in ornithology began to yield to other important matters of social and political nature; and finally, the grievous loss by theft of an enormous mass of ornithological manuscripts, comprising his materials for "The Birds of the British Asian Empire," and the whole of his Museum Catalogue, contributed to his determination to abandon his intention of working out his collection, and to present it to some museum where others might utilise the materials he had collected.

It is very gratifying that Mr. Hume, "considering the British Museum as the one that has most claims upon him, and Mr. Sharpe as the man most capable in Europe of doing justice to the collection," offered to present it to the Trustees of that institution. The Trustees, fully aware of the scientific importance of the collection, had no hesitation in accepting the offer. Still, before actually transferring the collection, Mr. Hume was desirous of completely rearranging and placing it in thorough good order, and also of preparing at the same time a Catalogue of the Birds of the Indian Empire containing the results of his long and careful studies. Unfortunately this project could not be carried out owing to the difficulty of finding a competent coadjutor in the work, or rather of obtaining the means of properly remunerating such a person. And as there was great risk in leaving the collection without due curatorial supervision exposed to the deteriorating influences of another rainy season in India, the Trustees obtained Mr. Hume's consent to transmitting the collection without further delay to England.

Mr. Sharpe, who is always ready to sacrifice his personal comfort to duty, started for Simla almost at a moment's notice, and although, unseasoned as he was, he had to travel and work during the hottest part of the year, he seems to have infused his energy into all who had to help him in the gigantic task of packing the collection. He started on April 25, arrived in Simla on May 21, completed his work by the end of June, and returned to the Museum on August 15, having the satisfaction to find on his return the half of the collection which had preceded him safely lodged in the Museum, while the other half was delivered a week later without loss of, or damage to, any of the cases.

The collection comprises about 400 skins of mammals, 63,000 skins of birds, 300 nests, and 18,500 eggs. It was packed in eighty-two cases, the majority with a capacity of 30 cubic feet. Even to those who are used to the inspection of large collections, these figures can hardly convey a correct idea of the magnitude of this addition to the National Museum. Mr. Hume may truly say that such a collection has never been made before; and such will probably never be made again. Each specimen is enveloped in a brown paper wrapper with the name of the species and locality written on the outside, proper labels being, besides, attached to the specimen. The skins themselves are in excellent condition, and, thanks to the precautions taken by Mr. Sharpe, they are not likely to harbour or to develop destructive inmates. Specimens which had suffered from damp or insects and to which no special interest was attached, were eliminated during packing.

The scientific value of the collection, of course, is not to be measured by the number of specimens only, but by the judgment which determined their selection, by the history attached to many of them, and by the completeness of the series. We may reasonably assume that it contains about 2000 species, so that on an average each species is represented by some thirty specimens, which number in the majority of the cases would not go beyond a fair illustration of its range and variation. Therefore the number of duplicates which will be eliminated by Mr. Sharpe during the progress of the examination will probably be much smaller than one might anticipate on a superficial inspection; and I need not say that Mr. Hume's earnest wish that the series which he has brought together with so much discrimination and care should remain intact, will be strictly carried out. No doubt a considerable number of duplicates will be eliminated, and, according to the wish of the donor, of these a complete set has to be transmitted to the Museum of Comparative Zoology of Harvard College, whilst the remainder are to be utilised for the benefit of the ornithological collection generally.

Ornithologists need not go many years back in recalling to their memory the extent of the collection which the late Mr. G. R. Gray had arranged in such a handy fashion in and about his study in the old building at Bloomsbury. What was then regarded a good reference collection has since been enriched by the addition of the Wallace collection from the Indian Archipelago, Capt. Pinwill's Malayan birds, Sharpe's African collection, the Gould collection, Salvin and Godman's European, Australian, and American collections, the Sclater collection, and now by this immense collection from every part of the Indian Empire. Years of unremitting labour will be required to get these vast materials into order and to work them out in a manner which will satisfy the aims of so advanced a branch of science as ornithology is at the present day.

ALBERT GÜNTHER

THE FORSTER HERBARIUM

BOTANISTS will learn with pleasure that this herbarium, a portion of the collections of Cook's second voyage, has been acquired by exchange from the Liverpool Corporation for the Kew Herbarium; and it will be incorporated in the general collection. From the introduction to the "Catalogue of Plants" in the Botanic Gardens at Liverpool, published in 1808, it appears that the proprietors of that establishment possessed, at that date, about 3000 specimens of dried plants, "collected by the late Dr. Forster in his voyages to the South Seas, with large and valuable contributions from his friends and correspondents." How these plants came into their possession is uncertain, but they could hardly have been presented to them by Mr. Shepherd, the Curator, as stated by Sir Joseph Hooker in the introductory essay to his "Flora Novæ-Zealandiæ," or his name would almost certainly have been mentioned as the donor. At least this may be inferred, because on the very next page a very high tribute is paid to Mr. John Shepherd for his services to the Garden. Be that as it may, the collection will shortly be accessible to botanists generally, thanks to the perseverance of Sir Joseph Hooker and the sensible view of the matter taken by the present members of the Corporation when it was represented to them that these dried plants were practically useless where they were, but would be valuable at a botanical establishment like Kew. This act of the Corporation deserves to be recorded, because some thirty years ago, when Sir Joseph Hooker was engaged writing his "Flora Novæ-Zealandiæ," he applied to the then custodians of the collection to transmit it temporarily to Kew for comparison and publication, and his request was refused.

Botanical investigations in connection with the *Challenger* expedition again brought to mind the existence of this interesting collection at Liverpool, and it was determined to make another effort to rescue it from oblivion, which was fortunately successful. A few words respecting the botanical collections of Cook's voyages generally, and of this one in particular, will be welcome to those interested in botany. Sir Joseph Banks and Dr. Solander accompanied Capt. Cook on his first voyage round the world; John Reinhold Forster and George Forster, father and son, were the botanists of the second voyage (1772-75), and Mr. Anderson, the surgeon of the expedition, collected a little on the third voyage. From a statement in Sparmann's "Travels in South Africa," it seems that Forster the elder undertook the duties of naturalist to the expedition for the sum of 4000*l.*, and he took his son with him, then only seventeen years old, as an assistant. On arriving at the Cape of Good Hope they fell in with Sparmann, who, at the instance and expense of Forster, was added to the scientific staff, and continued with them until the return to the Cape in 1775. Considerable collections of plants were made in New Zealand, many parts of Polynesia, and the extreme south of America, and smaller collections in some of the Atlantic Islands, including St. Helena, Cape Verd Islands, and Canaries. On returning to England the Forsters soon commenced publishing the botanical results of the expedition, and an authenticated set of all the published plants at least was deposited in the British Museum. The Cape plants, however, which they did not publish, are apparently not represented there. The first botanical work, "Characteres Genera Plantarum," appeared in 1776, and the title-page bears the names of both father and son, and this was the only one published in England. For the rest, the botany was done by the son alone. His "Florula Insularum Australium Prodromus" appeared at Göttingen in 1786, and "De Plantis Esculentis Insularum Oceani Australis" at Berlin in the same year, followed by "De Plantis Magellanicis et Alanticis" at Göttingen in 1787.

These works, we believe, constitute the whole of the published botany of the expedition, and, though very meagre, are extremely interesting, being the foundation of our knowledge of New Zealand, Antarctic, and Polynesian vegetation. The collection now acquired for Kew is excellently preserved, and the plants mostly named and localised. It comprises altogether 1359 species, 785 of which were collected on the voyage with Cook, and the rest, from various parts of the world, are probably some of those alluded to above as having been presented to Forster by his friends. The collection includes a large proportion of the plants published by the Forsters, but it is not complete. Roughly, there are 187 species from Polynesia, 119 from New Zealand, 21 from the extreme south of America, 23 from the Atlantic Islands, including all those described by Forster from St. Helena, and 9 from Australia. Besides the foregoing, which are all phanerogams, there are 36 ferns, but they include only a small portion of the species described by Forster.

In addition to this botanical work George Forster's name appears on the second title-page of the Narrative of the second voyage as joint author with James Cook. He died, a violent death, we believe, at Paris in 1794, four years before the decease of his father. The philosophical writings of the latter, entitled "Observations made during a Voyage round the World," London, 1778, deserve special mention

W. BOTTING HEMSLEY

THE INTERNATIONAL METEOROLOGICAL COMMITTEE

THIS Committee held its third meeting in Paris at the Ministry of Public Instruction on September 1 to 8. The Meeting was attended by the President, Prof. Wild (Russia); the Secretary, Mr. R. H. Scott; Profs. Buys Ballot (Holland), Hann (Austria), Mascart (France), Mohn (Norway), Dr. Neumayer (Germany), and Prof. Tacchini (Italy). M. de Pinto Capello (Portugal), the only remaining member, was unfortunately unable to be present.

In addition certain gentlemen were present by invitations at some of the meetings, among these we may mention Brigadier-General Hazen (Chief Signal Officer, U.S.A.), Prof. Hildebrandsson (Upsala), and M. Leon Teisserenc de Bort.

The following is a brief notice of the most important subjects discussed, with the action taken on each.

A valuable report on cirrus observations by the Committee appointed at Copenhagen (1882), MM. Capello, Hildebrandsson, and Ley, was submitted, and will be printed.

The subject of Atlantic telegrams was discussed with General Hazen. It was decided to maintain the present system of reports from ships' logs which has been carried on since Christmas by the Meteorological Offices of France and this country, and to endeavour to improve it.

At the same time a proposal made by M. L. Teisserenc de Bort for the telegraphic transmission of a daily *résumé* of the weather in the New England States was considered. General Hazen expressed perfect readiness to furnish such reports, and it was resolved to procure such telegrams provided the cost of the service could be guaranteed by the European offices which would participate in it.

It was decided to recommend that barometrical observations should be corrected for the force of gravity at lat. 45°.

A letter from General Hazen respecting the reduction of barometer readings to sea-level, which has been lately circulated, was considered, and two memoranda on the subject from Hamburg and St. Petersburg respectively were handed in and will be printed.

It was considered *desirable*, as absolute synchronism in weather observations appears to be unattainable in Europe, that the same hours of local time should be adopted in each country (which would mean a change from 8 a.m. to 7 a.m. in this country).

It was decided that each of the International Reduction Tables (proposed by the Committee at its meeting at Berne in 1880) as did not involve any question which is still in an undecided state (such as, *e.g.*, hygrometrical tables, or tables of sea-level reduction) should be published.

It was decided to recommend that the next Congress should not take place till 1889, and Prof. Mascart stated that probably the French Government would propose that it should be held in Paris.

THE BRITISH ASSOCIATION

JUDGED by the quantity of work which the sections have put through their hands the Aberdeen meeting has been successful almost beyond precedent. Moreover much of this work has been of the best quality. The addresses come up to a very high standard, and in the first four sections, at least, not a few of the papers were really important original contributions to science, while the discussions in Sections A and B on certain great questions in physics and chemistry were a marked and commendable feature—a feature which, it is hoped, will in time become common to all the sections. Mr. Murray's lecture on deep-sea research has been justly considered one of the leading events of the meeting; a full report will appear in our columns.

At the concluding general meeting a deservedly hearty vote of thanks was accorded to the Aberdonians for their abundant hospitality. Birmingham seems determined to make next year's meeting a memorable one; and we may remind our readers that Sir William Dawson, of McGill College, Montreal, will be the President.

The total number of persons who attended the Aberdeen meeting was 2203.

The following is a synopsis of grants of money appropriated to scientific purposes by the General Committee at the Aberdeen meeting. The names of the members who would be entitled to call on the General Treasurer for the respective grants are prefixed:—

A—*Mathematics and Physics*

*Foster, Prof. G. Carey—Electrical Standards	£40
*Stewart, Prof. Balfour—Solar Radiation	20
*Stewart, Prof. Balfour—Meteorological Observations at Chepstow	25
Darwin, Prof. G. H.—Instructions for Tidal Observations	50
*Stewart, Prof. Balfour—Comparing and Reducing Magnetic Observations	40

REPORTS

Report of the Committee, consisting of Mr. Robert H. Scott (Secretary), Mr. J. Norman Lockyer, Prof. G. G. Stokes, Prof. Balfour Stewart, and Mr. G. J. Symons, appointed for the purpose of co-operating with the Meteorological Society of the Mauritius in their proposed publication of Daily Synoptic Charts of the Indian Ocean from the year 1861. *Drawn up by Mr. R. H. Scott.*—The Committee forward, for the inspection of the members of the Association, a copy of the charts for the month of March, 1861, with some specimens for January of the same year, and the complete number for February which appeared some years ago. These documents have recently arrived from the Mauritius. As the work has now made decided progress the Committee have applied for and obtained the grant of 50*l*. placed at their disposal by the General Committee. As soon as the requisite documents are received from Dr. Meldrum the Committee will submit a formal account of their expenditure with the necessary vouchers.

Second Report of the Committee, consisting of Prof. Schuster (Secretary), Prof. Balfour Stewart, Prof. Stokes, Mr. G. Johnstone Stoney, Prof. Sir H. E. Roscoe, Capt. Abney, and Mr. G. J. Symons, appointed for the purpose of considering the best methods of recording the direct Intensity of Solar Radiation.—The Committee have come to the following conclusions:—(1) It seems desirable to construct an instrument which would be a modification of Prof. Stewart's actinometer adapted for self-registration—the quantity to be observed being, not the rise of temperature of the enclosed thermometer after exposure for a given time, but the excess of its temperature when continuously exposed over the temperature of the envelope. (2) As the grant to the Committee will not admit of the purchase of a heliostat, it will no doubt be possible to procure the loan of such n instrument, and, by making by its means sufficiently numerous comparisons of the instrument proposed by the Committee with an ordinary actinometer, to find whether the arrangement suggested by the Committee is likely to succeed in practice. The Committee would therefore confine their action for the present to the carrying out of such a series of comparisons. (3) The size of the instrument might be the same as that of Prof. Stewart's actinometer. (4) The instrument should have a thick metallic enclosure, as in the actinometer above-mentioned, and in this enclosure there should be inserted a thermometer to record its temperature. Great pains should therefore be taken to construct this enclosure so that its temperature shall be the same throughout. (5) The interior thermometer should be so constructed as to be readily susceptible of solar influences. It is proposed to make it of green glass (a good absorber), and to give it a flattened surface in the direction perpendicular to the light from the hole. (6) It seems desirable to concentrate the sun's light by means of a lens upon the interior thermometer, as in the ordinary instrument. For if there were no lens the hole would require to be large, and it would be more difficult to prevent the heat from the sky around the sun from interfering with the determination. Again, with a lens there would be great facility in adjusting the amount of heat to be received by employing a set of diaphragms. There are thus considerable advantages in a lens, and there does not appear to be any objection to its use.

Third Report of the Committee, consisting of Profs. G. H. Darwin and J. C. Adams, for the Harmonic Analysis of Tidal Observations. Drawn up by Prof. G. H. Darwin.—"Record of Work during the past Year." The edition of the computation forms referred to in the second report is now completed, and copies are on sale with the Cambridge Scientific Instrument Company, St. Tibbs' Row, Cambridge, at the price of 2*s*. 6*d*. each. Some copies of the first report, in which the theory and use of these forms are explained, are also on sale at the same price. A few copies of the computation forms have been sent to the librarians of some of the principal scientific academies of Europe and America. In South Africa, Mr. Gill, at the Cape, and Mr. Neison, at Natal, are now engaged in reducing observations with forms supplied from this edition. A memorial has been addressed to the Government of the Dominion of Canada, urging the desirability of systematic tidal observation, and the publication of tide-tables for the Canadian coasts. There seems to be good hope that a number of tide-gauges will shortly be set up on the Atlantic and Pacific coasts, and in the Gulf of the St. Lawrence. The observations will probably be reduced according to the methods of the British Association, and the predictions made with the instrument of the Indian Government. Major Baird has completed the reduction of all the tidal results obtained at the Indian stations to the standard forms proposed in the Report of 1883, and Mr. Roberts has similarly reduced a few results read before the Association by Sir William Thomson and Capt. Evans in 1878. All these are now being published in the *Proceedings* of the Royal Society, in a paper by Major Baird and myself. A large number of tidal results have been obtained by the United States Coast Survey, and reduced under the superintendence of Prof. Ferrel. Although the method pursued by him has been slightly different from that of the British Association, it appears that the American results should be comparable with those at the Indian and European ports. Prof. Ferrel has given an assurance that this is the case; nevertheless, there appears to be strong internal evidence that, at some of the ports, some of the phases should be altered by 180°. The doubt thus raised will probably be removed, and the paper before the Royal Society will afford a table of reference for all —or nearly all—the results of the harmonic method up to the date of its publication. The manual of the tidal observation promised by Major Baird is now completed, and will be published shortly. This work will explain fully all the practical difficulties likely to be encountered in the choice of a station for a tide-gauge, and in the erection and working of the instrument. Major Baird's great experience in India, and the success with which the operations of which he has had charge have been carried out, render his advice of great value for the prosecution of tidal observation in other countries. The work also explains the method of measuring the tide diagrams, entering the figures in the computation forms, and the subsequent numerical operations.

Second Report of the Committee, consisting of Prof. Balfour Stewart (Secretary), Mr. J. Knox Laughton, Mr. G. J. Symons, Mr. R. H. Scott, and Mr. Johnstone Stoney, appointed for the purpose of cooperating with Mr. E. J. Lowe in his project of establishing a Meteorological Observatory near Chepstow on a permanent and scientific basis.—Since their re-appointment in 1885 this Committee have met twice, and have placed themselves in correspondence with Mr. Lowe, to whom the following letter was written by their Secretary: "The Committee request me to point out to you that the main feature of your proposal, which interests the British Association and the scientific public generally, is the prospect which it holds out of the establishment of a *permanent* institution, by means of which meteorological constants could be determined, and any secular change which may take place therein in the course of a long period of years be ascertained. It will be for you and the local authorities to decide what amount of work of *local interest* should be contemplated, and on this will the scale of the observatory mainly depend. The Committee are therefore unable to say what amount of capital would be required. They would point out four conditions which they hold to be indispensable:—(1) The area of ground appropriated should be sufficient to ensure freedom from the effects of subsequent building in the neighbourhood. (2) A sufficient endowment fund of at least 150*l*. annually should be created. (3) The control should be in the hands of a body which is in itself permanent as far as can be foreseen. (4) The land for the site shall be handed over absolutely to the above-mentioned governing body. Until the precise amount of the local meteorological requirements is ascertained and further progress is made in the scheme the Committee consider that they would not be justified in any more prominent action than that which they have already taken.

Report of the Committee, consisting of Profs. A. Johnson (Secretary), J. G. MacGregor, J. B. Cherriman, H. T. Bovey, and Mr. C. Carpmael, appointed for the purpose of promoting Tidal Observations in Canada.—The Committee, in order to strengthen their representation to the Canadian Government on the necessity of establishing stations for continuous tidal observations, deemed it well to get the opinions of Boards of Trade and ship-owners and ship-masters. On inquiry it appeared that the Montreal Board of Trade were at the very time considering the question, which had been brought independently before them. On learning the object of the Committee they gave it their most hearty support, and addressed a strong memorial on the subject to the Dominion Government. The Boards of Trade of the other chief ports of the Dominion also sent similar memorials. The ship-owners and masters of ships, to whom application was made, were practically unanimous in their testimony as to the pressing need for knowledge on the subject. The representations were made through the Minister of Marine, with whom an interview was obtained, at which a memorial was submitted. Copies of the answers of the ship-masters (a large number of which had been received) were submitted at the same time. The reply of the Minister of Marine stated that, owing to the large outlay on the Georgian Bay Survey and on the expedition to Hudson's Bay during the past summer (1885), the Government did not propose to take action in the matter of tidal observations at present. The Committee have reason to believe that if the financial prospects improve by next session of Parliament the Government will take the matter into earnest consideration; they therefore suggest that the Committee be reappointed.

Seventeenth Report of the Committee, consisting of Profs. Everett and Sir W. Thomson, Mr. G. J. Symons, Sir A. C. Ramsay, Dr. A. Geikie, Mr. J. Glaisher, Mr. Pengelly, Prof. Edward Hull, Prof. Prestwich, Dr. C. Le Neve Foster, Prof. A. S. Herschel, Prof. G. A. Lebour, Mr. Galloway, Mr. Joseph Dickinson, Mr. G. F. Deacon, Mr. E. Wethered, and Mr. A. Strahan, appointed for the purpose of investigating the Rate of Increase of Underground Temperature downwards in various Localities of Dry Land and under Water. Drawn up by Prof. Everett (Secretary).—The present Report is for the two years since the summer of 1883. Observations have been taken in a deep bore at Richmond, Surrey, by Mr. Collett Homersham, C.E., the engineer of the boring, on the premises of the Richmond Vestry Waterworks, on the right bank of the Thames, and about 33 yards from high-water mark. The surface is 17 feet above Ordnance datum. The upper part consists of a well 253 feet deep, with an internal diameter of 7 feet at top and 5 feet at bottom, which was sunk in 1876 for the purpose of supplying water to the town of Richmond, and carried down to the chalk. From the bottom of the well a 24-inch bore-hole was sunk to the total depth of 434 feet, thus penetrating 181 feet into the chalk. This portion of the work was completed in 1877. Above the chalk were tertiaries, consisting of 160 feet of London clay, 60 feet of the Woolwich and Reading beds, and some underlying sands. The water yielded at this stage was about 160 gallons a minute, and, when not depressed by pumping, was able to rise 4 or 5 feet above the surface. Its ordinary level, owing to pumping, was about 130 feet lower. In 1881 the Richmond Vestry determined to carry the bore-hole to a much greater depth, and the deepening has been executed under the direction of Mr. Homersham. The existing bore-hole was first enlarged and straightened, to enable a line of cast-iron pipes, with an internal diameter of 16¼ inches, having the lower end driven water-tight into the chalk at a depth of 438 feet, to be carried up to the surface. The total thickness of the chalk was 671 feet. Below this was the upper greensand, 16 feet thick; then the gault clay, 201½ feet thick; then 10 feet of a sandy rock, and a thin layer of phosphatic nodules. Down to this point the new boring had yielded no water. Then followed a bed 87½ feet thick, consisting mainly of hard oolitic limestone. Two small springs of water were met with in this bed at the depths of 1203 and 1210 feet, the yield at the surface being 1¼ gallons a minute, with power to rise in a tube and overflow 49 feet above the ground. A partial analysis of this limestone rock showed it to contain 2·4 per cent. of sulphide of iron in the form of pyrites. At the depth of 1239 feet this limestone rock ended, and hard red sandstone was found, alternating with beds of variegated sandy marl or clay. After the depth of 1253 feet had been attained, the yield of water steadily increased as the boring was deepened, the overflow at the surface being 2 gallons a minute at 1254 feet, 8 gallons at 1363 feet, and 11 gallons at 1387 feet. It rose to the top of a tube carried 49 feet above the surface, and overflowed; and a pressure-gauge showed that it had power to rise 126 feet above the surface. The diameter of the bore was 16¼ inches in the chalk, 13½ inches in the gault, 11¼ inches in the oolitic limestone, and at the depth of 1334 feet it was reduced to a little under 9 inches. At 1337 feet the method of boring was changed, and, instead of an annular arrangement of steel cutters, a rotary diamond rock-boring machine was employed. The bore-hole, with a diameter of 8½ inches, was thus carried down to 1367½ feet, at which depth, lining tubes having to be inserted, the diameter was reduced to 7¼ inches, and this size was continued to 1447 feet, at which depth the boring was stopped. The bore-hole was lined with strong iron tubes down to the depth of 1364 feet; and those portions of the tubes that are in proximity to the depths where water was struck were drilled with holes to admit the water into them. Three observations of temperature taken with an inverted Negretti maximum at the depth of 1337 feet, when the bore-hole was full of water, recorded 75½° F. In the first observation, March 25, 1884, the thermometer was left for an hour and a quarter at the bottom of the bore-hole, and three weeks had elapsed since the water was disturbed by boring. The second observation was taken on March 31, when the thermometer was 5½ hours at the bottom. In the third observation special precautions were taken to prevent convection. The thermometer was fixed inside a wrought-iron tube, 5 feet long, open at bottom. The thermometer was near the lower end of the tube, and was suspended from a water-tight wooden plug, tightly driven into the tube. There was a space of several inches between the plug and the thermometer, and this part of the tube was pierced with numerous holes to allow the escape of any cold water which might be carried down by the tube. The tube was one of a series of hollow boring-rods used in working the diamond drill-machine. By means of these it was lowered very slowly, to avoid disturbance of the water as much as possible; and the tube containing the thermometer was gradually worked through the sand at the bottom of the bore-hole. The lowering occupied five hours, and was completed at noon on Saturday, June 7. Cement, mixed with sugar, for the purpose of slow setting, was immediately lowered on to the surface of the sand, and above this a mixture of cement and sand, making a total thickness of 3 or 4 feet of cement plugging. The thermometer was left in its place for three full days, the operation of raising being commenced at noon of Tuesday, June 10, and completed at 5 p.m. The thermometer again registered 75½° F., exactly the same as in the two previous observations which were taken without plugging. It would therefore appear that the steady upflow of water in the lower part of the bore prevents any downward convection of colder water from above.

The boring has since been carried to the depth of 1447 feet, with a diameter reduced to 7¼ inches, and Mr. Homersham lowered the thermometer to the bottom without plugging. It remained down for six days (February 3 to 9, 1885), and gave a reading of 76¾° F. The water overflowing at the surface had a temperature of 59° F. To deduce the mean rate of increase downwards, we shall assume a surface temperature of 50°. This gives for the first 1337 feet an increase of 25½°, which is at the rate of 1° F. in 52·4 feet, and for the whole 1447 feet an increase of 26¾°, which is at the rate of 1° F. in 54·1 feet. These results agree well with the Kentish Town well, where Mr. Symons found in 1100 feet an average increase of 1° in 55 feet.

Mr. Galloway has furnished observations taken during the sinking of a shaft to the depth of 1272 feet in or near the Aberdare valley, Glamorganshire. The position of the shaft is on the slope on the east side of the valley, about midway between the bottom of the valley and the summit of the hill which separates it from the Merthyr valley. The mouth of the shaft is about 800 feet above sea-level. Observations were taken at four different depths—546 feet, 780 feet, 1020 feet, and 1272 feet—the thermometer being in each case inserted, and left for twenty-four hours, in a hole bored to the depth of 30 inches at a distance not exceeding 2½ yards from the bottom of the shaft for the time being. About eight hours elapsed between the completion of the hole and the insertion of the thermometer. The strata consist mainly of shales and sandstone, with a dip of 1 in 12, and the flow of water into the shaft was about 250 gallons per hour. The first of the four observations was taken in the fireclay under the Abergorkie vein; the second in strong "clift" (a local name for argillaceous shale) in disturbed ground; the third in bastard fireclay under a small rider of coal previously unknown; the fourth in "clift" ground two yards above the red ash vein, which overlies the 9-foot seam at a height of from 9 to 12 yards. The observations were as follow:—At 546 feet, 56° F.; 780 feet, 59½° F.; 1020 feet, 63° F.; 1272 feet, 66½° F. Comparing consecutive depths from 546 feet downwards, we have the following increments of temperature:—3½° in 234 feet, giving 1° for 67 feet; 3½° in 240 feet, giving 1° for 69 feet; 3½° in 252 feet, giving 1° for 72 feet; showing a remarkably regular rate of increase. A comparison of the first and fourth observations gives an increase of 10½° in 726 feet, which is at the rate of 1° F. in 69·1 feet. As a check upon this result we find that this rate of *decrease* reckoned *upwards* from the smallest depth (546 feet) would give a surface temperature of (56 − 7·9 =) 48°·1, which, as the elevation is 800 feet, is probably very near the truth.

Mr. Garside has sent an observation of temperature taken by himself in the roof of the Mersey tunnel in August, 1883. The temperature was 53°, the depth below Ordnance datum being 92 feet. A great quantity of water from the river was percolating through the sides of the tunnel. On August 13, 1854, he verified his previous observation in Denton Colliery (15th Report). The second observation was made at the same depth as the first (1317 feet), in the same pit and level, and under the same circumstances, except that the thermometer was allowed to remain fourteen days in the hole bored for it, instead of only six hours. The temperature observed was the same as before—namely 66°, Mr. Garside has also supplemented his previous contribution to our knowledge of the surface temperature of the ground in the East Manchester coal-field (16th Report) by two more years' results from the same observing stations. The difference between them agrees well with the generally accepted rate of 1° for 300 feet, and indicates about 48° as the surface temperature at small elevations, such as 30 feet. The pits in the East Manchester coal-field from which we have observations—namely, Astley Pit (Dukinfield), Ashton Moss, Bredbury, Denton, and Nook Pit, are all sunk in ground at elevations of between 300 and 350 feet. It would therefore appear that the assumption of a surface temperature of 49°, which we made in reducing these observations, is about 2° in excess of the truth. A very elaborate paper on "Underground Temperature" has recently been communicated to the Royal Society by Prof. Prestwich. He is disposed to adopt 1° F. in 45 feet as the most probable value of the normal gradient.

Report of the Committee, consisting of Mr. W. T. Blanford and Mr. J. S. Gardner (Secretary), on the Fossil Plants of the Tertiary and Secondary Beds of the United Kingdom. Drawn *up by Mr. J. S. Gardner, F.G.S., F.L.S.*—The report opens with a list of all the principal works on the British Tertiary flora down to the year 1885. The number of species that had been more or less described were :—From the Thanet beds, 3 ; from the Reading beds, 9 ; from Sheppey, 108 ; from Alum Bay, &c., 43 ; from Bournemouth (deducting those not peculiar), 11 ; Bovey Tracy, 50 ; Upper Eocenes, 13 ; Mull, 9 ; Antrim, about 16 ; making a grand total of 262 species, not a tenth part of which, Mr. Gardner anticipates, would survive a rigorous examination. The study of only one group of plants—the Gymnosperms—has been the serious business of the past three years ; for not only have I had to study, but in the majority of cases to find the specimens as well. I trust that the results attending the expenditure of the grant I have been favoured with may be considered satisfactory, and these I now proceed to detail.

Bracklesham Flora.—Two visits have been made to Selsey. The beds, it is well known, are marine, but a few terrestrial fruits are from time to time procured from them. I was able to make a large collection of fossil shells while looking for plants, which, being from the highest beds, are less known, and are interesting as illustrating the passage from the Bracklesham to the Barton fauna, which is more gradual, I think, than is supposed. The surface of one of these beds is dotted over with fossil *Posidonias*, a marine monocotyledonous plant identical with the species now inhabiting the Mediterranean. It had not been previously recorded as a British fossil, though another species is abundant in the contemporary beds of the *Calcaire grossier* of the Paris basin. In our species the rhizomes radiate from a centre, whilst in the French and other European fossil species they are long and branching. They are found among beautiful *Tellina* shells, preserving, to a large extent, their banded colours. The only other fossil plant to record here is a *Nipadites*, which, unlike those of the Bournemouth beds, is large, flattened, and oval.

Reading Beds.—A considerable portion of the grant has been expended in working these beds with, I am pleased to report, the happiest results. The flora is found in the Katesgrove pit, on the banks of the Kennet, immediately beneath the mottled clay. The matrix is a fine porcelainous fuller's earth interstratified with sand, and the beds seem very local. The limit of the pit being reached, it is not probable that any part of the beds will be exposed for long. I have illustrated a beautiful specimen—one of several—of *Anæmia subcretacea*, Sap., from these beds. This fern is highly characteristic of the lower Eocenes in France, but had only previously been found in the middle Bagshot beds of Bournemouth in this country. I have also illustrated another fern (?) from these beds, of which I have only as yet found a small fragment. The figures are therefore taken from specimens found many years ago by Prof. Prestwich. Other valuable additions to the Reading flora are some splendid specimens of a conifer, which I can see no ground for distinguishing from *Taxodium heterophyllum* of China. Another interesting specimen from Reading is a pine leaf of two needles, about the size and substance of those of *P. maritima*, the first pine foliage, I believe, ever found in the English Eocene. One leaf bed is almost wholly made up of leaves of *Plutonis*, and a bed above is fairly sprinkled with fruits of the same. Fruits are very abundant, and include four kinds of leguminous pods, and there are many flowers. As a result of this work the Reading flora no longer appears so completely distinct from that of Bournemouth.

Woolwich Beds.—I regard these as thoroughly distinct in age from those of Reading. I have not found, in the course of two visits paid for the purpose, any bed worth collecting from, though I think such must exist at Lewisham.

Studland Beds.—We were able to reach a leaf bed in the Lower Bagshot at Studland, and to obtain a great number of specimens, nearly all of whieh are quite new to me. They are mostly dycotyledonous leaves and fruits, which will require time to determine. There are no Coniferæ among them, and I am only able to add one fern—a *Lygodium*, very near to that of Bournemouth—to the *Chrysodium langæanum*, procured abundantly by me ten years ago in a different bed at the same locality.

Hordwell Beds.—I have to add *Salvinia* to the flora, not previously found fossil in England, and exclusively confined to the Miocene in Austria and Switzerland.

Barton Beds.—A new species of pine from Highcliff was discovered quite unlike those hitherto found at Bracklesham. The beds are rapidly assuming an angle of repose, and becoming deeply buried under *débris*, so that some of them are no longer visible except by making excavations. Though the Barton series is one of the most interesting of our Eocene formations, the detailed bedding has not been worked out like that of the Bracklesham series below and the Headon series above, and the greatest misconceptions seem to prevail as to the number of species of fossils that it contains.

Bournemouth Beds.—Five series of leaves were obtained this year by Mr. Keeping and myself, the most noteworthy of which are some specimens of *Godoya* which exceed any I had previously seen. I have illustrated a new and very distinct species of *Adiantum*, a fragment of what may be *Gymnogramma*, and a trifid group of *Polypodium* leaves, which seem to be different from either of the species previously recorded.

The London Clay.—Mr. Shrubsole has kindly sent me some of the best of the fruits that have been found. I have not made any complete studies of them yet, but they promise to afford results of the highest value. Among a few recognised is the very unmistakable seed of *Verschaffeltia*, a genus of palms from Seychelles quite new to fossil floras.

Gurnet Bay Beds.—I have been able to ascertain that another fern rivals *Anæmia subcretacea* in range, *Chrysodium langæanum*, which extends from the town of Bagshot upwards into the Bembridge beds. The plants are as a rule dreadfully macerated and chopped up. Among them are small fragments of a *Gleichenia*, which, though not very beautiful, is a very important fern, coming from the horizon. By far the most important discovery, however, is that of *Doliostrobus*, the first really extinct conifer that I have met with in British Eocenes. It belonged to the tribe of *Araucarieæ*, and its identification has been thoroughly confirmed by correspondence and the interchange of specimens with Dr. Marion, the well-known botanist of Marseilles. It is certain that during the Eocene period, as the temperature increased from the base upward to the Middle Bagshot, when the maximum of heat seems to have prevailed, there was a tendency for the plant world to move northward. It is equally certain that in the later half of the Eocene, as the temperature began to decrease, the movement was in the opposite direction, and we find in the European Miocenes of Switzerland and Italy a number of plants that at an earlier period were growing in the far north.

Report of the Committee, consisting of H. Bauerman, F. W. Rudler, and Dr. H. Johnston Lavis, for the Investigation of the Volcanic Phenomena of Vesuvius, by H. Johnston Lavis, M.D., F.G.S., Reporter.—The unfortunate outbreak of cholera in Naples and the stringent local quarantine measures prevented work on Vesuvius being carried out during the autumn of 1884. Nevertheless, daily observations were made of the variations in the activity of the volcano, of which a careful record has been kept. All important changes of the crater-plain, and in the cone of eruption, have been photographed. Descriptions of the small eruption of May 2 of 1883 have already been given in NATURE, and the results of a microscopical examination of the sides of the remarkable hollow dyke then formed will soon be published. The Naples section of the Italian Alpine Club have generously undertaken to publish a journal of Vesuvius, which will contain reproductions of the photographs exhibited. The third sheet of the geological map of Vesuvius and Monte Somnia (scale 1 : 10,000) has been completed by the reporter, and is exhibited at the meeting. The relationship of the varying activity of a volcano in a Strombolian state of activity to barometric pressure, the lunar tides, and rainfall, cannot but be regarded as important in solving some questions of vulcanology. Instrumental means of measuring such present so many practical difficulties that a scale of activity has been drawn up, which requires only a few minutes to learn, can be practised by any one with good eyesight and moderate intelligence who is within visual range of the volcano, and, above all, requires no further outlay than pen, ink, and paper. The objections will be mentioned after describing the process. 1st degree, a faint red glimmer above the main vent interrupted by complete darkness ; 2nd degree, the glimmer is continuous, but the ejection reaches hardly above the central crater rim at the most ; 3rd degree, glimmer continuous and well marked ; the ejections are distinctly discernible as they rise and then fall on the slopes of the cone of eruption and roll down its slopes ; 4th degree, the ejections reach a considerable height, are brilliant, and light up the top of the great cone ; 5th degree, verging on an actual paroxysmal eruption, the ejections are shot up very high, being only very slightly or not at all influenced in their course by a strong wind. Each explosion follows with much rapidity, and corresponds with the "boati" heard all around the west, south, and south-east slopes of the mountain. The objections to this method of registering the variations in the activity of a volcano are: (*a*) cloud-cap, which may for days cut off the view; (*b*) after a great eruption, resulting in a deep crater, the changes of activity would be invisible from the neighbourhood of the mountain; (*c*) it is only applicable after dark, so that usually only one observation a day can be made; (*d*) should lava be flowing from a lateral outlet, as is often the case, the level of the fluid in the chimney would vary as the outflow took place with greater or less rapidity, dependent on its blocking the passage more or less. The reporter thinks it desirable to introduce a description of this method into the report, so that it may be made use of in the case of other suitable volcanoes.

Report of the Committee, consisting of Prof. Ray Lankester, Mr. P. L. Sclater, Prof. M. Foster, Mr. A. Sedgwick, Prof. A. M. Marshall, Prof. A. C. Haddon, Prof. Moseley, and Mr. Percy Sladen (Secretary), appointed for the purpose of arranging for the occupation of a Table at the Zoological Station at Naples.—In the Report read last year at Montreal it was announced that a scheme was on foot for the building of a large physiological laboratory in connection with the Zoological Station at Naples, and for the purchase of a new sea-going steamer, to be equipped as a floating laboratory. Your Committee are now able to report that both these projects are steadily advancing towards attainment. For the physiological laboratory the Municipality of Naples has made a grant of 400 square metres of ground, and the Italian Parliament has voted the sum of 50,000 lire towards the cost of building. In addition to this assistance from the Italian Government, a union of the maritime provinces of South Italy is about to be formed for the purpose of contributing towards the cost of the new laboratory, and of maintaining two tables there for the use of natives of the provinces concerned. The new steamship, which it is hoped will shortly be in the possession of the station, will form a further addition to the capabilities of the establishment This undertaking is in the hands of an influential committee in Germany, organised for the purpose of collecting subscriptions, and by whom the vessel will be presented to the station. It is intended that the steamer should be of 300 to 400 tons burden, with engines of 150 to 200 horse-power, and be fitted up in all respects as a floating laboratory. With such a vessel it will be perfectly practicable to remain weeks or months in any desired locality, and distance from home will be no obstacle, as naturalists will live and work on board. Concurrent with these strides of the Zoological Station, improvements in the general management, in methods of work, and in instruments of research are constantly being made. The general efficiency of the establishment is so well known that it will suffice to say that the whole organisation of the station is in a state of active and prosperous vitality. The best evidence of this is furnished by the accompanying lists:—(1) of the naturalists who have occupied tables during the past year, and (2) of the publications resulting from work carried out at the station.

The General Collections.—Additions have been again received from Capt. Chierchia, who has, since the last Report, sent two collections of specimens from the Pacific and Indian Oceans. Other collections have been likewise received from Lieut. Cercone, Lieut. Orsini, and Lieut. Colombo, from the Atlantic, the Red Sea, and the Mediterranean respectively. Some of the material previously obtained by Capt. Chierchia has already been utilised by Count Béla Haller in a paper on the molluscan kidney, recently published; and the same author is at present preparing a monograph on the Patellæ. In like manner the Pteropoda have been investigated by Dr. Boas, of Copenhagen, whose monograph upon the subject is now in the press. Since the last Report the British Association table has been occupied by Mr. Wm. E. Hoyle, who, although limited in time, was enabled to prosecute researches on the embryology of the Cephalopoda, and to collect material from which important results may be expected. The report forwarded by Mr. Hoyle is appended:—
