GREEK MATHEMATICS

A Short History of Greek Mathematics. By James Gow, M.A. (Cambridge University Press, 1884.)

"THERE are three classes of persons who, being mathematical students, require to know something of the history of their pursuit. The first want only a general view of leading points, such as can be furnished by one writer in a few volumes. The second wish to be able to compare the accounts given by different persons, and, up to a certain point, to examine the authorities used by those persons, or at least to keep watch upon their mode of using them. The third are desirous of being the critics of the historians, and of amending their works, if need be."[1] The catalogue, which the writer of this paragraph drew up, was intended for the second of the above classes. In some further remarks he arranges the histories under two heads—those which are written on the plan of Montucla, Bossut (we may now add M. Marie's "Histoire des Sciences mathématiques et physiques"), in which a general account is framed out of the writer's notes or remembrances of miscellaneous reading; or in that of Delambre, Woodhouse (we may add here the name of Todhunter, whose great historical treatises the late Henry Smith pronounced to be "so suggestive of research, and so full of its spirit"), in which the successive writings of eminent men are examined and described one after the other, so that each chapter or section is a description of the progress of science in the hands of some one person, and is complete in itself. The latter, De Morgan goes on still further to say, is the plan which is most favourable to accuracy and most interesting to the inquirers of the third class; the former, while it better suits the first and second class, leaves the writer open to many sorts of error which the latter avoids.[2]

[1] De Morgan, "References for the History of the Mathematical Sciences," Companion to "British Almanac" for 1843.

[2] Both M. Marie and Mr. Gow might profit by De Morgan's remarks on Indices. "No writer is so much read as the one who makes a good index, or so much cited." The former author may intend to give a thoroughly full index at the end of his seven volumes; the latter gives a fair index, but it is very far from being complete and satisfactory; for instance, "*et passim*" is not such a reference as one desires.

Mr. Gow's work being upon a special branch, viz. Greek mathematics—which he himself further limits to arithmetic, algebra, and geometry—comes under the second of the above two divisions, though for reasons which are more than once put forward, it is not so thorough a treatise as we could have wished. When, however, we learn that the book "represents part of a collection of notes which I have for many years been making with a view to a general history of the great City of Alexandria," and that "the materials for an account of the Alexandrian Mathematical School grew to exceed the reasonable limits of a chapter," we are glad that Mr. Gow determined to publish his results at an earlier date than he would otherwise have done. What of accuracy or perfection is sacrificed by a perhaps too early publication, he will have, we expect, an early opportunity of making good in a second edition, which we hope will be called for in the near future. It is a great reproach to English mathematicians that such books as this and M. Marie's have hitherto been conspicuous by their absence in this country. We can happily point to papers by De Morgan, to special treatises by Todhunter, to monographs by Allman, and to an interesting *résumé* by Dr. C. Taylor, but we look in vain for anything of the nature of a history of mathematical or physical science in the English language. A tendency of late years to give small historical notices of mathematical discoveries in our school text-books has been displayed, and we trust the time is not far distant when we shall have, if not a great original work, for which we can hardly look, yet a primer or primers founded upon the works of Bretschneider, Cantor, Hankel, Marie, and others.

Almost every page puts in evidence how greatly Mr. Gow is indebted to German and French writers; yet it is also evident, on a perusal of his work, that he is no blind follower of those predecessors in the field—he calls no one of them master—but when occasion arises he boldly differs from them, and gives good reasons for so differing. We note here that he does not appear to be acquainted with M. Paul Tannery's work in the same directions as his own. He refers to him but once (p. 101), and then he states he has not been able to find the article (quoted by Cantor). The journal in which the paper is published, viz. *Bulletin des Sciences Math. et Astronomiques*, is an easily accessible one, and we think from the analyses we have from time to time given in these columns of other papers by M. Tannery (in *Mémoires de la Société des Sciences Physiques et Naturelles de Bordeaux*) on Greek arithmetic and geometry, our author would have gathered useful material in the *Bulletin* paper and in the *Mémoires* also.[1] But this is the only case of omission we have come across; the reading is apparently most thorough, and the author's Greek scholarship enables him to improve upon the translations given by some of these foreign authorities.

The work consists of three parts. The first part, entitled "Prolegomena to Arithmetic," discusses the decimal scale and Egyptian arithmetic in a very thorough manner. Here, of course, much use is made of the "Rhind papyrus," a book written by one Ahmes (now put at 1700 B.C.), entitled "Directions for Obtaining the Knowledge of all Dark Things," which consists mainly of statements of results. One could wish some safe means could be discovered by the Museum authorities for unfolding the "olden leather-roll on a mathematical subject" which is "apparently too stiff to be opened"! (note, p. 16).

There are naturally statements in these early chapters which are fairly open to objection, but they are clearly put, and the results, as Mr. Gow gets them, are summarised on pp 20, 21.

The second part treats of Greek arithmetic under "Logistica, or Calculation and Arithmetica, or Greek Theory of Numbers." This part is very carefully done, and enables the reader to get a clear idea of the processes employed. Plato's appreciation of *logistic* may be inferred from his direction (Legg, 819 B) that "free boys shall be taught calculation, a purely childish art, by pleasant sports, with apples, garlands, &c."[2]

The third part treats of Greek geometry, and upon it we could expatiate at some length, but that is hardly our business on the present occasion. We need only say that there is much good work. Dr. Allman's powerful rectification of the position of Eudoxus did not appear in time to be of service to Mr. Gow (he mentions the fact of its publication on p. x. of the Addenda). Most of the geometers appear to have justice done them. We miss some of the touches which appear in M. Marie's work, but again we find a compensation in the fuller account given of Menelaus, and of the proposition now usually cited by the name of that geometer. Chapter V. discusses "prehistoric and Egyptian geometry," in which is given an account of Ahmes' work. Chapter VI. takes "Greek Geometry to Euclid" in five sections. Of the Pythagoreans, the Eudemian summary (which has in previous numbers been referred to in our notices of Dr. Allman's papers) says they made geometry "a liberal education;" and other writers, referred to by Mr. Gow, attribute to them the maxim, "A figure and a stride: not a figure and sixpence gained" (p. 153). In connection with this characteristic maxim we may give the story, which, in the Greek, forms the motto on the title-page of Mr. Gow's book, viz. "A youth who had begun to read geometry with Euclid, when he had learnt the first proposition, inquired 'What do I get by learning these things?' So Euclid called his slave, and said: 'Give him threepence, since he must make a gain out of what he learns.'" Many such boys there are, even in this nineteenth century, who are ever asking, "What is the use of learning Euclid?" We thank Mr. Gow for his story from Stobæus, which will possibly make us better prepared to answer the question the next time we are asked it. There is much other quotable matter, but we hasten to a close.[1] Chapter VII. gives an account of Euclid (what little is known of him, his writings, history of text of "Elements," and modern history of the book[2]), Archimedes, and Apollonius. Chapter VIII. is on "Geometry in Second Century B.C.;" Chapter IX., "From Geminus to Ptolemy;" and Chapter X., "Lost Years," principally occupied with an account of Pappus and his "Mathematicæ Collectiones."

Some matters of interest are illustrated, as the introduction of the *signs* in algebra, of the *sine* in trigonometry (it does not seem to be generally known that the first occurrence of "tangent" and "secant" is traced by De Morgan to a work by T. Finkius, "Geometriæ rotundi libri xiiii.," Basileæ, 1583), the derivation of "almagest" (cf. Chaucer's Clerk Nicholas, who had—

> "His almageste and bokes grete and small,
> His astrelabre, longing for his art,
> His augrim stones, layen faire apart
> On shelves couched at his beddes head")

and a few others.

On page 290, line 9 up, for λη read αη.

[1] In the *Bulletin* for March, 1885, there is a paper by M. Tannery, "Sur l'Arithmétique Pythagorienne" (pp. 69-88).

[2] It is curious to note that there was a Cocker before Cocker: cf. the Lucianic compliment, "You reckon like Nicomachus of Gerasa"; see also, in the opposite direction, "Budget of Paradoxes," p. 30.

[1] Hippocrates of Chios was one of the greatest geometers of antiquity; he lost his property, as a merchant, by piracy or chicanery. Aristotle speaks of him as "slow and stupid." "There seems to be no other ground for the criticism than that a Greek would call a man a fool who was cheated of his property. There are still extant mathematicians who are singularly deficient in ability for any studies but their own."

[2] In his "English Mathematical and Astronomical Writers" (companion to "British Almanac for 1837," p. 38), De Morgan made one of his shrewd guesses that Billingsley's (first English) Euclid was certainly made from the Greek, and not from any of the Arabico-Latin versions. This surmise has been found correct by G. B. Halsted in the *American Journal of Mathematics*, vol. ii. pp. 46-48. We notice that Mr. Gow gives the same reference in his Addenda. Mr. Gow gives a proof of a prop. (xxii.) of Euclid's optics which recalls a passage in the recent *brochure* "Flatland:" it is, "If a circle be described in the same plane as the eye, it will seem to be a straight line."

OUR BOOK SHELF

The Zoological Record for 1883, *being Volume XX. of the Record of Zoological Literature.* Edited by E. C. Rye, F.Z.S., &c. (London: John Van Voorst. 1884.)

ALTHOUGH bearing on its title-page the date 1884, it was not until the end of January in this year that the "Zoological Record for 1883" was, in its entire form, laid before the public. It comes to us with a melancholy interest, as being the last under the editorship of the late Mr. Rye, whose untimely death we have so recently recorded and deplored. Again in this volume we have to mention still further changes in the staff of the Recorders. Prof. Sollas takes Mr. S. O. Ridley's place as recording the sponges, and Prof. Haddon that of Mr. W. Saville Kent in recording the Protozoa. Other engagements have prevented the Rev. O. P. Cambridge recording the literature of the Arachnids for 1883, and it has been arranged that Mr. T. D. Gibson-Carmichael is to record the literature of this group for 1883 and 1884 in the next volume of the "Record."

A rapid glance over the contents of the volume brings to light the fact that in all the leading groups of the animal kingdom a goodly amount of work has been accomplished in the year 1883, and that many of the lacunæ in our knowledge are being steadily filled in. The Molluscoidea seem to have had more than ordinary attention paid to them, and the record of this group by Prof. E. von Martin appears to be extremely well done. As usual, Messrs. W. H. Kirby and R. McLachlan record the enormous section of Insecta, the lion's share falling to the former, the latter confining his attention to the Neuroptera and Orthoptera. In his treatment of the general subject (Insecta) the recorder frequently quotes memoirs relating to the structure, &c., of the groups recorded by Mr. McLachlan, and it is not without interest to note that, while some of these are the subjects of a double record, others are not. One interesting fact, showing the importance which a "Zoological Record," when complete, is to the working naturalist, is alluded to by Mr. McLachlan in his remarks introducing us to H. de Saussure (" Mémoires pour servir à l'Histoire naturelle du Mxeque des Antilles, et des États-Unis. Orthoptères de l'Amérique moyenne: Famille des Blattides." Genève, 1864): — " This very important memoir is noticed at the request of the author. It escaped notice in the early volumes of this 'Record' (which commenced with the year 1864), and also in the German *Bericht*. It would also appear to have escaped the notice of workers on Blattidæ generally, for none of the new terms employed therein for generic, &c., division are included in Scudder's just-published laborious 'Universal Index' which extends down to 1879." Scudder's New Index is, however, far from being a full record of generic names in any one group.

The new names proposed for genera or sub-genera, as recorded in this volume, amount, the editor informs us, to 1079, as against 1015 of last volume, and this without including any of the Arachnidæ. Of these, no less than 115 require re-naming, having been already in use. This number affords no clue to the amount of new species described, which is considerably larger, thus indicating for the present no lack of work for the systematic zoologist.

The British Association for the Advancement of Science still continues its grant of 100*l*., and the Government Grant Committee of the Royal Society renewed its vote of 150*l*., while the Zoological Record Association itself keeps up both the number of its members and subscribers.

A Treatise on Practical Chemistry and Qualitative Inorganic Analysis. By Frank Clowes, D.Sc. Lond. Pp. xv., 376. Fourth Edition. (London: J. and A. Churchill, 1885.)

THIS well-known manual has reached a fourth edition. It very thoroughly fulfils the aim which is set forth in the preface, viz. to place trustworthy and practical methods of qualitative analysis in the hands of the student. If the chemical student must still devote a large amount of his time to qualitative testing, then he certainly could not do better than follow the directions of this book. But the very excellence of the tables and methods of the book before us makes us more than ever doubt the wisdom of attempting to teach the science of chemistry by a course of "test-tubing." The art can be learnt by rules and formulæ, but the science comes not by such as these.

This book only includes what "directly bears on the ordinary requirements of the laboratory student"; its directions are those of a man who knows what he is writing about, and who has learnt what he teaches by good honest work in the laboratory. It contains many of those results of laboratory experience which are usually preserved in the private note-books of the teacher, and which may almost be regarded as trade secrets. The only fault we have to find is that the book tends too much in the direction of recipes. Were a student to work conscientiously through the book he would certainly be an accomplished analyst, but we are afraid he might have ceased to be a chemist. However excellent rules and tables may be in their own way, it is possible to have too much of them. In fact, the better they are the less one wants to be bound by them. The "tables of differences" given in the book are excellent; in the hands of a good teacher they might be made the basis of a really scientific training. But the ordinary student will not trouble to develope methods from the facts set before him in these tables; he will pass on to the systematic examination of simple salts, and be caught in the fatal whirlpool of "experiment," "observation," "inference."

M. M. P. M.

Original Researches in Mineralogy and Chemistry. By J. Lawrence Smith. Edited by J. B. Marvin. (Louisville, 1884.)

IN a recent number (vol. xxxi. p. 220) we gave a statement of the life and work of the late Prof. J. Lawrence Smith condensed from a memoir prepared at the request of the National Academy of Sciences, Washington, by Prof. B. Silliman, who was so soon to follow his friend to his long rest. The papers containing the original investigations of Prof. L. Smith have now been collected together and reprinted as a memorial volume intended for presentation to his friends. Three memoirs prepared by Mr. Marvin, Mr. Michel, and Prof. Silliman respectively, form an appropriate introduction, and give one a good glimpse into his life and character. The work is clearly printed on good paper, and will be highly appreciated by his numerous friends, to each of whom a copy has been presented by his widow.

Lehrbuch der Mineralogie. Von Dr. Gustav Tschermak. Zweite, verbesserte Auflage. (Wien: Alfred Hölder, 1885.)

WE are glad to find that a second edition of this work is already called for, although the latter part of the first edition appeared so lately as 1884. In our notice of the first part of that edition (vol. xxiv. p. 355) we directed attention to the excellent character of the work, and gave a brief statement of its contents; we now need only remind our readers that the author is a thorough master of his subject, who has done a large amount of original and valuable work, and further, has had a long teaching experience as Professor of Mineralogy in the University of Vienna. The work is but slightly changed in the present edition; the length is increased by a few pages through the incorporation of the results of investigations made since the first part left the press in 1881; the contents are well up to date. If some University Professor would provide us with an equivalent work written in our own tongue the study of mineralogy in this country would begin to revive.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Mr. Lowne on the Morphology of Insects' Eyes

I DESIRE to give an unqualified denial to the imputation made by Mr. Lowne in his letter to NATURE of April 9 (p. 528), that my opinion with regard to his paper on the structure of the eye in Arthropods was formed under the influence of my colleague, Prof. Lankester, or that any consultation upon the paper took place between us. References of papers for the Royal Society are strictly confidential, and I did not know the name of the second referee until after I had come to a conclusion upon the subject—a conclusion which was only arrived at as the result of a long and patient investigation of Mr. Lowne's preparations, and the nature of which may be inferred from the fact that I advised the author to withdraw his paper and submit the subject to a renewed investigation, with the aid of improved methods.

With regard to the question, which Mr. Lowne raises, as to my competency to form any opinion at all, on the ground that I had not myself devoted any special attention to the literature of the subject, I may remark that the points which had practically to be decided were (1) whether Mr. Lowne's statements were in themselves probable, and (2) whether they were corroborated by his preparations. Had I not felt myself qualified to form an opinion on these points I should not have accepted the reference. E. A. SCHÄFER

The Late Prof. Clifford's Papers

IN the "Mathematical Papers" (pp. 628–37) I was able to print the syllabuses of a series of ten lectures delivered by Prof. Clifford to a class of ladies at South Kensington in the spring and summer of 1869. Whilst turning over a collection of miscellaneous papers, in a box, Mrs. Clifford and I had the good fortune to light upon a manuscript quite ready for printing, and this ("Mathematical Papers," p. 628) subsequently formed part of the volume on "Seeing and Thinking;" but we could not find any trace of any more manuscript of the above-mentioned series of lectures. Just before the recent Easter holidays Prof. Karl Pearson returned to me a few pages of manuscript bearing on the International Scientific Series volume which I had lent him, and with them he sent me a large note-book which had been in the late Prof. Rowe's hands. On opening this book I at once saw that it contained very full notes of other lectures of the course. In fact, Lecture II. ("On Plane Surfaces and Straight Lines") is quite ready for press, as is also, I think, Lecture III. ("On the Rotation of Plane Figures"); Lecture IV. ("Of Similar Figures") is a fragment, and still more fragmentary is Lecture V. ("The First Principles of Calculation"). Of Lecture VI. ("The Theorem of Pythagoras") there are two loose sheets of figures: on one sheet is "the Bride's Chair," and the figures on this and the other sheet show that my information was correct, and that the remarks on pp. 633, 637 are *ad rem*. As Lecture IX. ("On the Shadows of a Circle") is very fully illustrated in the recent volume edited by Prof. Pearson, we see that we are in possession of a fairly complete presentment of Prof. Clifford's views on the subjects of the course of lectures.

Messrs. Macmillan have stated their willingness to publish the MS. of the second part of "The Elements of Dynamics," and I hope to be able, after a re-examination of it, to put the work into their hands for printing. When this book is got out, and the above lectures published in some shape yet to be determined, the mathematical world will be in possession of all that we can now look for from the hands of this great master.

University College School, April 25 R. TUCKER

Sir Wm. Thomson and Maxwell's Electro-magnetic Theory of Light

SHORTLY after writing my former letter I saw a copy of the verbatim report of Sir Wm. Thomson's lectures in Baltimore, and would have written to you to that effect and to apologise to Mr. Forbes for having doubted the accuracy of what I thought was his report, only that I met him in London about that time, and he then desired me not to do so. Sir William Thomson has now himself stated that the passage is correctly quoted, and I can only regret that he has expressed himself in the way he did.

I certainly think that anybody reading the passage would imagine that the velocity of propagation of electro-magnetic disturbances upon Maxwell's electro-magnetic theory of light, which he showed to be the same as the velocity of propagation of light, and to be a true velocity of wave-propagation—any one, I say, would suppose that this was the same thing as that Sir Wm. Thomson calculated in the year 1854.

Sir Wm. Thomson certainly says, "That is a very different case," but the rest of this sentence is rather ambiguous as to what the "it" after "putting" refers to, and I am afraid that many people will imagine that, in Sir William Thomson's opinion, Maxwell has made some unjustifiable assumption. I believe, however, that all he thinks is that Maxwell has not made a satisfactorily definite thing of the so-called electro-magnetic theory of light.

In Sir Wm. Thomson's article in Nichol's "Cyclopædia" he puts the matter very clearly indeed. He says:—"The law of this phenomenon [transmission of electric signals] is identical with that which Fourier . . . found as the law of propagation of summer heat and winter cold to different parts of the earth," *i.e.* it obeys the laws of a diffusion and not of a wave-propagation; and again:—"Now it is obvious from these results [experimental results] that the supposed velocity of transmission of electric signals is not a definite constant like that of light:" and afterwards he says that, when an initial current is started, the potential rises simultaneously at all points, and that the apparent velocity would depend on the delicacy of our instruments. All these obviously distinguish between the propagation of a variable current in a conductor and a true wave-propagation.

He has also clearly pointed out a direction in which to look for a true wave-propagation. It will make his position clearer, and also Maxwell's, to use his analogy between water in an elastic tube and a conductor of electricity. I will suppose the water contained in a tube bored out of a very large lump of india-rubber. He enumerates three electric qualities concerned, and their hydrodynamic analogues:—(1) "Charge" or electrical accumulation in a conductor subjected in any way to the process of electrification. (2) "Electro-magnetic induction" or electromotive force excited in a conductor by variations of electric current. (3) Resistance to conduction through a solid. The hydrodynamic analogues are:—(1) Accumulation of a greater or less quantity of water in any part of the canal or tube. (2) Inertia of the water. (3) Viscosity or fluid friction. He explains that a true wave-propagation arises from the compressibility of the water, combined with its inertia, and that if the tube be elastic, like india-rubber, there would also arise a wave-propagation. "Accordingly," he says, "a definite velocity of propagation of electric impulses, depending on the inertia and the capacity for charge, is to be looked for, as has been done in a first article, published by Kirchhoff, on the subject."

Now, in all this discussion Sir Wm. Thomson omits to mention the only thing that is at all analogous to Maxwell's propagation of wave disturbances in non-conductors, and it arises from his considering the water as contained in a tube like ordinary india-rubber tubes, instead of in a tube bored in an indefinitely large lump of india-rubber. If we consider this case it is evident that one of the conditions to be considered is the propagation of waves in this lump of india-rubber. In Sir Wm. Thomson's tube there would of course be a velocity of wave propagation in the india-rubber, but that is a very different matter from the propagation of disturbances away from the neighbourhood of the tube by which energy would be carried away from it. To do this Sir Wm. Thomson should have included the propagation of sound in the air or whatever he supposed surrounding the outside of his tube. Without including this, he was not including anything a bit analogous to Maxwell's electromagnetic theory of light. In Sir Wm. Thomson's tube the whole state of affairs at any time could be expressed in terms of variables that represented bodies near the tube, while in the other case it would be absolutely necessary to introduce variables representing every part of the india-rubber which I have supposed of indefinite extent. This is just the difference between Sir Wm. Thomson's and Maxwell's views. According to Maxwell's view there is a great deal more going on outside the conductor than inside it, and it is evident that the inertia of the water is a very bad analogue to electromagnetic induction, for this latter depends essentially upon the form of the circuit, and not only upon its section and length. Maxwell has shown that light may be a wave-propagation of what are on his theory *analogous*, though probably utterly *unlike* the distorsional waves propagated in the india-rubber, and has shown that a medium which would only transmit disturbances analogous to these would explain electric and magnetic phenomena. It is to be remembered that Maxwell's theory gets rid of all action at a distance, and that the only *experimentum crucis* between theories of action at a distance and of action through a medium is that in this latter case the energy may be propagated in time through the medium, while in the former it cannot.

I cannot conclude without protesting strongly against Sir Wm. Thomson's speaking of the ether as *like* a jelly. It is in some respects *analogous* to one, but we certainly know a great deal too little about it to say that it is *like* one. May be Maxwell's conceptions as to its structure are not very definite, but neither are any body's as to the actual structure of a jelly, and there is no real difficulty in supposing a medium whose condition is represented by symbols that obey the laws that Maxwell has shown should be the laws of symbols representing the condition of a medium that would explain electric and magnetic phenomena. It seems very unlikely that any jelly is at all *like* the ether that Maxwell supposes. It seems much more likely that what he called "electric displacements" are changes in structure of the elements of the ether, and not actual displacements of the elements. He guards against this being supposed a necessary part of his theory when he defines polarisation in terms that certainly require a change of structure rather than a change of position, so that I think the word "displacement" was unfortunately chosen. I also think that Sir Wm. Thomson, notwithstanding his guarded statements on the subject, is lending his overwhelming authority to a view of the ether which is not justified by our present knowledge and which may lead to the same unfortunate results in delaying the progress of science as arose from Sir Isaac Newton's equally guarded advocacy of the corpuscular theory of optics. GEO. FRAS. FITZGERALD

40, Trinity College, April 25

The April Meteors

IN 1882 the Lyrid meteor shower (epoch, April 19–20) was noticed to be far more conspicuous than usual. The display had been quiescent for some years; it appeared to have degenerated into a third rate shower, scarcely deserving the trouble of observation. But in the year mentioned the stream gave distinct intimation of greater intensity, and showed the necessity of continuing annual observations of periodical showers such as this, even though they may exhibit, during a comparatively long interval, but a very feeble sustenance of the richness recorded in former times.

On April 20, 1882, Mr. Corder, at Chelmsford, watching for three hours between dusk and 12h. 30m., counted 26 Lyrids and 8 meteors belonging to other contemporary radiants of minor character. He regarded the horary rate of apparition on that occasion as about two or three times as high as on any other occasion since 1877, when he had been able to watch for the display. He found the radiant at 268° + 37°, and remarked that four of the meteors seen were as brilliant as first-magnitude stars, but he had never found them a very interesting species in respect to their visible appearances.

No observations of the shower were obtained in 1883, the moon being near the full at the time of its occurrence; but in 1884 the conditions were more favourable. On the night of April 19, in the hour preceding midnight, 17 Lyrids were observed by the writer at Bristol. During the last quarter of an hour of the watch the sky was much clouded, and only one Lyrid seen. The horary number was computed as 22 for one observer—evidently, therefore, the display of 1884 was a notable one, and it was very unfortunate that a clouded sky prevented the development of the shower being watched through the morning hours of April 20, when possibly it may have attained a richness without parallel in late years. On the evening of April 20 it had evidently become exhausted, for in a watch of twenty minutes not a single shooting-star appeared, though the sky was very clear.

The present return of the Lyrids occurred under very auspicious circumstances. The moon offered no impediment to morning observations, which is far the best time to watch for these meteors, as the radiant, west of α Lyræ, is very low in the evening hours. The nights of April 17, 18, 19, and 20 were cloudless throughout, and on the three latter dates observations were made here with the following results:—

Date		Period h. m. h. m.		Duration of Watch Hours		Meteors seen		Lyrids seen		Radiant Point ° °
April 18	...	12 0 to 14 30	...	2½	...	16	...	6	...	260 + 33½ [1]
" 19	...	10 30 to 14 0	...	3½	...	26	...	10	...	267½ + 33 [2]
" 20	...	11 30 to 15 30	...	4	...	39	...	14	...	274 + 33½ [3]
Ap. 18-20	...	10 30 to 15 30	...	9½	...	81	...	30	...	267·2 + 33·3

After April 20 moonlight and cloudy weather effectually prevented further work.

The table furnishes us with some interesting facts. It shows that during the three nights the proportion of Lyrids to unconformable meteors was very nearly the same, namely, as 3 to 5, and that the horary rate of their apparition was little more than 3. It also shows a very marked displacement of the radiant (in the direction of east longitude) from night to night. I regard this as the most interesting and certain feature observed. The three centres resulting from the paths of short meteors, observed with the utmost care, may each be relied on as very accurate. It therefore appears most conclusive that the radiant point of the Lyrids, similar to that of the August Perseids, increases in right ascension from night to night, and the extent of this displacement is even greater for the Lyrids than for the Perseids.

[1] Sky clear; slight haze. [2] *Ib.* [3] Sky very clear.

On April 19, 1884, 11¼h., I found the radiant at 269° + 33°, and on April 19, 1885, 12½h. (the middle time of the observation), at 267½° + 33°. Allowing for the difference (about 12′) in the sun's longitude at the two epochs in applying the correction for the displacement of the radiant (7° of R.A. daily) observed this year, we shall find that the two positions are in *exact* agreement.

The recent display has been decidedly meagre in point of numbers. There is a great falling off since last year, when the horary rate was nearly eight times as great. But some of the meteors observed this year were very bright and in a great measure compensated for their scanty apparitions. It is curious that three of the most brilliant Lyrids, equal to or exceeding Jupiter, appeared in nearly the same region of the western boundaries of Virgo. On April 18, at 12h. 57m., one of these fell, with a bright flash and streak, 10° east of Spica Virginis. Another on April 20, at 13h. 14m., came out very suddenly 7° above that star; and a third, at 14h. 1m., descended, with a swift, diving motion, about 13° east of the star, so that the path was nearly similar to that of the first of the three. These five meteors gave transient

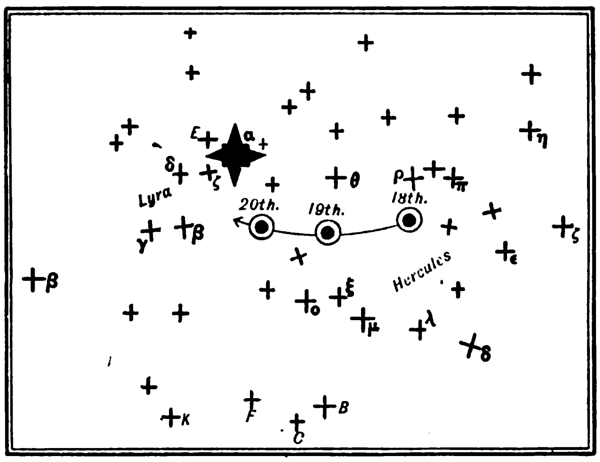

Diagram exhibiting the displacement in the radiant point amongst the stars of Hercules and Lyra on the nights of April 18, 19, and 20, 1885.

flashes of yellowish-white light, which brightly illumined the mist lying along the horizon, and left short streaks of very brief duration. I saw four other Lyrids, quite equal to first-magnitude stars, and these, together with the fainter members of the same shower, were nearly all registered amongst the stars surrounding Lyra, especially those of Hercules, Draco, and Aquila. Altogether I regard the April display of this year as one of considerable importance, for though much less rich than in 1884, it furnished meteors of greater interest and brilliancy. The low position of the radiant during observations last year may have influenced the visible aspect of the meteors from Lyra, especially as regards the swift, flashing characteristic so invariably noticed this year in the brighter members, or, possibly, the explanation may be that near the richer portion of the stream the corpuscles are smaller in almost the same ratio as the increased condensation. It will be advisable to regard this question during future observations of this shower, and especially the new feature detected this year as to the evident shifting of the radiant point from night to night. I believe the maximum of the shower is usually attained with the radiant at 269½° + 33° (the radiant point of its allied Comet I. 1861 is 270¼° + 32°). If the display extends over as long as seven days, and the radiant shifts 7° in R.A. every day, it is curious that the meteors will be *Herculids* on April 17, 18, and 19, *Lyrids* on April 20, 21, 22, and 23, and then *Cygnids* on April 24.

Contemporary with the special periodical display of this epoch there are vast numbers of feeble systems which annually give some indication of their presence. This year I ascertained the positions of several of these showers with great care. The number of meteors from them averaged from 3 to 5 only, but the paths intersect nearly at a point in the individual cases, so that the centres are entitled to the same value as positions resulting from a large number of tracks. I give the best of these co-Lyrid showers, and the nearest confirmations from previous observations:—

Observed 1885		Previous Observations	Authority
April 18	181 + 35½	184 + 35	March 31-April 12, D.S., 1872.
19	236 + 62	240 + 55	April 14, Schiaparelli and Zezioli.
20	226 + 41	223 + 40	March 12-April 30, Greg and Herschel.
18-20	296 ± 0	294 ± 0	April 16-19, 1877, D.
19-20	230 + 17	230 + 26	April 20-24, Heis.
18-20	299 + 24	298 + 25	April 16-19, 1877, D.
		300 + 20	April-May, Corder.
18-20	213 + 9	206 + 13	April 13-May 11, Heis.
18-20	226 ± 0	228 − 2	April 16-19, 1877, D.

The two radiants observed here in 1877 and 1885, with mean position at 295° ± 0° and 298°·5 + 24°·5, are very interesting. The former, just preceding η Aquilæ on the equator, supplies meteors of very great velocity, the latter in Vulpecula gives swift, streak-leaving meteors. This pair of showers, directed from points near the apex of the earth's way, are now, I believe, very exactly determined in regard to their centres of radiation. That they have hitherto evaded frequent detection is not surprising, as they only become well visible in the morning hours. It will be useful to watch for these special streams during future exhibitions of the Lyrids, as well as to note the several other interesting features closely associated with this well-known display.

W. F. DENNING

Chinese Insect Wax

THE beetle alluded to in connection with this subject in the last number of NATURE (vol. xxxi. p. 615) is a probably undescribed species of *Brachytarsus*, a genus of the family *Anthribidæ*, allied to the *Curculionidæ*. Through the courtesy of the authorities at Kew I have had specimens before me. The idea that it acts as a sort of midwife to assist at the birth of infant *Coccidæ* is quite erroneous. The genus *Brachytarsus* is a true parasite on *Coccus*, and its habits, in this connection, in Europe, have long been known. It is of course interesting to find "unity of habit" prevailing in the case of *Coccus Pè-la*, even to its parasite; but with regard to the latter there is nothing new; some points in the general economy of the wax insect, in the notes published, are of far greater importance.

Lewisham, May 1 R. MCLACHLAN

The New Bird in Natal

THERE can be little doubt from the description given by Mr. Turnbull in your issue of April 16 (p. 554) that the bird lately obtained by him in Natal is the Standard-winged Nightjar, *Cosmetornis* (seu *Macrodipteryx*) *vexillarius*, Gould. It has not been met with in Cape Colony, which accounts for Mr. Turnbull's inability to find mention of it in Layard's "Birds of South Africa;" but in Mr. Sharpe's new edition of Layard's work (which Mr. Turnbull would do well to procure) he will find an account of this bird given at p. 89. It appears to have a wide geographical range, being found both on the west and east coasts of Africa; in Angola and Damaraland, in Natal, on the Zambesi (where 300 miles up the river Dr. Kirk found it quite common), in the islands of Bourbon and Madagascar, along the Red Sea shore, and on the island of Socotra. With this extended range it is somewhat remarkable that it has not yet been met with in Cape Colony. According to the observations of Dr. Kirk the singular prolongations of the primaries are peculiar to the males, and a seasonal peculiarity observed only during the months from October until January. The habits of this bird, like those of other nightjars, are crepuscular. An excellent coloured figure of the male is given in Gould's "Icones Avium."

J. E. HARTING

Wild Bees

A FEW words respecting a colony of wild bees (a species of *Andrena*) which I have just discovered in our garden, may interest your entomological readers. A day or two ago, on walking beside a low-turfed mound which supports two trees on one of our towns, I noticed that the grassy surface on the south—therefore the sunny—side was covered with little hillocks of earth, such as ants throw up after rain. On examination each little heap showed the circular hole which denotes a bee's nest, and the bees themselves were seen in many places going in and out. Some holes were level with the ground, but most had the tiny mound of soil cast up in the process of excavation. The peculiarity of the case seems to me to lie in the great number of nests forming a complete colony. It is difficult to count them, but there cannot be less than eighty or ninety in an area—roughly calculated—of about sixty square feet. Have any of your readers noticed a similar city of these busy people? and can any one supply the specific name? E. BROWN

Further Barton, Cirencester, May 2

ON M. WOLF'S MODIFICATION OF FOUCAULT'S APPARATUS FOR THE MEASUREMENT OF THE VELOCITY OF LIGHT

NO one who has the true interests of scientific accuracy at heart can fail to welcome any innovation whereby the elements of a research may be varied, for thereby the ever-lurking constant error is most readily eliminated. It seems, therefore, that this in itself is sufficient reason for the interesting paper communicated by M. Wolf to the Académie des Sciences (*Comptes Rendus*, 9 Février), describing a very ingenious arrangement of Foucault's experiment, and that there was no occasion for disparaging other work in order to justify its publication. It is to be hoped that this was done rather through inadvertence than design, but I feel called upon to correct some of the misapprehensions under which the author labours, and particularly those concerning the appearance and distinctions of the image of the slit in my work on the velocity of light.

M. Wolf remarks that, under the conditions which I selected, this image, even under the most favourable circumstances, must be bordered with very large diffraction fringes, which the atmospheric disturbances transform into a badly-defined "*tache lumineuse*." In reply to this, though I grant that the fringes *ought* to be present, yet I can affirm as a matter of fact that they were not to be seen. Possibly M. Wolf and others may have been somewhat misled by a drawing of the appearance of the image given in my work (p. 124, *Astr. Papers*, *American Ephemeris*, and *Nautical Almanac*, vol. i. Part 3) where the image proper, which is quite clear, is surrounded by a luminous haze, from which, however, it is very easily distinguished.

I hardly think that if M. Wolf had given the "specimen observations" (p. 133 of my work) due consideration, he would have characterised as a "*tache lumineuse*" an image whose position was measured with the following results (each result is the mean of ten observations made by one observer, and recorded without divulging the result by another):—

No. 1	112·801 mm.	0·020 mm.
,, 2	112·773 ,,	0·006 ,,
,, 3	112·769 ,,	0·010 ,,
,, 4	112·772 ,,	0·007 ,,
,, 5	112·779 ,,	0·000 ,,
Average difference from mean =		0·0086 ,,

These are measurements of the *deflected* image, so that the differences are not merely errors of linear measurement, but include errors in the estimate of the speed of the revolving mirror.

Now, M. Wolf, in his most sanguine statement, does not hope for a greater degree of accuracy than one part in 3500 in this particular measurement, whereas the above results are on the average closer than one part in 10,000.

But let us examine the data on which he bases this most favourable estimate. In the first place, the image whose position is to be measured to within one-hundredth of a millimetre is the result of seventy-nine reflections from concave mirrors!

Secondly, one of these mirrors is to be 2 decimetres in diameter. Such a mirror used in a reflecting telescope would show signs of distortion if not carefully mounted—even at rest. But this mirror is required to make fifty revolutions per second, and the distortion is multiplied by forty reflections from its surface!

Finally, notwithstanding the avowed purpose of diminishing the path of the light ("*sans augmenter le trajet de la lumière*"), the distance required is *greater* than in my own experiments in the proportion of 1600 to 1200, and hence atmospheric disturbances would come into play in the same proportion—unless especial precautions were taken to guard against them.

And here, I am free to concede, is an important advantage, but one which is by no means limited to M. Wolf's arrangement, but is universally applicable—for by repeated reflection by plane or by concave reflectors the whole path, either in Fizeau's method or in Foucault's, may be confined to a limited space. But I think the chief object of such an arrangement—namely, to control easily the homogeneity of the air-column—could be more advantageously effected by a long underground tunnel containing a pipe, surrounded, if necessary, by running water, or, better still, exhausted of air.

At Prof. Newcomb's request I have repeated, with some alterations, the experiments described in the paper referred to, and occasionally the appearance of the image was better than in that work. On one occasion the width of the image was carefully measured, and found to be 0·25 mm. Evidently there is nothing remarkable in measuring the position of the centre of an image of this width within a hundredth of a millimetre.

Again, the "probable error" of my final result, 5 kilometres, would seem to show a somewhat greater degree of consistency than would be possible had I only a "*tache lumineuse*" to bisect.

I cannot forbear remarking that by astrononomical methods—if M. Wolf entirely mistrusts the results obtained by Cornu, Newcomb, and myself—the velocity of light is known certainly within 1 per cent., and that it would, therefore, denote rather an excess of caution to deduce a formula for the elimination of a possible uncertainty of from 5 to 10 per cent., as M. Wolf does in determining "*l'ordre* M *de cette déviation*."

In conclusion, I think M. Wolf is to be congratulated on the very happy combination he has devised for the solution of this most fascinating problem—a problem which, notwithstanding its difficulties, will ultimately yield a result correct not merely to one part in 3500, but, I firmly believe, one in 300,000—perhaps one in 1,000,000.

ALBERT A. MICHELSON

SELF-INDUCTION IN RELATION TO CERTAIN EXPERIMENTS OF MR. WILLOUGHBY SMITH, AND TO THE DETERMINATION OF THE OHM

IN a lecture delivered by Mr. Willoughby Smith before the Royal Institution in June last (see *Proceedings*) some experiments are detailed, which are considered to afford an explanation of discrepancies in the results of various investigators relating to the ohm, or absolute unit of electrical resistance. As having given more attention than probably any one else in recent years to this subject, I should like to make a few remarks upon Mr. Willoughby Smith's views, which naturally carry weight corresponding to the good service done by the author in this branch of science.

In the first series of experiments a primary circuit is arranged in connection with a battery and interrupter, and a secondary circuit in connection with a galvanometer and commutator of such a character that the make and break induced currents pass in the same direction through the instrument. Under these circumstances it is found that at high speeds the insertion of a copper plate between the primary and secondary spirals entails a notable diminution in the galvanometer deflection, and this result is regarded as an indication that the molecules of copper need to be polarised by the lines of force—an operation for which there is not time at the higher speeds. The orthodox explanation of the experiment would be that currents are developed by induction in the copper sheet, which thus screens the secondary spiral from the action of the primary, and the result is exactly what might have been anticipated from known electrical principles. I have the less hesitation in saying this, because as a matter of fact I did anticipate from theory the action of a combination very similar in character. The experiment is described in the *Philosophical Magazine* for May, 1882, and differs from Mr. W. Smith's only in the substitution of a telephone for the galvanometer, and of a microphone for the interruptor, no reverser in the secondary circuit being required. By the interposition of a thick copper sheet the sound is greatly enfeebled.

The second series of experiments were made with Faraday's "new magneto-electric machine," in which a copper disk rotates about its centre between the poles of a horse-shoe magnet. The currents developed are examined with a galvanometer whose electrodes touch two points upon the disk—in Mr. W. Smith's experiments, one at the centre, and the other at the circumference. At low speeds the distribution is symmetrical with respect to that diameter of the disk which is passing at any moment between the poles; but, as the speed is increased, a certain "drag" is observed, disturbing the symmetry. This drag, or lagging, was noticed by Nobili in a very similar arrangement as long ago as 1833 ("Wiedemann's Electricity," third edition, vol. iv., § 374), and is no doubt to be attributed to the induction of the currents upon themselves.

This question of self-induction is indeed a very important one in respect of certain methods for determining the ohm; but it certainly cannot be said to have been neglected, as Mr. W. Smith seems to suggest. Both in the original experiments of the British Association Committee with a coil revolving about a vertical axis, and in my own recent repetition of them, the self-induction of the coil is a most important feature, and may cause a displacement of the position of maximum current from the plane of the magnetic meridian through as much as 20°. In my paper (*Phil. Trans.*, 1882, p. 661) I thought I had discussed the question at almost tedious length.

It is possible that Mr. W. Smith had in his mind rather determinations by the method of Lorenz, in which Faraday's disk is used. The arrangement here, however, differs in one very important respect from that of Mr. W. Smith's experiments in that the lines of force are symmetrically arranged in relation to the axis of rotation. The consequence is that, however great the speed of rotation, there are no currents circulating in the disk, and therefore no question arises as to the self-induction of such currents. What is observed is simply the difference of electrical potential between the centre and the circumference. It is impossible to discuss the matter fully here, but the reader will find all that is necessary by way of explanation in the paper published in the *Phil. Trans.* ("Experiments by the Method of Lorenz for the further Determination of the Absolute Value of the British Association Unit of Resistance," &c.). My object in writing is to correct the inference, suggested by W. Smith's remarks, that the question of self-induction has been neglected by workers upon this subject.

RAYLEIGH

THE INVENTIONS EXHIBITION

IN the presence of a crowded and distinguished assembly the Inventions Exhibition was opened by the Prince of Wales on Monday. The Exhibition is, as usual on first days, still in a somewhat chaotic condition, and we can do no more this week than refer to the leading incidents of the opening ceremony. Sir Frederick Bramwell, Chairman of the Executive Council, in his address to the Prince of Wales, gave a sketch of the progress and objects of the Exhibition, which, he pointed out, is intended to illustrate the progress of inventions since the year 1862, and that of musical instruments and appliances since the commencement of the present century. The labours of the different committees were, he stated, rendered extremely onerous by the vast number of applications received—a number far greater then we had space to accommodate. Influential Commissions have been nominated by Austria-Hungary, France, China, Greece, Italy, Japan, Russia, Siam, and Switzerland, from which countries interesting and valuable exhibits have been received or are promised. Arrangements have been made with the Council of the Royal Albert Hall by which that building forms an integral portion of the Exhibition, with the National Fish Culture Association for the maintenance of the Aquarium, and with the Council of the Royal Horticultural Society for the holding of the usual periodical flower and fruit shows. The Old London Street, which was so popular a feature in last year's Exhibition, has been maintained. Many small annexes have been swept away, and in their places spacious galleries have been erected. Not only has greater exhibiting space been thus obtained, but the gardens, which are so great a source of attraction to visitors, have actually been enlarged. Notwithstanding the fact that the gallery used last year for machinery has been greatly extended to meet the requirements of exhibitors, it proved to be inadequate for the many important inventions for which motive power was desired; indeed, it has been found necessary to furnish such power in no less than three other galleries. "The employment of electricity for the purposes of lighting," Sir Frederick said, "is undoubtedly one of the most striking instances of the application of science to the purposes of daily life; we have, therefore, not hesitated to give this subject special prominence. The method we have adopted will, it is believed, render any sudden failure of the lights impossible, and will favourably display the most recent and improved apparatus, and the advances that up to this date have been made in electric lighting. After most careful experiments we have ventured to employ, for the garden illumination, the incandescent electric lamp, and we have done so in a manner and on a scale which, we believe, has never before been attempted. As a division of the Exhibition is devoted to music, we have set apart an important portion of the buildings to the illustration of instruments and appliances appertaining to that art; and we have invited the formation of a historical loan collection of musical instruments, which we believe is of a deeply interesting character. In requesting your Royal Highness to declare this Exhibition open we desire to express the hope that it may, on the one hand, be the means of bringing valuable and meritorious inventions prominently before the general public, to the benefit and credit of the exhibitors, and that it may, on the other hand, be the means by which that public may, within the area of one exhibition, be enabled to appreciate the marvellous progress which during the past quarter of a century every industry has achieved."

The Prince of Wales, in reply said: It is with much pleasure that I have listened to the report of the Executive Council, and I fully appreciate the labours which you have bestowed upon this great undertaking. At the closing of the International Fisheries Exhibition I took the opportunity of expressing a hope that an International Inventions Exhibition might be held in these buildings during the present year; and I am sincerely gratified to find that this hope has been realised. The scope of this Exhibition is, indeed, vast, and I can readily comprehend the difficulties which must have beset you and the Committee of Advice in your endeavours to secure adequate representation for each branch of industry. I have observed with much pleasure that the classification originally adopted has been made the practical basis of the allotment of space in the Exhibition, and that the exhibits in each group have, as far as possible, been placed together. I am convinced that by following this plan you have materially increased the educational value of the Exhibition. I readily echo the sentiments of gratitude which you have expressed for the invaluable aid rendered by the guarantors; and I join with you in welcoming the representatives of those foreign countries who are present here to-day.

The Prince of Wales, after declaring the Exhibition open, made a tour of the galleries in company with the Princess of Wales and many others of the distinguished visitors who were present.

THE FLORA OF BANK-NOTES

"LA Flore des Billets de Banque" is the title of an article in *Science et Nature*, an article which, in spite of an amusing tendency inseparable from all things savouring of sensational science, may suggest thoughts more or less alarming in view of recent discoveries in bacteriology. It is no new fact that books, coins, and other articles of a durable nature which pass much from hand to hand may be the means of transmitting

FIG. 1

infectious diseases, and if these infectious diseases are caused by visible and tangible agents, it is not going far to expect that the agents should be discoverable on the transmitting media by means of the microscope, and by other methods employed by the specialists who devote themselves to tracing the awful bacterium to its home. Of course it is now matter of fact that "bacteria" (using the term in its widest sense) can be and are causal agents in disease, and the writer of the article referred to shows that bacteria and other minute organisms always occur on bank-notes; there is, perhaps, no more in this observation than that it demonstrates a fact in a particular case which scientific biologists have shown to be true much more generally. All objects exposed to the air and passed from hand to hand are apt to have minute organisms settling upon them, and we should expect such things as bank-notes, which pass through many hands, to be favoured by more than their usual share of "germs," knowing that simple abrasion is no satisfactory means for removing such minute bodies. Nevertheless it is interesting to see what really have been found on European bank-notes. M. Reinsch some time ago undertook to examine the money in circulation, with the result that two very small algæ, which were named as species of *Chroococcus* and *Pleurococcus* respectively, proved to be not uncommon on coins. M. Jules Schaarschmidt has since undertaken to examine the paper currency of various States, with the result that such living organisms and other objects as those in the annexed woodcut were discovered. According to the statements to hand, the notes examined were particularly those of Austro-Hungary and Russia, and new as well as old ones furnished "an abundant cryptogamic vegetation," as well as "microbes," and objects such as grains of starch, particles of hair, &c.

The entire list comprises *Bacterium termo*, the common bacterium of putrefaction; *Saccharomyces cerevisiæ*, the

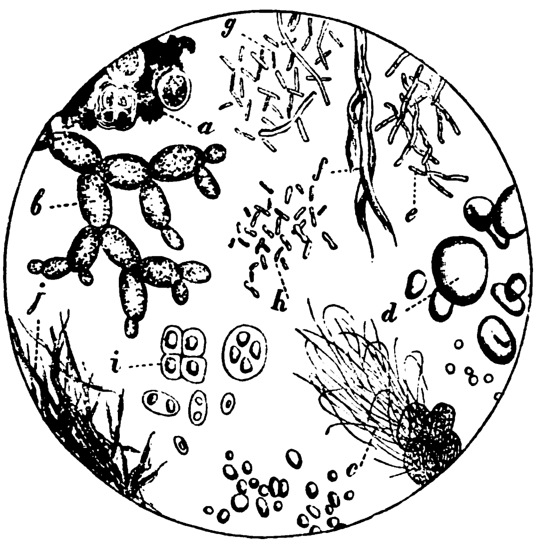

FIG. 2.—*a* and *i*, minute algæ; *b*, yeast cells; *c*, *Leptothrix*; *d*, starch-granules; *e*, *g*, *h*, various *Schizomycetes*; *f* and *j*, fibres.

yeast plant; various species of *Micrococcus*, *Leptothrix*, and *Bacillus*, as well as the two minute green algæ described by Reinsch.

We presume, in the absence of definite statements, that the groups of organisms sketched in Fig. 2 were obtained at different times, and on different notes; otherwise the "flora" is indeed a rich and abundant one, and may probably have been an isolated one, to allow the species of *Saccharomyces* to form such a fine growth.

There is obviously a very serious side to all this, however, if further researches prove that, as appears possible, our most minute and dreaded enemies are always in our midst on such apparently welcome visitants as coin and bank-notes: money will have earned a worse name even than it has heretofore! *En revanche*, there are two points which no doubt will be insisted on: in the first place, the observers named have not, so far, described any organism on the money investigated which is known to be inimical to us; and secondly, precautions have been taken from time immemorial against the transmission of currency passing from a plague-stricken community to a healthy one. Possibly the facts derived from these observations will be made use of to bring more forcibly before the minds of our less careful brethren the dangers of handling "filthy lucre" in times of disease.

STANDARD PITCH[1]

M. SORET raises the question of musical pitch, and advocates A 432, long ago proposed by M. Meerens, of Belgium. It is rather curious that in Belgium itself M. Meerens's proposal was considered and rejected by a Commission appointed in 1877, upon whose report the French pitch A 435 was adopted by Royal decree on March 19 of this year. There seems to be very little difference between the two; it amounts, in fact, to exactly 12 cents or hundredths of an equal semitone, of which 21½ make a comma. Hence there is no practical reason for making the change as affecting singers. But no instruments made for A 435 would be available for A 432, so that the advantage of uniformity would be lost, without any advantage to the voice or the quality of instruments. The arguments in its favour are almost entirely arithmetical. To begin with the inaudible 1 vibration and proceed by exact doubling to 64 is an arithmetical dream. It is true that König, by a most ingenious adaptation of a large tuning-fork acting in place of a pendulum to a clock going in a room at 20° C. (for about five days in a year), has succeeded in making a fork of that precise number of vibrations at that precise temperature. But at 15° C., the temperature adopted for the French *diapason normal* (standard fork), the pitch of this would not be 64, but, to take König's numbers, 64·036. The charm of the arithmetic vanishes, therefore, with a slight alteration of temperature, and the pitch has become fully 1 cent (hundredth of a semitone) sharper. Granted that this is an imperceptible amount, yet it is enough to alter the whole of the arithmetic. Then the arithmetic is itself founded on just intonation, which is not adopted anywhere. If we take the equal temperament, now generally accepted, we should get for A 432 the values C 256·9, C♯ 272·2, D 288·3, D♯ 305·5, E 323·6, F 342·9, F♯ 363·3, G 384·9, G♯ 407·8, A 432, A♯ 457·7, B 473·9, C 513·8. There is nothing charming here. M. Soret, in his table, quietly ignores the chromatic notes and the equal temperament. If, however, we took C 256 as the starting-point, the A of C major in just intonation would not be 432, but, as he owns, a comma flatter, 426·67. He bases everything physically on the violin, which is tuned in D and not in C, or the viola and violoncello, which are both tuned in G, not in C, and hence even for these instruments, with the great assumption of just intonation, his use of the major scale of C is incorrect.[2] The reasons that are to guide us in the choice of a pitch must certainly not be arithmetical. For more than two centuries up to 1813, when the Philharmonic Society was founded, all Europe used a pitch within a comma either way of Handel's fork A 422·5. Then, owing to the presentation of new instruments by the Emperor of Russia to a Vienna regiment at the Congress of Vienna, pitch rose gradually but slowly. In 1826 our Philharmonic Society, under Sir G. Smart, adopted A 433, between M. Soret's and French pitch, and this was known for many years in London as the Philharmonic pitch. France adopted A 435 in 1859. Under Costa our pitch rose to its present height, A 454·7. But our army pitch, used at Kneller Hall, and adopted for the forthcoming Exhibition, is A 452. Now, the trouble is that our classical composers wrote their music for Handel's pitch, while since 1860 Continental composers

[1] J.-L. Soret, "Sur le Diapason" (*Archives des Sciences physiques et naturelles*. January, 1885. Geneva).

[2] Savart, whom M. Soret quotes, was in error with regard to the pitch of the resonance of Cremona violins. It was not 256 vibrations. A series of instruments examined by Mr. A. J. Ellis in 1880 gave about 270 as the primary maximum, and 252 as the secondary. But the main character was the great uniformity of reinforcement for different pitches.—See his "History of Musical Pitch."

have used French pitch, and English composers our high pitch. The first and last may compromise with the second, but are incompatible with each other. To sing Handel in modern English pitch is to unduly strain voices and spoil the effect originally intended. But we submit to it even in Handel festivals. There is a greater difficulty in altering pitch in England than on the Continent. We have no subsidised Conservatoires or theatres to which we can say: "Use this standard of pitch, or go without subsidy." Even regimental bands are not supplied at the expense of the State. A new set of instruments is very costly, and more than that, it is long before makers learn how to manufacture correctly to a new pitch. The question is therefore beset with difficulties. But the solution is certainly not to be found in the arithmetic of M. Soret.

THE SCIENCE AND ART MUSEUM, EDINBURGH

We understand that Col. Murdoch Smith has been appointed by the Lords of the Committee of Council on Education to the Directorship of this Museum, in succession to the late Prof. Archer. As Lieut. Smith he was associated with Prof. Newton in the discoveries at Helicarnassus, and, subsequently, with Commander Pacher, R.N., undertook the explorations in the Cyrenaica which resulted in the acquisition by the nation of the valuable collection of sculptures now in the British Museum. Latterly, Col. Smith, while employed at Teheran, has acquired for the South Kensington Museum the large and valuable collection of Persian art and manufactures which is so well known there. We believe Col. Smith obtained his first Commission in the Royal Engineers direct from a Scottish University, and is one of the very few officers in that Corps who did not pass through the Royal Military Academy at Woolwich or Addiscombe.

NOTES

We take the following from the *Times*:—The following is the list of selected candidates recommended by the Council of the Royal Society for the election to the Fellowship:—A. W. Baird, Major R.E., P. Herbert Carpenter, D.Sc., Sir Andrew Clark, M.D., Mr. A. A. Common, F.R.A.S., E. W. Creak, Staff-Commander, R.N., Prof. E. Divers, H. Hicks, M.D., W. M. Hicks, M.A., F. R. Japp, Ph.D., A. M. Marshall, M.D., Prof. H. N. Martin, D.Sc., C. O'Sullivan, Prof. J. Perry, Prof. Sydney Ringer, and Sidney H. Vines, D.Sc.

Of the fifteen candidates who have thus been selected no less than five are Cambridge men. Mr. W. M. Hicks was bracketed seventh wrangler in the Mathematical Tripos of 1873. Prof. H. N. Martin, Prof. Milnes Marshall, and Dr. Vines were the seniors in the Natural Science Triposes of 1873, 1874, and 1875 respectively, while Dr. Herbert Carpenter obtained a First Class in the Tripos of 1874, together with Mr. J. N. Langley, who was elected to the Royal Society in 1883. The name of the late Prof. F. M. Balfour follows that of Dr. Martin in the Tripos list of 1873; while the late Prof. A. B. Garrod was senior in 1871, and the Tripos list of 1870 contains the names of Francis Darwin and E. J. Romanes. The Natural Science Triposes from 1870 to 1875, inclusive, have thus furnished no less than nine Fellows of the Royal Society, either actual or elect. The names of seven more occur in the Mathematical Tripos lists from 1871 to 1880 inclusive, viz.: J. Hopkinson (1871), J. W. L. Glaisher (1871), H. Lamb (1872), A. B. Kempe (1872), W. M. Hicks (1873), Rr. T. Glazebrook (1876), and J. J. Thomson (1880). To these may be added the name of Dr. W. H. Gaskell, who obtained mathematical honours in 1869, but has since devoted himself to physiology. All who know Cambridge will recognise how largely these results are due to the influence and example of the late Prof. Clerk Maxwell and of Prof. Michael Foster respectively.

We are informed that Dr. Frankland, F.R.S., has intimated his intention to resign the Professorship in Chemistry in the Normal School of Science and Royal School of Mines at the end of the current session. Applications for the post should be addressed to the Secretary, Science and Art Department.

The Fifty-fifth Annual Meeting of the British Association will commence on Wednesday, September 9, 1885, at Aberdeen. The President-Elect is the Right Hon. Sir Lyon Playfair, K.C.B., M.P., Ph.D., LL.D., F.R.S. L. & E., F.C.S., who will take the place of Lord Rayleigh. The Vice-Presidents are His Grace the Duke of Richmond and Gordon, K.G., Chancellor of the University of Aberdeen, the Right Hon. the Earl of Aberdeen, LL.D., Lord-Lieutenant of Aberdeenshire, the Right Hon. the Earl of Crawford and Balcarres, F.R.S., James Matthews, Lord Provost of the City of Aberdeen, Prof. Sir William Thomson, F.R.S., Alexander Bain, M.A., LL.D., Rector of the University of Aberdeen, the Very Rev. Principal Pirie, D.D., Vice-Chancellor of the University of Aberdeen, Prof. W. H. Flower, F.R.S., Pres.Z.S., Director of the Natural History Museum. General Treasurer: Prof. A. W. Williamson, F.R.S., University College, London, W.C. General Secretaries: Capt. Douglas Galton, C.B., F.R.S., A. G. Vernon Harcourt, F.R.S. Secretary: Prof. T. G. Bonney, F.R.S. Local Secretaries for the meeting at Aberdeen: J. W. Crombie, M.A., Angus Fraser, M.A., M.D., Prof. G. Pirie, M.A. Local Treasurers for the Meeting at Aberdeen: John Findlater, Robert Lumsden. The Sectional Officers are as follows:—A. Mathematical and Physical Science. President: Prof. G. Chrystal, M.A., F.R.S.E. Vice-Presidents: Prof. C. Niven, F.R.S., Prof. A. Schuster, F.R.S. Secretaries: R. E. Baynes, M.A., R. T. Glazebrook, F.R.S., Prof. W. M. Hicks, M.A. (Recorder), Prof. W. Ingram, M.A. B. Chemical Science. President: Prof. H. E. Armstrong, F.R.S. Vice-Presidents: Prof. A. Crum Brown, F.R.S., Prof. H. McLeod, F.R.S. Secretaries: Prof. P. Phillips Bedson, D.Sc., F.C.S. (Recorder), H. B. Dixon, M.A., F.C.S., H. Forster Morley, D.Sc., F.C.S., W. J. Simpson, M.D. C. Geology. President: Prof. J. W. Judd, F.R.S., Sec.G.S. Vice-Presidents: John Evans, Treas.R.S., Prof. W. C. Williamson, F.R.S. Secretaries: C. E. De Rance, F.G.S., J. Horne, F.R.S.E., J. J. H. Teall, M.A., F.G.S., W. Topley, F.G.S. (Recorder). D. Biology. President: Prof. W. C. McIntosh, F.R.S. Vice-Presidents: Prof. I. Bayley Balfour, F.R.S., Prof. J. S. Burdon Sanderson, F.R.S. Secretaries: W. Heape, J. Duncan Matthews, F.R.S.E., Howard Saunders, F.L.S., F.Z.S. (Recorder), H. Marshall Ward, M.A. E. Geography. President: Lieut.-General J. T. Walker, C.B., R.E. F.R.S., F.R.G.S. Vice Presidents: Prof. James Donaldson, F.R.S.E., John Rae, M.D., F.R.S. Secretaries: J. S. Keltie, F.R.G.S., J. S. O'Halloran, F.R.G.S., E. G. Ravenstein, F.R.G.S. (Recorder), Rev. G. A. Smith. F. Economic Science and Statistics. President: Prof. Henry Sidgwick, M.A., Litt.D. Vice-Presidents: Prof. R. Adamson, M.A., LL.D., Sir Rawson W. Rawson, K.C.M.G., C.B., Pres.S.S. Secretaries: Rev. W. Cunningham, D.Sc., F.S.S., Prof. H. S. Foxwell, F.S.S. (Recorder), C. McCombie, M.A., J. F. Moss, F.R.G.S. G. Mechanical Science. President: Benjamin Baker, M.Inst.C.E. Vice-Presidents: Prof. W. C. Unwin, M.Inst.C.E., Prof. H. C. Fleeming Jenkin, F.R.S., M.Inst.C.E. Secretaries: A. T. Atchison, M.A., M.Inst.C.E. (Recorder), F. G. Ogilvie, M.A., E. Rigg, M.A., H. T. Wood, M.A. H. Anthropology. President: Francis Galton, F.R.S., President of the Anthropological Institute. Vice-Presidents

W. Pengelly, F.R.S., Prof. W. Turner, F.R.S. Secretaries: G. W. Bloxam, F.L.S. (Recorder), J. G. Garson, M.D., Walter Hurst, B.Sc., A. MacGregor, M.B. The First General Meeting will be held on Wednesday, September 9, at 8 p.m. precisely, when the Right Hon. Lord Rayleigh, M.A., D.C.L., LL.D., F.R.S., F.R.A.S., F.R.G.S., will resign the chair, and the Right Hon. Sir Lyon Playfair, K.C.B., M.P., Ph.D., LL.D., F.R.S. L. & E., F.C.S., President-Elect, will assume the Presidency, and deliver an address. On Thursday evening, September 10, at 8 p.m., there will be a Soirée; on Friday evening, September 11, at 8.30 p.m., a discourse by Prof. W. Grylls Adams, M.A., F.R.S., F.G.S.; on Monday evening, September 14, at 8.30 p.m., a discourse on "The Great Ocean Basins," by John Murray, F.R.S.E., Director of the *Challenger* Expedition Commission; on Tuesday evening, September 15, at 8 p.m., a Soirée; on Wednesday, September 16, the concluding General Meeting will be held at 2.30 p.m. The lecture to working men will be on the "Nature of Explosions," by Mr. H. B. Dixon, M.A., F.C.S., Fellow of Trinity College, Oxford.

WE understand that the Marquis of Lorne is likely to succeed Lord Aberdare as President of the Royal Geographical Society.

SIR JOHN LUBBOCK responded to the toast of "Science" at the Royal Academy dinner on Saturday evening, and in doing so adduced one more argument on behalf of science as a training and discipline even from the standpoint of art. He claimed for the workers in science that the careful habit of observation and study in which they are necessarily trained enable them to derive peculiar enjoyment from the creations of artistic genius; and he might have suggested in this connection the great advantage to the artist himself of a preliminary training in practical scientific work.

SIR FREDERICK BRAMWELL has evidently a very high ideal of the training necessary to qualify a civil engineer for the performance of the duties of his calling. At the anniversary dinner last week he told his audience that the ideal engineer—"I am glad to say in many cases the real engineer—of the present day is one who has a scientific knowledge as the foundation for his technical training, and frequently that scientific knowledge is of a very extended character. Mechanics, it need hardly be said, are essential, but, in addition, many branches of physical science, such as heat, light, sound, hydraulics, pneumatics, magnetism, electricity, are all now within the knowledge of the accomplished engineer. Moreover, although I do not suggest that every engineer should be a chemist, it is quite certain that he should not be without some chemical instruction, even if it be confined to that which is needed to warn him that the time has arrived when he should seek sound chemical advice."

DR. NOETLING, of the University of Königsberg, has been despatched by the Prussian Academy of Sciences to Lebanon, to study the geology of the Greater Hermon.

THE Italians have lost no time in erecting a meteorological station at Massowah, which they have occupied quite recently.

EARLY in the afternoon of the 2nd a loud detonation was heard from Mount Vesuvius, and two new craters, from which lava issued abundantly, were opened on the southern side at a height of about 200 metres above the upper station of the funicular railway. The lava flowed in the direction of Pompeii and Torre del Greco. The stream descends in a straight line for about half a kilometre, and then, turning sideways, is directed towards the crater of 1872. The new craters present the appearance of a great cleft. The lava has not spread beyond the side of the mountain, and according to the latest telegram the eruption is not increasing.

AT half-past 1 o'clock on the morning of the 1st inst. two or three rather violent shocks of earthquake were felt at Vienna, accompanied by a rolling noise, and causing a great clattering of furniture. Shocks of far greater violence were experienced in Styria, where many houses were damaged and some persons were killed. In the western districts the shocks were of a slight character. The phenomenon appears to have extended southward as far as Grätz and westward to Bavaria. A shock was also felt at Monte Carlo at 10 minutes to 3 on the morning of the 2nd. The shock was strongest in the districts of Condamone and the Cap d'Aile.

THE Annual General Meeting of the members of the Iron and Steel Institute commenced yesterday. The Bessemer medal for the year was presented to Prof. Richard Åkermann by Dr. Percy, F.R.S., the newly-elected President, who gave his inaugural address. The meeting will be continued to-day and to-morrow. The following is a list of some of the principal papers:—On the blast furnace value of coke from which the products of distillation have been collected, by Mr. I. Lowthian Bell, F.R.S.; on the manufacture of steel, by Sir Henry Bessemer, F.R.S.; on the mechanical properties of steel, by Dr. H. Wedding; on the microscopic structure of steel, by Dr. Sorby; on the causes of failures in steel plates, by Mr. W. Parker, of Lloyd's; on a new description of wrought-iron castings, by Mr. T. Nordenfelt; on natural gas, and its utilisation for manufacturing purposes in the United States, by Mr. A. Carnegie; on a modified type of the Siemens gas-producer, whereby the gases are enriched and the bye-products recovered, by Mr. J. Head. We propose to draw attention to the scientific points in some of these papers next week.

PROF. W. ODLING will give the first of two lectures on Organic Septics and Antiseptics, at the Royal Institution, on Saturday, May 16.

THERE is an excellent programme for May at the Royal Victoria Hall and Coffee Tavern, Waterloo Bridge Road, S.E. The science lectures on Tuesdays will be given by Dr. Dallinger, on wonderful things we do not personally see, on the 12th; and by Prof. Perry on the spinning tops of Japan and other countries, on the 19th. Owing to the depression in trade and wishing to put enjoyable entertainments within every one's means, the management have decided to lower the prices of admission during May.

THE Russian Geographical Society has awarded, this year, its great Constantine medal to M. A. S. Woeikoff for his important work, "The Climates of the Globe, and especially of Russia." Analysing this work in the "Annual Report for 1884" of the Society, Dr. Robert E. Lenz shows how original it is in its fundamental idea. Instead of representing the climates as they result from the averages of climatological elements, as is usually done in meteorological works, M. Woeikoff, like Dr. Hann in his "Handbuch der Klimatologie," but with much more fullness and details, tries to explain the local alterations which the general meteorological laws are submitted to in various countries in consequence of the topographical features of these last; and he verifies his conclusions with regard to each country by comparing them with those arrived at as to the climates of neighbouring countries, and establishes thus the elements of a comparative meteorology. The extensive travels of the author in Asia and America have enabled him to recognise the leading meteorological features of the climates he describes and to become acquainted, by personal knowledge, with the topographical features of each separate region. The first twenty-two chapters of this volume, 640 pages, are devoted to a detailed analysis of the chief meteorological elements: the heat received from the sun; the dynamical and thermical consequences of the rising and falling of masses of air; the hydrometeors and their influence on the climates of separate regions—many quite new and original remarks and observations being embodied in these five chapters; the influence of snow and ice-coverings—two chapters again where the meteorologist and geologist will find a series of most interesting suggestions; the temperature of lakes, seas, and oceans; the influence of wind; the variations of temperature with the height—very carefully discussed; the diurnal changes and the unperiodical ones; and finally, the influence of climate on vegetation, and *vice versâ*—again two chapters full of new appreciations. The climates of eight separate regions—Atlantic, North and Middle America, Tropical America, Middle and South Africa, Mediterranean basin, North-West and Middle Europe, South-Eastern Asia, and finally Russia and Northern Asia, are discussed with great detail and with a richness of quite new data in ten separate chapters. Needless to add that the author, well acquainted with so many foreign languages, has embodied in his work all that is worthy of notice in meteorological literature. The work is illustrated by ten maps and fourteen drawings, and contains very numerous tables.

DURING the opposition of Neptune, just passed, we learn from *Science*, Prof. Pickering continued the observation of the planet's magnitude with the meridian photometer of the Harvard College Observatory in the same method as previously employed. Nine series of observations extend from December 16, 1884, to January 21, 1885, the final result from which, when corrected for atmospheric absorption, instrumental error, and reduction to mean opposition, becomes 7·63. The residual difference for only one series is as great as two-tenths of a magnitude. The corresponding results for two previous seasons are 7·71 and 7·77. Contrary to the experience of Mr. Maxwell Hall, of Jamaica, who found evidence for a rotation-period of Neptune in small variations of the planet's light according to his own observations, Prof. Pickering regards it as improbable that there is any variation in the light of Neptune of a strictly periodic character, and further calls attention to the influence, much neglected by observers, upon the observed brightness of objects when seen east and west of the meridian on the same night. This has to be taken account of in the observations of maxima and minima of many variable stars, and may to some extent account for the variations of Neptune's light detected by Mr. Hall.

THE report of the. Post Office, Telegraph, and Observatory Departments of South Australia for the past year contains a detailed account *inter alia* of the work of the Observatory Department in that colony since its foundation in 1867. It would be impossible to do more than refer generally here to numerous details given in the ten closely-printed foolscap pages devoted to the subject. Since its establishment the department appears to have kept pace with the strides of the colony to which it belongs. The astronomical observatory at Adelaide is now well supplied with meteorological appliances, having self-recording and other instruments necessary to constitute it a first-class station as defined by the Meteorological Congress at Vienna. There are also fourteen well-equipped stations of the second order, scattered all over the colony, from Port Darwin, in the extreme north of the continent, to Cape Northumberland in the extreme south. Rain-gauges are kept at every telegraph office in the colony; in 1870 there were reports from forty-six stations; in 1883 from 254, and there are still large gaps to be filled up. A system of weather-telegraphy has been arranged between the Australasian colonies, these being divided into districts or aspects to facilitate the transmission of the messages, and to afford the necessary data for laying down the isobars. The important operations undertaken to determine Australian longitudes are also described in detail. Mr. Todd, the head of the combined departments—post, telegraph, and observatory—anticipates great assistance in the inter-colonial meteorological part of his work from Mr. Clement E. Wragge's high-level meteorological station on Mount Lofty, "as he brings to his work great practical experience and almost unbounded enthusiasm."

THE last number (vol. v. No. 4, 1885) of the *Proceedings* of the Bath Natural History and Antiquarian Field Club contains papers on the group of stones at Stanton Drew, in Somersetshire, by Mr. J. Allen Tucker, in which he favours the theory that these huge monuments are the remnants of a temple, either erected by the Druids or by some primeval or prehistoric race, and only used by the Druids, and were not intended to commemorate a battle, which was too common an event in early times; by Rev. L. Blomefield, on a second specimen of the rare Longicorn beetle found in Bath; by Mr. Williams, on the natural history of British owls; and by Mr. Morgan, on water-supply, principally as applied to domestic purposes. There are also several minor contributions noticed in the summary of proceedings at the meetings.

WE have received the prospectus of a Field Club for Hampshire, the Honorary Secretary to which is Mr. E. Westlake, Fordingbridge, Salisbury. The first meeting is to be held at Winchester on May 28. The marvel is that a county as varied as any in England in this respect should have been so long without its Naturalists' Field Club. White of Selborne on the east, and Kingsley on the north, have made the county a classic one for students of nature. With these examples to live up to, and such a field as Hampshire (including the Isle of Wight) the Proceedings of the new club should be interesting and successful.

THE Report of the Committee of the Kelvingrove Museum of Glasgow for the past year illustrates the truth of a remark of Mr. Higgins in his pamphlet on museums recently noticed in these columns, viz. that the number of museums in which a sum of money could be best spent in making additions is very small; that is, as a rule, arrangement is more needed than acquisition. The Committee of the Kelvingrove Museum report that the establishment has been overcrowded for years, that the enormous amount of specimens of all kinds stored away out of sight is constantly increasing, and that the labour and unremitting watchfulness required to keep such stored specimens from deteriorating grows in proportion, and withdraws from essential and more useful museum work much of the time of the small staff, and it has thus become from year to year increasingly difficult to undertake any considerable project for improving the order, classification, or labelling of any section of the museum. This is certainly a grave evil, for it threatens to destroy the main object of such a museum, viz. public instruction. It is to be hoped that a wealthy and public-spirited town such as Glasgow will not permit this state of things to continue; for, as the Report points out, from the stores already within the museum, supplemented in some departments by inexpensive and easily acquired objects, a natural history museum could be equipped which would satisfactorily illustrate all the range of the animal kingdom, and prove at once of great value to the student of zoology, and a popular attraction to the public. For the rest, there has been "a large, steady, and well-maintained flow of visitors, which does not show any indication of waning."

THE Lyceum of Natural History of Williams College, Williamstown, Mass., the oldest natural history society but one connected with any college in the United States, will celebrate its fiftieth anniversary on the 24th of this month, at which a former member, Dr. W. K. Brooks, of the class of 1870, now Associate of Johns Hopkins University, will deliver an address. The Lyceum proposed to take advantage of the occasion to raise funds to enable it to undertake expeditions to some spot, similar to those which it has undertaken in former years to Labrador, Florida, &c.

WE learn from *Science* that the Leander McCormick Observatory of the University of Virginia was inaugurated on April 13, the ceremonies taking place in the public hall of the institution, and Prof. Asaph Hall, of the Naval Observatory, Washington, delivering the address. The principal instrument is the great Clark refractor of 26 inches' aperture. The Observatory has a house adjoining for the director, Prof. Stone, and is possessed of a considerable endowment fund, the gift of Mr. W. H. Vanderbilt, of New York.

CAPT. L. U. HERENDEEN, of San Francisco, communicates the following notes on prehistoric structures in Micronesia to *Science*:—A few years ago I visited Ponapé Island in the Pacific, in E. longitude 158° 22′, and N. latitude 6° 50′. The island is surrounded by a reef, with a broad ship-channel between it and the island. At places in the reef there were natural breaks, that served as entrances to the harbours. In these ship-channels there were a number of islands, many of which were surrounded by a wall of stone five or six feet high; and on these islands there stood a great many low houses, built of the same kind of stone as the walls about them. These structures seem to have been used as temples and forts. The singular feature of these islands is that the walls are a foot or more below the water. When they were built, they were evidently above the water, and connected with the mainland; but they have gradually sunk until the sea has risen a foot or more around them. The natives on the islands do not know when these works were built: it is so far back in the past, that they have even no tradition of the structures. Yet the works show signs of great skill, and certainly prove that whoever built them knew thoroughly how to transport and lift heavy blocks of stone. Up in the mountains of the island there is a quarry of the same kind of stone that was used in building the wall about the islands; and in that quarry to-day there are great blocks of stone that have been hewn out, ready for transportation. The natives have no tradition touching the quarry—who hewed the stone, when it was done, or why the work ceased. They are in greater ignorance of the great phenomena that are going on about them than the white man who touches on their island for a few hours for water. There is no doubt in my mind that the island was once inhabited by an intelligent race of people, who built the temples and forts of heavy masonry on the high bluffs of the shore of the island, and that, as the land gradually subsided, these bluffs became islands.

A CORRESPONDENT recently referred to the use of artificial teeth by the ancient Romans, as shown by a passage from Cicero, where one of the laws of the Twelve Tables is quoted. The law in question belongs to the Tenth Table (*de jure sacro*), which deals mainly with funerals, with the object of limiting the display and ceremonies attending them. Thus the body must not be burnt in more than three robes, or be attended to the grave by more than ten musicians; women must not tear their faces in time of mourning, nor must the bones be collected to make a new funeral with them, the bodies of slaves could not be embalmed, and the like. Section IX. of Table X., which is the one relating to teeth, reads as follows in Ortolan's text ("Histoire de la Législation Romaine," p. 121): "*Neve aurum addito. Quoi auro dentes vincti escunt, ast im cum illo sepelire urereve se fraude esto*—Add no gold; but if the teeth are bound with gold, then that gold may be buried or burnt with the corpse." The date of the Twelve Tables is put about 450 B.C., and it is thought possible by some writers that some of the provisions relating to funerals were taken from the laws of Solon. It would therefore appear that dentistry was known and practised to some extent in the earliest period of their history by the Romans—to an extent, at any rate, that they used gold for binding the teeth. How the artificial teeth were made, or whether they had artificial teeth at all, is not apparent. In the case of the Etruscan skull mentioned recently in NATURE, the artificial teeth are made from the teeth of animals.

M. SOROLOFF, who continues his regular analyses of the water of the Neva, has come to the conclusion that the differences between the average monthly content of solid mixture in the water and the yearly average may be expressed by a curve whose characteristics are the opposite to those of the curve for the average monthly temperatures. The solid inorganic deposit remaining after the evaporation of a given amount of water is also inversely proportionate to the amount of organic matter contained by the water of the Neva. When comparing these curves for the Neva with that showing the amount of solid matter contained by the Thames (as given in the *Journal* of the London Chemical Society for 1880), it appears that both rivers give the same curves, notwithstanding the wide difference of their origins, which coincidence may lead to the supposition that the above might be considered as a law for the rivers.

THE additions to the Zoological Society's Gardens during the past week include a Yellow Baboon (*Cynocephalus babouin* ♀) from West Africa, presented by Mrs. Wilson; a Lesser White-nosed Monkey (*Cercopithecus petaurista* ♀) from West Africa, presented by Mr. James S. Jameson; a Crested Pigeon (*Ocyphaps lophotes*) from Australia, presented by Mr. J. Harrison; a Glaucous Gull (*Larus glaucus*), European, presented by Mr. G. Edison; a Common Viper (*Vipera berus*), British, presented by Mr. W. H. B. Pain; four Common Lizards (*Lacerta vivipara*), British, presented by Mr. H. Hanauer; a Common Squirrel (*Sciurus vulgaris*), British, three Wigeons (*Mareca penelope* ♀ ♀ ♀), three Pintails (*Dafila acuta* ♀ ♀ ♀), two Shovellers (*Spatula clypeata* ♀ ♀), five Common Teal (*Querquedula crecca* ♂ ♂ ♂ ♀ ♀), European, purchased; a Yak (*Poephagus grunniens*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

TUTTLE'S COMET.—This comet returns to perihelion in the present year under circumstances which are not favourable for its re-observation, without an ephemeris deserving of some degree of reliance. For the last return in 1871 the perturbations during the previous revolution were very accurately determined by Tischler, of Königsberg, who lost his life before Metz in the Franco-German war; and the comet was detected at Marseilles about seven weeks before the perihelion passage, and was followed at the Cape of Good Hope for a still longer period after it. So far it does not appear that the observations of 1871-72 have been brought to bear upon the predicted elements, nor has it been notified that any one is occupied in ascertaining the effect of planetary attraction since the comet was last observed. Tischler's mean motion for 1871, neglecting perturbation, would bring the comet to perihelion again about 1885, September 23·5 G.M.T., and under this condition the comet's position will by readily commanded during the absence of moonlight in August, but unfortunately the theoretical intensity of light will be below the least value with which it has been thus far observed. Assuming the perihelion passage to fall on September 23, the following would be the rough places of the comet:—

At Greenwich Midnight

	R.A.	Decl.	Distance from Earth	Distance from Sun	Intensity of Light
	°	°			
August 10	106·5	+33·8	1·89	1·22	0·19
14	110·1	31·6	1·85	1·19	
18	113·6	29·3	1·82	1·17	0·22
22	117·0	26·7	1·78	1·14	
26	120·4	+24·0	1·75	1·12	0·26

In 1871, when the comet was detected by Borrelly at Marseilles with the aid of Tischler's ephemeris, the intensity of light was 0·54, and at the last Cape observation, 0·33. On August 10 the effect of an acceleration of eight days in the time of perihelion passage would be to increase the comet's right ascension rather more than 3°, and to diminish the declination about 4°·4.

In the middle of September it will have attained the value at which observations have been already made.

This comet was first observed by Méchain on January 9, 1790. It was rediscovered by Mr. Tuttle at Cambridge, U.S., on September 5, 1858: from the observations made in this year its period was ascertained to be about 13·8 years, so that the comet had completed five revolutions since it was found by Méchain, without having been perceived. According to Clausen's calculations it was in perihelion on the following dates:—1803, November 7; 1817, May 18; 1830, December 6; and 1844, June 28. It approaches nearest to the orbit of Jupiter in heliocentric longitude 264°, or at a true anomaly of about 144°, when its distance from the planet's orbit is 0·8. At the comet's last passage through this point in July, 1873, the distance from Jupiter was as great as 8·9.

Subjoined are the elements of the orbit for 1871, expressed as usual in the catalogues, and with a slight correction to the predicted time of perihelion passage, which the observations showed to be required:—

Perihelion passage, 1871, December 1·7974 G.M.T.

Longitude of perihelion	116° 4′ 36″	Mean
" ascending node ...	269 17 12	Equinox,
Inclination	54 17 0	1870
Eccentricity	0·8210540	
Log. perihelion distance	0·0128823	
" semi-axis major	0·7601603	

The corresponding period of revolution is 5044·7 days, or 13·812 years.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, *MAY* 10-16

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on May 10

Sun rises, 4h. 18m.; souths, 11h. 56m. 12·1s.; sets, 19h. 35m.; decl. on meridian, 17° 44′ N.: Sidereal Time at Sunset, 10h. 50m.

Moon (New on May 14) rises, 2h. 28m.; souths, 8h. 24m.; sets, 14h. 31m.; decl. on meridian, 1° 30′ S.

GEOGRAPHICAL NOTES

We regret to learn that the well-known African explorer, Dr. Gustav Nachtigal, died on April 24, on board the German gunboat *Möwe*, off the west coast of Africa. Dr. Nachtigal was born at Eichstadt in 1834, and was trained to the medical profession. In 1862 he went to Algiers on account of his health, and in 1868 he started on his memorable journey into the heart of Africa, visiting the territories of Bornu, Baghirmi, Wadai, Darfur, Kordofan, emerging at Khartoum in 1874. This work placed Dr. Nachtigal in the front rank of African explorers. At the time of his death, it is well known, he was looking after the interests of Germany in connection with its recent annexations in West Africa.

The death is announced from Königsberg of Dr. Karl Zöppritz, Professor of Geography in the University there, and well known as the author of the reports on the progress of geophysics and of African exploration in Behm-Wagner's Geographical Year-Book.

On Monday last a lecture was delivered at the Alexandra Palace by Prof. A. H. Keane, on "The Lapps: their Origin, Type, Affinities, Social Usages," in connection with the company of Lapps who have recently arrived in London and pitched their tents on the slopes of Muswell Hill for the summer months. The group consists of seven persons, mostly members of one family, from the Karasjok district in Finmark, Norway, and belongs to the "mountain" or nomad division of the race. As these "Mountain Finns," as the Norwegians call them, are of much purer descent than the "River" and "Sea" Lapps, who have given up their nomad life and now reside in settled communities either along the riverain tracts or on the sea coast, they afford ethnologists a favourable opportunity of studying the type of these primitive inhabitants of the Arctic regions of North-West Europe. They are accompanied by six reindeer, and two native dogs used for tending the herds, and have also brought with them specimens of the three kinds of sledges still in use, and some of the famous snow-shoes with which they travel with such surprising velocity over the frozen surface of the ground. The average height appears to be about five feet (extremes, 4·10 to 5·4 in.); but in some other respects the type seems to have deviated considerably from the Mongolic, to which it fundamentally belongs, and has been assimilated, especially in the colour of the hair and eyes, in the complexion and shape of the nose, to the surrounding Norse populations. But the lecturer seemed disposed to attribute this assimilation rather to like climatic influences than to actual intermixture, of which there is no direct evidence.

At the last meeting of the Geographical Society of Paris, M. Thouar described in detail the observations made by him during his recent journey in search of the remains of the unfortunate Crévaux expedition in the Northern Chaco. These were divided into notes on the flora and fauna, with specimens of the dialects of the Tobas, Matacos, and Chiriguanos, a description of the dress, ornaments, implements, utensils, &c., of the Tobas and Chiriguanos, anthropological details of the same tribes, an itinerary from Tarija to Asuncion, with numerous meteorological observations, and two documents belonging to the Crévaux mission. He added a study on the Peruvian and Bolivian affluents of the Amazon. With reference to the statement (recently quoted in Nature) that certain members of the mission were still alive amongst the Indians, M. Thouar stated that this information should be received with the greatest reserve, because the date to which it referred was prior to his own sojourn on the frontier, which he traversed from north to south when no one gave him any such information. Since his return to France he has received directly from Bolivia numerous communications from Dr. Gianneccini, who lives on the frontier; in these nothing is said on the subject. A monument to Dr. Crévaux is to be unveiled at Nancy on June 13.

The Geographical Society of Paris has awarded a gold medal (La Rouquette's prize) to the well-known Danish Government publication on Greenland, "Meddelelser om Grönland," in which are from time to time published the results of the Danish scientific expedition exploring that continent. The same honour has befallen Danish subjects twice before, viz. Lieut. Graak, for his explorations of the east coast of Greenland; and Messrs. Bredsdorff and Olsen, for their map, "Esquisse d'une Carte orographique de l'Europe."

GEOGRAPHICAL education in Sweden has for years left much to be desired, but of late steps have been taken for its improvement. In the so-called "Elementär-lärovarken" (classical schools) geography has hitherto been classed as an appendix to history, and at the "Lektor" (candidate) examinations in history and geography questions are only asked about the former study. And while the hours and parts of history-teaching in the schools are detailed, no such arrangement has been made as regards geography; the hours of teaching are, in some cases, even not fixed. However, at the congress of teachers held in Stockholm last year, a resolution was adopted to the effect that geography ought to form a separate study of the school education. The University of Lund is the only institution which possesses an eminent geographer for this Board of Science, viz. Baron von Schverin, who, last year, represented Sweden at the Geographical Congress in Toulouse.

THE last Annual Report of the Russian Geographical Society contains extracts from letters addressed by M. Prjevalsky to the Grand Duke Alexander Alexandrovitch, which contains some further interesting details about his Hoang-ho journey. About the end of May he reached, as known, the foot of the Burkhan-budda Mountains, which inclose the high Thibet plateau separating it from Tsaidam. Leaving there his baggage, he went with only thirteen men to the sources of the Yellow River. The climbing on the 15,700 feet high passage of the Burkhan-budda ridge took three days. The descent, on the contrary, was very short, the plateau of Thibet being there 14,000 to 15,000 feet high. Further 60 miles across the desert plateau brought the traveller to the sources of the Yellow River. They are 13,600 feet above the sea-level, and consist of two rivers coming from the south and west and rising in the hills scattered on the plateau. A wide marshy valley, Odon-tala, 40 miles long and 20 miles wide, feeds numerous springs. The Hoang-ho itself is only a rivulet dividing into two or three branches, each of them but 80 to 100 feet wide, and only 2 feet deep at low water. Some 13 miles below this place the Hoang-ho enters a broad lake, colouring its southern part with its muddy water, and, after leaving it on the east, it enters again another lake, whence it flows out as a large river; further down it makes a great curve to avoid the snow-covered Amis-matchin range, and breaks through, in a wild course, the parallel ridges of the Xuen-lun. On the Thibet plateau the expedition experienced dreadful cold. In the second half of May snow-storms were as strong as in winter, and the night frosts reached $-23°$ Celsius. Still the thin grass covering did not perish and a few flowers reappeared every day under the sun-rays. Even in June and July the thermometer fell during bright nights as low down as $-5°$. As to rain, it poured every day, sometimes several days without interruption. The amount of vapour brought by the south-west monsoon and deposited there is so great that, during the summer, Northern Thibet becomes an immense marsh. Needless to say that the advance was difficult for camels. Though uninhabited by man, these deserts were full of herds of yakes, khoulans, antelopes, and mountain sheep; even bears were seen in groups, sometimes of more than ten at once; some thirty pairs were shot down; they are altogether very cowardly, and fly even when wounded. After having spent a few days at the source of the Hoang-ho, M. Prjevalsky went south to the Blue River, called there Dy-tchou by the Tangoutes. The plateau remained hilly, mostly covered with marshes, where the Thibet rush, hard as iron wire, grows freely. The water-divide between the two rivers has an altitude of 14,500 feet. Further south the region takes the characters of an Alpine country, still devoid of forests, but with a richer and more varied grass vegetation. Tangoutes, of the Kam branch, were met with, and received the travellers, though not friendlily, yet not as enemies. Some 70 miles across a mountain region brought M. Prjevalsky to the Dy-tchou River, at an altitude of 12,700 feet. The river, deep and very rapid, is 350 to 420 feet wide. To ford it with camels was quite impossible, so that a further advance to the south had to be renounced. So it was decided to stay there a week and then return to explore the great lakes of the Hoang-ho. During this stay the Tangoutes fired once from the opposite bank of the Dy-tchou. Returning to the Hoang-ho, M. Prjevalsky took another route to reach the lakes of this river, finding his way without guides. The Tangoutes closely followed the party, and on July 13 suddenly attacked them. This attack, as also another one, were repulsed, and the only further difficulties were in the rains and snow-storms (end of July). On the southern foot of the Burkhan-budda Mountains a party of gold-washers was met with. They did not dig the soil deeper than one or two feet, and their washing was most primitive. Still they showed handfuls of gold, mostly in corns as large as a pea, or twice and thrice the size. After having thus laid over more than 670 miles the party returned to Tsaidam, which appeared to them, as desert as it is, a real Eldorado in comparison with the Thibet plateau.

BESIDES the special medals awarded to M. Woeikoff and M. N. J. Zinger, the other medals of the Russian Geographical Society have been awarded as follows:—Small gold medals to the members of the last Pamir expedition, Col. Putyata; M. Ivanoff, geologist; and M. Bendersky, topographer, as also to M. Gavriloff for a manuscript on the religious beliefs of the Votyaks, and to Prof. Zomakion for magnetic measurements at Kazan. The great gold medals were awarded this year by the Sections of Ethnography and Statistics to M. Shein for his "Materials for the Study of the Customs and Language of the Russian Population in the North-West Provinces of Russia," and to M. Yanjul on the manufactures of the Government of Moscow. Sixteen silver medals have been awarded for several papers published in the publications of the Society, for observations extended over more than ten years on thunderstorms and rainfall, to those students who helped Prof. Zomakion in his magnetic measurements, and so on.

THE eccentricities of the European nomenclature of distant regions is well exemplified in the case of the eastern portion of the Indo-Chinese peninsula to which so much attention is attracted just now by the political events in progress there. On some English maps we find four separate divisions: starting from the north, Tonquin placed next to China; then Annam; then Cochin-China, and finally French Cochin-China. In the map accompanying Mr. Colquhoun's recent work, "Amongst the Shans," territory inhabited by independent tribes is inserted between Tonquin and China, which gives five divisions. This latter, however, is wholly incorrect, as the Tonquin frontier proper marches with that of China. In other maps (chiefly in those published in France) Annam and Cochin-China are thrown in together and called indifferently Annam or Cochin-China; while in others, mainly those of from ten to twenty years old, the whole coast from the Chinese frontier to the French colony of Saigon is called sometimes Cochin-China, sometimes Annam. We derive the name Cochin-China from the early navigators, who applied it to the whole coast round from Siam to China; and various generations, in search of trade rather than of geographical accuracy, have added to the confusion. Since the beginning of the present century, when the rulers of Annam imposed their yoke on Tonquin, there has been only one political power on this coast, viz. Annam. As the territories of this State stood twenty-five years ago, it was bounded by China, the Shan States, Siam, Cambodia, and the ocean, and, with the exception that France obtained three small States at the extreme south in 1861, so it stands at present. Tonquin was a feudatory State of Annam when the present war broke out. In a history of Annam recently published by Abbé Launay, a missionary in these regions, we find his title-page runs thus: "Histoire Ancienne et Moderne de l'Annam—Tong-King et Cochin-Chine—depuis, &c., &c.;" and in some interesting preliminary observations on these names, he explains that the titles Tonquin and Cochin-China are relatively recent, and are employed only by Europeans, and never by the Annamites. Tonquin comes to us from *Dong-kinh*, formerly the name of the capital, now called Hanoi; while Cochin-China comes from *Chen-chin*, the name given to the ancient State of Ciampa, situated to the extreme south of the peninsula. *Chen-chin* was probably preceded at one time by *Cao*, an abbreviation of Cao-tchi (*Giao-chi*), and from *Cao-chen-chin* Europeans have made Cochin-China. The name Annam was first given by the Chinese in the third century of our era. It was never used in the official documents between the two countries, but it is that by which the Annamites now call their country. It was at first applied to Tonquin only, but it was extended by conquest to Cochin-China, the ancient Ciampa. It should not, says Abbé Launay, be used for Cochin-China as distinct from Tonquin, but to the two united. The term *Giao-chi*, above alluded to, was that employed in the earliest epochs for the people inhabiting Annam, and was extended to the country. Their historians record that when the Emperor of China, Hoang-ti, formed the Chinese Empire in the twenty-sixth century before our era, he took Giao-chi as his boundary in the south-west. An ancient sacred book of the Chinese, the "Chou-king," which was collected in the sixth century before our era by Confucius from the remnants of still earlier works, refers to a tribe south of the Chinese frontier as the Giao-chi, which means "toes spread out," or "far apart," a term which points to a wide separation between the great toe and the others. This curious distinctive racial mark exists to-day, notwithstanding the lapse of time and the social revolutions of twenty-five or thirty centuries amongst the Annamites. We might therefore adopt the native distinctions as stated by Abbé Launay *en bloc*, and call the whole region Annam, with sub-divisions Tonquin and Cochin-China; or, making a sacrifice of strict accuracy to long habit, we might call the whole Cochin-China, with sub-divisions Tonquin and Annam. But it is probably as hopeless at present to expect strict uniformity in these names as it is to expect it in the orthography of Tonquin, although uniformity even in doing wrong would be better here than the present confusion.

AT the meeting of the Dutch Geographical Society on April 18, Mr. Robidée Van der Aa delivered a lecture on "Papuans and Melanesians, and their Relation to the Malay-Polynesian Race." Succinctly stated, the opinions expressed in the lecture were these:—The opinion once prevailed that the Papuans were the autocthones of the Malayan Archipelago, but that they were conquered by the Malays. There is, however, no support for this supposition, since in the interior of none of the Sunda Islands has a tribe been found bearing any resemblance to the Papuans. Since the researches and discoveries of Miklucho-Maclay we may not consider their hair or their dark skin as a decisive distinction with regard to other tribes. Moreover, it is now stated that their language is related to the Malayan tongue; there are still many customs and usages found amongst them similar to those met with among Malays. From all this Mr. Van der Aa concludes that the Papuans are one of five families, all of which have descended from one "insular race," and were separated from each other at an early date.

THOUGH nothing was said at the Dutch Geographical Society on April 18 about the expedition undertaken to the West Indies by Prof. Martin and Prof. Suringar, we now learn that they left Curaçoa in March. The former, accompanied by Mr. Van de Poel, arrived at Paramaribo and intended to make an excursion to the "Boven Suriname" on March 30; the latter intends to go to Venezuela, and after that to some of the Windward Islands, viz. St. Martin's, St. Eustathius, and Saba.

WE take from the Annual Report of the Russian Geographical Society the following figures giving the average temperatures for twenty-two months at the Sagastyr Polar Station at the mouth of the Lena. The following figures are on the Centigrade scale, and the first of them gives the average of the corresponding month for the year 1882–1883, while the second is the average of the same month for the year 1883–1884:—September, 0°·1 and 0°·6; October, −15°·1 and 14°·1; November, −27°·9 and −25°·7; December, −33°·5 and −33°·3; January, −37°·2 and −35°·8; February, −41°·3 and −34°·0; March, −31°·5 and −35°·2; April, 20°·7 and −21°·8; May, −8°·1 and −9°·7; June, 0°·9 and −0°·2; July, 5°·1; August, 3°·8. Average of the first year. −17°·1; of the second (incomplete), −16°·7. As seen, both years are closely similar; the exceedingly low temperatures of February, 1883, are most remarkable, the average of the month being only −41°·3, and the lowest temperature observed having been −52°·3 for the first year and −48°·0 during the second. The auroras were also less frequent, and the magnetic perturbances feebler. The number of hours during which auroras were observed is seen from the following figures:—September, 13 hours in 1882–1883, and 23 hours in 1883–1884; October, 87 and 69; November, 179 and 83; December, 191 and 178; January, 194 and 151; February, 197 and 126; March, 137 and 118; April, 10 and 8; none in May to August. Total for the first year, 1008; for the second, 756.

IT results from the same report that the delta of the Lena extends, by nearly one-half a degree, further north than on our best maps. The northern cape of the Danube (Dounay) Island is under 73° 55′ north latitude. This determination does not correspond with the Vega map, where Sagastyr, being under 73° 21′, the northern extremity of the island is under 73° 27′, and the course of the Vega in this longitude is under 74° 8′. At any rate, M. Yurgens has been compelled to go for twenty miles north of Sagastyr before reaching the extremity of the Dounay Island.

SOME EXPERIMENTS ON THE VISCOSITY OF ICE

THAT ice will change its form under the influence of pressure is exemplified at large in glaciers, and may be illustrated by experiments in the laboratory. How far this is due to a true viscosity, and how far to a rearrangement of the particles by melting and regelation, is a question the discussion of which among physicists has been of long continuance, though there there may now perhaps be some signs of permanent yielding under the influence of continuous pressure.

In the first volume of NATURE (p. 534) Mr. Wm. Matthews describes experiments (1870) in which planks of ice, supported at each end, but free in the middle, become permanently bent. In the first of these experiments the plank was 6 inches wide, 2⅜ inches thick, and supported by bearers 6 feet apart. The temperature of the air was above the freezing-point of water. The plank bent rapidly, so that the total deflection was 7 inches in about as many hours. "At its lowest point it appeared bent at a sharp angle, and was rigid in its altered form." Its lower surface showed minute fissures. In a second experiment a plank of somewhat similar dimensions (1⅞ inch thick, 6¼ to 6½ inches wide, 6 feet between the supports) became permanently bent. The amount of deflection was 3⅜ for the upper surface and 3¼ for the lower surface. The time was 64½ hours. The temperature "never rose above the freezing-point"; but the fact that the thermometer registered 29°·5 F. one morning at 9·30 a.m., and 30° F. the next morning at the same time, would lead us to suppose that the midday temperature was not far from the freezing-point. Similar experiments were subsequently carried out (1871) by Prof. Tyndall, in Switzerland, and are mentioned in NATURE (vol. iv. p. 447).

In NATURE, vol. vi. p. 396, Mr. John Aitken describes experiments in which weighted shillings were caused to sink into blocks of ice. But when the block of ice was previously cooled to about 1° below the freezing-point, a shilling weighted with 90 lbs. and left for three and a half hours, "was found not to have entered in the slightest degree into the ice." Subsequently, in 1873 (NATURE, vol. vii. p. 287), Mr. Aitken described experiments which showed that ice bends the more readily the more air-bubbles it contains. "Temperature," he says, "seemed to have some influence on the rate of bending of these beams, but this point was difficult to determine on account of the different beams bending at different rates at the same temperature; but, so far as could be ascertained from the experiments, the beams bent slower the lower the temperature. The lowest temperature used in these experiments was rather more than 3° F. below freezing."

In 1875 Prof. Pfaff described in *Poggendorff's Annalen* (civ. p. 169, reported in NATURE, vol. xii. p. 317) a carefully conducted experiment in which a paralellopiped of ice 52 cm. long, 2·5 cm. wide, and 1·3 cm. thick, was supported in such a way that 5 mm. at each end rested on the bearers. This was left for seven days, from February 8 to February 15, the temperature varying between −12° and −3·5° C. The total bend was 11·5 mm. That is to say, to translate these measurements into inches for the sake of comparison with the other results, in a bar 20 inches in length between the supports, 1 inch in width, and ½ inch in thickness; the total bending was a little over ·45 of an inch. When the temperature rose to slightly under 0° C. the bending increased, and amounted to 9 mm. (·34 inches) in 24 hours. Other experiments are described by Prof. Pfaff in the same paper, and the general conclusion to which he is led is, "that even the smallest pressure is sufficient to dislocate ice-particles if it act continuously, and if the temperature of the ice and its surroundings be near the melting point."

In the current volume of NATURE (p. 329) there is a report of a paper recently read before the Royal Society by Mr. Coutts Trotter (to whom I am indebted for references on this subject) "On some physical properties of ice, &c.," in which were described some experiments on the shearing of ice, carried out in a glacier grotto at a nearly uniform temperature of about 0° C. In that report we learn that in the paper itself "reasons are given for supposing that the range of temperature through which ice is sensibly viscous is small."

So far as I know no experiments on the viscosity of ice at very low temperatures have been recorded. It is the object of the present communication to describe some such experiments which I have recently conducted, through the kindness and courtesy of Messrs. J. S. Fry and Sons, of Bristol, in the snow chamber of the refrigerator, at their well-known Cocoa Works.

In this chamber the air, which has been previously condensed and cooled, is allowed to deposit, in the form of snow, the moisture which it can no longer retain owing to the great diminution of temperature due to expansion. George Punter, whose business it is to look after this snow chamber, rendered the most intelligent assistance in preparing the bars of ice, and in conducting the experiments. In this mode of experimentation the great variation of temperature, namely, between $-30°$ C., when the engines are stopped in the evening, and $-12°$ C., as a maximum when they begin work in the morning is an unavoidable drawback. Still, I think that the experiments, although they give uniformly negative results, are worth putting on record.

Experiment 1.—A cylinder of ice was cast with a diameter of 3 inches. Over it was hung, as in the well-known Bottomley experiment (NATURE, vol. v. p. 185), a wire loaded with a total weight of 5 lbs. It was left in the freezing-chamber $6\frac{1}{2}$ hours. No dent was traceable on the surface of the cylinder.

Experiment 2.—With a similar cylinder and wire the load was increased to 10 lbs. and the time to 8 hours, with like negative results.

Experiment 3.—With a similar cylinder and wire the load was further increased to 14 lbs. and the time to $17\frac{1}{2}$ hours, with the same result or absence of result. This experiment would seem to show that the ice refused to yield to a pressure of 20 to 30 atmospheres, or probably more, applied in this way and for this time.

Experiment 4.—A bar of ice $1\frac{1}{2}$ inches thick, $2\frac{1}{2}$ inches wide, and supported on bearers $13\frac{1}{2}$ inches apart, was left in the chamber from 12 noon on Monday until 12 noon on Saturday. It showed no sign of bending under its own weight.

Experiment 5.—A similar bar similarly supported was weighted in the middle with 7 lbs., and left for the same time. No sign of bending.

Experiment 6.—A similar bar similarly supported was weighted with 18 lbs., and left for the same time. There was no bending perceptible to the eye; but, on removing the apparatus, the bar broke with the jar occasioned by setting it down somewhat carelessly, so that no exact measurement was taken.

Experiment 7.—A bar of the same length and width, but thinner, tapering somewhat from $\frac{7}{8}$ to $\frac{5}{8}$ of an inch in thickness, was weighted with 7 lbs., to which, during the last two days, seven additional pounds were added, and left for the same time. No bending by measurement.

Such negative results are just what one would expect on theoretical grounds, and as an inference from previous experiments conducted at temperatures nearer the melting-point. But it is well not to rely on theory or on inference where direct experiment is practicable.

The matter, then, would appear to stand at present somewhat thus. The viscosity of ice, due to whatever cause, is—

(1) At temperatures at and above the melting-point...considerable.
(2) ,, ,, below but near ,, ,, ...much less.
(3) ,, ,, between $-3°.5$ C. and $-12°$ C....very slight.
(4) ,, ,, below $-12°$ C. ... ...*nil*.

What seems now to be wanted is an experimental determination of the lower temperature-limit of viscosity, which would appear to lie somewhere between $-12°$C. and $-3°.5$ C., but probably nearer the latter temperature.

University College, Bristol — C. LLOYD MORGAN

BEN NEVIS

AT the meeting of the Royal Society of Edinburgh held on Monday last, Mr. John Murray, Vice-President, in the chair, Mr. R. T. Omond, Superintendent of the Meteorological Observatory on Ben Nevis, delivered, at the request of the Council, an address on two years' residence and work there. Mr. Omond, at the outset, recalled the advantages which Ben Nevis presented as a high-level meteorological station, the services of Mr. Clement S. Wragge, and the chief steps that led up to the erection and equipment of the existing permanent observatory. Glancing at some of their daily experiences during last summer and autumn, he mentioned that some 3000 or 4000 tourists climbed the mountain—sometimes at least 100 in a single afternoon. Since the middle of October, however, not more than half a dozen strangers had ventured up. Some came for information; others were disappointed at finding they could not be fed as well as sheltered; others came to spend the night, but were disappointed at finding they could not do so. Most of the visitors, however, were satisfied, though a little astonished, by the explanation that the building on Ben Nevis was primarily a scientific observatory, and not a hotel. Storms of exceptional and terrific violence were described. Beautiful optical phenomena that had been witnessed, and the comparative scarcity of animal life on the mountain, were next alluded to. Rainbows are seldom seen. Thunderstorms are very rare. The temperatures during winter are not so low as many people think—10° F. is about the lowest recorded as yet, and the ordinary winter temperatures ran from 15° to 25°. Observing that much must yet be done in the work of the discussion and interpretation of the observations made on Ben Nevis, before the observations could be safely used, he proceeded to state some of the more interesting points which Mr. Buchan had already succeeded in approximately establishing: (1) The normal or average temperature and barometric pressure for each month, and the normal differences between these averages and those at sea-level. (2) The daily variation of temperature and pressure during each month. (3) The daily variation in the average velocity of the wind—this being shown to be greater at night than during the day, exactly the reverse of what holds good at sea-level. (4) Variations in the direction of the winds as compared with those prevalent over Scotland at any given time. A comparison of the Ben Nevis winds with those at low-level stations sometimes shows that both are part of one system, whether cyclonic or anti-cyclonic; but the direction is almost always different, and in the case of cyclonic storms, coming from the west. The observed differences in direction seem to give an indication as to whether the storm centre is to pass to the north or south of Ben Nevis. If this point can be definitely made out, it will obviously be of immense value in forecasting weather. (5) The hygrometric observations indicate that the atmosphere on the Ben shows that during ordinary weather a state of persistent saturation, usually accompanied by fog or mist, prevails; but occasionally a sudden and extraordinary drought sets in, the temperature rises, and the sky clears, not merely of fog, but often of every vestige of cloud, and at the same time the valleys and lower hills are often shrouded in mist, showing that this dryness coming from above is not able to penetrate right down to the sea-level. The thorough investigation of these phenomena is one of the most important pieces of work connected with the Observatory, and may be expected to throw great light on the question of atmospheric circulation. (7) The rainfall of Ben Nevis is greatly in excess of what several theories of the distribution of rain led them to expect—a result possibly due to the great vertical movements of the atmosphere indicated by the hygrometric indications referred to above. Though there are many high-level stations in different parts of the world, none, perhaps, are so favourably situated as Ben Nevis for the investigation of what he had explained is the present great problem in meteorology, namely, the vertical movements of the atmosphere. If the Scottish Meteorological Society were possessed of sufficient funds to establish a completely-equipped observatory at the foot of Ben Nevis as well as on the summit, he was convinced that the science of meteorology would advance far more in a few years than it would by a generation of ordinary work with low-level stations alone.

SUNLIGHT AND THE EARTH'S ATMOSPHERE[1]

THERE is, we may remember, a passage in which Plato inquires what would be the thoughts of a man who, having lived from infancy under the roof of a cavern, where the light outside was inferred only by its shadows, was brought for the first time into the full splendors of the sun.

We may have enjoyed the metaphor without thinking that it has any physical application to ourselves who appear to have no roof over our heads, and to see the sun's face daily; while the fact is that if we do not see that we have a roof over our heads in our atmosphere, and do not think of it as one, it is because it seems so transparent and colourless.

Now, I wish to ask your attention to-night to considerations in some degree novel, which appear to me to show that it is not transparent as it appears, and that this seeming colourlessness is a sort of delusion of our senses, owing to which we have never

[1] Lecture delivered at the Royal Institution, April 17, 1885, by S. P. Langley. Communicated by the author.

in all our lives seen the true colour of the sun, which is in reality blue rather than white, as it looks, so that this air all about and above us is acting like a coloured glass roof over our heads, or a sort of optical sieve, holding back the excess of blue in the original sunlight, and letting only the white sift down to us.

I will first ask you, then, to consider that this seeming colourlessness of the air may be a delusion of our senses, due to habit, which has never given us anything else to compare it with.

If that cave had been lit by sunshine coming through a reddish glass in its roof, would the perpetual dweller in it ever have had an idea but that the sun was red? How is he to know that the glass is "coloured" if he has never in his life anything to compare it with? How can he have any idea but that this is the sum of all the sun's radiations (corresponding to our idea of white or colourless light); will not the habit of his life confirm him in the idea that the sun is red; and will he not think that there is no colour in the glass so long as he cannot go outside to see? Has this any suggestion for us, who have none of us ever been outside our crystal roof to see?

We must all acknowledge in the abstract, that habit is equally strong in us whether we dwell in a cave or under the sky, that what we have thought from infancy will probably appear the sole possible explanation, and that, if we want to break its chain, we should put ourselves, at least in imagination, under conditions where it no longer binds us.

The *Challenger* has dredged from the bottom of the ocean fishes which live habitually at great depths, and whose enormous eyes tell of the correspondingly faint light which must have descended to them through the seemingly transparent water. It will not be as futile a speculation as it may at first seem, to put ourselves in imagination in the condition of creatures under the sea, and ask what the sun may appear to be to them; for if the fish who had never risen above the ocean floor were an intelligent being, might *he* not plausibly reason that the dim greenish light of his heaven—which is all he has ever known—was the full splendour of the sun, shining through a medium which all his experience shows is transparent?

We ourselves are, in very fact, living at the floor of a great aërial sea, whose billows roll hundreds of miles above our heads. Is it not at any rate conceivable that we may have been led into a like fallacy from judging only by what we see at the bottom? May we not, that is, have been led into the fallacy of assuming that the intervening medium above us is colourless because the light which comes through it is so?

I freely admit that all men, educated or ignorant, appear to have the evidence of their senses that the air is colourless, and that pure sunlight is white, so that if I venture to ask you to listen to considerations which have lately been brought forward to show that it is the sun which is blue, and the air really acts like an orange veil or like a sieve which picks out the blue and leaves the white, I do so in the confidence that I may appeal to you on other grounds than those I could submit to the primitive man who has his senses alone to trust to; for the educated intelligence possesses those senses equally, and in addition the ability to interpret them by the light of reason, and before this audience it is to that interpretation that I address myself.

Permit me a material illustration. You see through this glass, which may typify the intervening medium of air or water, a circle of white light, which may represent the enfeebled disk of the sun when so viewed. Is this intervening glass coloured or not? It seems nearly colourless; but have we any right to conclude that it is so because it seems so? Are we not *taking it for granted* that the original light which we see through it is white, and that the glass is colourless, because the light seems unaltered, and is not an appeal to be made here from sense to reason, which, in the educated observer, recalls that white light is made of various colours, and that whether the original light is really white and the glass transparent, or the glass really coloured and so *making* the white, is to be decided only by experiment, by taking away the possibly deceptive medium? I can take away this glass, which was not colourless, but of a deep orange, and you see that the original light was not white, but intensely blue. If we could take the atmosphere away between us and the sun, how can we say that the same result might not follow? To make the meaning of our illustration clearer, observe that this blueness is not a pure spectral blue. It has in it red, yellow, blue, and all the colours which make up white, but blue in superabundance; so that, though the white is, so to say, latent there, the dominant effect is blue. The glass coloured veil does not put anything *in*, but acts I repeat like a sieve straining *out* the blue, and letting through to us the white light which was there in the bluishness, and so may not our air do so too?

I think we already begin to see that it is at any rate conceivable that we *may* have been hitherto under a delusion about the true colour of the sun, though of course this is not proving that we have been so, and it will at any rate, I hope, be evident that here is a question raised which ought to be settled, for the blueness of the sun, if proven, evidently affects our present knowledge in many ways, and will modify our present views in optics, in meteorology, and in numerous other things. In optics, because we should find that white light is *not* the sum of the sun's radiations, but only of those dregs of them which have filtered down to us; in meteorology because it is suggested that the temperature of the globe and the condition of man on it, depend in part on a curious selective action of our air, which picks out parts of the solar heat (for instance, that connected with its blue light), and holds them back, letting other selected portions come to us, and so altering the conditions on which this heat by which we live, depends; in other ways, innumerable, because, as we know, the sun's heat and light are facts of such central importance, that they affect almost every part of scientific knowledge.

It may be asked what suggested the idea that the sun may be blue rather than any other colour.

My own attention was first directed this way many years ago when measuring the heat and light from different parts of the sun's disk. It is known that the sun has an atmosphere of its own which tempers its heat, and, by cutting off certain radiations and not others, produces the spectral lines we are all familiar with. These lines we customarily study in connection with the absorbing vapours of sodium, iron, and so forth, which produce them; but my own attention was particularly given to the regions of absorption, or to the colour it caused, and I found that the sun's body must be deeply bluish, and that it would shed blue light except for this apparently colourless solar atmosphere, which really plays the part of a reddish veil, letting a little of the blue appear on the centre of the sun's disk where it is thinnest, and staining the edge red, so that to delicate tests the centre of the sun is a pale aqua-marine, and its edge a garnet. The effect I found to be so important, that if this all but invisible solar atmosphere were diminished by but a third part, the temperature of the British islands would rise above that of the torrid zone, and this directed my attention to the great practical importance of studying the action of our own terrestrial atmosphere on the sun, and the antecedent probability that our own air was also and independently making the really blue sun into an apparently white one. We actually know then, beyond conjecture, by a comparison of the sun's atmosphere, where it is thickest, and where it is thinnest, that an apparently colourless atmosphere *can* have such an effect, and analogous observations which I have carried on for many years, but do not now detail, show that the atmosphere of our own planet, this seemingly clear air in which we exist like creatures at the bottom of the sea, does do so.

We look up through our own air as through something so limpid in its purity that it appears scarcely matter at all, and we are apt to forget the enormous mass of what seems of such lightness, but which really presses with nearly a ton to each square foot, so that the weight of all the buildings in this great city, for instance, is less than that of the air above them.

I hope to shortly describe the method of proof that it too has been acting like an optical sieve, holding back the blue; but it may naturally be asked, "Can our senses have so entirely deceived us that they give no hint of this truth, if it be one? is the appeal wholly to recondite scientific methods, and are there no indications, at least, which we may gather for ourselves?" I think there are, even to our unaided eyes, indications that the seemingly transparent air really acts as an orange medium, and keeps the blue light back in the upper sky.

If I hold this piece of glass before my eyes, it seems colourless and transparent, but it is proved not to be so by looking through it edgewise, when the light, by traversing a greater extent, brings out its true colour, which is yellow. Every one knows this in every-day experience. We shall not get the colour of the ocean by looking at it in a wine-glass, but by gazing through a great depth of it; and so it is with the air. If we look directly up, we look through where it is thinnest; but if we look horizontally through it towards the horizon, through great thicknesses, as at sunrise or sunset, is it not true that this air, where we see its real colour most plainly, makes the sun look very plainly yellow or orange?

We not only see here, in humid English skies, the "orange sunset waning slow," but most of us in these days of travel can perfectly testify that the clearest heavens the earth affords, the rosy tint on the snows of Mont Blanc, forerunning the dawn, or the warm glow of the sun as he sets in Egyptian skies, show this most clearly—show that the atmosphere holds back the blue rays by preference, and lets the orange through.

If, next, we ask, "What has become of the blue that it has stopped?" does not that very blue of the midday sky relate the rest of the story—that blue which Prof. Tyndall has told us is due to the presence of innumerable fine particles in the air, which act selectively on the solar waves, diffusing the blue light towards us? I hope it will be understood that Prof. Tyndall is in no way responsible for my own inferences; but I think it is safe at least to say that the sky is not self-luminous, and that, since it can only be shini g blue at the expense of the sun, all the light this sky sends us has been taken by our atmosphere away from the direct solar beam, which would grow both brighter and bluer if this were restored to it.

If all that has been said so far renders it possible that the sun may be blue, you will still have a right to say that "possibilities" and "maybes" are not evidence, and that no chain of mere hypotheses will draw truth out of her well. We are all of one mind here, and I desire next to call your attention to what I think is evidence.

Remembering that the case of our supposed dweller in the cave who could not get outside, or that of the inhabitants of the ocean-floor who cannot rise to the surface, is really like our own, over whose heads is a crystalline roof which no man from the beginning of time has ever got outside of, an upper sea to whose surface we have never risen; we recognise that if we could rise to the surface, leaving the medium whose effect is in dispute wholly beneath us, we should see the sun as it is, and get proof of an incontrovertible kind; and that, if we cannot entirely do this, we shall get nearest to proof under our real circumstances by going as high as we can in a balloon, or by ascending a very high mountain. The balloon will not do, because we have to use heavy apparatus requiring a solid foundation. The proof to which I ask your kind attention, then, is that derived from the actual ascent of a remarkable mountain by an expedition undertaken for that purpose, which carried a whole physical laboratory up to a point where nearly one-half the whole atmosphere lay below us. I wish to describe the difference we found in the sun's energy at the bottom of the mountain and at the top, and then the means we took to allow for the effect of that part of the earth's atmosphere still over our heads even here, so that we may be said to have virtually got outside it altogether.

Before we begin our ascent, let me explain more clearly what we are going to seek. We need not expect to find that the original sunlight is a pure monochromatic blue by any means, but that though its rays contain red, orange, blue, and all the other spectral colours, the blue, the violet and the allied tints were originally there in disproportionate amounts, so that, though all which make white were present from the first, the refrangible end of the spectrum had such an excess of colour that the dominant effect was that of a blueish sun. In the same way, when I say briefly that our atmosphere has absorbed this excess of blue and let the white reach us, I mean, more strictly speaking, that this atmosphere has absorbed *all* the colours, but, selectively, taking out more orange than red, more green than orange, more blue than green; so that its action is wholly a taking *out*—an action like that which you now see going on with this sieve, sifting a mixture of blue and white beads, and holding back the blue while letting the white fall down.

This experiment only rudely typifies the action of the atmosphere, which is di criminating and selective in an amazing degree, and as there are really an infinite number of shades of colour in the spectrum, it would take for ever to describe the action in detail. It is merely for brevity, then, that we now unite the more refrangible colours under the general word "blue," and the others under the corresponding terms "orange" or "red."

All that I have the honour to lay before you, is less an announcement of absolute novelty than an appeal to your already acquired knowledge and to your reason as superior to the delusions of sense. I have, then, no novel experiment to offer, but to ask you to look at some familiar ones in a new light.

We are most of us familiar, for instance, with that devised by Sir Isaac Newton to show that white light is compounded of blue, red, and other colours, where, by turning a coloured wheel rapidly, all blend into a grayish white. Here you see the "seven colours" on the screen; but, though all are here, I have intentionally arranged them, so that there is too much blue, and the combined result is a very bluish white which may roughly stand for that of the original sun-ray. I now alter the proportion of the colours so as to virtually take out the excess of blue, and the result is colourless or white light. White, then, is not necessarily made by combining the "seven colours," or any number of them, unless they are there in just proportion (which is in effect what Newton himself says); and white, then, may be made out of such a bluish light as we have described, not by putting anything to it, but by taking away the excess which is there already.

Here, again, are two sectors—one blue, one orange-yellow with the blue in excess, making a bluish disk where they are revolved. I take out the excess of blue, and now what remains is white.

Here is the spectrum itself on the screen, but a spectrum which has been artificially modified so that the blue end is relatively too strong. I recombine the colours (by Prof. Rood's ingenious device of an elastic mirror), and they do not make a pure white, but one tinted with blue. I take out the original excess of blue, and what remains combines into a pure white. Please bear in mind that when we "put in" blue here, we have to do so by straining out other light through some obscuring medium, which makes the spectrum darker; but that, in the case of the actual sunlight, introducing more blue, introduces more light, and makes the spectrum brighter.

The spectrum on the screen ought to be made still brighter in the blue than it is—far, far brighter—and then it might represent to us the original solar spectrum before it has suffered any absorption either in the sun's atmosphere or our own. The Frauenhofer lines do not appear in it, for these, when found in the solar spectrum, show that certain individual rays have been stopped, or selected for absorption by the intervening atmospheres; and though even the few yards of atmosphere between the lamp and the screen absorb, it is not enough to show.

Our spectrum, as it appears before absorption, might be compared to an army divided into numerous brigades, each wearing a distinct uniform, one red, one green, one blue, so that all the colours are represented each by its own body. If, to represent the light absorbed as it progresses, we supposed that the army advances under a fire which thins its numbers, we should have to consider that (to give the case of nature) this destructive fire was directed chiefly against those divisions which were dressed in blue, or allied colours, so that the army was thinned out unequally, many men in blue being killed off for one in red, and that by the time it has advanced a certain distance under fire the proportion of the men in each brigade has been altered, the red being comparatively unhurt. Almost all absorption is thus selective in its action, and often in an astonishing degree, killing off, so to speak, certain rays in preference to others, as though by an intelligent choice, and destroying most, not only of certain divisions (to continue our illustration), but even picking out certain files in each company. Every ray, then, has its own individuality, and on this I cannot too strongly insist; for just as two men retain their personalities under the same red uniform, and one may fall and the other survive, though they touch shoulders in the ranks, so in the spectrum certain parts will be blotted out by absorption, while others next to them may escape.

To illustrate this selective absorption, I put a piece of didymium glass in the path of the ray. It will, of course, absorb some of the light, but instead of dimming the whole spectrum, we might almost say it has arbitrarily chosen to select one narrow part for action, in this particular case choosing a narrow file near the orange, and letting all the rest go unharmed. In this arbitrary way our atmosphere operates, but in a far more complex manner, taking out a narrow file here and another there, in hundreds of places, all through the spectrum, but on the whole much the most in the blue, the Frauenhofer lines being merely part of the evidence of this wonderful quasi-intelligent action which bears the name of selective absorption.

Before we leave this spectrum, let us recall one most important matter. We know that here beyond the red is solar energy in the form of heat which we cannot see, but not on that account any less important. More than half the whole power of the sun is here invisible, and if we are to study completely the action of our atmosphere, we shall have to pay great attention to this part, and find out some way of determining the loss in it, which will be difficult, for the ultra-red end is not only invisible, but compressed, the red end being shut up like the closed pages of a book, as you may notice by comparing the narrowness of the red with the width of the blue.

Now refraction by a prism is not the only way of forming a spectrum. Nature furnishes us colour not only from the rainbow, but from non-transparent substances like mother-of-pearl, where the iridescent hues are due to microscopically fine lines. Art has lately surpassed nature in these wonderful "gratings," consisting of pieces of polished metal, in which we see at first nothing to account for the splendid play of colour apparently pouring out from them like light from an opal, but which, on examination with a powerful microscope, show lines so narrow that there are from 50 to 100 in the thickness of a fine human hair, and all spaced with wonderful precision.

This grating is equal in defining power to many such prisms as we have just been looking at, but its light does not show well upon the screen. You will see, however, that its spectrum differs from that of the prism, in that in this case the red end is expanded, as compared with the violet, and the invisible ultra-red is expanded still more, so that this will be the best means for us to use in exploring that "dark continent" of invisible heat found not only in the spectrum of the sun, but of the electric light, and of all incandescent bodies, and of whose existence we already know from Herschel and Tyndall.

Now we cannot reproduce the actual solar spectrum on the screen without the sun itself, but here are photographs of it, which show parts of the losses the different colours have suffered on their way to us. We have before us the well-known Frauenhofer lines, due, you remember, not only to absorption in the sun's atmosphere, but also to absorption in our own. We have been used to think of them in connection with their cause, one being due to the absorption of iron-vapour in the sun, another to that of water-vapour in our own air, and so forth; but now I ask you to think of them only in connection with the fact that each is due to the absorption of some part of the original *light*, and that collectively they tell much of the story of what has happened to that light on its way down to us. Observe, for instance, how much thicker they lie in the blue end than in the red—another evidence of the great proportionate loss in the blue.

If we could restore all the lost light in these lines, we should get back partly to the original condition of things at the very fount, and, so far as our own air is concerned, that is what we are to ascend the mountain for—to see, by going up through nearly half of the atmosphere, what the rate of loss is in each ray by actual trial; then, knowing this rate, to be able to allow for the loss in the other part still above the mountain-top, and, finally, by recombining these rays to get the loss as a whole. Remember, however, always, that the most important part of the solar energy is in the dark spectrum which we do not see, but which, if we could see, we should probably find to have numerous absorption-spaces in it corresponding to the Frauenhofer lines, but where heat has been stopped out rather than light. To make our research thorough, then, we ought not to trust to the eye only, or even chiefly, but have some way of investigating the whole spectrum; the invisible in which the sun's power chiefly lies, as well as the visible, and both with an instrument that would discriminate the energy in these very narrow spaces, like an eye to see in the dark; and if science possesses no such instrument, then it may be necessary to invent one.

The linear thermopile is nearest to it of any, and we all here know what good work it has done, but even that is not sensitive enough to measure in the grating spectrum, in some parts of which the heat is 400 times weaker than in that of a prism, and we want to observe this invisible heat in very narrow spaces. Something like this has been provided since by Capt. Abney's most valuable researches, but these did not at the time go low enough for my purpose, and I spent nearly a year before ascending the mountain in inventing and perfecting the new instrument for measuring these, which I have called the "bolometer" or "ray-measurer." The principle on which it is founded is the same as that employed by my late lamented friend, Sir Wm. Siemens, for measuring temperatures at the bottom of the sea, which is that a smaller electric current flows through a warm wire than through a cold one.

One great difficulty was to make the conducting wire very thin, and yet continuous, and for this purpose almost endless experiments were made, among other substances pure gold having been obtained by chemical means in a plate so thin that it transmitted a sea-green light through the solid substance of the metal. This proving unsuitable, I learned that iron had been rolled of extraordinary thinness in a contest of skill between some English and American iron-masters, and, procuring some, I found that 15,000 of the iron plates they had rolled, laid one on the other, would make but one English inch. Here is some of it, rolled between the same rolls which turn out plates for an iron-clad, but so thin that, as I let it drop, the iron plate flutters down like a dead leaf. Out of this the first bolometers were made, and I may mention that the cost of these earlier experiments was met from a legacy by the founder of the Royal Institution, Count Rumford. The iron is now replaced by platinum, in wires or rasher tapes, from 1-2000 to 1-20,000th of an inch thick, one of which is within this button, where it is all but invisible, being far finer than a human hair. I will project it on the screen, placing a common small pin beside it as a standard of comparison. This button is placed in this ebonite case, and the thread is moved by this micrometer screw, by which it can be set like the spider line of a reticule; but by means of this cable, connecting it to the galvanometer, this thread acts as though sensitive, like a nerve laid bare to every indication of heat and cold. It is then a sort of sentient thing: what the eye sees as light it feels as heat, and what the eye sees as a narrow band of darkness (the Frauenhofer line) this feels as a narrow belt of cold, so that when moved parallel to itself and the Frauenhofer lines down the spectrum it registers their presence.

It is true we can see these in the visible spectrum, but you remember we propose to explore the invisible also, and since to this the dark is the same as the light, it will feel absorption lines in the infra-red which might remain otherwise unknown.

I have spent a long time in these preliminary researches; in indirect methods for determining the absorption of our atmosphere, and in experiments and calculations which I do not detail, but it is so often supposed that scientific investigation is a sort of happy guessing, and so little is realised of the labour of preparation and proof, that I have been somewhat particular in describing the essential parts of the apparatus finally employed, and now we must pass to the scene of their use.

(*To be continued.*)

THE INSTITUTION OF MECHANICAL ENGINEERS

A VERY interesting discussion on the merits of the Maxim automatic machine-gun, which was described in NATURE, vol. xxxi. p. 414, took place at the special meeting of the Institution held on the 30th ult. In reply to Mr. Carbutt, M.P., the inventor explained that the recoil of the gun, which is utilised for loading and firing, did not interfere with the accuracy of aim, and instanced the circumstance that as good target-practice was made in firing from the shoulder as with fixed rifles; whilst the energy of recoil was sufficient to carry on the automatic action, whether the muzzle of the gun was elevated or depressed. As regarded keeping the barrel cool, he found that the water-jacket around the body of the gun acted most efficiently, as gunpowder in exploding produced very little heat-energy, or, as he put it, "he should not buy gunpowder to raise steam." During all his experiments he had used only Government cartridges, and had never found one to fail; he thought it would be an advantage if cartridges were packed in cases containing calcium chloride or other hydroscopic material, so that they might not be injured by moisture.

The gun was frequently fired during the meeting, and its automatic action was thoroughly shown, as well as its freedom from danger should a cartridge hang fire. Mr. Maxim had a most enthusiastic reception, the general feeling of the speakers and of the meeting being in favour of the gun being taken up by the British Government, the President and Mr. Adamson giving it as their opinion that, if the necessity should occur, 1000 of these guns could be produced weekly at a month's notice, when their use might have as material an effect on a campaign as the needle-gun had at Sadowa. Mr. Maxim is now experimenting with a more recent form of gun of his invention, which fires a projectile 3 lbs. weight at the rate of 120 shots a minute; in this the cartridges are fed from above, which much simplifies the mechanical arrangement, as no apparatus has to be arranged for lifting the cartridges into the magazine of the gun; in this new form the total length of firing apparatus is 22 inches. This arrangement was not described, as the various patents for which the inventor had made application, amounting to over a hundred in all, were not yet complete.

On the 1st inst. was read Prof. Kennedy's abstract of the work of the Research Committee of the Institution on Riveted Joints. There can be no question of the value of a series of experiments of this character, covering in all 290,—64 on perforated (punched and drilled) plates, 97 on actual joints, 44 on the tenacity of the plates used in the joints, 33 on the tenacity and shearing resistance of the rivet steel used in the joints, and the rest on various other matters connected with them. The whole of the experiments were made upon soft steel supplied from the Landore Siemens-Steel Works, which was found to have a tenacity of from 28 to 30 tons per square inch, with an extension of 23 to 25 per cent. in a length of 10 inches. The limit of elasticity of the metal was generally about 60 per cent. of its ultimate resistance, the percentage of carbon in the plates was given as about 0·18.

The main conclusions drawn from these experiments are the following:—The metal between the rivet holes has a considerably greater tensile resistance per square inch than the same metal unperforated, the excess tenacity varying from 20 to about 8 per cent. The shearing resistance of rivet steel is a much more variable quantity than the tenacity of steel plate or of the rivet steel itself—a result due, Prof. Kennedy thinks, in some manner to the want of attention directed to this point, or of experiments specially upon it. The size of the rivet heads and ends plays a most important part in the strength of the joints, at any rate in the case of single riveted joints; an increase of about one-third of weight of metal in the heads and ends increased the resistance of the joint $8\frac{1}{2}$ per cent., the additional strength being no doubt due to the prevention of so great tensile stress in the rivets through distortion of the plates. The strength of a joint made across a plate is equal to that of one made in the usual direction. The intensity of bearing pressure on the rivets exercises, with joints proportioned in the ordinary way, a very important influence on their strength. The value of hydraulic as compared with hand riveting, in the case when sound hand-riveting is possible, lies in the increased security and stiffness it gives at ordinary working loads rather than in any actual raising of the breaking load.

The experiments point to very simple rules for proportioning joints of maximum strength. Assuming a bearing pressure on the rivet of 43 tons per square inch, and an excess tenacity of the plate of 10 per cent. of its original strength, the diameter of the rivet-hole should be $2\frac{1}{4}$ times the thickness of the plate, and the pitch of the rivets $2\frac{5}{8}$ times the diameter of the holes for single riveted joints, while for double-riveted lap-joints with the same ratio of diameter to thickness the ratio of pitch to diameter should be from 3·64 to 3·82. If a smaller rivet be used than that here specified, the joint will not be of uniform, and therefore not of maximum, strength; but with any other size of rivet the best result will be obtained by using a pitch calculated from the following formula, viz.:—

$$p = a\frac{d^2}{t} + d,$$

where p is the pitch, d the diameter of the hole, and t the thickness of the plate, whilst the mean value of the constant a is 0·56. By use of this formula for double-riveted lap-joints it is likely that the prescribed size of rivet may be inconveniently large in practice. In this case the diameter of the rivet should be taken as large as possible, and the above formula will give the pitch, by making the constant $a = 1·15$ in the mean. For double-riveted butt-joints of maximum strength the diameter of the rivet hole should be 1·8 times the thickness of the plate, and the pitch should be 4·1 times the diameter of the hole.

In a boiler the plate is much more affected by time than the rivets, and it is therefore not unreasonable to estimate the percentage by which the plates might be weakened by corrosion before the boiler would be unfit for use at its proper steam-pressure, and to add correspondingly to the plate area. In this case the joint should be proportioned not for the actual thickness of the plate, but for a nominal thickness less than the actual by the assumed percentage. The joint will thus be approximately one of uniform strength by the time it has reached its final workable condition, up to which time the joint as a whole will not really have been weakened, the corrosion only gradually bringing the strength of the plates down to that of the rivets.

There is an interesting point to which we propose reference on a future occasion, viz. the probable causes to which an increase of tensile strength in the remaining material of perforated plates may be due.

The President, at the conclusion of an interesting discussion, referred to the circumstances that the paper was an abstract of three years' work, the experiments having been carried on by Prof. Kennedy free of charge to the Institution, whilst the material supplied and the work of preparing the various joints tested had been performed at prime cost.

The main feature in connection with the Blooming Mill designed by Mr. C. B. Holland, of Ebbw Vale, a paper describing which was read, was the application of hydraulic power to all the work performed, except that of actually driving the rolls.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—On Tuesday last an effort was made to relieve Honour men in the non-classical final schools from the drudgery entailed by the present Pass Classical Moderations. Council brought forward a scheme substituting a Preliminary Honour Examination in each Honour School in lieu of "Pass Mods." Under this scheme the study of the classical languages would not be required of any candidate for honours in Natural Science or Mathematics after he had passed the present Responsions or "Smalls;" thus an extra year would be given to the study of the subjects chosen for the final schools. Unfortunately for the measure, the preamble—mainly of general character—contained one clause relating to Mathematics which would have exempted mathematical class-men from any literary work, and the preamble was therefore opposed by many who approved of its general policy bnt desired an opportunity of discussing or amending the Preliminary Examinations to be introduced into each Faculty. The preamble, after a long debate, was lost on a division by one vote only—71 voting for it and 72 against. No doubt a similar measure will be brought forward again.

SCIENTIFIC SERIALS

To the number of the *Journal of Botany* for March Mr. F. Townsend contributes an illustrated paper on the floral envelopes of Cyperaceæ and Gramineæ, in which he claims a closer homology between the corresponding parts in the two orders than has generally been allowed.—Mr. G. Murray has another and apparently a final word on the so-called "sclerotiets" found by Mr. A. S. Wilson and Mr. Worthington Smith in the leaves of diseased potatoes, and which he demonstrates not to have the organic structure attributed to them and to be unconnected with the potato disease.—In the number for April Mr. T. Hick gives a further observation on the continuity of protoplasm, which he finds to prevail throughout the frond of a seaweed belonging to a different group from those in which it had hitherto been obeerved, the common *Ascophyllum nodosum* (*Fucus noaosus*).—In addition to these papers there are in these two numbers others which are descriptive or refer to local botany.

THE most interesting article in the *Nuovo Giornale Botanico Italiano* for January, 1855, is by Signor Cugini on the anatomy of the inflorescence and of the flowers of *Dïöon edule*. The intermediate position occupied by the Gymnosperms, and especially by the Cycadeæ, between Cryptogams and the more highly developed flowering plants, renders especially valuable any fresh contribution towards the knowledge of the structure of their reproductive organs. The present paper deals especially with the anatomy of the ovule and of the ovuliferous leaves.—The greater part of the same journal for April is occupied by a very elaborate paper by Signor J. Danielli, illustrated by a number of plates, on the structure, distribution, and uses of the American aloe, *Agave americana*.—A shorter article of interest in the same number is by Signor A. Piccone, on the part played by herbivorous (phytophagous) fishes in the distribution of marine algæ. An examination of the intestines of several species of fish showed that, in addition to *Zostera* and other flowering plants, they contained the remains of a number of seaweeds, some of them in a fruiting condition, the spores of which are in all probability voided in the excrements, and are then in a favourable state for germination.—The remaining papers in these numbers are descriptive or contributions to local floras.

SOCIETIES AND ACADEMIES

LONDON

Physical Society, April 25.—Prof. Guthrie, President, in the chair.—The following papers were read:—On the theory of illumination in a fog, by Lord Rayleigh. The paper dealt with certain theoretical results based upon the assumption that the medium in which the fog was formed and the substance composing the fog itself were perfectly transparent. The effect of such a fog surrounding a source of radiation would be to diminish the radiation, and in the case of a supply of energy from without, as with the carbon filament of an incandescent lamp, the temperature of the source would be increased by the fog. A spherical envelope of such a fog surrounding the lamp, and sufficiently thick to be impervious, would act as a perfectly reflecting surface. A problem closely related to the above, and which is easily worked out, is that of light incident normally upon a pile of glass plates. If m be the number of such plates, and ρ the fraction of incident light reflected by one plate, $\phi(m)$ the light reflected, and $\psi(m)$ that transmitted by a pile of m plates, we have—

$$\frac{\phi(m)}{2m\rho} = \frac{1}{1+(2m-1)\rho} = \frac{\psi(m)}{1-\rho}.$$

If the transmitted light be allowed to fall upon another pile consisting of n plates, we have an infinite amount of reflection between the plates, and as the final result if A denotes the radiation in the original direction, and B that in the opposite,

$$A = \frac{2n\rho+1-\rho}{2(m+n)\rho} \quad B = \frac{2n\rho}{2(m+n)\rho+1}.$$

If m and n are large, we have—

$$A = B = \frac{n}{m+n},$$

which shows that by increasing n we can make the radiation between the plates as much as if the first pile did not exist whatever the number of plates in it.—On a monochromatic telescope, by Lord Rayleigh. This is a modification of Maxwell's colour-box. In this instrument, as is well known, light passes through a slit in the focus of a collimating lens; it traverses in succession this lens, a prism, and another lens by which it is brought to a focus upon a plane surface in which is a movable slit, the eye being placed behind which receives light approximately monochromatic. If, in addition, a lens be placed just behind the first slit, so as to bring some distant object into focus at a convenient distance from the eye, this object will be seen by the light that would enter the eye in the simple colour-box. The author suggested the use of this instrument to compare lights of different colours, and hinted at the possibility of choosing some colour towards the middle of the spectrum at which light might be compared for practical purposes.—On the self-regulation of the compound dynamo, by Prof. A. W. Rücker. If ϕ represents the current or electromotive force in the external circuit of either form of compound dynamo, it is given by means of an equation of the form

$$\phi = \frac{P}{A+x} - \frac{Q}{B+x},$$

where A, B, P, and Q are quantities which are different in different cases, but are always independent of the external resistance, and x is the conductivity or the resistance of the external circuit, according as ϕ represents the E.M.F., or current. The constant A in all cases depends only on the resistance of the various parts of the machine. If μ and m are respectively the largest and smallest values of x between which self-regulation is aimed at, then $\mu - m$ may be called the *range of x*. That value of x which corresponds to the resistance most frequently used may be called the *usual value* of x and indicated by ξ. The maximum efficiency η of the machine is connected with A and ξ by the relations

$$A = \xi\,(1+\eta)/(1-\eta) \text{ if } \phi \text{ be the external E.M.F.}$$
$$A = \xi\,(1+\eta)/(1+\eta) \text{ if } \phi \text{ be the external current.}$$

It can easily be shown that the function ϕ has two critical values, and that the value of x, corresponding to one of these, is necessarily negative, unless one of the inducing spirals is wound so as to diminish the magnetisation Various cases are considered, corresponding to different relations among the magnitudes of the constants A, B, P, and Q. The following indications of the method of treatment may suffice. If $A/B < 1 < \sqrt{P}/\sqrt{Q}$, ϕ is positive for all positive values of x, and the critical value of ϕ occurs for a negative value of x, so that ϕ diminishes as x increases. Hence, if we write

$$\frac{P}{A+m} - \frac{Q}{B+m} = \phi,$$

we must have

$$\frac{P}{A+\mu} - \frac{Q}{B+\mu} = \frac{\phi_1}{1+q},$$

where q is a positive quantity which will be less as the self-regulation is more perfect. These equations give

$$P = \frac{\phi_1}{1+q} \cdot \frac{\mu - m - q(B+m)}{(A-B)(\mu - m)}(A+\mu)\,(A+m)$$

$$Q = \frac{\phi_1}{1+q}\,\frac{\mu - m - q(A+m)}{(A-B)\,\mu - m)}(B+\mu)\,B+m).$$

Now since $A - B$ is negative, we must, if P and Q are positive, have

$$q < (\mu - m)/(A+m),$$

and *a fortiori*.

$$q < (\mu - m)/(B+m).$$

By similar methods inferior limits to q are found in other cases, and it is thus shown that for given values of μ and m, the limit is lower as A is larger. It has, however, been proved above that if the maximum efficiency of the machine is high, A will be large or small, according as it is taken from an expression that gives the external E.M.F. or the external current. Hence it is more difficult to combine high efficiency with good self-regulation if an approximately constant external current is desired than if an approximately constant external E.M.F. is aimed at. The equations do not lead to any simple rules for the relations which should hold between the various parts of compound dynamos; but if some of the constants are taken as given, the values which must be assigned to the others can be calculated if a given efficiency for the usual value of x and a given deviation from perfect self-regulation between given values of x are to be attained.—On the determination of the heat-capacity of a thermometer, by Mr. J. W. Clark. The method consists in the estimation of the masses of the mercury and glass of the thermometer by weighing the instrument in air and in water, and again in water when immersed to the extent usual in the thermal experiment. The specific gravity of the glass and mercury being known, the absolute masses immersed can be readily calculated, and consequently their thermal capacity.—A photometer which enabled a comparison to be made between the light of a lamp emitted at any angle and a standard was exhibited by Mr. Dibdin, and the action explained by Mr. Livingstone, who stated that the maximum amount of illumination took place at an angle of 45°.

Geological Society, April 15.—Prof. T. G. Bonney, F.R.S., President, in the chair.—John Rudd Leeson, M.D., was elected a Fellow of the Society.—The following communications were read:—A general section of the Bagshot strata from Aldershot to Wokingham, by the Rev. A. Irving, F.G.S. The author referred to earlier papers in the *Geological Magazine*, in which the green colouring-matter so common in the Middle and Lower Bagshot strata of the London Basin had been attributed to the presence of vegetable *débris* and the materials resulting from decomposition of vegetable matter. The marked difference in this respect between these strata and the higher members of the series furnishes a clue to the conditions under which they were respectively deposited, the former being delta- and lagoon-deposits, the latter the deposits of a marine estuary. This implies a transgressive overlap of the upper portions of the Bagshot series upon the London clay; and the present paper was devoted to a consideration of the stratigraphical evidence of this overlap. Sections were described in detail at Aldershot, Farnborough, Yateley, Camberley, Wellington College and the neighbourhood, and from the last-named place to Wokingham. From these a general section was constructed to exact scale, both as to thickness of strata and altitudes, showing a relation of the Bagshot formation to the London clay which was inconsistent with the generally received idea of their conformability and at variance with the mapping of the district as executed by the Geological Survey. The importance of the Bagshot pebble-bed as a basement-line of the upper division of the Bagshot strata was shown, as was suggested by the author so long ago as 1880. The synclinal arrangement of the London clay was shown to have been produced *before* the deposition of the Bagshot series, though a certain amount of movement (with a resultant amount of 150 feet of tilting in thirteen miles from south to north) has since taken place.—Notes on the Polyzoa and Foraminifera of the Cambridge greensand, by G. R. Vine. Communicated by Thomas Jesson, F.G.S.

Royal Meteorological Society, April 15.—Mr. R. H. Scott, F.R.S., President, in the chair.—The following papers were read:—Report of Committee on Decrease of Water-Supply. This Committee was appointed to take into consideration the question of the decrease of water in springs, streams, and rivers, and also the simultaneous rise of the flood-level in cultivated countries. As far as any inference can be drawn from the records collected by the Committee, it appears that the years 1820, 1821, 1824, 1835, 1838, 1845, 1847, 1850, 1854, 1855, 1858, 1859, 1864, 1865, 1871, 1874, 1875, and 1884 have been periods of marked low water. On the other hand, the years 1817, 1825, 1830, 1836, 1841, 1842, 1853, 1860, 1861, 1866, 1873, 1877, 1879, 1881, and 1883 have been periods when there has been exceptionally high water. In 1852 the water was very low in the early part of the year, while at the end of the year it was very high. In the intervening periods the water has been of moderate altitude. It does not appear from existing records that there is any diminution in the water-supply of this country, and the large quantity of water which has been stored or has flowed off the ground between 1876 and 1884 is confirmatory of this view. There appear, however, to be periods when there is exceptionally low water, and these are almost immediately followed by periods of exceptionally high water. With reference to the increase of floods, it does not appear from the records that there is any great increase in the height to which the floods rise in this country. Whether or not the height to which floods have risen in recent years has been affected by river improvements and the greater facility with which floods can be got rid of, or whether there is a diminution in the quantity of water, are questions upon which the Committee have not at present sufficient information to speak positively.—Report of Committee on the occurrences of the Helm-Wind of Cross Fell, Cumberland, from 1871 to 1884. In response to a letter inserted in the Penrith newspapers, the Committee has received a number of communications bearing on the subject of the helm-wind. With the view of ascertaining as far as possible the meteorological conditions which exist when the helm-wind is blowing, all the recorded occurrences that have been received have been chronologically arranged. The first systematic record commences in 1871, and in this report the Committee deals with all occurrences from that date to the end of 1884. Since that time more detailed records have been commenced at numerous stations in the locality at the instigation of the Royal Meteorological Society. Ninety-three instances of the helm-wind were recorded from 1871 to 1884; the months with the greatest frequency being February, March, April, and November. On examining the Daily Weather Reports it was clearly seen that, whenever the helm-wind was blowing there was an easterly wind, not only in the locality, but generally over the entire country. As the helm-wind seemed to occur so regularly with the easterly wind, the Committee further extended the inquiry with regard to the east wind. The Daily Weather Charts were consequently examined for each day from January 1, 1871, to December 31, 1884, and every occurrence of east wind tabulated; the instances with general easterly conditions over the whole country being kept separate from those instances in which the easterly wind was only partial, though of sufficient intensity to occasion the helm-wind. This examination showed that, although the wind over the United Kingdom is generally easterly when the helm occurs, yet the helm by no means occurs whenever the wind is easterly. Indeed, this step in the inquiry has not at all tended to the elucidation of the phenomenon in question, for it frequently happens that the conditions are, to all appearances, precisely similar when the helm is on, and yet no such occurrence has been recorded. This may in part be due to the occasional omission to record the helm, although it cannot possibly be, in the main, attributable to such an omission; but it points to other conditions being necessary besides absolute agreement of wind direction and isobaric lines. Possibly the different hygrometric qualities of the air with the existing easterly winds may be an important factor in deciding whether or no the helm will be formed, but it is not readily conceived why, even in this case, the helm-wind should not blow. It must, however, be borne in mind that the surface-winds can only be examined, whilst those at a comparatively small elevation may be intimetely connected with the phenomenon. From the observations made prior to those started at the beginning of 1885, no idea can be formed of the behaviour of the upper currents, even at the time of the occurrence of the helm-winds, far less with the occurrence of each east wind experienced. The Society has, however, provided for the extension of the inquiry in this direction in the records which are now being collected, the observers supplying observations of the upper currents by means of the clouds, as well as the direction of the winds at the surface of the earth. As soon as a sufficient number of these observations have been received, the Committee hopes to present a further report, which will tend to explain the phenomenon of the helm-wind.—Results of meteorological observations made at Asuncion, Paraguay, by R. Strachan, F.R.Met.Soc.

PARIS

Academy of Sciences, April 27.—M. Bouley, President, in the chair.—Experimental researches regarding (1) Attacks of an epileptic character excited by the electrisation of the excito-motor regions of the brain properly so-called; (2) the duration after death of the excitability so produced in the brain, by M. Vulpian. The main object of these experiments, made chiefly on dogs, is to confirm the conclusion already arrived at and communicated by the author in a previous paper, that the grey cortical substance of the cerebral regions known as motor centres does not play the indispensable part hitherto supposed in the production of epileptic attacks caused by the faradisation of those regions. The inference is also confirmed that amongst the higher mammals under normal conditions the cerebral substance proper loses its excitability as soon as the circulation has completely ceased in the nerve-centres.—Nebula discovered, observed, and tabulated at the Observatory of Marseilles, by M. E. Stephan.—Results of the boring recently carried out at Ricard, in the Grand'-Combe Valley, Gard, in search for coal, by M. Grand'-Eury. These borings tend to confirm the conclusion, already arrived at on other grounds, that no parallelism exists between the St. Barbe and Grand'-Combe geological systems, and as the former are unquestionably the older, they must, in the normal state, necessarily underlie the latter.—Report on the relation between the phenomena presented by the recent earthquakes in Andalusia, and the geological constitution of the region comprised within the area of disturbance, by M. Fouqué.—Remarks on an instrument analogous to the sextant, by means of which angles projected on the horizon may be directly measured, by M. E. H. Amagat.—Note on the calculations made to determine the solar parallax from the daguerrotypes taken by the French Commission during the transit of Venus in 1874, by M. Obrecht. The calculations have been carefully checked, and the definite result is represented by

$$\pi = 8''\cdot81 - 0''\cdot004\, dL \pm 0''\cdot06,$$

where π is the solar parallax, and dL the correction to be made for the longitude of Pekin.—Elements and ephemerides of the planet 246, deduced from the observations made on March 9 at Marseilles, Vienna, and Düsseldorf, on March 18 at Marseilles and Vienna, on March 31 at Berlin, and on April 9 at Marseilles, by M. Andoyer.—On a general law in the theory of the partition of numbers, by MM. Bougaieff.—A short and simple demonstration of M. de Sperre's theorem regarding Poinsot's "herpolhodie" curve, by M. A. de Saint-Germain.—Note on a method of regulating the velocity of electric motors, by M. M. Deprez.—*Régime* of combustion of explosive mixtures formed with illuminating gas, by M. A. Witz.—Description of the solar corona, the so-called "Bishop's ring," observed subsequently to the Krakatoa eruption in 1883, 1884, and 1885, by M. F. A. Forel.—Researches on the phosphates: a method of reproducing at pleasure a large number of crystallised phosphates and oxides, by M. H. Debray.—On the oxidation of iodine during the process of natural nitrification, by M. A. Müntz. The object of this paper is to determine the natural conditions under which were produced the extensive deposits of nitrates in certain tropical regions.—On the ammoniacal sulphate of copper, and on a basic sulphate of copper, by M. G. André.—On the dimorphism of telluric anhydride and on some of its combinations, by MM. D. Klein and J. Morel.—On the chemical constitution of cocaine, by MM. G. Calmels and E. Gossin.—Studies on the inhalation of bichloruretted formene (chloride of methylene) and of tetrachloruretted formene (perchloride of carbon), by MM. J. Regnauld and Villejean.—On the effects produced on man and animals by the stomachic ingestion and hypodermic injection of the microbes associated with the diarrhœic liquid of cholera, and cultivated in peptonised gelatine, by M. Bochefontaine. Experiments made by the author on himself and on the guinea-pig tend to show that these preparations, when swallowed or injected in small doses, produce no morbid symptom, although large doses may give rise to more or less serious local inflammation. He infers that the physiological disorders observed in cholera patients are due, not to the development of the microbe germs, but to the presence of a special substance not yet determined; further, that in its normal state the blood of man and other animals is destructive to the choleraic microbes artificially prepared in gelatine.

BERLIN

Physiological Society, March 27.—Prof. Ewald spoke on the occurrence of lactic acid in human gastric juices, which was now universally regarded as a pathological formation, *i.e.* a product of fermenting processes which did not obtain under normal conditions. In conformity with this opinion he had, in a former investigation, clearly demonstrated the absence of lactic acid, even after milk had been partaken. On the other hand, he had regularly found hydrochloric acid in the gastric juice. Two cases of hysteric vomiting, which had come under his observation in the infirmary, induced him to resume this investigation, one of the cases especially inviting such inquiry. The female patient was able to retain on her stomach and normally digest solid food, but whenever she swallowed anything fluid the whole contents of the stomach were at once vomited. Opportunity was, therefore, here offered at any time to examine the contents of the stomach after food had been received. Prof. Ewald mentioned the different chemical reactions by means of which the presence of lactic acid might be easily detected in the gastric juice, and among them he deemed carbolic acid and chloride of iron the most trustworthy. He then described the experiments he had carried out on the female patient above referred to, which had yielded the following results:—After a mixed meal (of bread, vegetables, and meat), lactic acid was found 26 times out of 31 in the contents of the stomach in the space of 10 to 100 minutes after the reception of the food; in 5 cases, however, not till 120 minutes or more after that point of time. Hydrochloric acid was found in the contents of the stomach only in the second hour and later, after the lactic acid had disappeared. Out of 26 cases in which white bread was alone eaten, lactic acid was demonstrated in 17 cases, occurring in 10 to 100 minutes from the time of eating. Out of 15 cases in which cooked albumen was administered, lactic acid was found only in one case, within one-and-a-half hours from the time of its being taken; while, on "schabefleisch" (scraped raw meat) being administered, lactic acid became again demonstrable; in the majority of cases in 10 to 100 minutes' time. From these experiments it was to be inferred that lactic acid occurred normally in the contents of the stomach, namely, in the first period of digestion. It was, however, in the opinion of Prof. Ewald, no normal constituent of the gastric juice, but in the case of a mixed and meat diet originated in the carno-lactic acid obtained from the meat and, in the case of white bread being taken, from the fermentation of the starch. On albumen being taken, lactic acid was, therefore, not found, because it occurred in the stomach only when it was introduced with the food—in the case of meat, for example—or when it arose from a fermentive aliment. With reference to the ulterior issues of the lactic acid, the speaker adopted the view of Prof. Maly, that it was employed towards the formation of the free hydrochloric acid afterwards appearing in the gastric juice.—Dr. Blaschko reported some observations he had made on sensations of pressure. In the course of investigations into the development of the skin, he had found that the hair-roots were provided with a rich nerve plexus in the same manner as the touch corpuscles in the touch balls of the hands and feet, and this induced him to examine the hairs in respect of their sensibility to pressure. When he took a stiff hair a little curved at the tip, and stroked the skin with it, he had only then a sensation when he touched a lanugo hair. By this and other means he became convinced that the hair papillæ possessed such a high degree of sensibility as entitled them to be placed in a series with the touch papillæ. While, however, the touch corpuscles had to be drawn hither and thither over the object to be touched, in the case of the touch hairs the body to be felt had, on the contrary, to be waved over it. Dr. Blaschko was therefore of opinion that a direct and an indirect, or a papillary and a ciliary feeling of the skin had to be distinguished. The first performed its functions at the unhaired cutaneous spots; the touch balls of the hand, and the foot, and at the lips; by means of the touch corpuscles. The indirect or ciliary sensations, on the other hand, were performed by the lanugo hairs covering the whole body, which were properly, therefore, touch hairs. If at a limited spot of the skin, such as the forehead, the lanugo hairs were shaved away, then would the fine sensations of pressure likewise disappear, and on waving that part of the skin with the stiff hair above referred to, a correspondingly large hiatus would become perceptible, at which nothing would be felt. In the course of this investigation the speaker had failed to convince himself of the existence of special points of pressure, and controverted the doctrine set up by Dr. Goldscheider in the former sitting of the Society respecting the specific energies of the nerves of feeling, and their punctiform distribution over the surface. In the discussion which followed, Dr. Goldscheider maintained the accuracy of his former statements, and invited Dr. Blaschko to convince himself of their correctness according to the method prosecuted by him.

VIENNA

Imperial Academy of Sciences, February 5.—Contributions to general nerve and muscle physiology (seventeenth communication): on the electric stimulation of the sphincter of Anodonta, by W. Biedermann.—Experiments on the oxidation of albumen by potassium permanganate, by R. Maly.—On *Clemmys sarmatica*, nov. spec., from the Hernalstegel, near Vienna, by C. A. Purschke.—Remarks on the velocity of light in quartz, by K. Exner.—Histological and embryological researches on the uro-genital apparatus, by T. Tanosik.—On a new vegetable parasite of the human body, by R. von Wettstein.

February 12.—On the bloodless-vessels in the tail of Batrachian larvæ, by S. Mayer.—On the constitution of isutivinic acid, by T. Schreder.—On the isogyric plane of double-refracting crystals, by H. Pitsch.—On the geographical distribution of the Jurassic formation, by M. Neumeyr.

THURSDAY, MAY 14, 1885

SIR WILLIAM THOMSON'S "MATHEMATICAL AND PHYSICAL PAPERS"

Mathematical and Physical Papers. By Sir William Thomson. Vols. I. and II. (Cambridge University Press. 1882, 1884.)

EVERY one interested in the study of physics of the more profound kind will welcome this collection of essays by the celebrated natural philosopher, so many of which, hitherto scattered throughout various periodicals, difficult to gather together, or even wholly inaccessible to readers out of the reach of large public libraries, are yet of decisive importance for those chapters of the science to which they refer. With the two volumes now before us, in conjunction with the late publication, "Reprint of Papers on Electrostatics and Magnetism," the collection is now completed down to the date of February, 1856. Vol. II. contains, besides, all that the author has written on the Transatlantic Telegraphs, which, according to the strict order of time, might have been looked for in later volumes. The first volume begins with a series of essays, for the most part of a mathematical nature, ranging from the year 1841 to 1850. So far as these essays relate to physical problems, their chief interest turns on the difficulties connected with the analytic method. These difficulties were, however, even at that early period, treated by the youthful author with great skill, and under comprehensive points of view. The problems are, in part, geometrical and mechanical, referring to lines of curvature, systems of orthogonal surfaces, principal axes of a rigid body, &c. Most of them, however, deal with the integration of the differential equations, on which is based the doctrine of thermal conductivity and potential functions. The latter, as is well known, form the mathematical foundation of a large number of chapters in physics—the doctrine of gravitation, of electrostatical distribution, of magnetic induction, of stationary currents of heat, of electricity and of ponderable fluids. By treating all these problems collaterally and rendering concretely in some what in others appears in the highest degree abstract, the author has succeeded in overcoming the greatest difficulties, and we can only recommend every student of mathematical physics to follow his example. A field particularly favourable for the exercise of his powers was opened up to Sir W. Thomson by the phenomena, newly discovered by Faraday, in diamagnetic and weakly magnetic bodies, crystalline as well as uncrystalline. These our author rapidly and easily succeeded in arranging under comprehensive points of view. One great merit in the scientific method of Sir William Thomson consists in the fact that, following the example set by Faraday, he avoids as far as possible hypotheses on unknown subjects, and by his mathematical treatment of problems endeavours to express the law simply of observable processes. By this circumscription of his field the analogy between the different processes of nature is brought out much more distinctly than would be the case were it complicated by widely-diverging ideas respecting the unknown interior mechanism of the phenomena.

From the year 1848 and onwards there follows a long series of important investigations into the fundamental problems of thermo-dynamics. These start first with Saadi Carnot's conclusions respecting the mechanical functions of heat arrived at before J. P. Joule had experimentally demonstrated the equivalence of heat and mechanical energy. At the time when Carnot published his investigations heat was, by the majority of physical scientists, deemed an imponderable substance capable of flowing from one body to another, of entering occasionally into a more intimate kind of union with ponderable matter, and becoming, so to say, chemically united with it, under changes in the state of aggregation and under chemical processes. According to this older view temperature signified as much as the pressure under which the imponderable fluid stood in the warm bodies. In the case of a great number of thermal processes heat, in point of fact, acts entirely like a substance, showing the constancy of quantity, which is the most characteristic criterion of substances. In this way large sections of the doctrine of heat, embracing great bodies of facts, could very well be treated under the substantial conception of this agent—such, for example, as the exchange of heat between different bodies, the confinement and liberation of latent heat, the chemical production of heat. All that was necessary to render the substantial conception of heat apparently satisfactory was but to leave out of account all cases in which other forms of work are produced by heat or in which heat is produced by such. Cases of this kind then known were indeed very few, whereas the sections of the doctrine of heat already referred to were exactly those which till towards the middle of this century engaged the attention of natural philosophers. Carnot's highly acute investigation was an attempt to bring the phenomena likewise of the performance of work by means of heat into harmony with the assumption of the substantial theory of heat. The result of this endeavour was remarkable enough. He showed, namely, that heat was capable of performing mechanical work only when a quantity of it passed from a body of higher temperature into another body of lower temperature. A complete analogy thus seemed to be established between heat and those gases which through their pressure are capable of performing work, expanding, as they do, and abating their pressure in a measure corresponding with their expansion. The heat of a warm body corresponds n a manner with a compressed gas; it diffuses itself in space, passing into neighbouring bodies, to the lowering of the temperature of the body in which it was originally compacted.

Carnot's deductions, although based essentially on the erroneous assumption that the quantity of heat was constant like that of a substance, proved in reality correct so far as they respected transitions of heat within very narrow limits of temperature. They cease, however, to be strictly accurate when they are extended to wider intervals of temperature, for in that case finite parts of the transferred heat become transformed into work and no longer continue as heat. We now know through the experiments of Joule that heat does not possess the absolute constancy of a substance, but only the relative constancy of an equivalent of work which, to be sure, can neither be produced from nothing nor come to nothing but is yet capable of being transferred into other forms of equivalents of work which may be presented in a very diverse and hardly recognisable manner.

In his first Essays, Art. XXXIX., "On an Absolute Thermometric Scale," and Art. XLI., "An Account of Carnot's Theory of the Motive Power of Heat," dating from the years 1848 and 1849, our author still occupies essentially Carnot's standpoint, but he nevertheless calls attention to the fact that the argument adduced by Carnot in support of his theorem, apparently valid though it was in all points, was yet defective if the experiments by Joule, which were just then made known, should be confirmed, according to which heat might be generated anew by work (vol. i. p. 116). That which more immediately directed Sir William Thomson's studies to this subject was the possibility of attaining, in accordance with Carnot's theorem, to an absolute scale of temperature, and he endeavoured to utilise the observations which Regnault had shortly before carried out with special care in reference to the pressure and latent heat of steam for he purpose of calculating such a scale. But in doing so, he was obliged to apply the hypothesis, not perfectly exact in this case, that the density of steam was to be calculated from pressure and temperature according to the laws of gases.

The theory of Carnot next obtained highly surprising confirmation from the theoretical deductions drawn by Prof. James Thomson, the elder brother of Sir William, touching the alteration of the freezing-point of water in consequence of differences of pressure. The accuracy in point of fact of this deduction was experimentally demonstrated by Sir W. Thomson. This was a discovery which perhaps more than any other served to draw the attention of physical scientists to the accuracy and the importance of Carnot's theorem.

Meanwhile our author, no longer able to doubt the correctness of Robert Mayer and Joule's thesis respecting the equivalence of heat and work, devoted himself to the problem of how Joule's and Carnot's laws might be combined. This question he answered in his treatise of March, 1851, "On the Dynamical Theory of Heat," Art. XLVIII. Prof. Clausius, in Germany, had, however, been busied with the same problem, and had published the results at which he arrived before Sir W. Thomson, in May, 1850. The essential results of the two investigations coincided exactly; only in their numerical values for the absolute scale of temperature, the two authors had started with two different hypotheses, and had therefore reached different conclusions. Sir William Thomson had, as above mentioned, calculated the density of steam from pressure and temperature, as if for complete gases, whereas Prof. Clausius had accepted the hypothesis set up by Robert Mayer, according to which the work of a gas expanding itself was exactly equivalent to its loss of heat. Later on, when his opponents set forth the unsatisfactory basis of this hypothesis, Robert Mayer pointed to an old and very little-known experiment of Gay-Lussac, according to which a gas diffusing itself in empty space without encountering any resistance suffered no diminution of heat. The same experiment was afterwards carried out by Joule without his having any knowledge of the earlier observation of a similar nature. This form of the experiment was, however, as a whole, not fitted to yield very precise results, seeing that the mass of air available for it, whose consumption of heat was to be measured, was necessarily very small in comparison with the mass of water of the calorimeter. It was not till the investigations into the changes of temperature undergone by a mass of gas made to pass through a very dense porous substance—an investigation carried out in common by J. P. Joule and Sir W. Thomson, in 1852, and described in Art. XLIX., "On the Thermal Effects of Fluids in Motion"—that it was demonstrated how, in point of fact, R. Mayer's hypothesis was accurate to within a very close degree of approximation, although not with absolute precision, in respect of hydrogen and atmospheric air, whereas carbonic acid showed greater deviations.

To this have to be added extended investigations into thermo-electric currents, and the equivalent of their operations (Appendix to Art. XLVIII. and Art. LI. "Experimental Researches in Thermo-electricity," Vol. I., Art. XCI. Bakerian lecture, pp. i., ii., and iii., Vol. II.). In a thermo-electric chain which, from its conducting wire, sets magnets in motion, or generates heat in them, the heat conducted to the soldering seams is manifestly the source of the operations. We know that in such a case, according to the important observations of Peltier, heat disappears from the warmer soldering seam, and becomes developed in the colder. That is, in fact, the condition, according to Carnot's law, under which heat becomes transferable into other forms of work. This particular process was, however, of special interest for the universal validity of the theory, seeing that the work of heat is here produced under conditions altogether different from those of the steam-engine and hot-air engine. Our author was by this investigation led to the conclusion that, contrary to the opinion hitherto entertained, it was not in the soldering-seams of the metals, at all events not in those alone, but in the whole length of the wires, by a process which he calls "electric convection of heat," that the essential cause of the thermo-electric force was to be sought; and, in point of fact, he succeeded by a series of very laborious and subtle experiments in demonstrating that the conduction of heat in iron proceeded more rapidly in the direction of the current of negative electricity, and in copper in the direction of the positive current.

In the first volume of the book which is the subject of notice, the consecutive stages may thus be followed in the development of one of the most remarkable chapters in the history of discoveries, a chapter specially remarkable also as an example of how discoveries are arrived at in a manner not always rational. The course of this discovery reminds one in some measure of the invention of achromatic telescopes. Starting with the erroneous supposition that the eye of man was achromatic, Euler inferred that Newton's assumption of the proportionality between refraction and dispersion of light was false, and that his conclusion as to the impossibility of achromatic telescopes was without foundation. Thereupon Euler gave the receipt for the making of achromatic telescopes—a correct conclusion from a false premiss; similar to the case of Carnot with the doctrine of heat. After all the confirmations which have been obtained in the different branches of physics for the validity of the deductions of the corrected Carnot law there can hardly longer remain any doubt that we have here found one of the most comprehensive and important laws of nature of unlimited applicability. Down to the present moment we are, however, not yet in a position to derive a complete argument for its truth from the general principles of kinetics. Our analytic methods are inadequate even to the problem of completely determining the movement of three bodies reciprocally attracting one another. In the case, however, of motion which we perceive as heat, there are myriads of atoms engaged, all in the most irregular movement, and influenced by forces the nature of which is still almost wholly unknown to us. It is highly probable that the peculiar difficulty of reducing thermal motion into other forms of mechanical energy, which is expressed in Carnot's thesis, is due to the circumstance that thermal motion is a completely "unregulated" movement, that is, that there is no kind of similarity between the movements of atoms immediately neighbouring one another. Even in the case of the most rapid vibrations of light and sound, on the other hand, the movements and conditions of neighbouring atoms are so much the more similar to one another the nearer they are to one another. These, therefore, I am in the habit of calling "regulated" in antithesis to thermal motion. Sir W. Thomson has introduced for this conception the name of "dissipation of energy." Prof. Clausius denotes the quantitatively determined measure of the same magnitude by a more abstract name, "entropie." The dissipation of energy is capable, according to Carnot's law, by every known process of nature in the inorganic world, only of constant increase, never of decrease, and this leads to the much-talked-of conclusion that the universe is tending towards a final state of absolute unchangeableness with stable equipoise of all its forces under the establishment of complete equipoise of temperature, as our author expressed it in the year 1852 (Art. LIX., "On a Universal Tendency in Nature to the Dissipation of Mechanical Energy").

On the other hand the ascertained laws of dynamics yield the deduction that if we were able suddenly to reverse the total movements of the total atoms of an isolated mechanical system the whole system would of necessity retraverse all the states which up to that point of time it had passed through. Therewith also would all the heat generated by friction, collision, conduction of electrical currents, &c., return into other forms of energy, and the energy which had been dissipated, would be all recovered. Such a reversion, however, is a postulate beyond the power of human means to fulfil. We have no agency at our disposal by which to regulate the movement of atoms. Whether, however, in the extraordinarily fine structure of organic tissues a mechanism capable of doing it exists or not is a question not yet to be answered, and I deem it very wise on the part of Sir W. Thomson that he has limited all his theses respecting the necessity of increasing dissipation by restricting their validity to "inanimate matter."

The recognition of this scientific law of so universal applicability and so rich in consequences is, be it repeated, due in the first place, through Carnot, to an erroneous assumption regarding the nature of heat. The universal demonstration given by him of the principle, a demonstration which in his day appeared completely satisfactory, is based purely on this assumption. And, what is still more noteworthy, it is hardly to be supposed that the principle in question could have been deduced from the more correct view—namely, that heat is motion, seeing that we are not yet in a position to establish that view on a completely scientific basis. The two natural philosophers, moreover, who brought Carnot's and Joule's principles into harmony with each other, and whom we have to thank for our present knowledge on this subject, are able to refer their conclusions only to an axiom generalising the experience that heat tends ever to expand, never to concentrate. Sir W. Thomson expresses this axiom in the following terms:—"It is impossible by means of inanimate material agency to derive mechanical effect from any portion of matter by cooling it below the temperature of the coldest of the surrounding objects."

The reviewer has, further, succeeded in demonstrating that the peculiar limitation affecting the transformation of heat into other forms of work likewise applies to other classes of motions revolving on themselves, so long as no external forces are brought into play directly opposing or accelerating the internal motion.[1]

When by J. P. Joule's experiment it was demonstrated that the basis of Carnot's proof was defective, it might have been apprehended that along with the element of error the element of truth in it would also be rejected. It must therefore be regarded as a special merit on the part of Prof. Clausius and Sir W. Thomson that, while removing the mistakes, they brought the truth into precise expression and into universal recognition, and that the recent theory of heat has become so fruitful in discoveries respecting the most secret connections between the different physical qualities of bodies in nature.

The second volume of these Reprints contains chiefly the researches having relation to the laying of the first submarine telegraph cable. The motion of electricity in these cables undergoes a peculiar retardation in consequence of the fact that the conducting-wire separated from the sea-water, which is likewise a tolerably good conductor, only by a thin isolating layer of gutta-percha, forms an enormous Leyden jar, which must first be charged with the electricity entering it before the current will pass with full force along the whole length of the wire to the other end. The physical laws of the processes which here come into play were generally known, but a far-searching mathematical investigation was still needed to determine the whole procedure of these currents and to ascertain the amount of influence exercised on them by the dimensions and conductivity of the wire, by the neighbourhood of other wires, and by the particular quality of the gutta-percha, as also to arrive at a knowledge of the conditions under which the most rapid series of signals might be transmitted and received at the opposite end.

All these questions our author disposed of thoroughly and exhaustively, having also to contend with opposition to his views based on observations made under restricted conditions on other cables. He was then a comparatively little-known young man, and did not enjoy that recognition and authority now everywhere freely accorded him.

To this were joined mechanical problems connected with the sinking or eventual raising and repairing of

[1] H. von Helmholtz, "Studien zur Statik monocyklischer Systeme." Sitzungsberichte der Berliner Akademie, 1884, März 6, 27, und Juli 10.

the cable; further, the construction of telegraphic signal apparatuses able to utilise the first weak beginnings of the current arriving at the other end of the cable. These ultimately led to the invention of the siphon-recorder—a writing apparatus in which the tube containing the ink does not come into immediate contact with the strips of paper on which it has to write, and is therefore not hindered by friction from moving even under the least electro-magnetic impulse. By electric charges it is brought about that the ink spurts over the paper in a series of fine points.

The conclusion of the second volume is formed by the Bakerian Lecture for 1856, which gathers up the results of the author's investigations into the qualities of metals as displayed under the conduction of electric currents, and under magnetisation, and the changes they undergo in consequence of mechanical, thermal, and magnetic influences.

Let us hope for an early continuation of this interesting collection. There are still nearly thirty years of scientific activity on the part of the author to be accounted for. When we think of that we cannot fail to be astonished at the fruitfulness and unweariedness of his intellect.

HERMANN L. F. HELMHOLTZ

OUR BOOK SHELF

Paradise Found. The Cradle of the Human Race at the North Pole. A Study of the Prehistoric World. By William F. Warren, S.T.D., LL.D., President of Boston University, &c. (London: Sampson Low and Co.)

IT has come to be an understood thing that when geologists or biologists propound theories as to past stages of life on the earth, and these theories attain to a certain popularity, some theologian shall twist the words of the Book of Genesis into a new interpretation, to show that this was what the inspired author meant all the time. A fresh musician has set Moses to dance to a new scientific tune. Since the publication of well-known modern views as to the diffusion of plants and animals from the Polar Region, it was to be expected that we should have a book proving that man was created in an Arctic Paradise with the Tree of Life at the North Pole; and here the book is. Other ancient cosmologies, such as the Greek and Indian, are made to bear their not always willing testimony. Those who take up the book should notice that the commendatory letters published from Professors Sayce, Tiele, and Whitney do not at all imply that these eminent scholars countenance the Polar Paradise doctrine. The President of Boston University seems to have sent them a paper some years ago on "Ancient Cosmology and Mythical Geography," their acknowledgments of which they are now perhaps hardly delighted to find figuring as certificates in a "Paradise Found."

Epping Forest. By Edward North Buxton, Verderer. (London: Stanford, 1885.)

THE public generally, and especially the people of London, and those who take some interest in natural history, are to be congratulated on the acquisition of so charmingly complete a little itinerary of Epping Forest as that now issued in a cheaper form by one of the Committee of Conservators, who is a resident on the borders, and an enthusiast as to the attractions of the Forest. It is, as the author observes in his preface, "hardly a desirable state of things" that so small a percentage of the summer visitors to the Forest "ever venture far from the point at which they are set down by train or vehicle;" and, with the choice of a score of beautiful walks, described in Mr. Buxton's book, and the guidance of his six carefully prepared maps, five of which are on the scale of three inches to the mile, there is no longer any reason for their not venturing into those depths of the Forest in which its chief beauties are to be seen. The chapter on the history of the Forest which the author has wisely prefixed to the itinerary, that visitors may be reminded of the events which secured this magnificent playground for their enjoyment, is most complete, though it is to be regretted that the late City Solicitor, Sir Thomas Nelson, is not mentioned *by name* on p. 22. The practical character of the book may be gauged from the inclusion of railway time-tables, the fact that the distinctive letters of each route have been cut on trees at some points, and from such suggestions as that an east wind is, in Epping Forest, the best for views, because not smoke-laden. Personal experience has convinced the present writer of the skill with which the routes have been selected; the "objects of interest within and around the Forest," and their historical associations, are fully described and illustrated by some excellent drawings, the latter by Mr. Heywood Sumner; but what must render the work peculiarly gratifying to all lovers of nature, is the ample space—more than half the volume—devoted to the fauna and flora of the Forest. The mammals, reptiles, birds; the chief moths and butterflies; the trees, flowering plants, ferns, fungi, and mosses, are all enumerated, with general, *i.e.* not too specific, localities; and the notes on the mammals and birds will be of interest to naturalists in other districts. Such lists can, fortunately, never be complete; insects marked as "rare" are notoriously liable at any time to prove common: even since the publication of this work evidence has been produced suggesting the addition of *Sparganium neglectum* to the list of flowers, and each year's cryptogamic meeting of the Essex Field Club has as yet added several species to the catalogues of the lower plants. There may yet be room for a more pretentious monograph of Epping Forest, and, of course, from the naturalist's stand-point, so rich a collecting-ground affords material for a library of expository literature—the freshwater algæ, for example, call for recognition;—but, for its purpose, the present work could hardly have been executed in a manner more creditable both to author and publisher.

G. S. BOULGER

Traité de Minéralogie appliquée aux Arts, à l'Industrie, au Commerce et à l'Agriculture, &c. Par Raoul Jagnaux. Avec 468 figures dans le texte. (Paris: Octave Doin, Éditeur, 1885.)

THIS work of 883 pages, as is stated in a title-page of corresponding length, is intended for the use of French students in their preparation for a degree in the subjects of engineering, chemistry, metallurgy, &c. We do not think that in its purely scientific contents it is likely to be of advantage to English students. The first part, devoted to the subject of crystallography, is rather incomplete and unsatisfactory, even if regard be had to the main purpose of the work. As usual, in the figure of Wollaston's goniometer the crystal is represented as adjusted in a way that every practical student is immediately taught to avoid. Nor will the chemical formulæ meet with the favour of English students: though the atomic weights of oxygen and silicon are given as 16 and 28 respectively, silica appears throughout as SiO_3, water is still HO, while to nitre is assigned the formula $KO . AzO_5$. Further, the ordinary symbols for the atoms are occasionally, as in the forty-nine formulæ of pp. 423-5, used to signify equivalent proportions of the oxides; olivine, for instance, being given as (Mg . fe)Si. The classification is likewise ancient; in the description of the species alum stone immediately follows the oriental chrysolite, a precious stone, merely because both substances contain alumina. In its explanation of the uses which have been discovered for the various subjects of the mineral kingdom, the work, however, supplies a want which has been long felt, and it will prove convenient for purpose of reference. The amount of detail will be better appreciated if we mention that in the description of the uses of carbonate of lime even the hammers used by stonemasons are specially figured.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Photographing the Aurora Borealis

I SHOULD be obliged if I might be permitted to state, with reference to the negative of the aurora borealis obtained by Mr. Tromholt in Christiania on March 15 (NATURE, vol. xxxi. p. 479)—the first ever obtained—that he now informs me that, although the plate was exposed for eight and a half minutes, the said impression is so faint and imperfect *that it cannot be reproduced as a positive*. My object in asking to be allowed to mention this important fact is to show that the opinion expressed by Mr. Tromholt in his work just published, "Under the Rays of the Aurora Borealis," that it is almost impossible to photograph the aurora borealis on account of the small strength of light and its limited chemical action, may be said still to hold good in the main.

CARL SIEWERS

Speed and Velocity

YOUR reviewer of Williamson and Tarleton's "Dynamics" (NATURE, February 26, p. 385) speaks of the confusion therein of *speed* and *velocity*. Does he mean that these words should now be used in distinct senses? If so, would he kindly specify the distinction, which is unknown to me and my friends.

B.

[Certainly. Velocity is a directed quantity, or Vector. Speed is its Tensor.—YOUR REVIEWER.]

Time.—Thunderbolts.—Vision.—Sunglows

ON my return from a magnetic tour along the Red Sea, I ask leave to refer to some back numbers of NATURE. In vol. xxxi. p. 125, Latimer Clark is quite right when he says that mean and sidereal time ought to be distinguished by names. I should prefer a step farther, and use for the latter the decimal angle, thus abolishing our frequent and tiresome conversion of time into space, and *vice versâ*. The resulting advantages would be obvious.

Answering Herr Von Danckelman's remarks in vol. xxxi. p. 127, I beg leave to quote my memoir, "Sur le Tonnerre en Ethiopie," published in 1858 by the French Institute, among its *Mémoires des Savants étrangers*. Facts mentioned there do not support the opinion that fatal thunderbolts are all but unheard of in Tropical Africa.

In your published remarks on vision, is it not Lord Rayleigh who says that the supposed superiority of eyesight among savages may be explained otherwise? Years ago, when reading Bergmann's travels among the Kalmouks, I noticed his remark that when examining camels *returning* to the fold, those natives distinguished sexes with their naked eyes just as well as he could through his excellent field-glass. In conclusion, Bergmann says that savage eyes are superior to civilised ones, or something to that effect. I must confess that I then accepted his opinion as being admirably warranted by the quoted facts. However, some time afterwards I was travelling on foot in the Pyrenees with a Basque illiterate peasant, and a splendid refractor by Cauchoix, which I proudly carried myself. My companion having tauntingly asked me why I had not left that lumber at home, I gave him, foolishly, a lecture on optics, and wound up by saying that the glass enabled me to distinguish a cow from an ox, even from that distant hill. He said he could do as much without my lumber. I then selected a cow grazing, and asked him what that was. "Wait till the brute walks," said the peasant; and at its first step he exclaimed: "it is a cow." I tried him, then, several times, and never found him in fault. He affirmed that cows and oxen do not lift their legs in the same way. May I request your rural readers to tell us whether that remark applies to English cattle? When on the Atlantic a sail was announced for the first time. I could perceive nothing, because I had not yet learnt what kind of a hazy thing I should distinguish. Having then sharp eyesight, I succeeded after a short practice, in discerning distant sails before any of my companions, and could turn tables on them by repeating their own saying, "*Ça crève les yeux.*"

To your lore on far-sightedness in vol. xxxi. p. 506, allow me to add two instances. Zach saw from Marseilles, Mount Canigou (2700 m.), at a distance of 158 English miles; he had calculated the true azimuth beforehand, and says that the peak bursts into view at sunset. Sir W. Jones informs us that the Himalayas have been seen at the great distance of 244 miles. I quote this from Carr's "Synopsis," a useful volume, which I regret to see behindhand in many cases since the death of its clever author.

May I intrude here a comment on our mysterious sunglows? My companion having a nice eye for discriminating colours, has confirmed my notion that on rising from the horizon the successive *nuances* of fiery red, faint red, rose, mallow, prussian blue, and green, are *not* the same on consecutive days, although thermometer, barometer, and wind have not changed. This suggests the hypothesis either that the lower strata of our atmosphere undergoes changes otherwise unperceived, or that there are maxima, minima, and perhaps regular epochs in the phenomenon. To those who, unlike myself, remain stationary under a rainless sky like that of Egypt, I would recommend a careful record of these changes, at least during a few months.

Cairo, April 22 ANTOINE D'ABBADIE

Plutarch on Petroleum

THERE is in "Plutarch's Lives," in the life of Alexander, an interesting notice of the petroleum of Media; I have not found any mention of this passage in "Plutarch" either in encyclopædia or chemical dictionary; I trust, therefore, that you will give me the opportunity of reproducing it in NATURE. I transcribe the passage from the translation of John and William Langhorne (9th edition, London, 1805):—

". . . and in the district of Ecbatana he (Alexander) was particularly struck with a gulph of fire, which streamed continually as from an inexhaustible source. He admired also a flood of naptha, not far from the gulf, which flowed in such abundance that it formed a lake. The naptha in many respects resembles the bitumen, but it is much more inflammable. Before any fire touches it, it catches light from a flame at some distance, and often kindles all the intermediate air. The barbarians, to show the king its force and the subtlety of its nature, scattered some drops of it in the street which led to his lodgings; and, standing at one end, they applied their torches to some of the first drops, for it was night. The flame communicated itself swifter than thought, and the street was instantaneously all on fire."

W. H. DEERING

Chemical Department, Royal Arsenal, Woolwich, May 6

Hut Circles

THE remains of the ancient British habitations on the downs on both sides of Dunstable are fairly well known to archæologists. I have often wished to expose the floor of one or more of these circles, as the task could be accomplished with a spade in an hour or two. It is, however, far better that the remains should be left alone, as it is not likely that anything would be found beyond a few flakes and the other simple forms, such as are abundant in the cultivated fields close to the huts.

On passing some of the circles on the east side of Dunstable, in the railway, about ten days ago, I noticed that the remains were covered with whitish soil instead of the normal green of the short pasture belonging to the downs. Thinking that some persons had been digging at these antiquities, I took an early opportunity of going to the spot. On reaching the circles I found they had been undermined in every direction by a large number of moles. A great deal of the material from the actual floors had been brought to the surface, and on examining this chalk rubble—for such it was—I had no difficulty in securing two or three handfuls of flint flakes. Mingled with them were a very few stones, which had been reddened and crackled by fire. No trace of burnt wood, ashes, or bone could be seen. It was remarkable that nearly all the stones found were flakes, as very few unworked pieces of flint could be lighted on. The flakes from the huts differ in condition materially from the flakes in the fields below, as all the flakes in the fields are marked with dark ferruginous strains, whilst those from the hut-floors are perfectly unstained, no iron having ever reached them.

In the immediate neighbourhood I have at different times found a large number of scapers, a lance-head, a few arrow-heads, and a few rudely-chipped celts, some broken. One small chipped celt has incurved sides, indicating, as Mr. John Evans has pointed out in his work on stone implements, that this particular form was possibly an imitation in flint of an early, flat bronze celt.

It is always well to examine the earth brought out of holes by rabbits, moles, foxes, rats, and other animals, in places where prehistoric relics exist on pasture-land. I have secured a considerable number of my antiquities from such places.

Last year I told a young niece of mine to keep a watch on such places at the spot where the five large tumuli are placed on Dunstable Downs, and where I had on previous occasions found flint flakes in the heaps made by moles, &c. It was not long before my niece lighted on two pieces belonging to the back part of a human skull. They had been scratched out of the base of the northernmost tumulus by some animal. Fortunately the two pieces fitted together; they are evidently of great antiquity, and probably represent part of the person who was buried in the tumulus, quite possibly one of the old chippers of Neolithic implements. WORTHINGTON G. SMITH

A Lady Curator

IN NATURE for November 27, 1884 (p. 90) you acknowledge the receipt of the "Catalogue of the Natural History Collections of the Albany Museum, Grahamstown, Cape of Good Hope," and allude to the "zealous curator." Are you aware that that individual is a young and accomplished lady? Here is another path opened for our daughters and "sweet girl graduates" to fame and fortune. Those who, like myself, have the pleasure and privilege of knowing and corresponding with Miss Glanville can appreciate the ardour and zeal with which she is following up her chosen vocation. May every success attend her. E. L. LAYARD

British Consulate, Noumea, February 25

Hoar Frost

A COMMUNICATION in NATURE of January 8 (p. 216), in regard to frost-formations, leads me to send a word from Maine. I have seen frost-work so like the description there given, that it would answer very well for an account of frosts in this climate. These frost-formations occur when the wind is chilly and blowing steadily, without the compass veering, for hours. I have compared these deposits to the most delicate designs of Oriental lace-work. At one time I witnessed an accretion on a wall, where the feathery forms were from two to four inches in length, with the points towards the wind. I think this is because each added particle adhered to the very tip of the previous one. Certainly no pen-description can do justice to the delicate beauty when the sun suddenly broke through the clouds and shone upon this forest of frost-ferns. CAROLINE W. D. RICH

Auburn, Me., April

Rainbow Phenomenon

ON Saturday night, about six o'clock, I observed, at Old Trafford, on the west side of Manchester, a rainbow with accompanying phenomena, which I had never observed before. Several very heavy showers had occurred during the day. The wind was within a point or two of west. At the hour above named a cloud was passing over, very dense and uniform in colour, and with that dark leaden hue so general in thunderstorms. There was, however, no thunder or lightning. Rain fell in torrents. As the cloud, which was of large area, passed off, the sun shone brightly in the north-west, and a magnificent rainbow painted itself on the dense black screen afforded by the cloud. The rainbow was double, the prismatic colours, of course, occurring in reverse order in the outer bow. The most remarkable feature of the display was the sharp contrast in the shadow of the cloud, evidently caused by the rainbow. Between the two bows it was of the densest leaden hue. Inside the inner bow it was exceedingly light coloured, with the faintest suggestion of luminosity. Outside the outer bow it was of an intermediate grey. The uniform mass of cloud was marked off by the two bows with geometrical accuracy into three regions, each perfectly homogeneous in itself, but distinctly contrasted with the two other tints. The effect was weird and startling, and was observed and commented upon by several spectators in whose company I was. There was another feature connected with the inner bow which I have never observed before. The green and violet colours were repeated inside the bow. Probably the whole tract from green to violet inclusive was repeated, but I could only make out those two colours distinctly.

Have these peculiarities, either or both, been observed before, and, if so, how are they accounted for? CHARLES CROFT

Prestwich, near Manchester, May 11

FIVE MATHEMATICAL RARITIES

A BRIEF reference to some recent reprints, &c., by Dr. Bierens de Haan, of Leyden, may not be unacceptable, though, unfortunately, ignorance of the language in which four of them are written prevents our giving more than the barest description of them.

The "Stelkonstige Reeckening van den Regenboog," or Algebraical Calculation of the Rainbow, is a rare tract, by no less distinguished an author than B. de Spinoza. It was for a long time supposed to be lost, if not burned; it is here printed in exact facsimile from a copy published at the Hague in 1687. Bound up with it is another rarity, similarly printed, entitled "Reeckening van Kanssen," or Calculation of Chances. No reference to this is made by Todhunter. There is a slight probability of this tract having proceeded from the same hand, as Dr. De Haan cites a reference to the forty-third letter in the collected works of Spinoza.

The third reprint is of a very rare book by A. Girard: "Invention nouvelle en l'Algèbre, tant pour la solution des équations, que pour recognoistre le nombre des solutions qu'elles reçoivent, avec plusieurs choses qui sont nécessaires à la perfection de ceste divine science" (Amsterdam, 1629). M. Marie writes: "Cet ouvrage est surtout remarquable par les idées justes que l'auteur émet au sujet des racines négatives des équations et de leur usage en géométrie."

The last two tracts have not been before printed: they are both the work of Simon Stevin, and are entitled "Van de Spiegeling der Singkonst" (*i.e.* Miroir de l'Art du Chant), and "Vande Molens." There is a full account prefixed to the former of these works, and we learn that the latter contains "le calcul de 19 moulins à vent, suivant la méthode usitée et suivant une nouvelle méthode de Simon Stevin lui-même, qui consiste à indiquer les roues, les dents et les pignons, afin de satisfaire à quelques conditions données."

Thanks are due to Dr. de Haan for the great care with which he has brought out these facsimiles, and we think he will certainly reap the reward he seeks. We quote his words in the last of these volumes: "J'ose espérer que la réproduction de ces ouvrages d'un homme si renommé pourra intéresser ceux qui s'occupent de l'histoire des sciences."

ON CERTAIN SPECTRAL IMAGES PRODUCED BY A ROTATING VACUUM-TUBE

THE beautiful effects produced by the rotation of a vacuum-tube when illuminated by a series of electrical discharges from an induction-coil are well known. The tube is generally attached to a horizontal axis, which is turned rapidly by means of a multiplying wheel; the images due to successive discharges which, if the tube were at rest, would be superposed, are thus caused to occupy different parts of the retina, and if the discharg follow one another at the rate of n per second, the number of images simultaneously visible will be about $n/8$, since the luminous image produced by each separate flash persists for about an eighth of a second after the flash itself has ceased. The result of these effects is the appearance of a gorgeous revolving star.

If the tube is made to rotate very slowly, there occurs a different and very curious phenomenon, which, so far as I know, has never hitherto been noticed. The tube used in my experiments was thirteen inches long, and contained various devices in uranium glass; the induction-coil had a resistance of 1400 ohms, and was worked by a single large bichromate cell. When the rotation is performed at about the rate of one turn in three seconds, the luminous images of the tube are almost superposed, forming a bunch which is slightly spread out at the ends. But about 40° behind the bunch, and separated from it by an interval of darkness, comes a *ghost*. This ghost is in shape an exact reproduction of the tube: it is very clearly defined, and distinctly shows every detail of the uranium glass devices. But the colour is entirely changed, the violet tint of the luminous bulb and the bright green fluorescence of the uranium glass being replaced by a uniform steel gray. If the rotation is stopped, the ghost still moves slowly on, and, after the lapse of about half a second, disappears in coalescing with the luminous tube. The phenomenon may be diagrammatically represented by the letter X, the thick stroke being the bunch of luminous images, and the thin stroke the spectral attendant. The direction of the motion is supposed to be opposite to that of the hands of a watch when seen from above. If the rate of rotation is too slow, the ghost approaches the luminous bunch so closely as to be obscured by its superior brilliancy; while, if it is too fast, the image becomes blurred and ill-defined. The strength of the inducing current should be regulated by trial. With too strong a current the effect is the same as when the rotation is too slow; with too weak a current the image is rendered feeble. Generally speaking, the best results are obtained with a somewhat weak current.

The experiment has been witnessed by a dozen persons, all of whom, with the exception of one adult, and the doubtful exception of a child, at once saw the spectral image. It is almost ludicrously difficult for those who are able to see it, to understand how any one else could possibly fail to do so.

This curious effect clearly belongs to the class of spectral images or "ocular spectra," which result from looking at a bright object, persistence of vision in the ordinary sense of the term having nothing to do with it. I proved this to be the case in a very simple manner. The vacuum tube being at rest in a feebly-lighted room, I concentrated my gaze upon a certain small portion of it while the discharge was passing. The current was then interrupted, and the luminous image was almost instantly replaced by a corresponding image which appeared to be intensely black upon a less dark background. After a period which I estimated at from a quarter to half a second (probably more nearly the latter), the black image again became luminous, assuming the characteristic steel gray colour: this luminous impression lasted but for a small fraction of a second, and the series of phenomena terminated with its disappearance. I found the effect to be most clearly marked when a narrow portion of the tube was observed; the definition of the spectral image was then exceedingly sharp, even the striæ being represented with perfect distinctness. It was also found desirable to make the preliminary illumination as short as possible, a single flash being generally sufficient to produce the phenomena. This is more easily effected by a judicious manipulation of the contact-breaker than by means of a key, or of the commutator attached to the coil. I may add that it is by no means certain that a person who is altogether new to the subiect will at first be able to see the appearances last described, even when he knows exactly what to expect. They belong to a class of phenomena which in ordinary life we habitually train ourselves to disregard, and our persistent neglect makes it difficult to perceive them when we desire to do so. With a little patient attention the difficulty will probably disappear.[1] It was probably owing to my constant habit of studying visual impressions that the appearance of the ghost attracted my notice in the first instance.

The series of phenomena seem to be due to an affection of the optic nerve which is of an oscillatory character. Abnormal darkness follows as a reaction after the luminosity, and again after abnormal darkness there is a rebound into a feebler luminosity. Following this idea I have endeavoured to detect the existence of a second ghost as the result of a further rebound, but hitherto without success.

It is an interesting fact, as proved by these experiments, that the formation of a spectral image does not occur until the expiration of a measurable interval of time after the exciting cause has ceased to operate.

SHELFORD BIDWELL

[1] The adult who failed to see the ghost is totally unable to perceive the subjective images in complementary colours, which generally result from gazing at brightly-coloured objects. Her general powers of vision are decidedly above the average, and she is in no degree colour-blind. The doubtful child is a daughter of this adult. A younger child can certainly see the phenomenon.

JUPITER

DURING the present opposition of this planet, the details of the belts and spots have continued to furnish materials of great interest. Some very obvious modifications have occurred since the previous year, and several curious new features have become conspicuous. The great red spot has surprised us by its extended duration. As early as 1882 it lost such a considerable depth of tone that its obliteration seemed imminent, but it has lingered on, until now its existence appears likely to be indefinitely prolonged, though under visible conditions far less imposing than at an earlier stage. All that at present remains of this remarkable formation is a dusky elliptic ring, darkest at the following end, and only well seen under good definition. Whether this ellipse is identical with similar appearances delineated by Dawes in 1857, Huggins in 1858, and Gledhill in 1869, 1870, and 1871 is involved in doubt, because of the lack of intermediate observations. We have no definite information as to what became of the various objects alluded to. It is very possible that they severally represent an object of considerable permanency. The changes such as observed may have been induced by atmospheric interference. There is every indication that the dense vaporous envelopes of this planet are rapidly variable, especially in the zone included by the two equatorial belts, and that the chief features undergo singular fluctuations, some of which may possibly be of periodical character.

The particular objects drawn by Dawes and others suggest a close relationship to the red spot as it now appears. There is far from being an actual coincidence either in the positions or forms of the features here sought to be connected, but small differences must actually occur in results based on estimation. A sufficient likeness is established between them to show that further investigation may have an interesting outcome as affirming the theory of recurrent markings of identical form. There is, however, an inability to trace the history of these singular objects, owing to the meagre number of observations available. This is a circumstance much to be regretted. Markings of specially interesting character deserve something more than mere record. They should be persistently watched during several oppositions, if possible, for it is only by this continuity of records that the really important questions affecting them admit of settlement. The red spot has now been followed since 1878, and though apparently on the verge of absolute extinction, it may yet linger on a considerable time in its present feeble aspect until possibly it is again enabled to obtrude upon general notice as an object of great prominence. It may not return under precisely the same outline as formerly, or exhibit the same depth of tone or degree of colouring, for, doubtless, some new development is to be anticipated on this disturbed region of the planet. In case of any distinct reappearance it will be important to determine that it occurred from the exact position so long tenanted by the old spot. The motion of this feature has been so thoroughly followed during the last seven years, that it will be feasible to compute its predicted place with great nicety in future months. In the mean time, and until the spot finally withdraws from reach, the same necessity exists as before of recording the times of its passages across the central meridian of Jupiter. And even assuming the total extinction of the spot, and that its place immediately south of the great equatorial south belt should resume the unbroken zonal arrangement existing in other longitudes, it will be necessary to re-examine this region occasionally for traces of any subsequent outbreak from the same focus.

During the last three years this object has given a rotation period of 9h. 55m. 39·1s., which has been steadily maintained throughout each opposition, subject to some minor disturbances partly due to errors of observation. The first few years of its existence it showed an increasing retardation of motion, which lengthened the period from 9h. 55m. 34s. to that already quoted, but, contemporarily with the decay of the spot in 1882, the velocity ceased to slacken, and the results accumulated during the past few oppositions prove it to have been equable in a marked degree.

With reference to the equatorial white spot some striking phenomena have been presented during the past winter. Between October 4, 1884, and January 13, 1885, its motion appears to have increased in an alarming ratio. The spot continued to rush on far in advance of its computed places, and all the while exhibited a more brilliant appearance than at any preceding epoch since the autumn of 1880, when it first came under systematic observation. The form and appearance of the spot have been so special as to prevent any confusion in mistaking it for other white spots in nearly the same latitude. Between October 4 and January 13, 1885, the rotation period was 9h. 49m. 51·95s., but the great increase in velocity evidently occurred towards the end of November. Between November 21, 1884, and January 13, 1885, the period was only 9h. 49m. 38·45s., or 34 seconds less than the mean period of 9h. 50m. 12·25s. shown by the same spot during the two preceding years.

When the first intimation of this great increase of speed forced itself upon my notice, I at once resolved to obtain as many observations as possible, in order to assure myself more certainly of the fact. Much cloudy, wet weather ensued, but I observed the spot on fourteen occasions between November 27 and January 13. A lengthened period of overcast skies then supervened, and I saw nothing more of Jupiter until January 27, when the place of the spot, computed on the basis of my prior observations, appeared absolutely vacant. About 15° E. there was, however, a remarkably brilliant spot, the exact counterpart of the one previously observed. Then arose the question of identity. Could the velocity have become so much retarded in the fortnight's interval from January 13 to 27 as to have occasioned so considerable a displacement in longitude? From my observation on January 13 and several preceding nights the spot had shown an increasing disposition to slacken, and, from records obtained in previous years, the motion was known to fluctuate in the most unaccountable manner. In the seventeen days from September 30 to October 17, 1881, I noted the spot underwent a sudden translation of 11°·6 in the direction of east longitude. The fact was independently confirmed by Prof. Hough at Chicago and Mr. Stanley Williams at Brighton. The most obvious departures from the mean rate of motion have been detected in other instances, and I am therefore led to conclude that the objects observed on January 13 and 27, 1885, were, notwithstanding their discordance of position, really identical objects. The consistent brilliancy of the marking alluded to, for several months before the cloudy period set in, is entirely opposed to the idea that it could have suddenly disappeared. And the real displacement is not so large as the limiting observations suggest. Deriving a mean from my results near January 13 and 27, I obtain the following figures:—

1885	Spot precedes 1st meridian m.	Long. (878°·34)
Jan. 7 to 13, mean of 7 obs.	64·0 ...	321·0
Jan. 27 to Feb. 6, mean of 6 obs. ...	46·4 ...	331·4

Adopting this mean, we practically eliminate errors in single observations, and in the present case it is fortunate I obtained so many transits just before and after the period of cloud. The real displacement is seen from this comparison to be only 10°·7, which is quite within the limits of previous experience. And if the fact of identity had not been rendered a very tenable hypothesis by past observation, I should have regarded the brilliant appearance of the spot and its comparative isolation as conclusive. Moreover, during the period that this object continued moving so rapidly, I often carefully examined the place where, had no change occurred, it must have been presented, but no object having a remote likeness to the old spot could be detected. Having observed this feature on the central meridian on more than 200 nights, I am familiar with its usual aspect, and could not possibly have overlooked it, on the many occasions when I looked for it in vain, had the spot retained the approximate place assigned to it from the observations of preceding years.

Let us now analyse the degree and period of the remarkable velocity alluded to. Arranging my observations into short intervals, the following are the rotation-periods severally derived from them:—

1884	Interval in Minutes	Spot gained on 1st. Mer. m.	Spot gained in Long. °	Number of Rotations.	Period. h. m. s.
Oct. 4 to Nov. 7 ...	48,985 ...	6·5 ...	4·0 ...	83 ...	9 50 7·55
Nov. 7 to Nov. 21 ...	20,064 ...	3·5 ...	2·1 ...	34 ...	9 50 6·07
Nov. 21 to Nov. 27 ...	8838 ...	15·1 ...	9·2 ...	15 ...	9 49 11·85
Nov. 27 to Dec. 9 ...	17,098 ...	17·4 ...	10·6 ...	29 ...	9 49 36·25
Dec. 9 to Dec. 18 ...	12,970 ...	13·8 ...	8·5 ...	22 ...	9 49 34·61
Dec. 18 to Dec. 24 ...	8843 ...	9·3 ...	5·6 ...	15 ...	9 49 35·05
Dec. 24 to Dec. 31 ...	10,023 ...	9·5 ...	5·8 ...	17 ...	9 49 38·72
Dec. 31 to Jan. 8 ...	11,208 ...	4·6 ...	2·8 ...	19 ...	9 49 57·73
1885					
Jan. 8 to Jan. 13 ...	7078 ...	3·5 ...	2·2 ...	12 ...	9 49 54·75
		Lost	Lost		
Jan. 13 to Jan. 27 ...	20,089 ...	24·9 ...	15·2 ...	34 ...	9 50 56·19
Jan. 27 to April 19 ...	118,042 ...	9·7 ...	5·7 ...	200 ...	9 50 15·16

The period of really great acceleration extended over forty days (November 21 to December 31), and it is remarkable that in the mean time the spot had completed exactly one revolution of Jupiter relatively to the red spot. In fact, the sudden increase and diminution of velocity occurred with the white spot following the red about 2h. 44m., so that there was a difference of 100° in the longitude. The maximum speed appears to have been shown between November 21 and 27, when the rotation-period was one minute less than the mean of the two preceding years. But my observation of November 21 was considered rather late, and the interval being a very short one of only six days, would originate a rather large error. But the four short intervals, from November 27 to December 31, exhibit a singular consistency in the resulting periods, the mean being 9h. 49m. 36·16s., which proves the real increase of speed to have been 36·09s. in each rotation; and, if we amalgamate the two preceding periods, from November 7 to November 27, we get a mean of 9h. 49m. 38·96s., which is closely accordant.

In the forty days, November 21 to December 31, the spot gained 65·1m. = 39·7° upon Mr. Marth's central meridian (*Monthly Notices*, vol. xliv. No. 9), based on the period of 9h. 50m. 12·25s. The spot must therefore have moved 28,700 miles to the westward at the rate of 717 miles per terrestrial day, and 294 miles per Jovian day. Then after January 13 it suddenly retrograded if we accept the

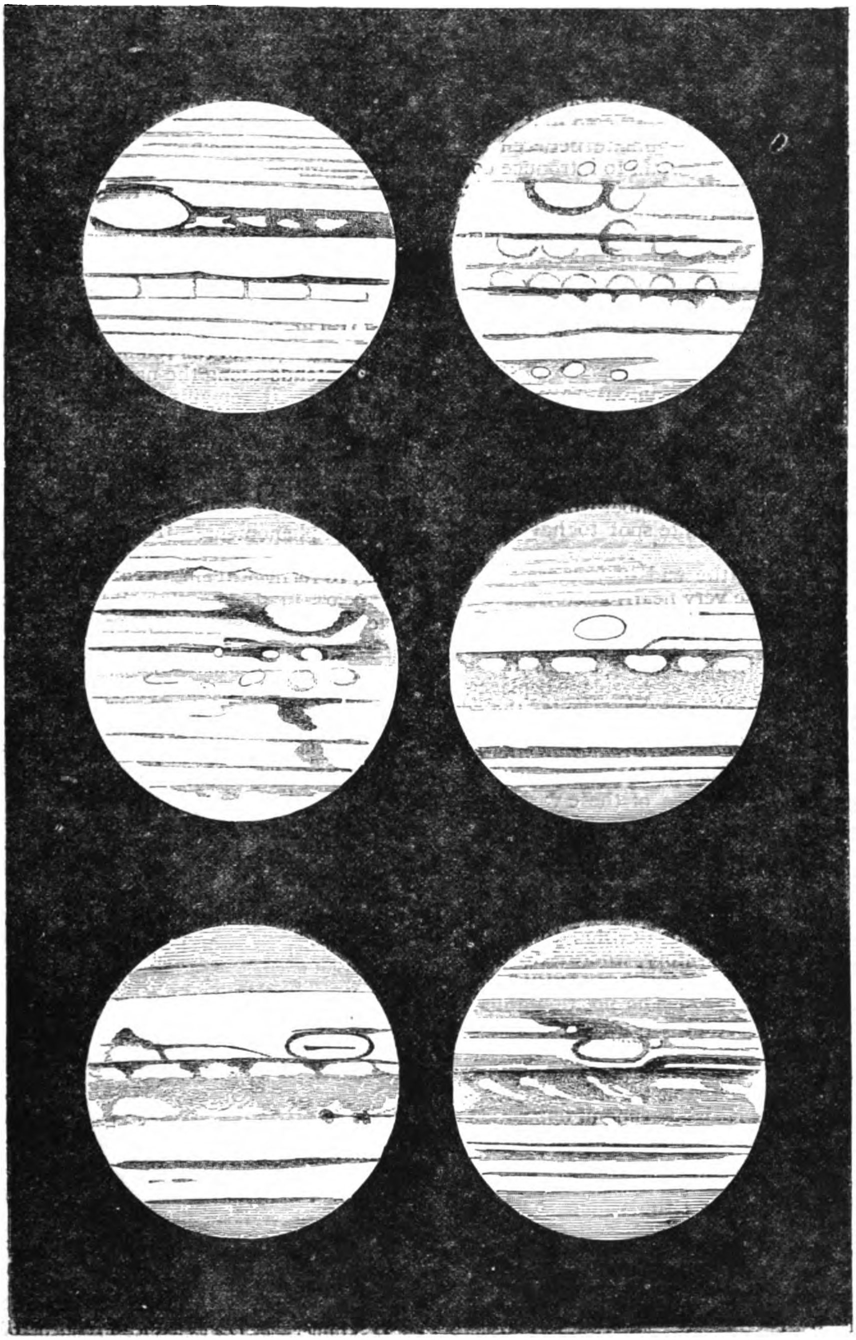

FIG. 1.—Probably recurrent markings on Jupiter. I. 1857, November 27 (Dawes). II. 1859, December 29, 10h. 50m. (Huggins). III. 1858, March 2, 9h. (Huggins). IV. 1870, January 23, 8h. 20m. (Gledhill). V. 1872, February 2, 10h. 30m. (Gledhill). VI. 1885, February 25, 12h. 50m. (Denning).

identity of the spots observed on January 13 and 27; so that in the fourteen days it lost nearly 11,000 miles, which is greater than the rate of its previous excess. But since the end of January the motion has steadied down to its normal degree, and thus we find the period closely agreeing with that adopted by Mr. Marth.

The motion of this brilliant white spot prior to January 13 is involved in no doubt whatever, so that the question of its identity with the one observed on January 27 is an entirely separate one, and cannot affect the remarkable phenomena, which the increased velocity exhibited, except as to the retrogressive motion which subsequently occurred. The question of identity may be definitely settled if any observations of the spot during the interval from January 13 to 27 are forthcoming from foreign observatories. In this part of England the sky was densely overcast at night during the whole of that time. If Prof. Hough at Chicago or some other systematic student of the planet can supply the missing links for the period referred to, it will be most important to ascertain how far they corroborate the assumed identity of the markings in question.

These white spots are liable to great variations in apparent brilliancy at short intervals; so that, unless an observer is very careful to discriminate between objects approximately situated, he is certain to introduce complications into his results. But, in regard to the conspicuous white spot which has been the subject of so much comment during the last few years, I have never found much difficulty in following it, because of its special character. Occasionally smaller spots slightly nearer the equator are seen on each side of it, but the leading spot of the trio is so bright and almost invariably shows a bright trail running from its north-east side towards the equator, that it may be readily identified. During the observations between October 4, 1884, and January 13, 1885, of the present opposition the extreme brilliancy of the spot was very noticeable, and the observations were pursued without any liability to error. I fear, however, that, morning observations being rendered necessary by the position of the planet in November and December will have enabled the singular vagaries of the white spot to have generally eluded notice.

It is curious that since the end of January this white spot has maintained a rate very nearly conformable to the first meridian of 9h. 50m. 12·25s., computed by Mr. Marth from the observations between 1882 and 1884; but there occurred a sudden deviation between March 14 and 18, amounting to some 8°. These singular displacements cannot be induced by changes in the form of the object, and they are far too considerable to be referred to errors of observation. Between February 9 and 16, 1882, Prof. Hough noticed an acceleration of 6¾°.

The verification and true cause of these variations can only be efficiently sought out by frequent and very accurate observation. Our own climate is very ill-adapted to an investigation of this kind where the most essential point consists in closely consecutive results. What we need is an almost unbroken series. It is to be earnestly hoped that some attention will be devoted to this important work at the Lick Observatory, where "the elevation is 4200 feet above the sea, and *for six or seven months of the year every night is clear!* The position thus commands natural advantages (in this work of far more importance than instrumental advantages) which would enable it to obtain some most valuable evidence bearing on the question of the remarkable variations affecting the white spots on Jupiter. Near the time of opposition they might be observed every night, and it is this consecutive, close treatment that is required before the phenomena will really admit of satisfactory discussion.

The question arises whether the whole southern belt partakes in these erratic and apparently frequent variations of speed, or whether they are confined to proper motions affecting the individual spots at different times. If several markings were made the subject of contemporary study it might soon be determined whether they exhibited uniform displacements, and, if so, it would have to be admitted that the whole equatorial atmospheric current is subject to the singular onrushes and alternating lulls which our recent observations have demonstrated.

Of the new features presented during the last few months the most striking are:—

(1) The appearance of large, bright spots indenting the north edge of the great northern equatorial belt. A peculiarity of these objects is that lines of light flowing from their west sides divide the dark belt and finally emerge near the equator, where they became indefinite. These spots show a rotation period only a few seconds less than the red spot.

(2) The outbreak of dark, reddish spots, elongated in longitude, upon the narrow belt which became visible in 1882, immediately outlying the great belt. The depression north of the red spot was formed by the ends of this belt suddenly dipping northwards before reaching the spot where they became blended with the old belt. The spots now visible here are very plain and will probably increase until finally their material is dispersed around the planet and the belt becomes much darker than before. The individual spots should be carefully watched to ascertain whether this is their ultimate development. The rotation period they have hitherto shown is precisely the same as that of the red spot. One of the most conspicuous of these new spots is about 10,000 miles long; it follows the red spot 1h. 48m., so that its longitude is 66° east.

(3) The fading away of the west shoulder of the depression north of the red spot. This is now very obvious, and extends along the narrow belt far to the west of the red spot. It remains to be seen whether this decadence will continue now that various other regions of the belt exhibit a confluent eruption of dark spots.

The several features referred to are of extreme interest, as suggestive of peculiar forms of atmospheric disturbance and as affording fresh materials for students of Jovian phenomena. It will be necessary to follow each of these special features during the two ensuing months, and to recover them, if still visible, when the planet reappears in the morning sky towards the end of October next.

W. F. DENNING

NOTES

AT the *conversazione* of the Royal Society on Wednesday evening last week, the Fellows, we are sure, were all glad to see their President back again, in renewed health, after his long absence. Prof. Huxley had to welcome a very large number of guests, and some of the objects exhibited were of much interest. Prof. H. N. Moseley exhibited a collection of Pueblo Indian pottery, charms, prayer-sticks, &c., from Zûni, New Mexico; Gen. Strachey, an instrument for drawing curves of sines adapted to graphical representation of the harmonic components of periodical phenomena; Mr. W. T. Thiselton Dyer lent some beautiful flowering specimens of Himalayan rhododendrons (the small, rosy-pink *R. glaucum* and the large, velvety-white *R. nuttalli*), a fruiting branch of coffee, and the various vessels and implements used in the collection and preparation of Para india-rubber; iridio-platinum weights, with a density of 21·5660, absolutely adjusted, and a piece of platinum wire ·00075 of an inch, prepared by drawing, &c., were exhibited by Mr. G. Matthey; the Linnean Society lent a remarkable set of drawings from the collection of Lady Impey, at Calcutta, painted by a native of Patna towards the end of the last century, and still in perfect preservation; the Anthropological Institute contributed ethnographic photographs of various races; and there were many highly interesting philosophical instruments shown.

THE Council of the British Association have nominated Prof. J. Struthers, M.D., as a Vice-President of the Association for the Aberdeen meeting, and have added the name of Prof. J. Stirling, M.D., D.Sc. (Aberdeen) to the list of those nominated for the Vice-Presidency of Section D.

AT the invitation of Prof. Flower, a meeting of the Essex Field Club will be held on Saturday afternoon, May 16, at 3.30, in the Lecture Room at the Zoological Gardens, when the Professor will speak of the principal objects of interest in the

Gardens, and will afterwards conduct the party to visit them in order, and give a demonstration of the most remarkable species.

A LETTER of Mr. Miklucho Maclay is inserted in the *Isvestija* of the Russian Geographical Society (1834, vi.), in which he expresses his regret that he cannot yet return to Russia, and explains the plan he has adopted for the publication of his reports. He wishes to have them published in two different parts, the first to contain (*a*) a statement of the reasons for any voyage or important excursion which he has undertaken, (*b*) a detailed narrative, and (*c*) scientific results of each of them; the second part to contain the scientific results concerning (*a*) anthropology, (*b*) ethnology, (*c*) zoology and comparative anatomy, (*d*) meteorology. In this manner Maclay hopes to suit both those who desire a general view of the outcome of his travels and those who wish to make themselves more particularly acquainted with the scientific results. By the way it may be mentioned that he has already described some new species, viz. (1) *Dorcopsis Chalmersii*, (2) *D. Macklayi*, (3) *Macropus Jukesii*, (4) *M. gracilis*, (5) *M. tibol*, (6) *Brachymelis garagassi*, (7) *Mus yelve*.

THE following, from *Science*, is a complete list of the papers read at the meeting of the National Academy of Sciences, April 21-24:—J. S. Billings and Dr. Matthews, U.S.A., methods of measuring the cubic capacity of crania; S. H. Scudder, winged insects from a palæontological point of view; A. S. Packard, the Syncarida, a hitherto undescribed group of extinct malocostracous Crustacea; the Gampsonychidæ, an undescribed family of fossil schizopod Crustacea; the Anthracaridæ, a family of carboniferous macrurous decapod Crustacea, allied to the Eryonidæ; Alexander Agassiz, the coral reefs of the Sandwich Islands; the origin of the fauna and flora of the Sandwich Islands; T. Sterry Hunt, the classification of natural silicates; Elias Loomis, the cause of the progressive movement of areas of low pressure; C. B. Comstock, the ratio of the metre to the yard; C. H. F. Peters, an account of certain stars observed by Flamsteed, supposed to have disappeared; J. E. Hilgard and A. Lindenkohl, the submarine geology of the approaches to New York; Theodore Gill, the orders of fishes; J. W. Powell, the organisation of the tribe; G. W. Hill, on certain lunar inequalities due to the action of Jupiter, and discovered by Mr. E. Neison; E. D. Cope, the pretertiary Vertebrata of Brazil; the phylogeny of the placental Mammalia; C. A. Young, some recent observations upon the rotation and surface-markings of Jupiter; H. A. Rowland, on the value of the ohm; F. A. Genth and Gerhard vom Rath, on the vanadium minerals—vanadinite, endlichite, and descloizite—and on iodyrite, from the Sierra Grande mine, Lake Valley, New Mexico; A. N. Skinner (by invitation), on the total solar eclipse of August 28, 1886; Theodore Gill and John A. Ryder, the evolution and homologies of the flukes of cetaceans and sirenians; Ira Remsen, chemical action in a magnetic field; A. Graham Bell, the measurement of hearing-power; A. Graham Bell and F. Della Torre, on the possibility of obtaining echoes from ships and icebergs in a fog. The following biographical notices of deceased members were also presented: of Dr. J. J. Woodward, U.S.A., by J. S. Billings; of Gen. A. A. Humphreys, U.S.A., by H. L. Abbot; and of William Stimpson, by Theodore Gill.

BOTANY, as well as geology, we are pleased to notice, is well represented upon the Afghan Boundary Commission. Mr. Condie Stephen, who has just arrived in London, speaking of the Penjdeh Valley or Koosh Valley, stated to a press representative that Dr. Aitchison, who has charge of the botany of the Expedition, is delighted with the country, and has made a very large and valuable collection.

THE *Times* Calcutta Correspondent telegraphs that the Indian Government has at last begun to fulfil a promise made years ago to the Asiatic Society, that a systematic zoological exploration of the depths of the Indian seas should be undertaken, in connection with a survey of the coasts. "A skilled naturalist, Dr. Giles, has been attached to the surveying steamer *Investigator*, which is supplied with proper appliances for deep-sea dredging. During a recent cruise in the Bay of Bengal some casts were made with very interesting results. Some of the animals found appear to be new, and have been sent home for examination. The dredgings also proved that the depression of the bottom, near the mouth of the Hooghly, known as the Swatch, regarding which much speculation had been indulged in, was merely a deep submarine valley, forming part of the original basin of the Bay of Bengal—as Sir Charles Lyall long ago suggested."

A PORTION of the work of Protestant missionaries in China, which has attracted little attention in this country, and which, nevertheless, is of great importance, is the preparation of school- and text-books in Chinese. For this purpose Protestant missionaries of all nationalities and denominations have united. At a general conference held in Shanghai in 1877, a committee of eight of the leading missionaries was appointed to superintend the preparation and publication of the series. The work has now been going on for eight years, and the Committee are able to report that over forty works have been issued, and that thirty more are in various stages of progress. In addition, four numbers have been issued of an "outline series" compiled with the object of supplying Chinese schools with small and simple treatises on scientific subjects at cheap rates, suitable either as elementary school-books or as popular tracts for general distribution. What "cheap rates" mean will appear from the fact that the outlines of astronomy costs rather less than a penny, that of political and physical geography and geology about twopence each. The larger works embrace anatomy, in five volumes; ancient religions and philosophies in three; arithmetic, charts of astronomy, birds and mammals, with accompanying handbooks (these charts, from the prices, are obviously intended for the walls of schools); chemistry, political economy, geology, universal history, international law (a translation of Bluntschli, it appears), zoology, and several on biblical topics. Those in preparation include treatises on various branches of elementary mathematics, botany, ethnology, hygiene, jurisprudence, logic, mathematical physics, meteorology, mineralogy, philology, and forty wall-charts with accompanying hand-books. These works, it must be remembered, have first to be compiled with a special view to the knowledge usually possessed by Chinese children, and then to be translated, representing in each case two distinct tasks. That the missionaries in China and elsewhere have schools where they teach the young is well known, but it will probably be a surprise to many to find that, in addition to their ordinary labours as preachers and teachers, the missionaries in China have had to undertake a task of such magnitude as the creation of school literature on all subjects of human knowledge, from arithmetic to jurisprudence, and from anatomy to logic. The statement on this subject is taken, it should be added, from the *Chinese Recorder* of Shanghai, a magazine which is itself a monument to the learning and enterprise of Protestant missionaries in China.

THERE will be an Exhibition of Plans, Maps, and Models in connection with the International Congress on Inland Navigation to be held in Brussels from May 24 to June 2. Those desiring to contribute are requested to send in their exhibits at once, addressed, carriage-free, to Mr. A. Gobert, 212, Rue de la Victoire, Brussels.

AN interesting scheme in connection with the Bedford School is that of higher education for adults by means of evening lectures on literary and scientific subjects, at nominal fees. The lecturers are drawn for the most part from the staff of Bedford School. Among the scientific subjects included in the course are mathematics, geology, physical geography, and botany. Bedford is fortunate in having amongst its residents men qualified and willing to organise and carry out an excellent plan of this nature for its benefit.

THE British Consul at Leghorn in his report for the past year makes some interesting observations on coral in the Mediterranean. Some centuries back the Mediterranean coral fisheries were carried on exclusively by the Spaniards, and the principal establishments engaged in the manufacture of coral ornaments were in the hands of Jews residing in Spain. Towards the close of the sixteenth century, to escape the persecutions to which they were exposed, a large number of these merchants removed to Leghorn, in order to enjoy the secure asylum afforded by the liberal enactments of Ferdinando di Medici. Crews were obtained from the Neapolitan coast, principally from Torre del Greco; hence this place at an early period became the chief seat of the coral fishery, and most of the boats engaged in it are still fitted out at that port, although the manufacture of coral ornaments and beads is carried on principally at Leghorn and Genoa. These ornaments are met with in almost every part of the world, and in many countries, even in Europe, coral is believed to be possessed of a peculiar charm. In Asia and Africa it is regarded with a sort of religious veneration, while in India it is largely used for the adornment of corpses when prepared for cremation. But the present situation of the coral trade is disastrous. In 1880, a coral bank several kilometres in length was discovered near the island of Sciacca, on the coast of Sicily, and consequently the yield of raw material has been far in excess of the demand, and the reef is still very far from being exhausted. A great depreciation in value has ensued, and as a consequence an extensive trade has sprung up in coral with Africa, where the natives now purchase coral ornaments in place of glass beads of Venetian and German manufacture. The raw coral comes from Naples, and is worked at Leghorn by women into beads, British India and Egypt being the chief customers for them.

ON April 24 Mr. Edward Berdoe, M.R.C.S., read a paper at University College, Gower Street, before the Browning Society, on "Browning as a Scientific Poet." The paper, as reported in the *Lancet*, opened with an exhaustive argument to prove that the progress of science need not, as some had said, tend to the destruction of the poetic art; that, in fact, some of the greatest poets had enriched their verse by the study of natural phenomena—Lucretius, Haller, Milton, and Goethe, and in our own times Tennyson and Browning, while students of natural and physical science had not found their exact acquaintance with natural laws impede the luxuriant growth of their poetic fancy. Many of Browning's most beautiful similes were the result of his intimate acquaintance with anatomy, physiology, and chemistry; and the use he constantly makes of figures drawn from the science of optics has enabled him to illustrate his favourite optimism by much beautiful imagery. The poet of the future will be denied his former "power of dealing capriciously with facts," but this restraint, Mr. Berdoe argued, would not repress the poetic spirit. Mr. Berdoe, in conclusion, claimed for Mr. Browning that he is essentially the poet for the scientific man: abreast of the highest culture of his time, and in close touch with the great aims of science.

HERR SCHWEIGER, writing from Widdin to the *Monatsschrift für den Orient*, refers to baldness amongst Orientals. In Europe the idea is general that baldness is the prerogative of scholars; in the East, on the other hand, it is the common characteristic of two races—the Spanish Jews and the Turks, whose nervous system has never been overwrought by any devotion to serious studies. In some measure to explain the origin of this phenomenon we must commence at the cradles of the two peoples living side by side. The indolence of Oriental women is well known and is manifested in sins of omission rather than of commission. The Oriental mother neglects the principal duties to her offspring. During the first eight days of its earthly career the infant is sprinkled with a little tepid water once a day by some old woman, then wrapped in coloured rags to save the trouble of frequent changes, the head being wrapped in a well-wadded cap tied under the chin. This process is repeated during the succeeding weeks once every two days, until finally it has become too toilsome even for this repetition, and is abandoned altogether, through fear, it is said, that the child would catch cold from frequent washings. Superstition has added its force to laziness, for the women believe that the head of an infant should never be washed, as the scab produced by the dirt is good for the eyes. This dirt, mixed with the secretions from the sebaceous and other glands, becomes the home of numerous animal and vegetable parasites, which prevent the development of hair and destroy that already grown. The open air, which might assist in destroying these parasites, is, however, carefully excluded by the custom which is imperative among Semitic peoples of never, by day or night, or upon any occasion whatsoever, taking off the head-covering. At night the fez is changed for a linen cap of similar shape. This perpetual covering naturally retards the growth of the hair, and transmission and propagation do their work. Herr Schweiger, who has lived in the East for many years, first noticed chronic baldness amongst the lower classes of the Turks, especially the so-called Spaniols of Salonica.

THE National Fish Culture Association's hatchery at South Kensington is now gradually becoming depleted of fry, which are being transmitted to public waters gratuitously, and to the fishery at Delaford belonging to the Association. The spawning and hatching season has been very prosperous and successful, there being but a very low minimum mortality amongst the fish produced.

THE Aquarium at the International Inventions Exhibition is assuming a more complete aspect, and has been an attractive feature with visitors from the first. An Aquarium Handbook is now in the press and will be shortly published by Messrs. Clowes and Sons, containing a natural history of the fish in captivity and a series of articles upon the culture of fish, the management of aquaria, &c.

ON April 22 a meteor was seen descending in a straight line from the zenith at Fogelsta railway station in Östergötland, Sweden, and fall some distance off. On the station-master proceeding to the spot he found a stone, about the size of a hand, and brown in colour, which smelt strongly of phosphorus when struck against a hard object. It was split into three pieces, each being forwarded to a museum.

THE *Calcutta Gazette* has published a resolution of the Government directing the institution of an inquiry, under a specially selected officer, into the castes and occupations of the people of Bengal. The results of this inquiry should be of great ethnographical value.

THE exceptionally heavy rainfall at Bergen on October 25, 1884, when 74 mm. were registered for the twenty-four hours, was commented on at the time by the Scandinavian press as affording confirmatory evidence of the truth of the popular opinion that this town is the rainiest place in Norway. This notion, however, like many other traditional beliefs, has been dissipated by the test of carefully-conducted scientific observations, for we learn from *Naturen* that the annual mean of its rainfall is exceeded by that of two among the other seventy Norwegian meteorological stations. Thus while at Bergen 1722 mm. are measured annually, the rainfall at Domsten and Florö amounts respectively to 1951 mm. and 1873 mm. It has further been shown that 105 mm. rain were registered at Holmedal on the Söndfjord, on the same day that the rainfall at Bergen reached 74 mm., the highest recorded since rain-measurements have been made there. There are in fact eighteen instances given by the meteorological reports in which the rainfall has elsewhere exceeded the latter measure. Among these the most remarkable have been supplied by Ullensvang and Flesje, at the former of which stations there fell in one day (December 8, 1884) 113 mm. rain, while at the latter 112 mm. were registered for the twenty-four hours on March 15, 1882. These downfalls, the highest recorded in Norway since the observations were begun in 1875, have been exceeded, according to Dr. Hamberg of Stockholm, at the Swedish station of Hernösand, where 118·5 mm. rain fell on August 19, 1878. Facts such as these effectually refute the opinion, alike strenuously maintained by natives and foreigners, that more rain falls at Bergen both in the year and in the course of one day than at any other place in Scandinavia. Such, however, is the character of the annual distribution of rain in this locality, that the chances are about equally in favour of a wet or a dry day.

In reporting to the Empress of China the occurrence of a violent earthquake at the town of Pu-erh on November 14 last year, the Viceroy of Yunnan observes with humility that this awful visitation is to be regarded as a penalty of Heaven for his own inefficiency and incompetency and that of his staff. They will, the memorialist promises, endeavour to take the lesson to heart and earnestly amend their ways. Pu-erh will be remembered by readers of Mr. Colquhoun's "Across Chrysê" as an important town on the borders of the Shan States, with a large trade in tea. The earthquake here referred to is also worth notice as showing that seismic activity during the past winter was manifested over a vast area, and indeed seems to have affected the greater part of the Old World. At Pu-erh the shock lasted an hour, causing the collapse of a large number of houses, temples, and public buildings, while many lives were lost, and much injury was caused to the inhabitants.

M. Léo Errera calls attention in the *Bulletin Scientifique du Département du Nord* to the value of Indian ink, on account of its harmlessness and its intense coloration, for the study of certain microscopic organisms. He has succeeded in keeping infusoria, &c., alive for several days in the liquid, the carbonic matter not appearing to affect them in the slightest degree. For making durable preparations ink diluted with water should be gradually replaced by that diluted with glycerine. Many organisms which are distinguished with difficulty in water, are easily observed in water charged with Indian ink; this is especially the case with many *Algæ*. M. Errera thinks that this new method could probably be applied with advantage to the study of the digestion of the infusoria, and to the movements of ciliated organisms.

The additions to the Zoological Society's Gardens during the past week include a Green Monkey (*Cercopithecus callitrichus* ♀) from West Africa, presented by Mrs. Wall; a Rhesus Monkey (*Macacus rhesus* ♂) from India, presented by Miss Margaret Ellis; a Getulen Gronnd-Squirrel (*Xerus getulus*) from North-West Africa, presented by Mr. W. Cook; a Grey Ichneumon (*Herpestes griseus* ♀) from India, presented by Mrs. Dundas; two Martinican Doves (*Zenaida martinicana*) from Bahamas, presented by Mrs. Blake; two Horned Lizards (*Phrynosoma cornutum*) from Texas, presented by Mr. J. G. Witte; a Dorsal Squirrel (*Sciurus hypopyrrhus*) from Central America, an Indian Mynah (*Acridotheres ginginianus*), four White-backed Pigeons (*Columba leuconota*), a Black Hill-Squirrel (*Sciurus macrurus*) from India, two Chinese Jay-Thrushes (*Garrulax chinensis*) from China, a Sun Bittern (*Eurypyga helias*) from Brazil, two Greek Partridges (*Caccabis saxatilis*), South European, a Double-banded Sand-Grouse (*Pterocles bicinctus*) from Senegal, a Talapoin Monkey (*Cercopithecus talapoin*) from West Africa, a Negro Tamarin (*Midas ursulus*), a Humboldt's Lagothrix (*Lagothrix humboldti* ♂), a Rosy-billed Duck (*Metopiana peposaca* ♀) from South America, a Viscacha (*Lagostomus trichodactylus*), a Scorpion Mud-Terrapin (*Cinosternon scorpioides*) from Buenos Ayres, a Gadwell (*Chaulelasmus strepera* ♂), nine Spotted Salamanders (*Salamandra maculosa*), European, purchased; a Crossoptilon (*Crossoptilon mantchuricum* ♂) from Northern China, received in exchange; a Gayal (*Bibos frontalis*), two Long-fronted Gerbilles (*Gerbillus longifrons*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

The Harvard College Observatory, U.S.—The thirty-ninth Annual Report of this Institution has been issued, and with it Prof. Pickering's summary of observations of variable stars in 1884, made agreeably to the plan suggested by him in a communication to the American Academy of Arts and Sciences (vol. xix. p. 296). Thirteen observers, private and professional, have co-operated in these observations, amongst them Mr. Knott, of Cuckfield, and Mr. T. W. Backhouse, of Sunderland. In the summary referred to, the positions of the stars for 1875, the limits of variation and the periods, as far as reliably determined, are repeated from the circular of last year, and these particulars are followed by a statement of the number of observations of each star, made by the various observers in the course of 1884, so that it is easy to see which objects most require attention. It is certain that in this branch of observational astronomy there is ample work for a much larger number of co-operators, which it may be hoped that Prof. Pickering will succeed in enlisting amongst our amateurs, and eventually it may be possible to particularise the objects which each one may undertake to watch effectively, so as to secure observations of the whole or the majority of the list in each year.

With regard to the general proceedings of the Harvard Observatory, it is stated that photometric observations of the eclipses of Jupiter's satellites have been continued upon the system adopted in 1878, and 284 eclipses have now been thus observed, forty-seven since the end of October, 1883. The revision of the zone-observations of stars between 50′ and 60′ north of the equator has been completed during the year. Selections of stars for standards of stellar magnitude have been made for regions extending four minutes (time) in right ascension, and ten minutes in declination, and additional photometric methods of measurement are under consideration for determining such magnitudes with satisfactory precision. Observations of comets, of the spectra and colours of stars, and a tentative revision of the magnitudes of the *Durchmusterung*, have also formed a part of the year's work. We do not learn from the report that any attempt has been made to repeat the valuable series of observations on the rings of Saturn, made by the Bonds, &c., with the Harvard 15-inch refractor, when the planet was previously situated in the position it occupied in 1884; but the class of observations more especially attended to at present may have rendered this impracticable. Vol. xiv. parts 1 and 2 of the *Annals* have been published; the latter part has been circulated very recently.

Tempel's Comet (1867 II.).—Up to the 7th inst. it does not appear that the editor of the *Astronomische Nachrichten* had received any notice of the re-observation of this comet. Doubtless, of the last degree of faintness, it could only have been commanded last month by instruments of the highest order. In the next period of absence of moonlight the theoretical brightness will have diminished. The comet will be due in perihelion again in the spring of 1892, a more favourable condition for the observation of this body than has existed in the present year.

NEW NEBULÆ.—M. Stephan publishes positions and descriptions of 100 nebulæ discovered at Marseilles in the years 1883–85, in addition to the large number previously detected at that observatory. Not the least notable characteristic of M. Stephan's catalogues is the precision of the places given in them. He mentions that on October 1 and 2, 1882, neither the nebula Dreyer-Schultz 5085 nor *h* 12 were perceptible in the positions assigned to them by the discoverers.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, *MAY* 17–23

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on May 17

Sun rises, 4h. 7m.; souths, 11h. 56m. 10·8s.; sets, 19h. 46m.; decl. on meridian, 19° 26′ N.: Sidereal Time at Sunset, 11h. 29m.

Moon (at First Quarter May 21, 6h.) rises, 6h. 59m.; souths, 14h. 53m.; sets, 22h. 44m.; decl. on meridian, 18° 7′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	3 37	10 30	17 23	9 41 N.
Venus	4 18	12 10	20 3	19 55 N.
Mars	3 24	10 36	17 48	13 13 N.
Jupiter	11 0	18 15	1 30*	13 38 N.
Saturn	5 43	13 51	21 59	22 18 N.

* Indicates that the setting is that of the following day.

THE IRON AND STEEL INSTITUTE

THE Iron and Steel Institute met on Wednesday, the 7th inst., when Dr. Percy gave the presidential address. After inviting the co-operation of the members in supplying him with materials for the new edition of his work on "Iron and Steel," and referring to Mr. Lowthian Bell's recent valuable work on the same subject, Dr. Percy drew attention to the existing universal depression, due, in his opinion, to over-production. "Darwinianism prevails in the manufacturing world as it does in the natural world, however painful and unwelcome may be that truth—only the fittest will survive. The struggle may be severe and to many persons disastrous, but so long as supply exceeds demand, it is inevitable, and the result is not doubtful."

In the matter of technical education he regretted that a few of its professed friends should have indiscreetly attempted to imbue all our artisans with the notion that the one thing which at present they urgently need is technical education, and that it will be certain to benefit them all alike, whereas in some trades, such as that of the file-cutter, the marvellous skill which is alike the surprise and admiration of all is to be obtained only by the practice of his art. He referred with pleasure to the judicious and enlightened way in which Sir Bernhard Samuelson, M.P., had advocated technical education in its widest sense, and rejoiced over the liberality of the founders of the Owens College (now the Victoria University) in Manchester, the Mason College in Birmingham, and the Firth College in Sheffield, and of the Whitworth Scholarships, through whose aid scientific instruction is placed within the reach of the artisan class.

The major portion of the address was devoted to the physical and chemical properties of iron and steel, and the learned President's remarks brought out in strong relief the prevailing want of knowledge. How comes it, he inquires, that the force of cohesion should be increased by mechanical treatment, which, *à priori*, might be supposed would tend in greater or less degree to produce disaggregation? Why is iron or steel wire increased in strength by wire-drawing? What is the cause of the physical changes which some metals and alloys have been observed to undergo spontaneously while at rest and under ordinary atmospheric conditions?

"It is not many years since that we had to grope about to discover an analysis of iron ore or of pig iron, whereas now we are actually overwhelmed with such analyses. We are deluged with percentages of carbon, graphitic or combined, of silicon and manganese, of sulphur and phosphorus. We are bewildered by this vast accumulation of material. What is now wanted is the man to reduce it to law and order, to evolve from it principles for our sure guidance. But the problem is so intricate and complex that no common brain can solve it. What are the physical properties of pure iron after fusion? What are the chemical and physical properties of compounds of pure iron and pure silicon in various proportions? What are the modes of existence of manganese, silicon, and phosphorus when present together in pig iron? What is the *modus operandi* of manganese in the manufacture of iron and steel? Why are animal matters or certain other substances rich in nitrogen, required in case-hardening iron? Is any nitrogen or any compound of it imparted to the case-hardened part of the iron? These and such like questions the metallurgist asks of the natural philosopher and chemist, and has failed hitherto to receive a reply."

Having concluded what may be called the technical part of his address, Dr. Percy treated the question of the extent to which the Government of a country should engage in manufacture, and stated "that, if it could be shown that the people as a whole would be benefited by the Government's engaging in manufacture, then the Government was bound to take that course." Treating the various cases of armour-plates, steel for guns, and steel for ship-plates, he showed that in each case, owing to competition, co-operative management, and other causes, private industry was always able to produce articles as good as and cheaper than the Government.

The address was listened to with the greatest attention throughout, both on account of the inherent interest of the matter and the great oratorical skill employed in its delivery. The closing paragraphs are of such universal interest that we quote them verbatim:—

"Everything in this world, nay, there is reason to believe everything in the universe itself, is changing from moment to moment. There is, as I have stated in print long ago, nothing constant but change, however paradoxical that statement may appear. Every drop of rain that falls, for instance, exerts a levelling action on the hills and mountains, and carries down with it in its course to the ocean a minute yet sensible portion of earthy material. In the moral world the like incessant change is going on, and no one can predict what the final result ef that change will be. Our globe may, it seems to me, be fitly compared with the laboratory of the philosopher. The one, to our finite understandings, may appear the scene of social and political experiments, just as the other is the scene of chemical and physical experiments. But of this we may be sure, that invariable and irresistible law guides all things, immaterial as well as material. When I reflect on the intricate social problems of the day, the solution of which excites dread in the minds of many, I fancy I see the social molecules, if I may use such an expression, actively at work in rearranging and adjusting themselves to new conditions, and producing results as surprising as they are remarkable. The mysterious forces, whatever they may be, which regulate the movements of those molecules, are as certain in their operation as those which determine the course of the planets in their orbits. Both are equally uncontrollable by the agency of man, and politicians will in vain struggle against them.

"There is a question that must often occur to us, namely, what will Great Britain be when our vast reservoir of material force, coal, is exhausted—a result which many members of the Iron and Steel Institute are doing their utmost to accelerate? The time must come when, in consequence of that exhaustion, Great Britain will cease to be a great manufacturing nation, unless some new source of force should be discovered, which there is not the least reason to anticipate. But, as I wrote many years ago, however mournful and unwelcome this proposition may be, we have the satisfaction of knowing that we are now laying the foundations of prosperous and mighty kingdoms in various parts of the world, which we hope will be the strongholds of virtue, of order, and of freedom. When our great manufactories shall have crumbled into ruins, and their sites have become green pastures or golden corn-fields, the old country may yet be precious in the eyes of her children. Every spot of her soil will be classic, and command reverential respect. There is no other land more worthy of everlasting remembrance, whether as to its heroes, its poets, its philosophers, its statesmen, or its philanthropists. The glory of Old England may, after all, not depart. On the sites of her soot-stained Birminghams and Manchesters, new and splendid cities may arise, where the merchant-princes of Anglo-Saxon descent, from the remotest regions of the globe, shall rejoice to dwell and end their days in peace."

After the address the President presented the Bessemer Medal to Mr. Lowthian Bell for delivery to Prof. Äkermann, after which the papers were read. The first paper read was that of Mr. Lowthian Bell, on "The Blast-Furnace Value of Coke, from which the Products of Distillation from the Coal used in its Manufacture have been collected." The experiments which formed the foundation of the paper were made upon the same coal coked in the beehive and Simon Carvé's oven, the total quantity of coke operated upon being 5605 tons; it was found that the beehive coke was about 10 per cent. more economical, although the other was 13·83 per cent. denser. In order to ascertain the cause of the inferiority, samples were finely ground and analysed. Similar samples were exposed for half an hour to the full heat—sufficient to soften porcelain—of a gas blast-furnace, access of air being excluded by placing the crucible containing the sample within a larger one and covering it with charcoal. From the loss of weight and the analysis of the original and residual coke, and from the previously-ascertained moisture, it was found that 5·23 per cent. of the Simon Carvé's coke was expelled by ignition, and 3·27 per cent. of the beehive. This accounts for an inferiority of 1·96 per cent. only out of about 10 per cent. It is, however, a well-known fact that certain forms of carbon are less easily burnt than others, and the author sought to account for the superiority of beehive coke in this manner, and found it to be due to the less solvent action of carbonic acid upon it.

At the Wednesday evening meeting Dr. H. C. Sorby, F.R.S., gave an account of his microscopical examination of the structure of iron and steel. His results were based upon the examination of flat surfaces, carefully ground and polished, as the study of fractured surfaces is unsatisfactory, not only on account of optical difficulties, but because a fracture shows the line of weakness between the crystals and not their internal structure. In some cases the surfaces were acted upon by very dilute nitric acid to develop the structure; in others it was found best to polish with dry rouge on parchment, and not to use acid. Thin glass covers were afterwards mounted over the surface with Canada balsam. The objects thus prepared were examined by means of two special kinds of surface illumination, viz. first the side parabolic reflector now common, but which the author believes was originally made for this purpose, which gives oblique light; and secondly, by means of a small silver reflector covering half the object-glass, which throws the light directly down on the object, from which it is reflected back through the other half of the lens. With oblique illumination a polished surface looks black, but, with direct, bright and metallic. A truly black substance looks black in both cases. A magnifying power of about sixty linear is most generally suitable, but the sections will bear a higher perfectly well. The lecturer exhibited photographs and drawings of the microscopic appearance of the surfaces, the peculiarities of which he described.

The following is a summary of some of the chief results:—Iron containing little or no carbon, and of uniform character, shows little, if any change, when acted upon by dilute acid, and no well-marked structure is developed. Hammered blooms show an intimate mixture of varying crystals of iron, with minute or larger portions of slag. In iron bars rolled *hot*, the slag is drawn out into long thin rods, which in some cases are so numerous as to form a very considerable portion of the whole bulk, whilst the iron shows no elongation of the ultimate crystals, the metal apparently recrystallising on cooling. When hammered *cold*, the crystals are compressed, broken up, and elongated in the line of the bar. Many specimens of malleable iron show clearly that two constituents are present, viz. iron, and a compound of iron and carbon, which has a pearly structure; one of these is like the main constituent of such bar iron as contains little or no carbon, having no trace of linear marking, after being acted upon by dilute acid, whereas the other constituent shows linear markings, varying in distance, but often about 1-20,000th of an inch apart, which, when the acid has acted to a proper extent, gives rise to all the splendid colours of mother-of-pearl, the tints being raised when the section is seen in water, and still more so when mounted in balsam. By oblique and direct illumination the colours are nearly complementary. Swedish iron partly converted into blister steel by cementation, shows a mixture of well-formed crystals of free iron and of the pearly compound in the centre; around this a ring of the pearly compound, with colours of great variety and beauty; whilst on the outside is a part in which occurs a network of veins of an extremely hard substance, giving an intensely brilliant reflection and no trace of colour, which seems to contain more carbon than the pearly constituent. The three constituents just described are totally distinct from one another. There is no more passage from one to the other than there is between the mica, felspar, and quartz of granite.

The varying character of ingots of soft and hard steel to a great extent depends on the varying proportion of the three principal constituents. Soft Bessemer steel is seen to be a mixture of free iron and the pearly compound. In medium steel this latter occurs almost alone, whereas in hard steel there is little, if any, free iron, but numerous thin plates of the very hard compound. Besides these three constituents in steel, the microscope gives evidence in cast-iron of the presence of graphite and silicon. The specimen of spiegeleisen studied, consisted mainly of the intensely hard compound, crystallised in large plates, the inter-spaces being filled up with a mixture of very much smaller crystals with a little of the pearly substance, so as to have a most beautiful and fine-grained structure. Taken, then, as a whole, the various kinds of iron and steel are seen to be varying mixtures of three or four out of six or seven substances having very different properties, viz. free iron, the pearly compound with carbon, the intensely hard compounds, probably with more carbon; the residual, probably variable, substance; graphite; possibly crystallised silicon; slag, including fused iron oxide.

On the second day the attention of the meeting was occupied with the subject of the coking of coal by different processes and the recovery of bye-products. Mr. Head's paper contained a description of a modified form of the Siemens old type gas-producer, in which the latter result is effected by dividing the gas-producer by means of a vertical wall into two compartments, one of which receives the hydrocarbons—the volatile constituents of the coal—and the other the carbonic oxide formed by the decomposition of its solid carbonaceous matter. Two other papers referred to results obtained in connection with the Simon-Carvé's coking process. Prof. Armstrong's note with reference to the methods proposed for coking coal and recovering volatile matter has much scientific interest, and we propose to refer to it shortly. The problem consists in as complete a recovery as possible of the matters latent in coal, in the most economical manner and advantageous forms, the treatment depending upon the class of coal acted upon. The author considers the compounds in coal to be mainly of two kinds—phenolic compounds, which are the primary source of the phenols (carbolic acid, &c.) contained in coal tar; and paraffinoid compounds, capable of yielding hydrocarbons such as are obtained on distilling shale; the high-temperature tars such as are obtained at gas-works, not being primary but secondary products of distillation, may be considered final products, the quality of which it will be impossible to improve, whereas the object should be to produce low-temperature tars, which by after-treatment might be made to produce a large proportion of benzene and other valuable products.

The author's idea of a theoretically perfect coking oven is one more or less like the present beehive, with the upper part extended. Heat should be *radiated* upon the surface of the charge of coal, which would soon become coked, thus forming a protecting layer, below which distillation would take place, the products of distillation being sucked away as rapidly as possible through the cool bottom of the oven. The products of combustion which penetrate below would carry no oxygen with them. On this account, and on account of the large volume of steam and other gases generated within the mass, and of the low temperature, the ammonia would probably almost entirely escape destruction. The gas would be of low illuminating quality, but would be available for carbonising, oil and ammonia being removed from it by efficient scrubbing. The author was of opinion that nothing was known practically of what happens when coal is distilled, and that the coking of coals and manufacture of gas were now only empirical operations, and could not be conducted scientifically, with our present imperfect knowledge, but that the interests involved were so great, the subject being one of national importance, that failure to initiate and execute the necessary systematic experiments without further loss of time would be inexcusable.

On the last day of the meeting Mr. Carnegie's paper on "Natural Gas Fuel and its Application to Manufacturing Purposes" was read. This fuel is found in the Pittsburg district, and one of the wells is estimated as yielding 30,000,000 cubic feet of gas in the twenty-four hours; the pressure of the gas as it issues from the mouth of the well is about 200 lbs. to the square inch, and even at the works, nine miles from the wells, it is 75 lbs. per square inch. Eleven lines of pipe convey the gas from the various wells to the manufacturing establishments in and around Pittsburg. The number of men whose labour will be dispensed with when gas is generally used is 5000. In the steel-rail mills, for instance, where before would have been seen thirty stokers, stripped to the waist, firing boilers which require a supply of about 400 tons of coal in twenty-four hours—ninety firemen in all being employed, each working eight hours—there would now be found one man walking around the boiler-house, simply watching the water-gauges, and not a particle of smoke is to be seen.

Dr. Hermann Wedding's paper on "The Properties of Malleable Iron deduced from its Microscopic Structure" draws attention to the value of microscopic analysis, as, though the chemical and physical properties of iron are closely connected, the one cannot be directly deduced from a knowledge of the other, nor do either of these aid in acquiring a knowledge of the mechanical properties. The pieces of iron to be tested are carefully polished, and then etched with very dilute nitric acid. After etching, the section is carefully heated, whereupon the portions attacked acquire varying tints, mostly golden-yellow, purple-red, violet, or dark blue. It is the difference of colour that is characteristic. As regards the formation of grains and fibres, the size of grain increases with slowness of cooling, and decreases with increase in the proportion of carbon up to 2 per cent. Each individual grain in malleable iron is ductile, the malleability of the entire piece depending on that of the separate grains, which are drawn out into fibres; the strength of fibrous iron depending on the fact that, like the individual hemp-fibres in a rope, the fibres lie with their ends in various sections. The microscope shows, further, that none of these wires or fibres is directly connected with its neighbours, either in a longitudinal or lateral direction. In fact each fibre may, by careful etching, be picked out like those of a muscle in the human body. The paper treats also of the constitution of individual iron crystals and of welding. The general result of the analysis shows that the strength of a finished piece of iron depends on the sectional area of the mass of iron it contains, the slag inclusions in weld-iron and blow-holes in ingot-iron being deducted.

It was announced that the autumn meeting of the Institute would be held at Glasgow.

SUNLIGHT AND THE EARTH'S ATMOSPHERE[1]

II.

We have been compared to creatures living at the bottom of the sea who frame their deceptive traditional notions of what the sun is like from the feeble changed rays which sift down to them. Though such creatures could not rise to the surface, they might swim up towards it, and if these rays grew hotter, brighter, and bluer as they ascended, it would be almost within the capacity of a fish's mind to guess that they are still brighter and bluer at the top.

Since we children of the earth, while dwelling on it, are always at the bottom of a sea, though of another sort, the most direct method of proof I spoke of, is merely to goup as far as we can and observe what happens, though as we are men, and not fishes, something more may fairly be expected of our intelligence than of theirs.

We will not only guess, but measure and reason, and in particular we will first, while still at the bottom of the mountain, draw the light and heat out into a spectrum, and analyse every part of it by some method that will enable us to explore the invisible as well as record the visible. Then we will ascend many miles into the air, meeting the rays on the way down, before the sifting process has done its whole work, and there analyse the light all over again, so as to be able to learn the different proportions in which the different rays have been absorbed, and, by studying the action on each separate ray, to prove the state of things which must have existed before this sifting—this selective absorption—began.

It may seem at first that we cannot ascend far enough to do much good, since the surface of our aërial ocean is hundreds of miles overhead; but we must remember that the air grows thinner as we ascend, the lower atmosphere being so much denser, that about one-half the whole substance or mass of it lies within the first four miles, which is a less height than the tops of some mountains. Every high mountain, however, will not do, for ours must not only be very high, but very steep, so that the station we choose at the bottom may be almost under the station we are afterwards to occupy at the top.

Besides we are not going to climb a lofty lonely summit like tourists to spend an hour, but to spend weeks; so that we must have fire and shelter, and above all we must have dry air to get clear skies. First I thought of the Peak of Teneriffe, but afterwards some point in the territories of the United States seemed preferable, particularly as the Government offered to give the Expedition, through the Signal Service, and under the direction of its head, General Hazen, material help in transportation and a military escort, if needed, any where in its own dominions. No summit in the eastern part of the United States rises much over 7000 feet, and though the great Rocky Mountains reach double this, their tops are the home of fog and mist, so that the desired conditions, if met at all, could only be found on the other side of the Continent in Southern California, where the summits of the Sierra Nevadas rise precipitously out of the dry air of the great wastes in lonely peaks, which look eastward down from a height of nearly 15,000 feet upon the desert lands.

This remote region was, at the time I speak of, almost unexplored, and its highest peak, Mount Whitney, had been but once or twice ascended, but was represented to be all we desired could we once climb it. As there was great doubt whether our apparatus, weighing several thousand pounds, could possibly be taken to the top, and we had to travel 3000 miles even to get where the chief difficulties would begin, and make a desert journey of 150 miles after leaving the cars, it may be asked why we committed ourselves to such an immense journey to face such unknown risks of failure. The answer must be that mountains of easy ascent and 15,000 feet high are not to be found at our doors, and that these risks were involved in the nature of our novel experiment, so that we started out from no love of mere adventure, but from necessity, much into the unknown. The liberality of a citizen of Pittsburgh, to whose encouragement the enterprise was due, had furnished the costly and delicate apparatus for the expedition, and that of the trans-continental railroads, enabled us to take this precious freight along in a private car, which carried a kitchen, a steward, a cook, and an ample larder besides.

In this we crossed the entire continent from ocean to ocean, stopped at San Francisco for the military escort, went 300 miles south so as to get below the mountains, and then turned eastward again on to the desert, with the Sierras to the north of us, after a journey which would have been unalloyed pleasure except for the anticipation of what was coming as soon as we left our car. I do not indeed know that one feels the triumphs of civilisation over the opposing forces of Nature anywhere more than by the sharp contrasts which the marvellous luxury of recent railroad accommodation gives to the life of the desert. When one is in the centre of one of the great barren regions of the globe, and, after looking out from the windows of the flying train on its scorched wastes for lonely leagues of habitless desolation, turns to his well-furnished dinner-table, and the fruit and ices of his desert, he need not envy the heroes of Oriental story who were carried across dreadful solitudes in a single night on the backs of flying genii. Ours brought us over 3000 miles to the Mojave desert. It was growing hotter and hotter when the train stopped in the midst of vast sandwastes a little after midnight. Roused from our sleep, we stepped on to the brown sand and saw our luxurious car roll away in the distance, experiencing a transition from the conditions of civilisation to those almost of barbarism, as sharp as could well be imagined. We

[1] Lecture delivered at the Royal Institution, April 17, 1885, by S. P. Langley. Communicated by the author. Continued from p. 20.

commenced our slow toil northward with a thermometer at 110° in the shade, if any shade there be in the shadeless desert, which seemed to be chiefly inhabited by rattlesnakes of an ashen gray colour, and a peculiarly venomous bite. There is no water save at the rarest intervals, and the soil at a distance seems as though strewed with sheets of salt, which aids the delusive show of the mirage. These are, in fact, the ancient beds of dried-up salt lakes or dead seas, some of them being below the level of the ocean; and such a one on our right, though only about twenty miles wide, has earned the name of "Death Valley," from the number of human beings who have perished in it. Formerly an emigrant train, when emigrants crossed the Continent in caravans, had passed through the great Arizona deserts in safety until after their half-year's journey, their eyes were gladdened by the snowy peaks of the Sierras looking delusively near. The goal of their long toil seemed before them; only this one more valley lay between, and into this they descended, thinking to cross it in a day—but they never crossed it. Afterwards the long line of wagons was found with the skeletons of the animals in the harness, and by them those of men, women, and little children dead of thirst, and some relics of the tragedy remained at the time of our journey. I cite this as an indirect evidence of the phenomenal dryness of the region—a dryness which, so far, served our object, which was, in part, to get rid as much as possible of that water-vapour which is so well known to be a powerful absorber of the solar heat.

Everything has an end, and so had that journey, which finally brought us to the goal of our long travel, at the foot of the highest peak of the Sierras, Mount Whitney, which rose above us in tremendous precipices, that looked hopelessly insurmountable and wonderfully near. The whole savage mountain region in its slow rises from the west, and its descent to the desert plains in the east, is more like the chain called the Apennines, in the moon, than anything I know on the earth. The summits are jagged peaks like Alpine "needles," looking in the thin air so delusively near, that, coming on such a scene unprepared, one would almost say they were large grey stones a few fields off, with an occasional little white patch on the top, that might be a handkerchief or a sheet of paper dropped there. But the telescope showed that the seeming stones were of the height of many Snowdons piled on one another, and the white patches occasional snow-fields, looking how invitingly cool, from the torrid heat of the desert, where we were encamped by a little rivulet that ran down from some unseen ice-lake in that upper air. Here we pitched our tents and fell to work (for you remember we must have two stations, a low and a high one, to compare the results), and here we laboured three weeks in almost intolerable heat, the instruments having to be constantly swept clear of the red desert dust which the hot wind brought. Close by these tents a thermometer covered by a single sheet of glass, and surrounded by wool, rose to 237° in the sun, and sometimes in the tent, which was darkened for the study of separate rays, the heat was absolutely beyond human endurance. Finally, our apparatus was taken apart and packed in small pieces on the backs of mules, who were to carry it by a ten days' journey through the mountains to the other side of the rocky wall which, though only ten or twelve miles distant, arose miles above our heads; and, leaving these mule trains to go with the escort by this longer route, I started with a guide by a nearer way to those white gleams in the upper skies, that had daily tantalised us below in the desert with suggestions of delicious, unattainable cold. That desert sun had tanned our faces to a leather-like brown, and the change to the cooler air as we ascended was at first delightful. At an altitude of 5000 feet we came to a wretched band of nearly naked savages, crouched around their camp-fire, and at 6000 found the first scattered trees; and here the feeble suggestion of a path stopped, and we descended a ravine to the bed of a mountain stream, up which we forced our way, cutting through the fallen trees with an axe, fighting for every foot of advance, and finally passing what seemed impassable. It was interesting to speculate as to the fate of our siderostat mirrors and other precious freight, now somewhere on a similar road, but quite useless. We were committed now, and had to make the best of it—and, besides, I had begun to have my attention directed to a more personal subject. This was, that the colder it grew the more the sun burnt the skin—quite literally burnt, I may say, so that by the end of the third day my face and hands, case-hardened, as I thought, in the desert, began to look as if they had been seared with red-hot irons, here in the cold where the thermometer had fallen to freezing at night; and still as we ascended the paradoxical effect increased: the colder it grew about us, the hotter the sun blazed above.

We have all heard probably of this curious effect of burning in the midst of cold, and some of us may have experienced it in the Alps, where it may be aided by reflection from the snow, which we did not have about us at any time except in scattered patches, but here by the end of the fourth day my face was scarcely recognisable, and it almost seemed as though sunbeams up here were different things, and contained something which the air filters out before they reach us in our customary abodes. Radiation here is increased by the absence of water vapour too, and on the whole this intimate personal experience fell in almost too well with our anticipations that the air is an even more elaborate trap to catch the sunbeams than had been surmised, and that this effect of selective absorption and radiation was intimately connected with that change of the primal energies and primal colour of the sun which we had climbed towards it to study.

On the fourth day, after break-neck ascents and descents, we finally ascended by a ravine, down which leaped a cataract, till, at nightfall, we reached our upper camp, which was pitched by a little lake, one of the sources of the water-fall, at a height of about 12,000 feet, but where we seemed in the bottom of a valley, nearly surrounded as we were by an amphitheatre of rocky walls which rose perpendicularly to the height of Gibraltar from the sea, and cut off all view of the desert below or even of the peak above us.

The air was wonderfully clear, so that the sun set in a yellow rather than an orange sky, which was reflected in the little ice-rimmed lakes and from occasional snow-fields on the distant waste of lonely mountain summits on the west.

The mule train sent off before by another route, had not arrived when we got to the mountain camp, and we realised that we were far from the appliances of civilisation by our inability to learn about our chief apparatus, for here, without post or telegraph, we were as completely cut off from all knowledge of what might be going on with it in the next mountain ravine as a ship at sea is of the fate of a vessel that sailed before from the same port. During the enforced idleness we ascended the peak nearly 3000 feet above us, with our lighter apparatus, leaving the question of the ultimate use of the heavy ones to be settled later. There seemed little prospect of carrying it up, as we climbed where the granite walls had been split by the earthquakes, letting a stream of great rocks, like a stone river, flow down through the interstices by which we ascended, and, in fact, the heavier apparatus was not carried above the mountain camp.

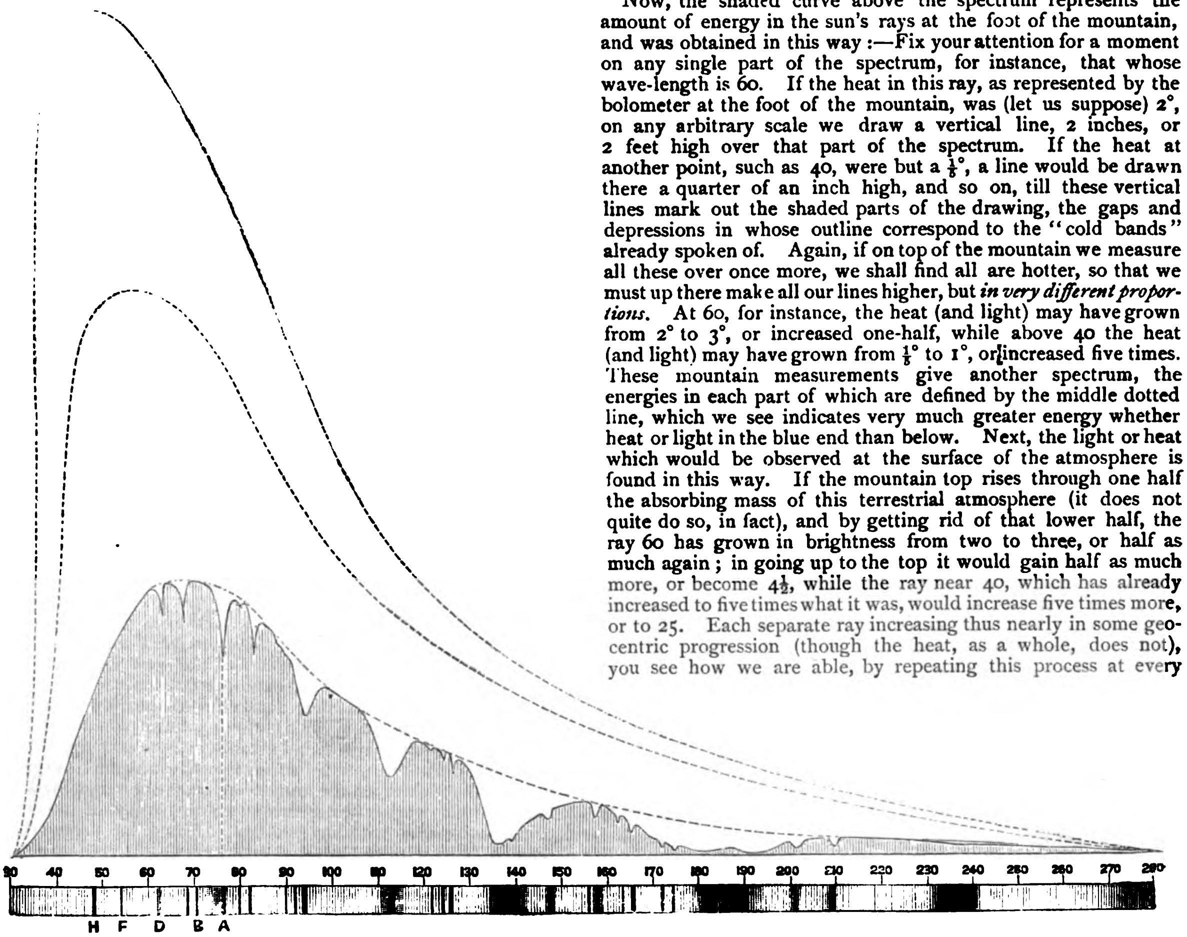
The view from the very summit was over numberless peaks on the west to an horizon fifty miles away, of unknown mountain-tops, for, with the exception of the vast ridge of Mount Tyndall, and one or two less conspicuous ones, these summits are not known to fame, and, wonderful as the view may be, all the charm of association with human interest which we find in the mountain landscape of older lands is here lacking.

It was impossible not to be impressed with the savage solitude of this desert of the upper air, and our remoteness from man and his works, but I turned to the study of the special things connected with my mission. Down far below the air seemed filled with reddish dust that looked like an ocean. This dust is really present everywhere (I have found it in the clear air of Etna), and though we do not realise its presence in looking up through it, to one who looks down on it, the dwellers on the earth seem indeed like creatures at the bottom of a troubled ocean. We had certainly risen towards the surface, for about us the air was of exquisite purity, and above us the sky was of such a deep violet blue, as I have never seen in Egypt or Sicily, and yet even this was not absolutely pure, for, separately invisible, the existence of fine particles could yet be inferred from their action on the light near the sun's edge, so that even here we had not got absolutely above that dust shell which seems to encircle our whole planet. But we certainly felt ourselves not only in an upper, but a different region. We were on the ridge of the continent, and the winds which tore by had little in common with the air below, and were bearing past us (according to the geologists) dust which had once formed part of the soil of China, and been carried across the Pacific Ocean; for here we were lifted into the great encircling currents of the globe, and, "near to the sun in lonely lands," were in the right conditions to study the differences between his rays at the surface and at the bottom of that turbid sea where we had left the rest of mankind. We descended the peak and hailed with joy the first arrival of our mule trains with the requisite apparatus at the mountain camp, and found that it had suffered less than might be expected, considering the pathless character of the wilderness. We went to work to build piers and mount telescopes and siderostats, in the scene shown by the next illustration on the screen, taken from a sketch of my own, where these rocks in the immediate foreground rise to thrice the height of St. Paul's. We suffered from cold (the ice forming 3 inches deep in the tents at night) and from mountain sickness, but we were too busy to pay much attention to bodily comfort, and worked with desperate energy to utilise the remaining autumn days, which were all too short.

Here, as below, the sunlight entered a darkened tent, and was spread into a spectrum, which was explored throughout by the bolometer, measuring, on the same separate rays which we had studied below in the desert, all of which were different up here, all having grown stronger, but in very different proportions. On the screen is the spectrum as seen in the desert, drawn on a conventional scale, neither prismatic nor normal, but such that the intensity of the energy shall be the same in each part, as it is represented here by these equal perpendiculars in every colour. Fix your attention on these three as types, and you will see better what we found on the mountain, and what we inferred as to the state of things still higher up, at the surface of the aëreal sea.

You will obtain, perhaps, a clearer idea, however, from the following statement, where I use, not the exact figures used in calculation, but round numbers, to illustrate the process employed. I may premise that the visible spectrum extends from H (in the extreme blue) to A (in the deepest red), or from near 40 (the ray of forty one hundredth thousandths of a millimetre in wave-length) to near 80. All below 80, to the right, is the invisible infra-red spectrum.

Now, the shaded curve above the spectrum represents the amount of energy in the sun's rays at the foot of the mountain, and was obtained in this way:—Fix your attention for a moment on any single part of the spectrum, for instance, that whose wave-length is 60. If the heat in this ray, as represented by the bolometer at the foot of the mountain, was (let us suppose) 2°, on any arbitrary scale we draw a vertical line, 2 inches, or 2 feet high over that part of the spectrum. If the heat at another point, such as 40, were but a $\frac{1}{5}$°, a line would be drawn there a quarter of an inch high, and so on, till these vertical lines mark out the shaded parts of the drawing, the gaps and depressions in whose outline correspond to the "cold bands" already spoken of. Again, if on top of the mountain we measure all these over once more, we shall find all are hotter, so that we must up there make all our lines higher, but *in very different proportions*. At 60, for instance, the heat (and light) may have grown from 2° to 3°, or increased one-half, while above 40 the heat (and light) may have grown from $\frac{1}{5}$° to 1°, or increased five times. These mountain measurements give another spectrum, the energies in each part of which are defined by the middle dotted line, which we see indicates very much greater energy whether heat or light in the blue end than below. Next, the light or heat which would be observed at the surface of the atmosphere is found in this way. If the mountain top rises through one half the absorbing mass of this terrestrial atmosphere (it does not quite do so, in fact), and by getting rid of that lower half, the ray 60 has grown in brightness from two to three, or half as much again; in going up to the top it would gain half as much more, or become $4\frac{1}{2}$, while the ray near 40, which has already increased to five times what it was, would increase five times more, or to 25. Each separate ray increasing thus nearly in some geocentric progression (though the heat, as a whole, does not), you see how we are able, by repeating this process at every point, to build up our outer or highest curve, which represents the light and heat at the surface of the atmosphere. These have grown out of all proportion at the blue end, as you see by the outer dotted curve, and now we have attained, by actual measurement, that evidence which we sought, and by thus reproducing the spectrum outside the atmosphere, and then recombining the colours by like methods to those you have seen on the screen, we finally get the true colour of the sun, which tends, broadly speaking, to blue.



Distribution of Solar Energy at Sea-level and at various Altitudes.

It is so seldom that the physical investigator meets any novel fact quite unawares, or finds anything except that in the field where he is seeking, that he must count it an unusual experience to come unexpectedly on even the smallest discovery. This experience I had on one of the last days of work on the spectrum on the mountain. I was engaged in exploring that great invisible heat region, still but so partially known, or, rather, I was mapping in that great "dark continent" of the spectrum, and by the aid of the exquisite sky and the new instrument (the bolometer) found I could carry the survey further than any had been before. I substituted the prism for the grating, and measured on in that unknown region till I had passed the Ultima Thule of previous travellers, and finally came to what seemed the very end of the invisible heat spectrum beyond what had previously been known. This was in itself a return for much trouble, and I was about rising from my task when it occurred to me to advance the bolometer still farther, and I shall not forget the surprise and emotion with which I found new and yet unrecognised regions below,—a new invisible spectrum beyond the farthest limits of the old one.

I will anticipate here by saying that after we got down to lower earth again the explorations and mapping of this new region was continued. The amount of solar energy included in this new extension of the invisible region is much less than that of the visible spectrum, while its length upon the wave-length scale is equal to all that previously known, visible and invisible, as you will see better by this view, saving the same thing on the normal as well as the prismatic scale. If it be asked which of these is correct, the answer is "both of them." Both rightly interpreted mean just the same thing, but in the lower one we can more conveniently compare the ground of the researches of others with these. These great gaps I was at first in doubt about, but more recent researches at Alleghany make it probable that they are caused by absorption in our own atmosphere, and not in that of the sun.

We would gladly have stayed longer, in spite of physical discomfort, but the formidable descent and the ensuing desert journey were before us, and certainly the reign of perpetual winter around us grew as hard to bear as the heats of the desert summer had been. On September 10 we sent our instruments and the escort back by the former route, and, ourselves unencumbered, started on the adventurous descent of the eastern precipices by a downward climb, which, if successful, would carry us to the plains in a single day. I at least shall never forget that day, nor the scenery of more than Alpine grandeur which we passed in our descent, after first climbing by frozen lakes in the northern shadow of the great peak, till we crossed the eastern ridges, through a door so narrow that only one could pass it at a time, by clinging with hands and feet as he swung round the shoulder of the rocks—to find that he had passed in a single minute from the view of winter to summer, the prospect of the snowy peaks behind shut out, and instantly exchanged for that below of the glowing valley and the little oasis where the tents of the lower camp were still pitched, the tents themselves invisible, but the oasis looking like a green scarf dropped on the broad floor of the desert. We climbed still downward by scenery unique in my recollection. This view of the ravine on the screen is little more than a memorandum made by one of the party in a few minutes' halt part-way down, as we followed the ice-stream between the tremendous walls of the defile which rose 2000 feet, and between which we still descended, till, toward night, the ice-brook had grown into a mountain torrent, and, looking up the long vista of our day's descent, we saw it terminated by the Peak of Whitney, once more lonely in the fading light of the upper sky.

This site, in some respects unequalled for a physical observatory, is likely, I am glad to say, to be utilised, the President of the United States having, on the proper representation of its value to science, ordered the reservation for such purposes of an area of 100 square miles about and inclusive of Mount Whitney.

There is little more to add about the journey back to civilisation, where we began to gather the results of our observation, and to reduce them—to smelt, so to speak, the metal from the ore we had brought home—a slow but necessary process, which has occupied a large part of two years.

The results stated in the broadest way mean that the sun is blue—but mean a great deal more than that; this blueness in itself being perhaps a curious fact only, but in what it implies, of practical moment.

We deduce in connection with it a new value of the solar heat, so far altering the old estimates that we now find it capable of melting a shell of ice sixty yards thick annually over the whole earth, or, what may seem more intelligible on its practical bearings, of exerting over one-horse power for each square yard of the normally exposed surface. We have studied the distribution of this heat in a spectrum whose limits on the normal scale our explorations have carried to an extent of rather more than twice what was previously known, and we have found that the total loss by absorption from atmosphere is nearly double what has been heretofore supposed.

We have found it probable that the human race owes its existence and preservation even more to the heatstoring action of the atmosphere than has been believed.

The direct determination of the effect of water-vapour in this did not come within our scope; but that the importance of the blanketing action of our atmospheric constituents has been in no way overstated, may be inferred when I add that we have found by our experiments that if the planet were allowed to radiate freely into space without any protecting veil, its sunlit surface would probably fall, even in the tropics, below the temperature of freezing mercury.

I will not go on enumerating the results of these investigations, but they all flow from the fact, which they in turn confirm, that this apparently limpid sea above our heads, and about us, is carrying on a wonderfully intricate work on the sunbeam, and on the heat returned from the soil, picking out selected parts in hundreds of places, sorting out incessantly at a task which would keep the sorting demons of Maxwell busy, and as one result, changing the sunbeam on its way down to us in the way we have seen.

I have alluded to the practical utilities of these researches, but practical or not, I hope we may feel that such facts as we have been considering about sunlight and the earth's atmosphere may be stones useful in the future edifice of science, and that if not in our own hands then in those of others, when our day is over, they may find the best justification for the trouble of their search, in the fact that they prove of some use to man.

May I add an expression of my personal gratification in the opportunity with which you have honoured me of bringing these researches before the Royal Institution, and of my thanks for the kindness with which you have associated yourselves for an hour, in retrospect at least, with that climb toward the stars which we have made together, to find, from light in its fullness, what unsuspected agencies are at work to produce for us the light of common day.

ZOOLOGICAL RESEARCH[1]

THE *Vettor Pisani* is soon expected in our port, on her return from a long voyage of no little scientific importance. We think we cannot better hail her arrival than by publishing that portion of Prof. Dohrn's report in which he speaks of the scientific mission fulfilled by this vessel—a mission which, besides meeting with a success far surpassing the highest expectations, has redounded not a little to the benefit of our "Stazione Zoologica."

The time has now arrived, writes the illustrious Professor, for me to speak of an event which took place towards the end of 1881, and which has since borne no inconsiderable fruit. And this, in its turn, takes me back to a conversation which I had in 1878 with the Italian Minister of Marine. I had already proposed that, instead of sending out a young naturalist on board the frigates which sail around the world, a young naval officer should be sent to the "Stazione Zoologica," where, in about four months, he might pick up so much knowledge as would enable him to collect and preserve specimens of marine animals. Owing to a change in the Ministry, my proposition, though accepted in the main, was forgotten; and I only succeeded in getting it put into execution in 1881.

On December 27, 1881, a young naval lieutenant, Signor Gaetano Chierchia, a Neapolitan by birth, introduced himself to me with these words: "I have been sent by the Ministry to learn under your direction at the 'Stazione Zoologica' how to collect and preserve specimens of marine animals. I present myself accordingly, and beg to be allowed to begin work at once." These few words, modest, yet full of energy, made a deep impression on me; for they not only marked the beginning of a new epoch in the active life of the Zoological Station, but also promised a more intimate connection between it and the officers of the Italian navy—an intimacy to which I had looked forward from the very day in which I conceived the idea of the future floating Zoological Station.

With the same modest energy which characterised his first interview with me, Signor Chierchia continued for four months his studies under the special direction of the Curator, Salvatore Lobianco; and all the employes and naturalists of the Zoological Station were astounded at the rapid progress he made in a field so entirely new to him. And when the moment came for establishing my laboratory on board the corvette *Vettor Pisani* (which came most appositely to Naples), and there had been put on board all the fishing apparatus, chemical reagents, alcohol, glass vessels, &c., we accompanied him as a dear friend, and looked forward to results which should mark a distinct advance in the culture of our science. And our expectations, far from being disappointed, were widely surpassed. After only five months there arrived the first consignment—the product of deep-sea work, of dredging and coast-fishery along the shores of Gibraltar, Brazil, and Montevideo. The whole collection was in excellent preservation, carefully labelled and packed, and accompanied by a minute report as to the place and circumstances of each find. And I do not for a moment hesitate to affirm that never has so important a collection of oceanic

[1] From the *Pungolo*, April 23, 1885. Naples, Italy.

animals before reached Europe. Scarce four months had elapsed when there arrived a second consignment, still more extensive than the first, and the result of collections made during a voyage from Montevideo to Cape Horn, around the islands of the Patagonian archipelago (a course which the obliging commander of the corvette, Capt. Palumbo, had followed at my especial desire).

This collection, too, contained most interesting specimens, among which are especially worthy of mention a vast number of tubes filled with the produce of deep-sea fishing (pelagic products). In the same way there have come to hand two other consignments from the Peruvian coast, from the Galapagos Isles, from the coast of Panama; and also some most interesting animals found in small pools and rivers in Peru. Among these, of special importance are two complete series of embryonic forms—first, of a Peruvian ray, and secondly of a toad, which Lieut. Chierchia, at my desire, and to aid my studies in the history of the origin of vertebrate animals, reared with great care, and kept in an excellent state of preservation. In this he was assisted by Dionigi Franzese, who had been trained in the Zoological Station, and had embarked as a sailor on board the *Vettor Pisani*. The *Vettor Pisani* continued its course from Peru across the ocean towards the Philippine Islands and China, and we may look for a new shipment of specimens. In this we have a striking confirmation of my opinion that zoology might receive material aid in its work from naval officers trained for the purpose, rather than from the employment of young naturalists. The example thus presented has been followed by other individuals, and already three more naval officers, Lieuts. Cercone, Orsini, and Colombo, have been trained in the same way at the Zoological Station. It is a matter for regret that the first-mentioned has made but one voyage, a short one towards the West Indies, in which violent gales were encountered. The result of his researches may be seen at the "Station." Lieut. Orsini is in the colony of Assab, at the mouth of the Red Sea, and has despatched thence a valuable and well-preserved collection. Lieut. Colombo is the only one of the three whose studies have been of a more extensive and continuous nature, and for them opportunitp has on several occasions been given him by the Minister of Marine. On board the vessel attached to the Hydrographical Survey, commanded by Capt. Magnaghi (equally well known as a man of science and an officer), he has made excellent collections in the Mediterranean itself, and has now returned once more to the "Stazione" to further prosecute his studies there.

From the very first it has been my intention to invite the naval services of other nations to join us in this line of research, and accordingly, in the autumn of 1882, I proposed to the German Minister of Marine that he should send a naval officer or surgeon to Naples to receive a training such as I have indicated. The head of the Admiralty then, Herr Von Stosch, accepted my proposal, and sent a naval surgeon, Dr. Sander, for four months to Naples. In the autumn of the following year Dr. Sander embarked on board the frigate *Prinz Adalbert* for Eastern Asia. We still await its arrival, and hope for valuable results from the expedition.

A preliminary conversation which I had last summer at St. Petersburg with the head of the staff of the Russian Marine Admiral Tchichatchoff, leaves room for hope that Russia too will consent to join us in the matter, and that so in the course of a few years we may look for a still further and wider development of this connection between the "Stazione Zoologica" and the various marine war services of the world. From such a connection great advantages would accrue, not only to science in general, but also to the naturalists of those several countries, which in their turn would be the richer for the collections made by their respective navies.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—There will be an examination in certain branches of natural science for minor scholarships at Downing College, on Tuesday, June 2 next, and following days. Persons who have not entered at any college in the University are eligible to the minor scholarships, which will be of the value of from 40*l.* to 70*l.* per annum, and tenable until their holders are of standing to compete for a Foundation Scholarship. Further information will be given by Dr. Perkins or the Rev. J. C. Saunders, tutors of the College.

SCIENTIFIC SERIALS

Annalen der Physik und Chimie, No. 3, March, 1885.—Prof. R. W. Bunsen, on capillary absorption of gas. Shows a direct dependence between the capillary pressures and the volumes of gas absorbed. This discovery, doubtless, has important relations in physiological processes. Prof. G. Quincke, electric researches (No. 10), on the measurement of magnetic forces by hydrostatic pressure. The author adopts the formula

$$p = \mathfrak{K}_1 H_1^2/8\pi,$$

where H_1 is the intensity of the magnetic field, and $\mathfrak{K}_1$ a "dimagnetisation constant" analogous to the dielectric constant in the analogous formula for the pressure in the electric field. Observations have been made on many magnetic liquids to ascertain the numerical values of this constant.—O. Lummer, on the theory and form of some newly-observed interference curves. These relate to certain phenomena of thick plates.—C. Christiansen, researches on the optical properties of finely-divided bodies. —W. Möller, on Wild's photometer.—E. and L. Natanson, on the dissociation of the vapour of hyponitrous acid.—M. Thiesen, researches on the equation of state; a discussion of the laws of gaseous pressure.—Prof. L. Pfaundler, on the action of strongly-compressed carbonic acid on glass under the influence of light. W. Voigt, reply to Prof. Wüllner's remarks respecting Jamin's observations on metallic reflection.

Journal of the Russian Chemical and Physical Society, vol. xvi. fasc. 9.—On the oxidation of acetones (second memoir), by G. Wagner. The behaviour of ketones to chromic acid mixture are described, and the general laws of their oxidation are deduced. —On the action of the iodides of allyl and zinc on epichloridrine, by M. Lopatkin. —On isopropyl allyl dimethyl carbinol, by M. Kononovitch.—On the relation between diamagnetism and the temperature of fusion of bodies, by P. Bachmetieff. The absolute heat of fusion being represented by the equation $W = (t + 273) cs + bs$, where c is the specific heat, b the latent heat of fusion, and s the specific weight of the body; then, the series $(t + 273) s$ being taken according to the figures of Regnault and M. Carnelley—it appears to be in reverse order to Faraday's diamagnetic series, the bodies appearing in the following series which culminates with Bi and Sb:—K, Na, P, Br, S, Mg, Ca, I, Al, In, Sn, Bi, Sb, Zn, Cd, Pb, Ag, Cu, Pd, An, Ur, W, Pt, Ir, Os.—On the atmospheres of planets, the temperature of the sun in cosmic space, and the earth's atmosphere, by E. Rogovsky.—On some new demonstrations of the conditions for a minimum of deviation of a prism, by N. Poltschikoff.—A note in answer to M. Stankevitch, by the same. —Studies in cosmical physics: III. the heating of meteorites when falling on to the earth, by Th. Schwedoff.—Answering to an objection made at the British Association of 1882 by Sir William Thomson to his cosmic theory of hail, the author discusses the heat which a meteoric stone may receive when piercing our atmosphere. He shows by several examples, by our experience of meteorites, and by M. Daubrée's testimony, that they never have been brought to fusion. The meteorite must be compared to a fire syringe (*Briquet pneumatique*), which condensates the air and raises its temperature, remaining nearly cold itself when its conducting power is feeble. The *vis viva* of the meteorite is spent in piercing the layers of air—that is, in bringing them into motion (like a bullet which would spend its force in piercing 1000 sheets of paper before reaching the target), and to admit that its *vis viva* be transformed into heat, would be to forget the force spent in piercing the air.—Index to the sixteenth volume.

Bulletin de la Société des Naturalistes de Moscou, 1884, No. 2. —Materials for the flora of Central Asia, by Prof. N. Sorokine. After having twice visited several parts of Russian Turkistan and the delta of the Amu-daria, M. Sorokine returned with a rich collection of phenogams, which proved this part of the Central Asian flora to be very rich, original, and interesting. The department of Gasteromycetes alone offered the greatest interest, on account of its containing forms peculiar to Algeria, Egypt, Cuba, and so on. There are even several indices which would seem to indicate that the Aral-Caspian region has been a centre of dispersion of several forms, whose sporæ were transported by winds across the Red Sea to Africa, and thence to Spain and France. The whole work of the author could not be published at once, on account of its numerous plates. The description of the Chytridiaceæ has appeared in the *Archives botaniques du Nord de la France*, the remainder will appear in the Moscow *Bulletin*, which contains now the descriptions, with five plates, of the Hypodermei and the Gasteromycetes.—Plantæ Raddeanæ Monopetalæ, by Ferd. von Herder (continued).—Solution of a problem of the theory of comets, by N. Joukovski (Russian). The geocentric position of a particle of the tail which has left the nucleus since a given time under the action of a given repulsive force, to determine the displacement of the particle for a given change in the repulsive force—such is the problem treated. —Analyses of salt and mud from a volcano of Trans-Caucasia. —An essay on the solution of the geodetical problem, by Th. Sloudsky (in French). The already-known formulæ already give the possibility of embodying all anomalies less than 30" in latitude and less than 15 oscillations of the pendulum in twenty-fours against the calculated ones. The author tries, however, to give a more theoretical formula, which might at the same time embody larger anomalies.—List of the herbaria of the Moscow University and of the Society of Naturalists, by J. Goroshankin.—Studies on the averages of the relative moistness, by Dr. K. Weihrauch (continued; in German).—Necrology and Annual Report.

Rendiconti del R. Istituto Lombardo, March 26.—History of the first century (1783–1883) of the Reale Istituto, by G. B. Venturi.—On the persistence of the thymus gland in children and adults, by Prof. Giovanni Zoja.—Account of a successful operation performed on a young girl for the purpose of closing an open sore on the left cheek produced by a severe attack of typhoid fever.—Further notes on conformable representations in higher mathematical analysis, by Prof. Giulio Ascoli.—Meteorological observations made at the Royal Observatory of Brera, Milan, during the month of March.

Rivista Scientifico-Industriale, March 31.—A new explanation of the red crepuscular lights that have been attributed to the Krakatoa eruption, by Prof. Carlo Marangoni.—Variations in the electric resistance of solid and pure metallic wires according to the temperature (continued), by Prof. Angelo Emo.—A visitation of caterpillars (*Lithosia caniola*, Hl.) in Florence during the present season, by P. Bargagli.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, April 23.—"On the Changes produced by Magnetisation in the Length of Rods of Iron, Steel, and Nickel." By Shelford Bidwell, M.A., LL.B.

The earliest systematic experiments on the effects produced by magnetisation upon the length of iron and steel bars are those of Joule, an account of which is published in the *Phil. Mag.* of 1847. Joule's experiments have many times been repeated, and his general results confirmed. In particular, Prof. A. M. Mayer carried out a series of very careful observations with apparatus of elaborate construction and great delicacy. The conclusions at which he arrived were in accord with those of Joule, so far as regards iron; in the case of steel there was some apparent discrepancy, which, however, might to a great extent be accounted for by differences in the quality of the metal used and in the manner of conducting the experiments. In 1882 Prof. Barrett published in NATURE an account of some experiments which he had made, not only on iron but also on bars of nickel and cobalt, with the view of ascertaining the effect of magnetisation upon their length.

The knowledge on the subject up to the present time may be summarised as follows:—

(1) Magnetisation causes in iron bars an elongation, the amount of which varies up to a certain point as the square of the magnetising force. When the saturation-point is approached the elongation is less than this law would require. The effect is greater in proportion to the softness of the metal.

(2) When a rod or wire of iron is stretched by a weight, the elongating effect of magnetisation is diminished; and if the ratio of the weight to the section of the wire exceeds a certain limit, magnetisation causes retraction instead of elongation.

(3) Soft steel behaves like iron, but the elongation for a given magnetising force is smaller (Joule). Hard steel is slightly elongated, both when the magnetising current is made and when it is interrupted, provided that the strength of the successive currents is gradually increased (Joule). The first application of the magnetising force causes elongation of a steel bar if it is tempered blue, and retraction if it is tempered yellow: subsequent applications of the *same* external magnetising force cause temporary retraction, whether the temper of the steel is blue or yellow (Mayer).

(4) The lengh of a nickel bar is diminished by magnetisation, the maximum retraction being twice as great as the maximum elongation of iron (Barrett).

In order that the results of Joule and Mayer might be comparable with those obtained by the author, he made an attempt to estimate the magnetising forces with which they worked. From data contained in their paper, it was calculated that the strongest magnetising force used by Joule was about 126 units, while the strongest used by Mayer did not on the highest probable estimate exceed 118 units. In the author's experiments the magnetising force was carried up to about 312 units. The metal rods, too, were much smaller than any which had been before used for the purpose, ranging in diameter from 1·40 to 6·25 mm. Their length was in every case 100 mm., and the apparatus was capable of measuring with tolerable certainty an elongation or retraction equal to a ten-millionth part of this length.

By using thinner iron rods and greater magnetising forces than those previously employed, the following curious and interesting fact was established. If the magnetisation be carried beyond a certain critical point, the consequent elongation, instead of remaining stationary at a maximum, becomes diminished, the diminution increasing with the magnetising force. If the force is sufficiently increased, a point is arrived at where the original length of the rod is totally unaffected by magnetisation; and if the magnetisation be carried still further, the original length of the rod will be reduced. It also appeared that the position of the critical point in steel depended in a very remarkable manner upon the hardness or temper of the metal; considerable light is thus thrown on the apparently anomalous results obtained by Joule and by Mayer. Further experiments disclosed strong reason for believing that the value of the critical magnetising force in a thin iron rod was greatly reduced by stretching; this would explain the fact that Joule obtained opposite effects with stretched and unstretched wires.

By ascertaining the relative values of the temporary moments induced by gradually increasing external magnetising forces, an attempt was made to connect the point of maximum elongation with a definite phase of the magnetisation of the several rods in which the elongation had been observed.

Though more experiments must be made before it is possible to generalise from them with perfect safety, the results so far obtained by the author indicate the laws given below. The elongations and magnetisations referred to are temporary only; before the beginning of an experiment the rod was permanently magnetised by passing through the magnetising coil a current equal to the strongest subsequently used. In iron the greatest elongation due to permanent magnetisation was generally found to be about one-third of the total elongation, while in nickel the permanent retraction amounted only to about one-twenty-fifth part of the whole.

I. IRON

(1) The length of an iron rod is increased by magnetisation up to a certain critical value of the magnetising force, when a maximum elongation is reached.

(2) If the critical value of the magnetising force is exceeded, the elongation is diminished until with a sufficiently powerful magnetising force the original length of the rod is unaffected, and, if the force is still further increased, the rod undergoes retraction. Shortly after the critical point is passed, the elongation diminishes in proportion as the magnetising force increases. The greatest actual retraction hitherto observed was equal to about half the maximum elongation, but there was no indication of a limit, and a stronger magnetising force would have produced further retraction.

(3) The value of the external magnetising force corresponding to maximum elongation is for a given rod approximately equal to twice its value at the "turning point."

Definition.—The turning point in the magnetisation of an iron bar is reached when the temporary moment begins to increase less rapidly than the external magnetising force.

(4) The external force corresponding to the point of maximum elongation increases (when the quality of the iron is the same) with the diameter of the rod. So also does its value at the turning point.

(5) The amount of the maximum elongation appears to vary inversely as the square root of the diameter of the rod, when the quality of the iron is the same.

(6) The turning point, and therefore presumably the point of maximum elongation, occurs with a smaller magnetising force when the rod is stretched than when it is unstretched.

II. Steel

(7) In soft steel magnetisation produces elongation, which, as in the case of iron, increases up to a certain value of the magnetising force, and afterwards diminishes. The maximum elongation is less than in iron, and the rate of diminution after the maximum is passed is also less.

(8) The critical value of the magnetising force for a steel rod diminishes with increasing hardness up to a certain point, corresponding to a yellow temper; after which it increases, and with very hard steel becomes very high. There is therefore a critical degree of hardness for which the critical magnetising force is a minimum; in steel of a yellow temper the value of the critical magnetising force is lower than in steel which is either softer or harder.

(9) In soft steel a strong magnetising force subsequently diminished may cause a greater temporary elongation than the diminished force is capable of producing if applied in the first place.

(10) A temporary elongation when once produced in soft steel may be maintained by a magnetising force which is itself too small to originate any perceptible elongation.

III. Nickel

(11) Nickel continues to retract with magnetising forces far exceeding those which produce the maximum elongation of iron. The greatest observed retraction of nickel is more than three times the maximum observed elongation of iron, and the limit has not yet been reached.

(12) A nickel wire stretched by a weight undergoes retraction when magnetised.

Anthropological Institute, April 28.—Francis Galton, F.R.S., President, in the chair.—Mr. A. L. Lewis read a paper on the past and present condition of certain rude stone monuments in Westmoreland. The highest point of the railway between Lancaster and Carlisle is a little to the south of the village and station of Shap, in Westmoreland, where there were formerly some very extensive rude stone monuments, now unfortunately almost entirely destroyed. Allusion is made to them by Camden and Dr. Stukeley, and a circle is said to have been destroyed when the railway was made; some remains of this circle may be seen from the train, but only a few stones are left on the spot. The most interesting monument now remaining in the vicinity of Shap is situated at a place called Gunnerskeld, two or three miles to the north, and consists of two irregular, concentric, slightly oval rings, about 50 and 100 feet in diameter respectively, the longest diameters being from north to south.—A paper by Admiral F. S. Tremlett on quadrilateral constructions near Carnac was read. These inclosures were explored by the late Mr. James Miln; in each case the boundary walls are formed of coarse, undressed stones, put together without any kind of cement, and having built up in them a series of small menhirs; they also contained beehive structures for cremation, reddened and become friable from the effects of great heat. It would appear that the cremation had been perfect, as not a particle of calcined bone was found in either of the inclosures.—A paper by M. Jean L'Heureux on the Kekip-Sesoators, or ancient sacrificial stone of the North-West Territory of Canada, was read. Elevated two hundred feet above the level of the surrounding plain, Kekip-Sesoators, the Hill of the Blood Sacrifice, stands like a huge pyramidal mound commanding an extensive view of both Red Deer and Bow River Valleys. A natural platform of about one hundred feet crowns its summit; at the north end of the platform, resting upon the soil, is the Sesoators, a rough boulder of fine-grained quartzose, fifteen inches high and about fourteen in diameter; upon its surface are sculptured half an inch deep the crescent figure of the moon with a shining star over it. Two small concave basins about two inches in diameter are hollowed into the stone, one in the centre of the star, the other about seven inches from it in a straight line; around them are traced various hieroglyphic signs, and all over the surface are numerous small circlets, which remind one of the sacrificial stone of Mexico. Here at a time of private or public necessity, when extraordinary blessings are sought, comes a solitary warrior, himself the priest and the victim; from the time of sunset he sits in solemn vigil gazing in the far east for the coming of the star-god of his ancestors; and when the first ray of the morning star lights the distant horizon, he lays a finger of his left hand on the top of the stone and cuts it off, leaving the blood to flow into the basin. He then presents the bleeding finger to the morning star, and, leaving it in the basin of the star-like figure, retraces his steps towards the lake at the foot of the hill, where he dresses his wound, and at sunrise enters his own village, where he is received with triumphant honours. Amongst the Blackfeet these self-inflicted wounds ranked equal to those received in battle, and are always mentioned first in the public recital of the warrior's great deeds in the national feast of Ocan.

Geologists' Association, May 1.—William Topley, F.G.S., President, in the chair.—A paper was read on wingless birds—recent and fossil—and on birds as a class, by Dr. Henry Woodward, F.R.S. The author prefaced his remarks on wingless birds by giving first a brief account of the characters of birds as a class. He described the peculiarities of the skull and the fore- and hind-limb, the cervical, thoracic, sacral, and caudal vertebræ, with the shoulder-girdle and pelvis. He compared the highly-specialised fore-limbs in existing birds with that of *Archæopteryx*, the former, with three rudimentary digits, having the metacarpal bones anchylosed together; the latter, with three free digits in each manus, armed with claws. He compared the bones of the hind-limb of an adult *Iguanodon* with those of a young *Dinornis*, and showed how closely the characters observable in the former are repeated in the latter. Many interesting analogies were also pointed out in the form of the ilium, ischium, and pubis in *Struthio* and Iguanodon. The *Archæopteryx*, although possessing so many points of divergence from the Avian type, was shown to be the earliest known ancestor of the great division of *Carinatæ* (birds with a keel to the sternum) to which nearly all modern (flying) birds belong. For the *Ratitæ* (or boat-breasted birds), to which division the Ostrich, Rhea, Emu, Cassowary, Apteryx, Dinornis, Æpyornis, &c., belong, an earlier ancestor must be sought. The author contended that, on the evidence before us we have a right to claim a higher antiquity for the *Ratitæ* than for the *Carinatæ*, not only from the present wide distribution of this division of the class, but also from the fossil evidence which embraces for the Struthious order even a still larger geographical area than that shown from existing species. And if we are at liberty to add to this the evidence of the footprints of bipedal animals in the Trias (which agree with the tracks of birds in the number of digits in the foot), then these footprints may be taken as further evidence of their priority in geological time. For the primitive forms of this class we must evidently look to the palæozoic rocks.

Zoological Society, May 5.—Prof. Alfred Newton, F.R.S., Vice-President, in the chair.—A communication was read from Mr. Jean Stolzmann, containing observations on the theory of sexual dimorphism.—Mr. J. Bland Sutton, F.Z.S., read a paper on hypertrophy and its value in evolution, in which he attempted to show that material changes in structure might be the result of what was originally a pathological condition.—Mr. E. T. Newton, F.Z.S., read a paper on the remains of a gigantic species of bird (*Gastornis klasseni*), which had been obtained by Mr. H. M. Klaassen from the "Woolwich and Reading Beds" of the lower Eocene series. The author observed that these fossils proved that in early Eocene times England was inhabited by a race of birds which equalled in their proportions some of the more massive forms of the New Zealand moas.—A communication was read from Mr. R. B. Sharpe, F.Z.S., containing the description of a new species of Hornbill from the Island of Palawan, which he proposed to name *Anthracoceros lemprieri*.—Prof. E. Ray Lankester, F.R.S., read some notes on the right cardiac valve of the specimens of *Apteryx* dissected by Sir Richard Owen in 1841.—A communication was read from Lieut.-Col. C. Swinhoe, F.Z.S., being the third of his series of papers on the Lepidoptera of Bombay and the Deccan. The present paper treated of the second portion of the Heterocera.—A communication was read from Dr. St. George Mivart, F.R.S., containing a correction of a statement concerning the structure of *Viverricula*, contained in a former paper.

Manchester

Literary and Philosophical Society, Feb. 16.—Thomas Alcock, M.D., in the chair.—A proposed revision of the species and varieties of the sub-genus Cylinder (Montfort) of Conus (L.), by Mr. J. Cosmo Melvill, M.A., F.L.S.

March 10.—Prof. W. C. Williamson, LL.D., F.R.S., President, in the chair.—On making sea-water potable, by Thomas Kay, President of the Stockport Natural History Society. Communicated by F. J. Faraday, F.L.S.

March 16.—Thomas Alcock, M.D., in the chair.—On the breeding of the Reed Warbler (*Acrocephalus arundinaceus*) in

Cheshire, by Francis Nicholson, F.Z.S.—On *Lagena crenata*, by Dr. Alcock.—The Post-Glacial Shell-beds at Uddevalla, Sweden, by Mark Stirrup, F.G.S.

PARIS

Academy of Sciences, May 4.—M. Bouley, President, in the chair.—Summary of the meteorological observations made during the year at four stations on the Upper Rhine and in the Vosges district (Schlucht, Munster, Colmar, and Thann), by M. G. A. Hirn. Tables are given of the actinometric observations, of the prevailing winds with their mean and greatest velocities, of the mean and extreme temperature, of the atmospheric pressure and rainfall for each month of the year at all these stations. During the period in question the most salient phenomena were the severe frosts of the month of April, which proved very destructive, especially to the vines, and the sudden and violent hurricane of July 16, which swept with tremendous rapidity over the Vosges, almost unaccompanied by rain, and with very little thunder.—Remarks on the influence exercised by seismatic disturbances on Phylloxera, by M. S. Villalongue. The case is mentioned of a vineyard near Malaga affected by this parasite and supposed to have been destroyed, which nevertheless broke into leaf with fresh vigour after the earthquakes which recently devastated the southern provinces of Spain.—Application of the general laws of the theory of the partition of numbers to numerical functions, by M. N. Bougaieff.—On an easy method of controlling the velocity of electric motor currents (one illustration), by M. Marcel Deprez.—Note on the suppression of the nitrous vapours of the Bunsen pile, and on a new pile which becomes depolarised in the atmosphere, by M. A. d'Arsonval.—On a new variety in the anomalous group of Cyclocephalians, by M. A. Lavocat. This variety, for which the term "ophthalmocephalous" is proposed, is illustrated by the recent case of a still-born lamb, in which nose and eyes were entirely absent, and, in place of the orbits, showing in the median plane a cavity formed by the union of the two temporal fosses. At the same time the tongue, the ears, and all the parts corresponding with these organs were in the normal state.—On the system of canalisation present in the cellules of plants, and on the continuity of the protoplasm in vegetation, by M. L. Olivier. In opposition to the generally accepted views, the author infers from his microscopic studies that in the thickness of the membranous walls of plants there is a highly developed network of canals, by means of which the continuity of the protoplasm is effected throughout the cellular system.—An attempt to determine the relative age of the Grand'-Combe Carboniferous deposits by means of their fossil vegetation, by M. R. Zeiller.

ROME

Reale Accademia dei Lincei, January 4.—On pleasurable and periodic respiration. Prof. Mosso communicated an abstract of a memoir in which he expounds various observations made by him on respiration. By means of tracings taken from a man in a state of complete rest, he has recognised that in the respiratory movements periods of greater or less depth in breathing alternate with one another, and that such periods are observable in all animals, especially during sleep. The author has likewise ascertained that man breathes a greater quantity of air than is necessary, and it is that respiration that he calls pleasurable (*respirazione di lusso*). It is in consequence of this excess in the ordinary breathing that a man does not increase the extent of his respiratory movements in ascending a mountain or in undergoing a change of atmospheric pressure. Prof. Mosso has determined the limit of this pleasurable respiration which is manifested in sleep when no cause would render it necessary. According to the pauses which the periodic respiration undergoes, the author divides it into *remittent* (*remittente*) and *intermittent* (*intermittente*). These pauses do not depend on the movements of the blood-vessels nor on psychical factors. It is a recognised fact that respiration has not a single centre, but that various muscles subserve this function independently of each other. Prof. Mosso concludes that not only is periodic respiration a normal physiological phenomenon, but that it is nothing else than the respiration of Cheyne and Stokes, which has hitherto been looked upon as a morbid condition. The author closes his own paper with a critical review of the theories of the nature of the movements of respiration.—Other communications:—Dr. Piccini described the analyses and the methods of preparation of certain fluor salts of titanium, corresponding to the sesquioxide, which had been obtained by him.—Drs. Ciamician and Silber described the results of the action of nitric acid on pyril-methyl-ketone.—Drs. Ciamician and Magnagui communicated a first note on the action of carbonyl chloride on the potassic compound of pyrrol.—The sanction of the Academy was likewise given to the printing, in the *Atti Academici*, of a memoir by Prof. Belloni, in which the author describes the olfactory and olfactory-auditory apparatus of the teleosteans (the *nuclei rotundi* of Fritsch).—The Secretary, Signor Blaserna, read a communication by Signor Laure, in which the author insists on the necessity of paying great attention to the barometric variations in cases of earthquakes and volcanic eruptions.

January 18.—Articles belonging to the Stone Age discovered in the commune of Breonio Veronese. Prof. Pigorini observed that of all the localities containing remains of the Stone Age Breonio Veronese is the most interesting and the richest, on account of its numerous caves in which primitive man has left his traces. The numerous flint implements found in that locality were attributed by ancient writers to the Cimbri. Some of these have common forms, but others are of very singular shape, and the use of the latter cannot be determined. The importance of such articles, which are found also in the sepulchres of the Stone Age near the caves, but which are there reproduced almost in miniature, consists in the fact that articles of the same form are found among the remains belonging to the prehistoric American stations, which leads us to surmise the existence of a bond of connection in the earliest times between the inhabitants of the Old World and the New. Prof. Pigorini, while dwelling on the great value of the collection of such curiously-shaped articles made by Signor S. de Stefani, and described by him before the Congress at Venice, was glad to be able to announce to the Academy that the collection had been acquired by Prof. Landberg, whose attachment to Italy and whose philanthropic character were well known, and that it was his generous intention to present the collection to the Prehistoric and Ethnographical Museum at Rome. This valuable scientific material is thus to remain in Italy.—On the observations on the solar maculæ and faculæ made in the Observatory of the Collegio Romano in 1884. From the observations made, Signor Tacchini believed that he could conclude that the solar activity was diminishing and that it would very soon reach its minimum. Comparing the observations of 1883 with those of 1884, he found that in 1884 chromospherical phenomena attained a considerable development. Signor Tacchini, although he has not yet completed his labours in reducing the observations, i sof opinion that 1884 will have to be remembered as a year of maximum frequency of hydrogenic perturbations, but he intends to return to the question when he has completed the calculations relating to it.—On an ancient vase representing Sappho.—Signor Comparetti read some preliminary notes regarding an ancient vase belonging to the collection of the Archæological Society of Athens. On this vase, the drawing on which is rather rude, Sappho is represented in the midst of her disciples, she herself being in the act of reading some epic lines written on a roll held in her hand. This vase belongs to the fourth century B.C., and hence to the period in which Sappho was most popular in the refined and gallant society of Athens. According to Prof. Comparetti, the two disciples who are listening to Sappho, must, judging from their names which are written on the vase, be two Athenian hetæræ.—Discovery of an ancient encyclopædia, and the plagiarism practised on it. Signor Narducci announced that he had discovered in the Biblioteca Angelica, at Rome, a parchment MS. belonging to the end of the thirteenth century, containing in its first 129 pages an encyclopædia, hitherto unknown, compiled by Egidio Colonna, of Rome. After giving an account of the contents of this work, Signor Narducci drew attention to the shameless manner in which the encyclopædia of Colonna had been plagiarised by the Englishman Bartholomew Glanville, commonly called *Bartholomeus Anglicus*, who flourished about 1630. This writer acquired the greatest reputation by a book of his called "Liber de proprietatibus rerum," which is in great part copied word for word from the encyclopædia of Colonna.—Other communications: Signor Fiorelli gave an account of the excavations of antiquities made during the month of December.—Dr. Nasini made a communication regarding some researches he had made on the atomic refraction of sulphur, and on the higher value of that refraction.—Dr. Piccini read a note containing some general considerations on peroxides of the type of peroxide of hydrogen, and made a communication as to the continuation of his researches on a new series of titanium compounds.

February 1.—On the hydrogenic protuberances of the sun, observed at the Royal Observatory of the College of Rome in 1884.—Prof. Tacchini, in continuation of his previous note to the effect that 1884 must be considered as a year in which the phenomena of the chromosphere had attained their maximum development, presented the results of observations made by him on 242 days. From these it appeared that the number of the protuberances increased from March to October. In order to get rid of the anomalies which are met with in various observations, and to obtain a curve representing the course of the phenomena in the quinquennial period 1880 to 1884, Prof. Tacchini has taken as monthly means the means of three months, considering each month along with the month before and after it. The curve so constructed shows three culminating points or periods of maximum activity, these corresponding to July, 1880, September to October, 1881, and March, 1884, which last is the highest in the whole series. The maximum of the protuberances follows that of the sunspots, and recent observations make it probable that 1885 will be a year of greater activity in the chromosphere and solar atmosphere.—On the degree of precision in the determination of the density of gases. Dr. Agamennone stated that the first to experiment with a certain amount of success on the density of gases were the physicists Dumas and Boussingault, and that Regnault had introduced the most important improvements in the methods of working adopted by them. He observed, however, that even these improved methods of Regnault were not exempt from certain errors, the nature of which the author pointed out and described, indicating the precautions that had to be used in the various operations of weighing, in order to avoid some of these errors by taking advantage of the accurate instruments which we possess at the present day. The author insisted specially on the constant source of error proceeding from the property which glass has of condensing gases on its surface, and on the exactness of measurement required in determining the pressure at which the gas to be weighed is contained in the vessel in which the weighing is effected. Dr. Agamennone has repeated in the Royal Physical Institute of Rome all the experiments of Regnault, and, correcting an error found in one of the experiments of that physicist, he finds that for the value of the weight of a litre of air, which, according to the corrections made by Kohlrausch and Lasch, would be 1·292756 grammes, there ought to be substituted 1·292767 grammes—a determination which, according to Dr. Agamennone, is subject to a maximum uncertainty of about $\pm$ 0·0005 gramme, and to a mean uncertainty of $\pm$ 0·000067 gramme.—Determination of the density of the air. Dr. Agamennone having in his previous paper shown how in the determination of the density of gases the errors affecting the final result proceed from the measurements of weight and pressure, announced that he had executed two series of experiments for the determination of the density of the air, making use of weights and pressures separated from one another by pretty wide limits. The pressures employed in the two series of experiments were: (1) that of the atmosphere; and (2) one of two atmospheres. The author, after describing his methods of procedure and the precautions taken by him, communicated his results, which showed a great difference between the mean values of his two series, and that because the air under pressure departs from Mariotte's law. Dr. Agamennone concludes that when the density of a gas is to be determined, the gas being weighed in a compressed state, it is necessary above all to know by direct experiments the variations in volume of the gas operated on, and to know what amount of condensation there is on the walls of the vessel in which the gas is compressed. For the determination of the deviation of a gas from Mariotte's law, which is a matter of so much importance in researches of this kind, the gas might be weighed at different pressures in a resisting vessel with a sufficiently delicate balance. Some experiments of Regnault have shown this method to be sufficiently satisfactory.—Consequences of a new hypothesis of Kohlrausch on thermo-electric phenomena. Dr. Battelli, after giving a *résumé* of the theoretical explanations offered by Thomson and Tait to account for the results obtained experimentally in thermo-electric phenomena, stated also the hypothesis of Kohlrausch on the electrical transport of heat, and showed how, from the conclusions of Kohlrausch, all the formulæ confirmed by experiment might be deduced.—Other communications:—Drs. Ciamician and Silber have continued their studies on the compounds of pyrrol, and explained minutely the method by which they had succeeded in converting pyrrol into pyridin.—Prof. Cassani communicated a paper on the angles of linear spaces.—Dr. Tonelli presented a note on the analytical representation of certain singular functions.—An abstract was communicated of a memoir by Messrs. Vanecek, entitled "Sur la Génération des Surfaces et des Courbes gauches par les Faisceaux de Surfaces."

February 15.—On the worship of stone weapons in the Neolithic age. Signor Pigorini exhibited a singular flint implement which had been found in one of the caves in the commune of Breonio Veronese, referred to the Neolithic age. It has the triangular form of a lance- or arrow-head, but is of rather large dimensions. It weighs, in fact, 1·710 kilo., and one of the equal sides of the triangle is more than 21 cm. in length. It cannot be supposed that this colossal spear-head could have been used as a weapon, chiefly because its dimensions would have required a shaft of quite unmanageable size, but also because the cavity at its base would have rendered the shafting extremely fragile. Signor Pigorini called to mind how, even at the present day, the common people attributed a celestial origin to the weapons of stone—a superstition which also existed among the ancients; but there are proofs that at the very time when these weapons were made they were held as emblems of divinity. There was, in fact, in the Neolithic age, a worship of the axe, since specimens of that weapon are found, of dimensions so small or so large, like that of Breonio Veronese, that they cannot be regarded as anything else than votive offerings.—Concerning a fragment of a manuscript of Cicero belonging to the ninth century. Signor Narducci found, in the Vatican Library, a valuable manuscript containing numerous Ciceronian fragments collected by a certain Hadvardo. Signor Narducci transcribed the manuscript page by page, in the hope that, by collating it with the works of Cicero, now known, he might find some fragments of lost books of the great orator. After identifying each of the fragments, he found that the compiler had not had at his disposal any of the works of Cicero known in the Middle Ages, but not at the present day. Signor Narducci gave a short specimen of the manuscript, with the various readings found at the present day in the most esteemed versions of the various works of Cicero, and he announced that Prof. Schwenke is preparing a critical study of the manuscript in question.

THE BRITISH MUSEUM CATALOGUE OF LIZARDS

Catalogue of the Lizards in the British Museum (*Natural History*). By George Albert Boulenger. Vol. I. *Geckonidæ*, *Eublepharidæ*, *Uroplatidæ*, *Pygopodidæ*, *Agamidæ*. Second Edition. (1885.)

IT would be difficult to name any order of vertebrates more urgently in need of cataloguing than the lizards. The last general work on the group published in any country was Dr. J. E. Gray's Catalogue, which appeared forty years ago, only six years after the completion of the volumes devoted to lizards in Dumeril and Bibron's great work on Reptiles. The additions made in Dr. Gray's Catalogue were considerable, but many of them were of doubtful value. Thus of fourteen new genera therein added by him to the family of Geckoes alone, but three survive in the present edition, the remainder swell the synonymy.

Mr. Boulenger's Catalogue is a boon to herpetologists and to biologists generally, not only because it places within their reach in a few handy volumes descriptions that have hitherto been widely scattered, but also because the classification proposed, whether it be generally accepted or not, is a distinct advance upon the artificial system hitherto in vogue. It is to be hoped that lizards so closely resembling each other as do, for instance, *Gongylus*, *Ablepharus*, and *Euprepes*, will no longer be classed in three distinct families solely because of trivial differences in the form of the nasal shield and in the development of the lower eyelid. At the same time, as naturalists have but rarely access to a collection of lacertilian skeletons, it is to be regretted that a few diagrams have not been added to the present catalogue, to show the cranial characters and the forms of the vertebræ, clavicles, &c., upon which Mr. Boulenger's families are founded.

A considerable change in some well-known reptilian genera is proposed in the present work, and it is probable that the union, for instance, of *Stellio* and *Trapelus* with *Agama* and of *Brônchocela* with *Calotes* will not be universally acceptable. But no change appears to have been proposed without valid reasons, and the tendency to excessive multiplication of genera on insufficient grounds has become so serious a nuisance in zoology that a diminution in the number is welcome. It is satisfactory to find, on comparison with the catalogue of 1845, that whilst the species attributed to the *Geckonidæ* have increased from 97 to 270, the genera have only augmented in number from 40 (or if *Eublepharis* and *Uroplates*, now placed in other families, be excluded, 38) to 49, whilst the *Agamidæ* which, in the earlier list, comprised 79 species, distributed amongst no less than 34 genera (35, including *Hatteria*) now contain 202 species, but only 30 genera. But six new generic names are proposed by Mr. Boulenger in the present work, and only three of these are used for generic groups not previously recognised, the others being intended to replace terms that are inadmissible.

It is almost impossible to form an adequate opinion of the descriptions and synopses in a catalogue of this kind without testing them extensively, and the only thorough test is to try, by means of them, to identify unknown forms without having a series of specimens of allied species at hand. Most museum publications are deficient in this respect, because the writers do not make sufficient allowance for the difficulties under which those who have occasion to identify animals find themselves. An example or two may be taken from the present work. In the synopsis (p. 114) of *Hemidactylus*, one of the largest and most difficult genera of Geckoes, two groups of species are distinguished, the one by having the "free distal joints of all the digits remarkably short," the other by having them long. In a museum, with other species for comparison, this is a good distinction, but away from any specimens except the one that he is endeavouring to identify it is difficult for a naturalist to tell whether the joints of the lizard he is examining are remarkably short compared with those of other forms. Again, in *Draco* (p. 254) several species are distinguished by having the snout longer or shorter than the diameter of the orbit, but it is not stated how the snout is measured. It is but right to say that such instances appear exceptional in the present catalogue, and that it is very rare to find a work in zoology from which similar examples might not be taken.

One of the chief desiderata in books like the present is accuracy as to localities. The museum catalogues of a past age left much to be desired in this respect, and their shortcomings have had a pernicious influence on the progress of a study of wide biological and geological interest, that of the geographical distribution of animals. It will probably be a long time before all the erroneous localities are weeded out, but it is satisfactory to note the great improvement that has taken place in British Museum catalogues of late years. Where so much care has been expended on the subject as is shown in the present work, it appears almost ungracious to point to such trifling shortcomings as appear, though a few mistakes have naturally crept in. Thus the locality for *Acanthosaura* (*Oriocalotes*) *Kakhienensis* is not in the Khasia hills as stated at p. 305, but Ponsee, in the Kakhyen hills, on the borders of Yunan. Again, considering the extensive collections that have been made of late years throughout Bengal, it is very extraordinary, if *Hoplodactylus duvancelii* and *Gonyocephalus bellii* really occur in the province that neither of them has been rediscovered, and the locality should not be recorded without doubt.

Altogether the present volume quite maintains the level that the best recent museum catalogues have led naturalists to expect. Why it should be called a "second edition" is not clear. A comparison of the two editions resembles an antiquarian research. It is necessary to recall a state of zoological knowledge as extinct as the dodo before the conditions under which the so-called first edition was produced can be understood. When the head of the zoological department in the British Museum could propose to divide reptiles into two sections, one called *Squamata*, comprising the orders of lizards and snakes, and the other, called *Cataphracta*, consisting of tortoises, crocodiles, and amphisbænians, on the ground that the former were clad with scales and the latter with plates, the knowledge of the animals classified was evidently in a rudimentary stage. As if the classification thus proposed was not sufficiently startling, it was gravely suggested (p. 2) that the five orders of reptiles were "analogous" to similar subdivisions in birds and mammals; the lizards as "climbers" representing the *Insessores* in the former and the *Primates* in the latter, serpents being "carnivorous" corresponding to *Accipitres* and *Feræ*, Emydosaurians (crocodiles) because they are "aquatic" to *Anseres* and *Cete*, tortoises in virtue of being "large-footed" to *Gallinæ* and *Ungulata*, and *Amphisbænians* for no particular reason to *Grallæ* and *Glires*. It is doubtful whether the authorities of the British Museum would not have done wisely by leaving this farrago of nonsense, one of the last echoes evoked by the once popular quinquennial system of Vigors and Swainson, in well-merited oblivion, and in not calling attention to it by suggesting a comparison between the work by Dr. Gray and that by Mr. Boulenger. However great may be the changes in zoological classification during the next forty years, the difference between the views now held and those that may prevail in the future will scarcely be so revolutionary as that which exists between the first and the second edition of the British Museum Catalogue of Reptiles.

THE SILVER-LEAD DEPOSITS OF NEVADA

The Silver-Lead Deposits of Eureka, Nevada. By J. S. Curtis. 4to. 200 pp. (Washington, D.C., Government Printing Office, 1884.)

THE remarkable mineral district which is dealt with in this memoir is situated in the eastern part of the State of Nevada, about the centre of the dreary region known as the Great Basin, between the Great Salt Lake of Utah and the Sierra Nevada range of California. The business centre of the town, or "mining camp," of Eureka is about 90 miles south of the Palisades Station, on the Central Pacific Railway, with which it is united by a narrow-gauge branch railway. The principal mines situated about Ruby Hill, about 1½ miles west of the town, extend for about a mile along the contact of a limestone, supposed to be of Cambrian age, with an underlying quartzite. The quartzite forms the axis of a steep anticlinal arch, which has been modified on one side by a great fracture known as the Ruby Hill fault, and between this and some secondary fractures, an enormous mass of crushed limestone is included, containing the mineral deposits, or ore bodies proper, which are essentially cave deposits, the hollows between the limestone fragments, which are of all sorts of shapes and sizes, being filled with products of the oxidation of galena, pyrites and mispickel, such as sulphate, carbonate, and arsenate of lead, and brown iron ore, in addition to the unaltered minerals in smaller quantities. The chief mineralogical find of these mines has, however, been of Wulfenite or molybdate of lead, which has been produced in considerable quantity, both in detached crystals of great beauty and interspersed through the mass of the other minerals. As a whole, the ores contain about 33 per cent. of lead, 30 ozs. of silver, and about 1⅝ ozs. of gold per ton. These ore bodies are of every possible form and size, from small strings up to masses measuring upwards of 100 feet in all directions; but in spite of this great irregularity of form, they are generally connected with systems of fissures or channels, and it is by following these fissures that most of the great discoveries have been made.

Although mines extend for nearly a mile along the hill, the most valuable portions of the deposit are included within a length of about 500 yards at the north-western end belonging to the Eureka and Richmond Mining Companies; and, as the largest development of ore has been on or near the boundary dividing the two properties, disputes as to the ownership of different masses have been followed by litigation culminating in a law-suit which in some way recalls the famous Torbane Hill case of the Scotch courts; the principal mining and geological experts of the United States, when called in as witnesses, being about equally divided in opinion as to whether the zone of limestone containing the ore was a lode or not. In the first judgment the affirmative view prevailed, and was maintained on appeal, although the case appears to have been ultimately decided upon considerations of previous agreements as to boundary lines between the two companies rather than on technical definitions. The absurdity of attempting to apply precise definitions to such essentially irregular objects as mineral deposits has never been so well demonstrated as in this famous case.

As regards the origin of the ores, the author considers them to have been deposited by hot springs constituting the final episode of a period of volcanic activity, evidence of which is found in the neighbourhood, though not in the immediate vicinity of the mines. A large number of assays of the limestone and quartzite rocks enclosing the deposits have been made, proving them to contain silver of the value of from fourpence to twenty-two pence per ton, which, however, in the author's opinion shows conclusively that the materials for the ore could not have been derived from any of the sedimentary formations.

The systematic assaying of the rock has been attempted to be utilised as a method of discovering ore bodies, as have also experiments upon variations in electrical activity, but as yet without practical results, although a curious coincidence has been observed in the indications given by the two methods.

The yield of precious metals of the Ruby Hill mines between 1869 and the date of the author's report, 1883, has been about 15,000,000*l.*, the value in the proportion of about one-third of gold to two-thirds of silver, in addition to about 225,000 tons of lead. Both the smelting and desilverising of the ore are done on the spot, the latter being effected by the inverse Pattinson process of Luce and Rozan, in which the lead is crystallised by injecting steam, and the liquid lead is run off from the impoverished crystals. This is perhaps the largest application that this process has yet received.

The lower workings of the mines, although they have been extended to a depth of 1200 feet, have not as yet led to any discoveries comparable with those made between 300 and 700 feet below the surface. The author, however, considers the chances of finding ore in depth to be favourable.

Taken as a whole the volume is a very interesting one, and is well illustrated, although for practical purposes the scale of the plans and sections is rather small, and the description of the underground workings is scarcely sufficient to enable the reader to appreciate exactly the value of the author's theoretical conclusions.

H. B.

OUR BOOK SHELF

Den Norske Nordhavs-Expedition, 1876 to 1878. XIII. Spongiadae. Ved G. Armauer Hansen. 25 pp., 7 plates, 1 map. (Christiania, 1885.)

THE thirteenth report on the zoological collections of the Norwegian North Sea Expedition treats of the sponges, and is by one who, though well known as a student of other branches of zoology, has not, we fancy, been hitherto known as a spongologist. We do not know whether we may not associate with this fact the somewhat alarming percentage of new species which he describes; of the forty-five enumerated, thirty, or two-thirds of the whole, are new; many of the species, among which it is interesting to note there is a new Hyalonema, *H. arcticum*, are very briefly described; on the other hand, the figures, as in other parts of this report, are well executed, and will be of considerable assistance in the detection of the species by other workers. The author was, unfortunately, unable to obtain any preparations in which he could trace out the canal system, or the structure of the soft parts, and he has, therefore, confined himself to an account of the spicules. With regard to these he has, we are glad to note, made use of the stenographic system which was invented by Dr. Vosmaer; any and every proposition for abbreviating the descriptions of species ought to be tested, for the abundance of "literature" is a very threatening danger to science. It is not likely that all the methods that have been from time to time suggested will be found to be useful; no one, for example, has followed the two methods proposed by the late Prof. Garrod, or that adopted by Prof. Jeffrey Bell in the description of species of starfishes; on the other hand, Dr. Herbert Carpenter has taken up and improved the method suggested by Prof. Bell for the species of Comatulids, and will, we understand, adopt it in his forthcoming *Challenger* Report. The chief objections to formulæ as applied either to species, or spicules, or other organs, are, of course, that a particular method has to be learned, and that, if it is too brief, it tells us too little. The latter, for example, is true of the Owenian method of formulating the dental characters of Mammalia; it tells us that, while *Gymnura* has eight premolars above and below, *Erinaceus* has six above and four below, but it does not tell us which are missing in the latter. If we desire to register our knowledge on this point, we must make use of the more elaborate system devised by Prof. Flower and Dr. Dobson. As to the former objection, we must bear in mind that some spicules have had such names as floricomo-hexradiate, or patento-ternate, applied to them, and we can well imagine that a formula may well be accepted as a not unpleasant alternative.

The Hunterian Oration. Delivered at the Royal College of Surgeons, by John Marshall, F.R.S., &c. (London: Smith, Elder, and Co., 1885.)

NOT only the wide range and perennial importance of the work of John Hunter—the surgeon and anatomist whom the clear judgment of Buckle places second only to Aristotle among inquirers into organic nature—but also the fertility of human ingenuity, is shown by the fact that, for nearly a century, every year has seen some eminent surgeon discourse with more or less variety and freshness upon the life and achievements of this graet man.

The novelties of Mr. Marshall's treatment of the well-worn theme are, first, recounting the life of his hero backwards in successive decennia from his grave to his cradle; and, secondly, bringing Hunter into the modern world of science, and imagining the way in which he would be affected by modern methods and modern results. No doubt he would be delighted to see the splendid collection which has grown out of his "Hunterian Museum," but whether he would be more pleased or puzzled by the technics of histology and the elaborate machines of a physiological laboratory may perhaps be doubted.

An orator must be an eulogist, and in this case there is ample room for praise; but it would be a valuable contribution to criticism if Mr. Marshall, or some equally qualified man, would discuss Hunter's achievements as an anatomist, compared with Meckel and Cuvier; as a surgeon, with his contemporary Pott, and his successors Astley Cooper and Brodie; as a physiologist with Haller and Bichat; and as a naturalist—on the broad ground which includes human and "comparative" anatomy, normal and morbid structure, "the physiology of disease" (to use Hunter's own phrase), as well as that of health—with the only successor he has had, or, we may predict, ever will have, the illustrious Johannes Müller.

To such a critic might be suggested as shades in the intellectual portrait, Hunter's neglect of the aid of magnifying glasses such as were used to good effect before him by Leewenhoeck and Grew; his want of learning and cultivation, with a certain consequent narrowness of mind; and such occasional obscurity of language as may not unfairly be taken to imply some obscurity of thought. "Definitions," he says, "of all things on the face of the earth are the most cursed." But may not the use of terms without definition sometimes excuse a choleric word?

After the most exacting criticism, there is no question that Hunter's name would remain one of the glories of this country—to be mentioned next to those of Harvey, Newton, and Darwin. It is therefore most fitting that his fame should be kept green by the annual piety of successive orators, and of these Mr. Marshall is a worthy compeer.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

Notes on the Action of the Wimshurst Induction Machine

AN interesting notice on the different influence-machines now in use occurs in NATURE, vol. xxviii. p. 12. Of these ingenious instruments, that lately devised by Mr. Wimshurst is likely to recommend itself beyond others, on account of the ease with which it may be excited, even in a damp atmosphere, and the high tension of the electricity discharged from its accumulators.

The following remarks lay no claim to originality, but they may nevertheless afford some interest to those who would witness its effects at a small pecuniary outlay; indeed its construction is well within the powers of the amateur mechanic.

Makers advertise sparks of fabulous length from comparatively small machines, but dense discharges of $4\frac{1}{2}$ inches may be obtained under favourable circumstances from disks of 15 inches diameter, if care be taken adequately to insulate the collecting apparatus. It is obvious that an *unassisted* spark of 9 inches cannot be produced from plates whose minimum air-spaces of insulation do not exceed $3\frac{1}{2}$ inches. The weakest part of insulation in these machines is usnally between the metal inductors and the attachments of the driving-gear and spindle. In the dark, beautiful brushes of light flash across these spaces, and thus they point where the electricity leaks away from the accumulators. The tendency to form these brushes may be much diminished by cementing a small disk of sheet caoutchouc over the inner ends of each metal-inducing strap.

The machine in full work presents several points of interest, the explanation of which, perhaps, is not very obvious. The first I would notice is, that although 15-inch plates will scarcely give an *unassisted* spark of more than 1¼ inches in length, the interposition of a trifling condenser, showing only a coated surface of 6 square inches, will entirely change the character of this spark, the almost continuous stream of short sparks giving place to fewer, zigzag, snapping, 4-inch discharges, of much increased density and brilliance. The attachment of a condensing tube, constructed as follows, will be found a valuable addition to such machines as collect separately the positive and negative electricities.

About 18 inches of thin glass combustion-tubing of ¾-inch diameter is taken. Within, and at 4 inches distance from each end, a space of 2 inches is coated with tinfoil, leaving a space of 5 inches or so of clear glass between them. Two similar pieces of foil are fixed by a thin coat of gold-size on the exterior of this tube. They superpose the inner pieces of foil, and act as the outer coats of two small Leyden jars united as it were in one. These outer coatings are connected by a strip of tinfoil. The inner coats are placed in contact respectively with the plus and minus collectors of the machine, by means of thick brass wires thrust through caoutchouc plugs. The wires are so bent that their ends may drop into suitable holes, from which they may be at any time detached.

A thin coat of spirit lac-varnish spread within and without much favours the insulation of the tube.

Thus arranged, bright angular sparks of 4 or more inches in length will pass between the knobs of the discharger at *every three-quarter turns* of the handle.

Another point of interest offers itself when the knobs of the discharger are placed beyond their usual striking distance. In such a case the spark very frequently passes within the tube from coating to coating, quite silently, and with an optical illusion of comparative slowness of transit. When first I noticed these bright flashes of light, they suggested the form of an undulating fire-ball, and this brought to my remembrance the often-described but obscure phenomenon of "ball-lightning." I could not, however, detect any real retardation of the discharge by a somewhat rough experiment with the ordinary spark-wheel.

When two large jars are connected with the machine the disruptive discharge of 4 inches is accompanied by a sharp report, like that of a small pistol. I was not prepared for the fact that such a noisy discharge made to pass through the condensing-tube is quite silent, just as if it flashed through a partial vacuum. It may also be noted that the spark through the tube may be made much to exceed the length of the discharge in the ordinary way.

The last point I now mention, and concerning which I should value the remarks of Mr. Wimshurst, or any other competent electrician, is the increasing intensity of charge taken up by the metal inducers, or sectors, as they pass each other between the point of their contact with the earth through the metallic brush and the next following comb-collector. In the electrophorus such a contact is required once between the delivery of each spark; whereas in the machine here used, having perhaps twenty-eight sectors, a contact is given only once in seven inductive processes.

It will be found that well-varnished jars, without the usual wooden tops, are much the most efficient. Nevertheless, even these sometimes become so highly charged, that the electricity will force itself over their edges, doubling back, as it were, over a distance of 5 inches.

A pretty, but somewhat trifling experiment may be made by attaching two jars of unequal capacities to the collectors. Thus a jar of half a pint capacity placed on one side may be flanked by a quart jar on the other. Here the small jar, if the coatings be not too distant from the lip, will discharge itself three different times, whilst the large jar is getting sufficient tension to strike, say, at 3½ inches. Both jars will then discharge together across the upper knobs. It may thus be shown that four half-pints of electricity make one quart of the same, as in liquid measure.

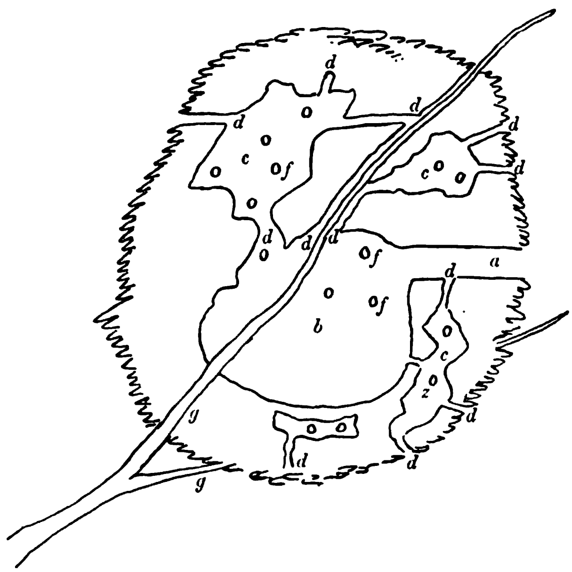
G. B. BUCKTON

Nesting of Micropternus Phæoceps

IN continuation of the communication from my friend, Mr. Wm. Davison, regarding the nesting of woodpeckers in ants' nests, published in NATURE (vol. xxxi. p. 438), perhaps the following note may be of interest:—

Camp Meplay, Thoung-yeen Valley, Tenasserim, April 20, 1882

This morning, in going from my camp to the Meplay Forest Reserve, I had to pass through several densely overgrown phonzohs.[1] While making my way along with some difficulty, I startled a brown woodpecker (*Micropternus phæoceps*) from a small pyingado tree (*Xylia dolabriformis*). Looking up into the branches I saw a large ants' nest, in the centre of which appeared a circular hole so exactly like the borings made by woodpeckers ordinarily in the trunks of trees, that I sent up a Karen boy who was with me to ascertain whether it was possible the Micropternus had been boring into the ants' nest, as, I had heard was the bird's curious habit. The ants' nest was only about ten feet above the ground, placed in a fork of the pyingado, two small branches of which passed clean through it. Climbing up, putting in his fingers and then a twig, my Karen follower announced that there were two eggs. Leaving the nest alone for the time being, in the evening I returned by the same route, and was able not only to cut off and carry into camp the whole nest as it was; but I managed to secure also the hen bird as she flew from the eggs. Arrived in camp, I got the two eggs out, and then very carefully made a cross-section through the



a, entrance tunnel made by woodpecker; *b*, retort-shaped nesting-chamber of woodpecker; *c*, excavations made by the ants; *ddd* ...... *d*, entrances to them; *fff* ...... *f*, tunnels made by the ants; *gg*, fork of pyingado branch—one twig passing through the egg-chamber excavated by the woodpecker.

ants' nest so as to divide the boring made by the woodpecker longitudinally.

The accompanying is a rough diagrammatic sketch of the appearance of the cross-section of the nest as hollowed out by the woodpeckers. The ants' nest was a large, spherical, solid mass of leaves and clay, the leaves outside being arranged one over the other something like the tiles on the roof of a house, but riddled in many places with the entrance tunnels made by the ants—a small black and red species of *Myrmica*, the trivial or specific name of which I do not know. It is probably closely allied to the *Myrmica* mentioned by Sir J. Lubbock in his "Ants, Bees, Wasps" as having been described by Sykes in the *Trans. Ent. Soc.*, vol. i. Very few of the ants

[1] The wild hill-tribes of Burmah and Tenasserin have a wasteful system of cultivation called "toung-yah." Yearly, in February, the heads of families in a village choose, each head for himself, a spot of well-grown, often virgin forest, generally on a hill-side, and within as convenient a distance of the village as is obtainable, cut down all the trees big and small, and allow them to dry during the hot months of March, April, and May, and towards the latter end of the last month set fire to them. The ashes thus obtained from the timber forms a splendid manure for paddy, and *toung-yah* rice is preferred by the Karens to ordinary *quin* (field) rice. The "toung-yah," or clearing after the paddy has been gathered in, is abandoned, and in two or three months, under a hot sun and excessive moisture, becomes an inaccessible jungle, full of thorny bamboos, creepers, and elephant grass. Such deserted *toungyahs* are called *phonzohs*, and are not again cultivable for from ten to fifteen years.

remained in the nest, and the few that were about seemed agitated and stung virulently. Probably the mass of them had been driven off or eaten by the woodpeckers. The tunnel the latter had made was about two inches in diameter and four inches long, bored horizontally in, and ending in an irregular-shaped egg-chamber about ten and a half inches in cross diameter, but narrowed by the branch of pyingado which pierced the nest through and through, and crossed the egg-chamber diagonally. The bottom of this chamber alone was smooth, but there was no lining, and the two translucent white eggs of the woodpecker had rested on the bare boards, so to speak, of the ants' house. In the excavations *c c c* made by the ants themselves there were neither eggs, larvæ, nor pupæ; probably these all had been removed when the woodpeckers invaded the nest.

Staminody of Petals

The cases of staminody of petals not being very frequent, it may be of interest to draw the attention of the readers of NATURE to such a modification as observed in Fuchsia.

The places of the four petals of the flower examined are occupied by four almost colourless filaments of an average length of three-fifths of an inch. Each of them bears on its top a nearly circular dark red lamina of three-tenths of an inch diameter. These laminæ are so strongly vaulted as to have the shape of a segment of a globe, the hollow side being turned outward, the convex inward. At the base of the lamina, *i.e.* at the top of the filament, a short protuberance is seen, resembling in external shape the lower part of an anther. This anther occupies the concave side of the lamina and is consequently turned outward. Though the anther of one of the petals is only slightly developed, yet it may be admitted as a matter of fact that, instead of petals, this flower has produced four stamens, whose anthers bear a petaloid appendage. A microscopic examination, namely, showed not only the peculiar composition of the anther-wall, but also the presence of pollen-grains.

Of the stamens, properly so called, the outer whorl is present, but the inner one is only represented by two of the four. One of these two is inserted in the ordinary way, viz. at the base of the petal. The second, however, has grown together half way up with the petal's filament; there it has, in consequence of a spiral turning, arrived at the back side of the petal, whence it bends obliquely outward. By this union the impression is created of a stamen rising from the back of the (modified) petal, concealing its anther in the lamina's concavity. This occurrence brings to recollection the case of *Monarda fistulosa* as cited by Maxwell T. Masters from Turpin ("Vegetable Teratology," p. 298), with this difference, however, that what is probably only adhesion is mistaken for petalody, whilst the case above described offers an antheroid petal grown together with a true stamen.

Catalogue of Fossil Mammalia in the British Museum, Part I.

IN the review of the above work in a late number of NATURE (vol. xxxi. p. 597) the reviewer entertains such a complete misapprehension of my system of naming the premolar teeth of typical heterodont Eutherian mammals that I must beg space to correct it.

The reviewer asserts that this system is untrue because it implies that in general with a smaller number than the full complement of four premolars the diminution must have commenced with the first, proceeded with the second, and so on. In reality it implies nothing of the kind, and if he had taken the trouble to turn to pp. 152 (No. 39,732) and 174 (No. 48,787) he would have seen instances where I have mentioned the absence of the middle teeth (*pm.*2 and *pm.*3) and the retention of the terminal teeth (*pm.*1 and *pm.*4). Similarly in the "Palæontologia Indica," ser. 10, vol. iii. p. 48, I have adopted the same system for the incisors, and have shown that in *Hippopotamus* it is *i.*2, and not *i.*3, that disappears in some species.

I am well aware that in many of the Insectivora and Chiroptera there is often great difficulty in deciding on the homology of the individual premolars when these are reduced in number; and the reviewer might have noticed that in the former order I have not ventured to definitely determine the position of any tooth in advance of the last premolar. Among the Chiroptera I have considered the three premolars of *Vespertilio* (p. 13) as homologous with the last three of the typical series, as there is apparently no evidence to the contary; the small size of *pm.* 3 indicates, however, that an allied genus may retain only *pm.* 2 and *pm.* 4; but the minute size of the one tooth in advance of *pm.* 4 in *Rhinolophus* has induced me to regard it as *pm.* 3, although it may be *pm.* 2.

The advantage of the system employed in the "Catalogue" is well instanced when we contrast the premolar dentition of *Canis*, and *Lepus* or *Theridomys*; the homology of the last tooth of this series (and there is only one in *Theridomys*) being at once seen, whereas it is entirely lost if we employ a method like that used in Dr. Dobson's "Catalogue of Chiroptera," where the actual first tooth in each genus is called the first of the series. I claim for the system adopted by myself every advantage in those cases where it is possible to determine the homology of the individual premolars in any form in which the number does not exceed four; and even in cases where such determination is not absolutely certain, the error can be but very slight, and does not lead to the utter confusion caused by the system (or, rather, the want of system) which I presume the reviewer would prefer.

When we come to those mammals in which the number of premolars is more than four, my system fails; and, in view of this, some German writers have adopted the plan of numbering the premolars the reverse way—*i.e.* terming the premolar next the first molar *pm.* 1, and then counting towards the incisors. Although this system would be advantageous if we could always be sure of the division between the premolars and molars in homœodont mammals; yet it has several disadvantages, and has not, therefore, been adopted.

In reference to the suggestion of your reviewer, that instead of making a catalogue of the fossil Mammalia in the collection of the British Museum (as I was instructed to do by the Museum Authorities), I should have made one of all the known species of fossil Mammalia, any person having the slightest pretence to any knowledge of the present state of mammalian palæontology would have at once known that it would be utterly useless to attempt any such work at the present time, when new species and genera are being made almost daily, and a host of those already made are as yet but empty names.

As a minor matter, I may mention in regard to the lower jaws of *Crossopus*, alluded to in the review, that their identification rests solely on the authority of Prof. Sir R. Owen, and that perhaps I have acted in a too conservative spirit in admitting them.

Harpenden Lodge, May 2 RICHARD LYDEKKER

Fossil Insects

"THE Earliest Winged Insects of America; a Re-examination of the Devonian Insects of New Brunswick in the Light of Criticisms and of New Studies of other Palæozoic Types," is the title of a *brochure* by Mr. S. H. Scudder, of Cambridge, Mass., recently published.

These Devonian insects are fragments of five wings; a sixth is now dropped, as "too imperfect for any satisfactory discussion," though in 1881 its description filled about two quarto pages. These insects have been, since 1865, so often discussed that their literature is a rather voluminous one. A number of far-reaching conclusions elaborated by the author would have to be abandoned if the determination of the insects should be proved incorrect. This I endeavoured to do in *Bull. Mus. Comp. Zool.*, viii. No. 14, Cambridge, 1881, and in NATURE, xxiii p. 483. The principal aim of the author's new paper is to show that my determinations are erroneous. Concerning his statement that I have studied in nature only the (in most cases poorer) reverses, I may remark that his paper gives nothing more, after his study of the obverses; even less for Gerephemera.

These Devonian insects have been decidedly unfortunate from the very outset. Eminent palæontologists denied their Devonian origin, and put them to the Carboniferous or to the "Ursa Stufe" of the sub-Carboniferous. One of the insects, *Xenoneura antiquorum*, said to possess a stridulating organ on the wing, caused an unusual sensation. Poetic palæontologists were delighted to be introduced by this insect to the sounds of the Devonian woods. Now these woods are silent again, except in some text-books. "It does not appear reasonable," said the author, "to maintain my former hypothesis of a stridulating organ." Everybody acquainted with such organs will be of his opinion.

Another insect, *Homothetus fossilis*, was said to have a small basal vein, considered to be homologous with the arculus of the Odonata, and therefore to form a connecting link between Neuroptera and Pseudoneuroptera. A new synthetic family, Homothetidæ, was proposed. But now a re-examination of this wing convinces the author "that he had been mistaken about this arculus." It does not exist at all.

The third insect, *Platephemera antiqua*, was determined by me as the apical half of the wing of a gigantic dragon-fly. As this is the only species claimed now by the author to belong to the Ephemeridæ, he defends vigorously his determination by four objections:—(1) "In no dragon-fly, living or fossil, is there found beyond the nodus between the mediana and margin, more than a simple longitudinal vein, the marginal vein." If the author will examine any Odonate wing *from below*, he will find such a vein, which is the prolongation of the subcosta, bent on the nodus to the marginal vein, and running close to it. Near the nodus it is more widely separated in larger species. (2) "The reconstruction of the wing, after the dimensions given by Dr. Hagen, would, on the most favourable showing, make a wing of ridiculously extravagant appearance." But such forms occur in living species of Tramea, Rhyothemis, &c." (3) "The narrowing of the second cubital space is a common feature in Ephemeridæ (six genera after the Rev. Mr. Eaton's plates are quoted); and, as this varies in different species of the same genus, it seems to be a very unimportant matter." I had purposely stated *suddenly narrowing*, and *this* does not exist at all in Ephemeridæ, namely *not in the six quoted* genera, and cannot therefore vary in the different species of the same genus. It exists in Odonata. (4) "The sector subnodalis does not run unbroken to the tip, as in all dragon-flies I have examined, but is lost in reticulation shortly before the margin." This last-quoted character is a very common feature in dragon-flies (Tramea, Rhyothemis, &c.). Only *very exceptionally* this sector runs unbroken to the tip in the large sub-family of Æschnidæ (*cf.* De Selys's "Revue des Odonates d'Europe," p. 122).

As all objections have been proved *to be incorrect*, and only based upon insufficient knowledge of the venation of Odonata and Ephemeridæ, Platephemera belongs by the simple evidence of facts to the Odonata. The new proposed family of Palephemeridæ dies unborn, and the conclusions made from Palephemera are without value.

The fourth species, Gerephemera, gives much trouble to the author, and he is now inclined to bring it into the same group with the Protophasmida. As only a part about 4 mm. broad can be said to exist in both figures (Brongniart and Scudder) which could be compared, and as this part contains only a few sectors running to the margin, the relationship of Protophasma to Gerephemera is not at all obvious. The reverse of Gerephemera contains more than the author has seen. The basal part of a hind wing to the sector trigonali inferior, the basal part of a front wing with the same sector, and some veins belonging, probably, to another (front?) wing. The part figured and described by the author belongs, probably, to the other hind wing. No student of Odonata will be in doubt that Gerephemera belongs to this family, perhaps near Isophlebia. His statement "that the superior origin of the branches of the sector medius is entirely inconsistent with an Odonate hypothesis, and is the most salient point in the wing," is directly recognised as an error by looking at the figures in De Selys's "Monograph Caloptérygines" (*cf.* Cleis, Vestalis, Neurobasis, &c.). This statement is only surpassed by the emphatic repetition "that the marginal would then be an elevated, and the mediastinal a depressed, vein, *which combination is never the case*." This statement is just the contrary to what exists in all Odonata—unless it is preferred to examine the wings from beneath.

There exists still no monograph of the Sialidæ; therefore it is impossible to make conclusions and form new families for the other three Devonian species. The opinion on the Devonian insects given by Rev. A. E. Eaton (NATURE, vol. xxiii. p. 507) is still very just: "Palæontologists have adopted a ridiculous course with regard to some insect fossils. Whenever an obscure fragment of a well-reticulated insect-wing is found in a rock, a genus is straightway set up, and the fossil named as a new species. The species is then referred to the Ephemeridæ, and is immediately pronounced to be a synthetic type of insects at present distantly related to one another in organisation. This enunciation of synthetic types is often nothing less than a resort at random conjecture respecting the affinities of animals which the writer is at loss to classify. I thought that the Ephemeridæ had served quite long enough as an asylum for fossil cripples. I wished to intimate gently, that refuse of other groups of insects should be henceforth shot elsewhere."

Cambridge, Mass., March 12 H. A. HAGEN

High-Level Stations

IN NATURE, vol. xxxii. p. 17, I find the abstract of an address by Mr. Omond, on "Ben Nevis." There are many points of interest, but I regret that one was not mentioned—viz. the exceedingly rapid decrease of temperature with elevation from Fort William to the Ben, anything nearly approaching, in middle latitudes, being only found on the Brocken, and all high-level stations of the Alps showing a much smaller decrease. At the Brocken, as well as at the Ben, the great difference from the Alps is not in summer, but in the colder months of the year. The reason seems to lie in the nearly constant winds, which bring air from below, which is cooled by ascension. The cases of great dryness of the air with descending currents in anticyclones in the colder months of the year, when isolated mountains are often much warmer than the valleys,[1] are comparatively rare in the North of Scotland, but frequent in the Alps, and certainly must and do have a great influence on the mean temperature. Where they are frequent, as in the Alps—especially the eastern—the mean amount of decrease of temperature with elevation must be slower.

I think all meteorologists will concur with me that the greatest points of interest in the Ben Nevis station is the study of the meteorological phenomena near the centres of cyclones, as no high-level station in the world is so favourably situated as this for this study. A. WOEIKOF

St. Petersburg, May 1 (13)

Rainbow Phenomena

YOUR correspondent Mr. C. Croft (NATURE, No. 811, p. 30) has noticed phenomena which are perfectly familiar to students of physical optics. The internal bands of colour within the primary bow are the "supernumerary" bows due to diffraction. They were described by Langwith in the *Philosophical Transactions* for 1722: a partial theory of them was given by Young in 1804, and a complete theory by Sir G. Airy in 1836. The illumination of the sky in the regions within the primary and without the secondary bows, and also the relative darkness of the space between the two bows, Mr. Croft will find the desired explanation in any elementary treatise on optics; Osmund Airy's Geometrical Optics may be cited as giving a good account of these matters. The particular bow seen by Mr. Croft appears to have been of unusual brilliancy; did he notice any of the radial streaks, which I described in 1878 as frequently accompanying rainbows? SILVANUS P. THOMPSON

Finsbury Technical College, May 16

Aurora

LAST night at about 10.30 to 10.35 p.m. there was a well-marked aurora visible from here. It did not last long, the bright bands fading rapidly into a general glow towards the north. The wind, which was easterly yesterday, has gone round to north-west to-day with tendency to rain and low temperature.

Red Hail

MR. W. H. MITCHEL, of Newry, has sent me the accompanying note, which he thinks may be of interest to the readers of NATURE. C. EVANS

Downshire Hill, Hampstead, N.W., May 18

On May 7, Mr. R. A. Mullan, solicitor, of Newry, was driving in a gig near Castlewellan, co. Down, when he was overtaken by a shower of hail. To his surprise he observed that some of the hail-stones—perhaps one in a hundred—were of a

[1] This is well explained in the "Handbuch der Climatologie" of T. Hann. See also my paper in the *Zeitschr. f. Meteorologie*, 1883, pp. 211, 241.

decided red colour, the rest being white, as usual. Taking up some that fell in the gig, Mr. Mullan found that the colour was not merely superficial, but pervaded the substance of the hailstone, and, on melting, they stained the fingers. He did not think, or had not the means, of preserving any of the water resulting. Has the like been observed before?

Spectral Images

MR. BIDWELL's notice of spectral images (NATURE, vol. xxxii. p. 30) calls to mind certain phenomena I witnessed while riding in a railway train in Kentucky last October. The fence of the railway consisted of posts of about 6 inches in diameter, and twenty paces apart, connected by wires. The posts had newly been painted green. I was seated on the right side of the carriage, face forwards; the speed fully twenty miles an hour, with the sun behind my right shoulder, when looking at the posts on the left side, brightly illuminated by the sun, I observed that each post had the appearance of a twin post immediately in advance of it—touching it—of a red colour. To make myself sure that I was not deceived by some abnormal affection, I called the attention of a niece of mine to the phenomenon, and she saw it quite as well as I did. Another niece, however, failed to make it out. I am under the belief that the red post was the complementary colour of the green one, appearing the instant after the latter had been seen, and though apparently in advance in space of the green post, really was seen later in time. The fact of both being apparently seen simultaneously, is accounted for by the well-known law of retinal images lingering on vision. HENRY MUIRHEAD

Cambuslang

THE NEW OUTBURST OF LAVA FROM VESUVIUS

YESTERDAY, May 2, up to two o'clock, Vesuvius appeared to be in its natural state of activity, such as persisted with slight variations for some considerable time. At that hour the lava, which was at some height within the cone of eruption, forced a way out at its base, traversing the plain of old lava filling the crater of 1872, and producing a rent about one quarter the way down the great Vesuvian cone. This rent represents the extension outwards of a volcanic dyke that has been in process of formation for over two years. A visitor during that period who walked around the southern rim of the 1872 crater, might have noticed a fissure varying from a few inches up to 2 feet wide, and extending inwards across the crater plain, until lost beneath the *ejectamenta* of the cone of eruption. From this fissure issued a powerful current of hot air, and in part of its course an abundance of HCl. This latter was indicated by the continual decomposition of the scoria and ash in its immediate neighbourhood, so that a large patch of yellow dust filled with the unattached pyroxene crystals was a point of bright colour in the black scoria-covered lava-plain. The lava at first actually issued, or, more properly, welled up from this fissure, but its point of exit was soon lowered by the cutting down of the outer slope. The lava soon commenced to flow down the cone with considerable rapidity, forming two distinct parallel streams averaging fifty metres apart, so that in the evening the landscape was lit up by these two brilliant streaks of fire. This morning I started early, and ascended on foot to the eastern side of the two streams, though often inconvenienced by the hot wind and exhalations blown off the lava. The streams take origin close together, and no doubt conjoin, but are covered by scoria—a vast quantity of *lapillo* and ash that has been slipped downwards and forward, forming a rough annular space which would require a drawing to explain. At the upper end of this we have part of the great cone slipped down, showing in section the dyke, which I may call hollow; we have a fissure which was filled by lava, and which consolidated and adhered to its sides, forming *salbam;* but before the central part solidified, the general level was lowered, and it drained away, leaving the dyke divided in two by an empty space. At 2 p.m. to-day the streams of lava had the following dimensions at their exit:—

	Eastern		Western
Breadth	about $1\frac{1}{2}$ metres	...	About $2\frac{1}{2}$ metres
Depth	estimated at 1 metre	...	at 2 metres

Rate of flow on both, about 1 metre per second.

The output therefore equals for the eastern stream about 90 cubic metres per hour, or 2160 cubic metres in 24 hours, whilst that of the western stream represents 300 cubic metres per hour, or 7200 in 24 hours. The two streams, therefore, represent an output of 9360 cubic metres during the 24 hours, from May 2 to 3, at 2 p.m. This quantity would equal a deposit of rock of about 1 km. long, 9 m. broad, and 1 m. thick, which is rather an under-estimation of what now lies on the side of the mountain, for the two streams had at the hour of observation traversed more than two-thirds of the *pedimenture.* The amount of lava represents far more than what occupied the chimney above the level of the lateral opening, and the mechanism of the increased quantity extruded I have gone into fully in a paper read last week before the Geological Society. The cone of eruption only now gives forth vapour, its stone-throwing propensities being stopped by the lowering of the magma level. In consequence of the want of support of its inner walls by disappearance of the fluid column, these are rapidly crumbling in, and the craterial inner cavity much increased in size. In the same way a breach has been made in the line of the dyke by falling in of that part of loose materials immediately above it.

This change in Vesuvius will no doubt be put down in history as an eruption, and possibly a relationship sought between contemporaneous earthquakes, or some other phenomena. It is nothing more nor less than the final giving way of part of the cone before a dyke that has been working its way out for years.

I send you these few notes after a long day's climb, exposed to great changes of temperature and mephitic vapours. I ask, therefore, that this will be taken as an excuse for these rough and ready notes, which I thought your readers would be interested to have quickly.

Naples, May 3 H. J. JOHNSTON-LAVIS

EXPERIMENTS WITH COAL-DUST AT NEUNKIRCHEN, IN GERMANY

IN a former article on this subject which appeared in NATURE of Nov. 6 last (p. 12), I described the apparatus employed by the Prussian Firedamp Commission in making their experiments, and at the same time I gave an account of four experiments that were seen by Mr. Wm. Thomas Lewis and myself.

No official account of these experiments had been published at that time, but quite recently Herr Hilt and Herr Margraf have made a joint report in the name of the Commission. As this report is intended to be only a preliminary one, it does not give the whole of the details of each experiment, but it shows as far as it goes that everything has been conceived and carried out in a spirit of liberality and thoroughness.

At the outset Herr Hilt states that the uncertainty which seemed to surround this important question, and in particular the peculiar views that had been enunciated by MM. Mallard and Le Chatelier, who reported upon it to the French Commission du Grisou,[1] had induced him to address a letter on the subject, dated December 15, 1883, to the Prussian Wetter-Commission, urging them as a matter of duty to take it up and investigate it by a series of large-scale experiments. The French Commissioners, referred to, stated at the end of their report that "they considered it established that coal-dust in the absence of fire-damp does not constitute an element of

[1] *Annales des Mines*, Janvier—Février, 1882.

danger." "It may, however, play an important part in aggravating the consequences of a firedamp explosion." I had myself keenly felt how difficult it would be after a verdict of this kind, emanating from such high authorities, to make further progress in the work of convincing practical mining men of the truth of the views I had previously advocated in the pages of the Royal Society's *Proceedings*. For that reason, and in the absence of some powerful weapon wherewith to meet the French Commissioners with some chance of success, I have hitherto desisted from doing battle with them, although I have been satisfied they were in error from the first. The required weapon has been provided by Herr Hilt, the spokesman of the Prussian Commission, and may now, I think, be made use of without much fear of future contradiction.

Speaking of coal-dust from Pluto Mine, in Westphalia, Herr Hilt says, as the outcome of a long series of practical experiments on the largest scale yet attempted: "Es kann keinem Zweifel unterliegen dass mann mit dieser Staubsorte bei Verlängerung der Strecke und Streuung auch der Flamme eine beliebige Länge würdegebenkönnen. Ganz ähnlich erhält sich der Staub von Neu Iserlohn." Or: "There can be no doubt that with this kind of dust the flame could be lengthened out to any desired extent, provided the gallery and the layer of dust on its floor were made equally long." "The dust of Neu Iserlohn behaves in exactly the same way."[1]

After carefully examining the details of this report, I think it not improbable that many, if not most, of the other twenty-four kinds of coal-dust that were subjected to experiment would have given results similar to those which led to the foregoing remarks had they been employed in the same state of minute subdivision. Differences in chemical composition do not appear to have as much effect in controlling the length of flame produced by a given dust under a certain set of conditions as the comparative fineness of the particles of which it is composed. In order to show the effect of fineness Herr Margraf has divided the dusts into five classes, as follows:—

Number of Dusts in each Class.	Designation of Class.	Length of Flame produced by firing 230 grm. of powder in cannon next floor, the floor being strewn with coal-dust for a length of 10 m.
Five, beginning with Pluto	Very fine ...	21 to 31 m.
Twelve, ending with Camphausen	Fine	13 to 21 m.
Four	Medium ...	12 to 15 m.
Five	Coarse	6 to 12 m.

Some experiments were also made with dust passed through sieves having meshes of various widths, which showed that the finer the state of subdivision, the longer was the corresponding flame.

From this it is obvious that before anything definite can be ascertained regarding the influence of chemical composition, it will be necessary to reduce the dusts to a uniform standard of fineness. Herr Margraf proposes to do this by passing them through a sieve with meshes 1 mm. wide. I am afraid, however, that some more exact method of effecting a separation of the very fine from the moderately fine particles will have to be resorted to before a satisfactory result can be looked for. A current of air ascending slowly at a uniform rate would be a better means than any conceivable kind of sieve.

I have on several previous occasions pointed out that when a colliery explosion has been begun in a dry mine the coarser particles of coal-dust are winnowed from the finer ones by the blast of air which sweeps through the workings in advance of the flame. It seems to me that under these circumstances experiments made with any other than the finest particles of each kind of dust can serve no practicable purpose whatever, and that any general conclusions drawn from them must necessarily be misleading. It is further highly probable that this is the rock upon which the French Commission was shipwrecked.

They had ascertained by actual experiment that, as the coarser particles of any given dust were removed by sifting, the flame produced under the same set of conditions became longer and larger in proportion to the fineness of the remaining dust. Yet they failed to carry the argument to its legitimate conclusion. They appear to have been misled either by too much speculation, or by the negative results of their experiments, due, it may be, to the smallness of the scale upon which they were made. They finally pronounced coal-dust to be an element of very secondary importance in colliery explosions, thereby allowing a splendid opportunity to slip from their grasp. The Prussian Commissioners were not slow to take advantage of the opening thus afforded them. Thanks partly to the large scale upon which they have set to work, partly to the natural fineness of Pluto and Neu Iserlohn dust, they have been fortunate in obtaining a series of positive results which amply confirm those previously obtained with the somewhat smaller apparatus belonging to the Lords of Committee of Council on Education set up in this country under the auspices of the Royal Society (No. IV. paper, "On the Influence of Coal-dust in Colliery Explosions," *Proc. Roy. Soc.*, 1881).

The dust brought from Camphausen Colliery does not appear to stand very high on Herr Margraf's list, and yet, since the publication of the memoir, that colliery has been devastated by one of the most violent explosions on record, in which it is admitted, I believe, that coal-dust, and not fire-damp, was the principal agent of destruction. Are we to conclude from this that the nine dusts which lie between Pluto and Camphausen in the order of relative danger are equally liable to produce a flame of indefinite length under like favourable conditions? and, if so, is it not obvious that the experiments are not as reliable as might be wished, since they fail to tell us so?

Before concluding, I might mention that Herr Hilt refers to and agrees with a remark made by MM. Mallard and Le Chatelier to the effect that the method of experiment followed by Sir Frederick Abel and myself when using the apparatus described in my first paper was "too little exact" to determine accurately what percentage of gas is required to render a mixture of coal-dust and air inflammable. My earliest experiments here referred to were made with the view of finding, if possible, some rational explanation of great colliery explosions which up to that time appear to have baffled every attempt to grapple with them, and were not intended to form a kind of counterpart on the large scale of the exact eudiometric processes resorted to in the laboratory. At the same time I may state, however, that, so far as I have been able to ascertain by reading and observation, the methods then employed will compare not unfavourably, as regards exactness, with any that have succeeded them, not excluding those of the Prussian Wetter-Commission.

W. GALLOWAY

[1] It may be instructive to compare this conclusion with the second sentence of No. 1 paper, "On the Influence of Coal-dust in Colliery Explosions," *Proc. Roy. Soc.*, 1876; the second last sentence of No. 2 paper, *ibid.*, 1879; the conclusion of No. 3 paper, *ibid.*, 1881.—(Abstract).

THE FAUNA OF RUSSIAN CENTRAL ASIA

UNTIL within the last thirty years Turkistan has been unknown to science, and what is now ascertained concerning its fauna and flora is for the most part inaccessible to the scientific world because written in Russian. Not that autoptic writers of eminence upon the zoology of the country are numerous. They do not number a dozen, the names most conspicuous being Prjevalsky, Alpheraky, Bogdanoff, Severtsoff, and especially Fedchenko. Prjevalsky's routes do not touch mine, except in the Kuldja region, where also Alpheraky travelled, and collected Lepidoptera, with a list of which he has favoured me. To Bogdanoff and Severtsoff I am indebted for information not previously published in English, whilst in connection with the immense work that bears Fedchenko's name I have had the valuable help of Madame Olga Fedchenko, who both accompanied her husband on his scientific journeys and, after his lamented death, edited his works. When I add that I have before me proofs of between three and four thousand species of fauna and flora, in about twenty lists with introductions, the scientific reader will not need to be told that in the compass of a single article I can but touch the fringe of the subject. I have ventured to think, however, the readers of NATURE might be interested in a plain statement that would give some idea of the little-known fauna of Turkistan, as well as indicate what I hope to publish shortly in fuller form.

The part of Russian Central Asia through which I recently travelled, and with which this paper will be mainly concerned, lies between the Oxus and Irtish Rivers, and between the 38th and 50th parallels of north latitude, which region comprises vertically all altitudes from the salt plains, 600 feet above the sea, to the mountain plateaus of the Pamir, 15,000 feet high.

The species of mammals in Turkistan exceed 80 in number. Among them may be mentioned 7 species of bats, the long-eared hedgehog, and the white-clawed bear. To these must be added the badger, otter, and other *Mustelidæ*, including three species of marten. Of the last I was able to secure some skins and skeletons, which are now in the British Museum. The wolf abounds; also a wild dog; 3 species of fox; the tiger, snow-leopard, cheetah, and other cats. The salt-plains are frequented by the souslik, and many other rodents, including the hairy-nosed porcupine. To these should be added the Persian gazelle, the Saiga antilope, the Siberian ibex, and the Maral stag. I saw at Kuldja and Tashkend specimens of the skull and horns of the Thian Shan sheep, which is bigger than a donkey. The horn is more than four times the length of the skull, and the head complete weighs upwards of 70 lbs. The yak is kept by the Kara-Kirghese. The Russians, too, as an experiment, have introduced some cross-breeds into the plains.

The birds of Turkistan number nearly 400 species, to which may be added 27 frequenting the Pamir. The diurnal birds of prey, such as vultures, eagles, hawks, &c., number 36 species, some of which the Kirghese train for hunting. Of nocturnal birds of prey there are 9 species of owls. There are thirteen species of crows, and no less than 40 of the finch family, including a new species of sparrow. The thrush family is represented by the blackbird, black-throated, misletoe, and some other thrushes. There are more than 40 of the warbler family, many of them being known in Western Europe, such as the greater nightingale, the bluethroat, redstart, redbreast, and others. Six species of the titmouse family are found in Turkistan, only one of which, however, the well-known oxeye, is common also to England. Two species of dipper are found throughout the country, and other small birds are the Nepalese and European wrens, the Syrian nuthatch, and no less than 10 forms of wag-tails. Of pipits there are 7 species, and 14 of larks. The hoopoe I saw when coming south from Sergiopol, and again in the streets of Vierny. Other Turkistan birds are the bee-eaters, the three-toed woodpecker, the ubiquitous cuckoo, and the wonderful Pallas's sand-grouse, which last, some twenty years ago, invaded Europe in such an astonishing way.

Among gallinaceous or game birds are found in Turkistan the black grouse, the capercailie, four species of partridge, the quail, Mongolian pheasant, pea-fowl, and common cock. Of the swan, goose, and duck tribes there are nearly 30 species. Wading-birds, again, are found in great variety, and among them a red-billed curlew, thought at first to be a new species. It has red legs, and a remarkably long red beak, bent at the end, and well adapted for picking up worms from between the pebbles of the beds of the mountain streams it frequents.

Reptiles are represented in Turkistan by 33 species of lizards, vipers, and tortoises. Of the last I tried to bring for the Zoological Gardens a species (*Homopus horsfieldi*), and it travelled asleep with me some hundreds of miles from Tashkend, but on approaching Odessa it was found to be the sleep of death. Almost all the serpents are non-venomous. Of amphibians there are five species, including the edible frog and green toad.

The fishes of Turkistan are composed half of European and half of Asiatic forms. The European forms belong principally to the lower course of the Syr-daria, Amu-daria, and part of the Zarafshan, whilst certain genera belong exclusively, so far as is known, to the high mountainous countries of Central Asia. The total number of Turkistan species probably exceeds fifty. Of these twenty-five at least belong to the carp family, and there are taken besides sturgeon, trout, pike, barbels, gudgeon, rudd, roach, bleak, bream, loaches, and perch. The fishes of the Zarafshan are particularly noticeable. Of fifteen species found therein not less than five belong to genera met with in numbers in Kabul, Kashmir, Nepal, and the Himalayas. To one of these genera belongs the *Marinka*, remarkable for its poisonous eggs. The greatest find, however, among the ichthyological fauna of Turkistan has been the *Scaphirhynchus*, of great importance, not only from a zoological, but also a biological point of view, on account of the extreme smallness of its eyes and the rudimentary condition of its air-bladder. This fish, and certain geological questions connected therewith, was referred to in NATURE in connection with a letter on the Oxus that appeared in the *Times* on January 7 last.

If for Mollusca we enlarge our area to take in Kashgar and Ladak, then we have in "Central Asia" thus formed 93 species known up to the present time, the land snails being scarce in the desert plains as compared with the larger number and more peculiar forms in the mountain regions. Among the fresh-water Mollusca the predominant feature is the large number of air-breathing species which live in stagnant water, and the almost total absence of the genera living in running water. It has been suggested that this scarcity may be due, as in Switzerland, to the low temperature and stony bed of the rivers.

Among the 50 species of Crustacea known in Turkistan there was not discovered for a long time a crayfish; but Madame Fedchenko informs me that one of a variety new to the species hitherto known in Russia has been recently found. Among the Crustacea inhabiting the fresh waters of Russian Central Asia a very large number of West European species is found, and the new species are, in the majority of instances, very similar to the commonest in Central and Southern Europe.

Of the 16 families to which European spiders are said to belong, all, except two groups very limited in number, have their representatives in Turkistan. The 146 species known there belong to 55 genera, which constitute approximately one-half of the total of European genera. The *Tarantulæ* are remarkable in that there are found in the Zarafshan Valley forms which in Europe are met with in countries far apart from each other, and have been reckoned as different species. The most widely distributed form is that with the lower part of the abdomen quite black; next comes the form with coloured edges; and, finally, that with the lower part almost entirely orange. The scorpions of Turkistan are identical with those met with in Trans-Caucasia, and the distribution of one species (*Solpuga intrepida*) is remarkable. First found in Spain, it was seen later on the Indersk Mountains, then in the Zarafshan Valley, besides which specimens of this harvestman have been found in Vierny.

The animal is reckoned poisonous, and its bite has in certain cases been followed by death, although nothing is yet known of its poison-apparatus.

The species of Turkistan beetles are estimated at 1000. I have before me a list of 500, some of them as yet unpublished. Amongst the most remarkable is the *Copris tumulus*, the largest specimen measuring one inch and three-quarters long.

The hymenopterous fauna of Turkistan is not yet fully worked out, but I may observe that of *Mellifera* there are known 438 species, and of *Sphegidæ* upwards of 150. As regards the latter, the valleys of Ferghana and the Zarafshan do not present many specialities. On the other hand, the Kizil Kum desert abounds in new species and even genera, sharply distinguished from known species both in the form of the body and in the beauty and size of the individuals. There is, moreover, a remarkable similarity between the species belonging to the Kizil Kum and the Egyptian sands. Of *Scoliidæ* 30 species are known, whilst of *Mutillidæ* 18 species have been treated by Gen. Radoszkovsky, who informs me that Gen. Komaroff, now military governor of the Trans-Caspian district, has quite recently made scientific explorations between Askhabad and Merv, and that among the insects collected by him about Askhabad are six speces of *Mutillidæ*, four of which are marked as new, and one as a new genus. Of 36 species of ants collected in Turkistan, 7 only were new. The Formicidæ of the region seem to be very similar to those of South Europe. This is not astonishing, since the mean temperature of a Turkistan summer differs little from the mean summer heat in Southern Europe, and this case only proves once more that, in general, countries with summers alike have greater similarity with regard to fauna and flora than countries lying under identical isotherms with different summers. This peculiarity is evident with regard to Formicidæ, because, for example, in Italy and Turkistan they have an identical summer; and though the winter in Turkistan is long and cold, it does not appear to have much influence over the ants, which are protected therefrom. European species which live in trees and woods appear to be in most cases absent from Turkistan. Of the new Turkistan species one *Ischnomyrmex rhaphidiiceps*) is specially interesting, as closely allied to two species inhabiting countries between the tropical and subtropical zones of the southern hemisphere. It is remarkable, therefore, to meet with a species of the same genus in the temperate zone of the northern hemisphere, and it may be presumed that these last have existed in Turkistan since the Tertiary period. I have yet to mention *Chrysidiformes*, of which 53 species have been found in Turkistan, and among them 2 new genera and 15 new species.

Before passing from hymenopterous insects I may mention that, though saw-flies are not numerous in the Zarafshan Valley, yet there is one form particularly remarkable, for, with a normal male, related to the group *Selandridæ* is a female without traces of wings. Affected by this absence of wings, the thorax undergoes important changes, and appears greatly swollen, and all the females generally have the appearance of little bags. Its relation to this family is said to be astounding, since it is the only example of the wingless form in the whole family of saw-flies. All the other specialities of structure, however, as well as the wings of the male, confirm it.

One of the first lists made of the butterflies and moths of Turkistan enumerated 367 species, of which 122 species were of *Microlepidoptera*. The great majority (284) were caught in the oases and hilly districts between 750 and 4500 feet above the sea; 41 species also were taken on mountains up to 8000 feet high, and 28 species from 8000 to 13,000 feet. Mr. Alpheraky, of Taganrog, has furnished me with a list in manuscript of 377 species of Lepidoptera collected by him in 1879 in the district of Kuldja and the surrounding mountains; but even these two lists together, I am told, give only an incomplete enumeration of the Lepidoptera of Turkistan, which contains a large number of new forms.

As we travelled from Tashkend to Khojend dragon-flies were so numerous that we caught several specimens by extending a butterfly-net from our carriage. The neuropterological fauna, however, of Turkistan is only partially known. Mr. MacLachlan has treated upwards of 60 species, most of them European in character, and many of them belonging even to Western Europe, whilst there is also an unimportant mixture of the Indian element.

There is a mingling again of the Indian element in the orthopterous fauna of Turkistan, but the Indian species are much fewer than the European. This fauna is particularly like that of South Russia, and it contains a large number of West European species. The non-European species are from South Asia, among which are a few from more distant countries, particularly from Africa. The total number of species known in Turkistan exceeds 70. Among them should be mentioned two locusts, and a third called locally *Prus*. Ravages of the former have been complained of in the neighbourhood of Perovsk and of the "*Prus*" in the Zarafshan Valley.

Of *Hemiptera* I have no list of species, but I saw a fine collection at Tashkend, made by Mr. Oshanin.

I come, lastly, to *Cestodes*, or intestinal worms. Of 47 species known in Turkistan, 2 are found in man, 3 each in the dog and sheep, 2 each in the cat and goat, and 1 each in the horse, ox, and marmot; 30 are found in birds, 2 in reptiles, and 1 in fishes. Of all the Vermes the most interesting is what the Bokhariots call the *Rishta* (*Filaria medinensis*). The parasite is found at Bokhara and certain adjacent towns in the water of stagnant pools, which the natives drink, and suffer in consequence from the *rishta* disease. The worm develops under the skin, lengthening at the rate of about an inch in a week, until an abscess is formed, through which the head (as is said) of the parasite appears. The problem, then, is to extract the animal entire. Native specialists insert a needle, and one end is drawn out by the fingers of the right hand, whilst those of the left press the adjacent part. Russian medical men wind off the animal on a reel, so much as comes out daily without force, till the whole, commonly three feet in length, is extracted. If, however, the worm should break, thousands of fresh germs are liberated from the broken part, and the illness continues for several months. I met with an unsuccessful case at Samarkand, and was given by the doctor some pieces of the *rishta*, which I brought in spirits to London.

The appearance of the worm is of a milk-white colour, resembling cooked vermicelli, and it can be stretched like a piece of elastic. The investigations of Prof. Fedchenko brought to light some very interesting facts concerning the *rishta*, the first of which was that the germs of the parasite cannot live in very fresh water, which is in keeping with the fact that the parasite appears only in those places where the people are forced to use standing water. The *rishta* is the last of the Turkistan fauna that I can mention here, but I hope within a few weeks to publish fuller particulars, through Messrs. Sampson Low and Co., in a new work entitled "Russian Central Asia, including Kuldja, Bokhara, Khiva, and Merv, with Appendices on the Fauna, Flora, and Bibliography of Russian Turkistan."

HENRY LANSDELL

FIELD EXPERIMENTS AT ROTHAMSTED[1]

THE above Report, forwarded to us, bears the name of no publisher, and is not priced. It therefore may be taken as a private issue, copies of which can only be

[1] "Memoranda of the Field Experiments conducted on the Farm and in the Laboratory of Sir John Bennett Lawes, Bart., at Rothamsted, Herts., June, 1884."

had by application to Sir John Lawes at Rothamsted Park, St. Albans.

The task of reviewing matter of so condensed a character as this is by no means easy. Ever since 1840, Sir John Lawes has carried out field and stall experiments on a scale well worthy of a national enterprise. Elaborate papers by this most enterprising of experimentalists, and his equally well-known coadjutor, Dr. T. H. Gilbert, have poured forth from Rothamsted during the entire memory of the present generation. During the last twenty-five years the scientific staff presided over by Dr. Gilbert has consisted of two, and sometimes three, chemists, and as many competent assistants, a botanical assistant, two to four computors and record-keepers, besides laboratory men. From 1847 to 1884 ninety-six memoirs have been contributed upon subjects bearing upon the soil, the plant, the atmosphere, drainage water, and rainfall, utilisation of sewage, animal nutrition, feeding-materials, manures, the occurrence of fairy rings in pastures, &c., &c. There is, in fact, scarcely a topic of agricultural or pastoral life which has not been investigated at this great English Agricultural station, and that through the enterprise of one man.

The Memoranda commence with a summary of rainfall and drainage extending backwards to 1851. Not only is the local rainfall given for each month over a period of nineteen years, but also the amount percolated through gauges of 20, 40, and 60 inches in depth of soil, the amount evaporated, and the amount retained by capillary attraction in the soil. Thus, as a general summary of the total rainfall, we find 45·3 per cent. percolated through 20 inches depth of soil, 47·4 per cent. through 40 inches of soil, 41·9 per cent. through 60 inches of soil, as indicated by rain- or drain-gauge, while the remainder is accounted for by evaporation or retention in the interstices of the soil. The averages obtained by unremitting observation from 1851 to 1870 are used in comparison with subsequent years, as in the case of the last completed record from September, 1882, to August, 1883. The three last columns of the tables given are devoted to the nitrogen removed in solution by percolation of drainage-water calculated in pounds per acre, by which we see that, at the depths above-mentioned, from 36 to 44 lbs. of nitrogen per acre are annually carried down from the upper layers of the soil to a depth of 5 feet and more.

One of the most attractive series of experiments, extending now over a period of thirty years, is that carried out upon permanent grass-land in the Park at Rothamsted. Space forbids more than a most cursory sketch of these experiments. Like all the Rothamsted investigations, the first aim is practical and comparative. The questions asked are as follows:—What is the effect of various applications to grass land? Which gives the largest return? What is the effect upon the herbage of continuous and of varied treatment? What is the effect upon the soil of long-continued privation and of long-continued *feeding* with simple and combined dressings? The investigation is at once chemical, physical, and botanical, and the change wrought in the character of the herbage of various contiguous plots of natural pasture, as well as upon the soil to a great depth, is most remarkable.

Perhaps the chief interest in the experiments upon crop cultivation will still centre around wheat. Broadbalk field, on the Rothamsted estate, is unique, so far as treatment and cropping goes. In 1839 this field carried a crop of turnips, manured with farm-yard dung; in 1840 it was barley; in 1841, peas; in 1842, wheat; in 1843, oats; all the four last crops being unmanured. The field was, therefore, according to all farming rules, in an exhausted state when the first experimental crop of wheat occupied it in 1844. Every year since 1843 has this field carried wheat, and, with some exceptions, nearly the same description of manure has been applied to each plot. In this field the visitor, during the present summer, will see the forty-second wheat-crop growing without manure of any description upon the unmanured portion of the field, still keeping up a wonderfully uniform yield of about thirteen bushels per acre—or about the average yield of wheat-lands in the United States of America. This is a striking fact for those who fear the eventual exhaustion of our soils. Equally startling is the result from the continued use of nitrate of soda year after year. This fertiliser is looked upon by many landlords and agents with suspicion as a stimulator and exhauster of the soil; and yet after forty-one years application of nitrate of soda, and nothing else, we have the astounding result of an average of 23½ bushels per acre, or double the yield of the unmanured plot. And, although it is true that the yield of the unmanured and nitrate of soda plots is less upon an average from 1868 to 1883 than it was from 1852 to 1867, yet it is equally true of the plot manured with 14 tons of farmyard manure annually; and this falling off is therefore probably due to a succession of bad seasons, more than to any actual exhaustion of the soil. Another striking fact brought out in these experiments is the excellent results achieved by applications of artificial fertilisers as contrasted with those obtained from farm-yard manure. In the latter case, where 14 tons of dung have been annually applied to the wheat-plot for forty years in succession, the very satisfactory yield of 33½ bushels per acre has been obtained over the entire period. When, however, a well-compounded mixture of artificial fertilisers has been applied, a larger yield has been obtained. For example, 200 lbs. of sulphate of potash, 100 lbs. of sulphate of soda, 100 lbs. of sulphate of magnesia, 3½ cwts. of superphosphate, and 600 lbs. of ammonia salts, have given upon an average over the same long period 36 bushels per acre year by year. We must not draw these remarks to a conclusion without at least noting the interesting experiments upon barley, the leguminous crops, clover sickness, root crops, and potatoes. The memoranda close with a synopsis of a series of experiments upon rotations of crops commenced in 1848 in order to test the effect of growing crops in rotation, instead of continuously, and so to arrive at precise results when a system of mixed farming is pursued with and without manures, and in conjunction with sheep farming.

JOHN WRIGHTSON

RECENT EXPLORATIONS OF THE PAMIR

THE third fasciculus of the *Izvestia* of the Russian Geographical Society contains three very interesting papers, by D. L. Ivanoff, on the Pamir, being the results of the expedition of MM. Ivanoff, Putyata, and Bendersky, already mentioned in NATURE. The first of these papers deals with the journeys of the members of the expedition; the second contains the author's views on the orography of the Pamir; and the third gives a description of the flora, fauna, and inhabitants of this "Roof of the World." Leaving aside the purely geographical part (M. Ivanoff's papers should be translated into English), I shall sum up the most important orographical results arrived at by the author, as also his observations on the natural history of the Pamir.

As to its limits, so variously determined by geographers, M. Ivanoff places them—rightly in my opinion—as follows:—The Alay Mountains in the north, the Hindukush in the south, and the Kashgar Mountains in the east. As to its western limits, the following remarks ought to be made:—The whole of the highlands on the upper Amu-daria must be divided into two parts—the Eastern Pamir and the Western. The Eastern Pamir is a very high plateau, intersected by numerous valleys, rivers, and lakes, with an average height above the sea-level of 12,000 feet (from 10,000 to 14,000). These valleys are either separated by chains of mountains or by low swellings which mostly reach only from 1100 to 1500 feet above the level of the surrounding valleys, and very seldom 3000 feet. The slope of these swellings above the valleys is so gentle that water-sheds only 1100 to 1500 feet high are often twenty to fifty miles distant from their foot. These high valleys strictly correspond to what the inhabitants call "Pamir." "Pamir" signifies, in fact, "a flat roof," and when the inhabitants want to describe it in more detail, they add: "broad valleys between low mountains, so high, however, that nothing but grass may grow on them; where there is nothing," they say, "and the earth is like the palm of the hand, that is the Pamir." So they describe what a geographer would call a High Plateau. This plateau has, on the whole, the shape of a great horse-shoe, in the middle of which are situated the mountains of the Murghab and Alichur. This does not imply, however, that there are absolutely no mountain-ridges on the plateau; no *angehaufte Gebirge*, as Karl Ritter would say. The Pamir chain of mountains which runs east-north-east between the Pamir and the Alichur rivers in the south belongs to this category. It rises above the Great Lake as a stone wall 3500 to 5000 feet high; but it has its foot in the 10,000-feet-high valleys which surround the lake, and belongs to the category of the *angehaufte Gebirge*. Several other lower chains, such as the Alay, Trans-Alay, Riang-kul, Murghab, Alichur, and Vakhan, run in the same direction over the surface of the great plateau, and have the same character.

As to the Western Pamir, which might be described as the mountainous Pamir, it has quite another character. The whole of the plateau sinks towards the west, but, at the same time, numerous chains of mountains make their appearance. We have there, according to Ritter's classification, an Alpine country. The rivers, which flow lazily in the east, become rapid, their valleys narrow; crags, rocks, and hills confine them; the routes become difficult, and the mountain-passes very rare. The rich prairies of the east disappear also, giving place to forests, and, lower down, to agriculture, which rises as high as 8000 feet in the north and 10,000 feet in the south. Even the inhabited valleys are mere mountain-gorges. It is obvious that, under such conditions, the real western limits of the Pamir cannot be determined with exactitude; and we consider M. Ivanoff very near the truth when he says that the Western Pamir merges into the Alpine highlands of the Darwaz, Shugnan, and Badakshan. The limits are thus far more undefined in the west than in the north and east. The author considers, thus, that the Shugnan and Darwaz ought not to be included in the Pamir proper; they might be considered rather as a highland which has risen at the intersection of the eastern with the north-western ones of the Hindu-kush (as border ridges?). The Pamir would thus appear as a mighty plateau about 170 miles long, 200 miles wide in the meridional direction, and covering nearly 34,000 square miles.

As to the much-spoken-of meridional upheaval of the Bolor, M. Ivanoff points out that there are absolutely no traces of upheavals having a direction either from north to south, or even towards north-north-west or north-north-east. On the contrary, all his observations on the stratification of rocks—and they are numerous—show that the stratification follows the direction either of east-north-east (that of the whole Central Asian plateaux), or north-west, that is, that of the Hindu-kush. The same is true with regard to longitudinal valleys, which always follow a direction towards north-north-east. As to the Kashgar Mountains, still unexplored, they seem to represent a repetition of shorter chains running towards north-west, and arranged in *échelon*.

If this opinion of M. Ivanoff is confirmed—and it most probably will be, as it pretty well corresponds with the broad lines of the structure of the Central Asian plateaux, as also with what is already known as to their structure—we shall have definitely to renounce seeking for meridional chains in this part of Asia. We have already been brought to renounce them in North-Eastern Asia, where I believe I have proved that neither the Great Khingan nor the Kuznetzki Alatau, nor even the Sikhota-alin, have this direction. On the contrary, we will perceive that the Pamir is only the highest terrace of a series of plateaux extending throughout the central parts of Asia in a north-eastern direction from the source of the Amu to Behring Strait.

But let us return to M. Ivanoff's papers, and to his observations on the flora and fauna of the Pamir. The high valley of the Alay already belongs to the Roof of the World. It is covered with rich prairies, the chief elements of which are Gramineæ. Nearer to water you find a thick growth of *Carex physodes*, which has given its name, *Riang*, to so many parts of the Pamir highlands. Numerous species of Papilionaceæ, many of them relations of the flowers of our European meadows, give a pleasant aspect to the steppes of the Alay in June. The same character—a mixture of the vegetation of the steppes with that of cold climates and highlands—is found also on the Eastern Pamir as you advance further south. But it is sufficient to descend into the valleys of the west to find immediately a far richer flora and, very soon, corn-fields.

The animals inhabiting the Pamir are also a mixture of those of the steppes with those of Alpine regions. The tame yak (*Bos indicus*) is met with the well-known "arkhars." Although their horns are scattered in great numbers on the Pamir, they are far from disappearing, and M. Ivanoff has seen numerous herds of from 100 to 150, and considers that they ought to be counted by thousands in the neighbourhood of the Great Lake. In the mountains the "kiiks" (*Capra*, probably *sibirica*) are numerous, but very difficult to approach; the brown bear is common, and M. Ivanoff's men killed four of them. The wolf of the steppes unavoidably accompanies the herds of arkhars. The yellow marmots (*Arvicola caudatus*) are very numerous; the steppes of the Pamir are their true dwelling-places, and the expedition has met also with great numbers of small Siberian hare, which is common on the Issyk-kul. The Indian goose, the *Syrrhaptes* of the high steppes, the *Megaloperdix tibetana* in the rocky hills, and the *Perdix chukar*—this last met with only once at a height of 14,000 feet—are especially worthy of notice.

As to the climate of Pamir, it is, of course, very severe. The winter reigns in full for seven months. As to frosts, there is hardly one single month without them, and even on July and August nights the expedition experienced frosts of 6° below zero. There are places on the Pamir where snow rarely reaches a great depth, but, its distribution depending mostly upon the prevailing winds, there are places where it falls in thick layers. As to the rivers, even the Murghab freezes for some time.

The true inhabitants of the Pamir are the Kirghizes, namely, the Kara Kirghizes, who belong to four different stems—Teit, Gadyrsha, Nayman, and Kiptchak. The chief settlements are situated in the valleys of the Northern and Southern Ghezia, about the Riang-kul, on the Ak-baital, the Ak-su, the Alichur, and in the basin of the Kokui-bela. They are found also on the Upper Tagarma. These Kirghizes are very much like those of the Alay, but a special feature of them—very rare, on the whole, with the Mongolian race—is that they continually suffer from tooth-ache; perhaps it depends upon the climate; at any rate, common disease—an inflammation of the eyes—obviously depends upon the clouds of salt dust raised on the Pamir by the western winds. They spend the winter, at a height of 11,000 to 12,000 feet, in the same tattered *kibitkas*, that they inhabit in the summer, and know nothing of the warm dwellings erected for the winter by the Alay Kirghizes.

In the summer they ascend to the hilly tracts, reaching about 14,000 feet, in order to save their cattle from the mosquitoes. Though living chiefly on milk produce, they still are dependent upon the inhabited countries of the west, for they are accustomed to the use of bread. The other race inhabiting, if not the Pamir itself, then its outskirts, are the Tadjiks. In the high valleys of the Shugnan, the Roshan, the Darwaz, and the Karategin, they occupy the narrowest gorges of the mountains, trying to escape there from the persecutions of their khans, who are themselves vassals to the neighbouring larger states like Bokhara, Kokan, or China. Being Shiites, they are still more persecuted by their Sunnite rulers. Their dwellings are miserable hovels built of rough stones. Broad wooden platforms, under which fowls and young goats are kept, are divided into numerous compartments, which might be called rooms, each of them having its special destination as a kitchen or as a room for weaving, and so on. Notwithstanding the surrounding poverty, one feels comfortable in their poor hovels, the walls of which are decorated with numerous clay pillars, niches, and a variety of paintings very artistically made by the women, who have found the means of fabricating even boxes from clay mixed with husk. The pottery, all made by women without instrumental aid, is striking in the artistic feeling infused into its fabrication. Their fields are not less striking by the incredible labour which has been spent in clearing them from millions of stones. There are "fields" not larger than a common-sized table, cleared with effort, or artificially made by the side of a mountain stream. They keep some cattle, and, during the summer, mount with it to higher tracts. The Pamir is visited by many *savdagars*, or traders, from Kashgar, Badakshan, or Ferghana, who supply the Kirghizes and Tadjiks, at very high prices, with manufactured produce, receiving in exchange their own produce.

M. Ivanoff remarks that the small preliminary map published in the *Izvestia*, to illustrate the explorations of his expedition, is still incomplete, and does not quite correctly represent the results of his investigations. The larger completed map will therefore be welcomed when it appears.

P. K.

NOTES

A MEETING of the General Committee of the Darwin Memorial Fund was held last week at the rooms of the Royal Society, Prof. Huxley, President, in the chair, when it was stated by the treasurer, Dr. Evans, that, after payment for the statue and other expenses, a balance of about 2200*l*. would remain. The following resolutions were then passed :—"That the statue of Darwin be made over to the Trustees of the British Museum in trust for the nation." "That the balance of the fund, after payment for the statue and medallion and incidental expenses, be transferred, under the name of the 'Darwin Fund,' to the President, Council, and Fellows of the Royal Society in trust to invest the same in or upon any stocks, funds, or securities authorised by law as investments for trust moneys." "That the President and Council of the Royal Society apply from time to time the dividends and interest of such investments in such a manner as shall to them appear best calculated to promote biological studies and research." "That a list of subscribers and a statement of the accounts be printed and circulated, together with the resolutions now passed, and that a woodcut or some other representation of the statue accompany the statement." The statue, by Mr. Boehm, R.A., has been placed in the great hall of the British Museum (Natural History), Cromwell Road, and arrangements for its unveiling will be made shortly.

THE vacancy created by Prof. Bayley Balfour's retirement from the Regius Chair of Botany in the University of Glasgow, which we announced some time back (NATURE, March 12, p. 441), has been filled by the appointment of Mr. F. O. Bower, F.L.S., Lecturer on Botany in the Normal School of Science, South Kensington. Both as a teacher and by his important researches in the morphology of Gymnosperms and the Vascular Cryptogams, Mr. Bower has rapidly assumed a leading position amongst the younger generation of botanists, and the loss of his services to the Normal School is much to be regretted. Mr. Bower is an M.A. of Trinity College, Cambridge.

THE Goldsmiths' Company has contributed one hundred pounds towards the fund which is being raised for the family of the late Henry Watts, to which we have already drawn attention in these columns.

THE Court of Assistants of the Fishmongers' Company has unanimously resolved that a grant of 2000*l*. be made to the Marine Biological Association of the United Kingdom—1000*l*. to be paid this year, and the remainder in annual sums of 200*l*. during the next five years.

THE subject of Mr. Romanes's Rede Lecture on June 2 will be "Mind and Motion."

THE subject of Prof. W. G. Adams's British Association address will be "The Electric Light and Atmospheric Absorption."

AT a meeting of the directors of the Ben Nevis Observatory held on Thursday last week, it was agreed to add a printing press to the establishment, for printing each day the hourly observations, with a view to their distribution among the more distinguished meteorologists and prominent meteorological institutions in different parts of the world.

THE verdict of the jury who considered the case of the Usworth Colliery explosion, whereby forty men and boys were killed early in the present year, is important as marking what appears to be the commencement of a new era in the history of these phenomena. It is probably the first expression of opinion from a public body of this class to the effect that coal-dust and a small percentage of fire-damp can play the part that has hitherto been usually ascribed to fire-damp alone. They found that the explosion was caused by a shot, the fire of which acted upon "*the coal-dust and a small percentage of gas.*" The convenient and time-worn "outburst of gas" theory, which consigned the helpless miner to the vicissitudes of chance, and exonerated colliery owners and their agents from all responsibility, seems on the point of giving way before its rival the coal-dust theory, which points out an easy means of preventing great explosions of this kind. The latter theory has doubtless a hard battle still to fight against prejudice and ignorance, but it has all the advantages of youth and vigour on its side, and is supported by a number of facts which appear to be incontrovertible.

THE Russian Geographical Society has just issued a programme of climatological and phenological observations, which, it is to be hoped, will be adopted by numerous observers. The number of plants and animals enumerated is smaller than in most similar programmes, it being the aim of the Society to make the task of the observers as easy as possible. A new feature of this programme are observations on the condition of the snow covering the ground, the time of its appearance and thawing, the rise of water in the rivers at the melting of the snow, &c.

M. FAYE has been continued on the roll of teachers of the Paris Polytechnic School, in spite of his having passed the time of incapacitation by old age. The exception has been grounded by the Minister of War on the plea of continued services rendered to science. A banquet has been given to the worthy astronomer by his admirers on this occasion.

THE Sanitary Congress opened yesterday at Rome.

IN the Spanish Congress on Monday, Señor Castelar called attention to Dr. Ferran's experiments in inoculation against cholera, and asked the Minister of the Interior to give a subvention to enable Dr. Ferran to continue his experiments on a larger scale. The Minister, in reply, said he was unable to do so at present, but as soon as it lay in his power he would grant a sufficient sum, although, in his opinion, Dr. Ferran's experiments had not yet reached a sufficient degree of certainty to prove a complete success. He added that a commission of medical men would be appointed to visit Valencia and other towns in order to study the experiments that are being made. In reference to this subject Dr. Cameron, M.P., writes to the *Standard* that the Under-Secretary for Foreign Affairs has promised to instruct the British Minister at Madrid to send home translations of any reports bearing on the system of inoculation with cholera virus attenuated by artificial cultivation, as a protection against Asiatic cholera, discovered by Dr. Ferran, of Valencia. This having come to the notice of Dr. Ferran, that gentleman has sent Dr. Cameron a telegram giving the results up to date of a great test experiment which is at present being conducted by him, under the eyes of scientific commissioners at Alcira, a town near Valencia, where an epidemic of cholera is raging. According to Dr. Ferran's telegram the population of Alcira is 16,000, and since the first of the present month 5432 of its inhabitants have been inoculated with his protective virus. That would leave the number of those not inoculated about 10,500; or, accepting 16,000 as an exact figure, precisely 10,568. Of the 10,500 persons who are not inoculated, cholera has attacked 64, and proved fatal to 30. Of the 5432 who have been inoculated it has, according to Dr. Ferran, attacked only 7, and proved fatal in no single case. In other words, since the commencement of the experiment on May 1, one person out of every 163 has been attacked among the uninoculated population, and one person in every 352 has died of cholera; while among the inoculated population only one person in 776 has been attacked, and not a single person in the entire 5432 has died of the disease. Dr. Ferran concludes his telegram by expressing the desire that a British Commission should be sent to Alcira to verify these results.

THE floating dome presented by M. Bischoffsheim to the Observatory at Nice is now finished, and has been on exhibition in Paris during the past week. It is intended to cover a colossal telescope; it is 22 m. in diameter inside, and has a circumference of 60 m., or 2 m. more than the dome of the Pantheon. Instead of rendering it movable by placing it on rollers, according to the ordinary method, it is closed below by a reservoir for air, which rests on the water in a circular basin. This system of suspension is said to be so perfect, that in spite of its great weight, a single person can turn it completely round the horizon. To provide against the water freezing, it has been proposed to dissolve in it a salt to the point of saturation, but it is feared that this may cause corrosion of the apparatus. Frosts, however, are rare in Nice, and special experiments on this subject will be made.

ON Friday night the House of Commons agreed, without a division, to a motion by Sir John Lubbock for a select committee to inquire whether, by the establishment of a forest school, our forests and woodlands could be rendered more remunerative. The proposer pointed out that, while our interests in the subject were greater than those of any other country in the world, as we had 2,800,000 acres under wood in Great Britain and about 340,000,000 in the Colonies, yet this was almost the only country without a forest school. He referred to the effect of scientific forestry in the Landes in France, and in India, where the net forest revenue fifteen years ago was only 52,000*l*., while, since the establishment of a forest department, it had risen to over 400,000*l*. per annum. As a result of neglect of the science in this country, students for India had to be trained at Nancy, a school of course specially adapted for French requirements, and the forests in our Colonies and other possessions (Cyprus and the Cape, for example) had to be put under the control of foreigners, as there were no Englishmen trained for the work. Sir John Lubbock, however, declined to commit himself to the establishment of a Government school; it could not be left altogether to private enterprise, because a school necessarily required access to a considerable area of forest. He thought it worthy of consideration whether some intermediate system might be adopted which would enable some one or more existing institutions to benefit by national forests. Mr. Gladstone, whose interest in arboriculture is well known, could not bind the Government to the establishment of a School of Forestry, although he recognised the universal ignorance on the subject prevalent amongst land agents and others in England. He distinguished the circumstances in India, where there are important facts connected with the climate, and with the due supply of moisture in the atmosphere, which are not present in this country. The School of Forestry, moreover, he said, which was established by the Indian Government in England, was open to every one who could pay the fees. There was also the difficulty that forests of large extent are rare here, and that they are kept, not for purposes of profit, but of landscape beauty, or pleasure and sport. In conclusion he said the Government gave their hearty approval to Sir John Lubbock's proposal, reserving, at the same time, their freedom with regard to the recommeudations which the committee might make.

A TRANSLATION of Prof. Cremona's well-known work on the "Elements of Projective Geometry," by Mr. C. Leudersdorf, of Pembroke College, Oxford, will shortly be published by the Clarendon Press. It is hoped that this may be useful to students of a subject which has been, comparatively speaking, neglected in this country, although much attention has been paid to it on the Continent. The opportunity has been taken to considerably enlarge and amend the book. All the improvements to be found in the French and the German editions have been incorporated, and a new chapter on "Foci" has been added. The text has been carefully revised throughout, and has received many additions and elucidations, some due to the author himself and others to the translator.

ON the night of Friday the 15th inst. one of the most terrible storms ever witnessed in Vienna occurred there, by which shrubs, trees, and even houses were wrecked; and the cold accompanying was so severe that several persons exposed to it during the night were found frozen to death in the morning. In the Paris *Bulletin International* of the morning of the 16th it is reported that 139 millimetres of snow fell at Vienna. In all parts of Austria and Hungary snow covers vineyards and fields, where the crops were in an advanced condition, and incalculably great damage has been done. The festivals of Pancratius, Servatius, and Boniface, the Ice Saints of 1885, will long be remembered in this part of Europe.

WE have received the report of the Rugby School Natural History Society for the past year. That portion of it which relates to the Temple Observatory at Rugby has already been noticed in these columns. The editors observe that it appears to be a law of the existence of the Society (like that of the animalcule *Amœba proteus*) that an infusion of life into one part produces a corresponding decline in another. For some years the botanical, geological, and archæological sections absorbed all energy, but now there is a decided movement towards zoology and a decline in those sections once most vigorous. A fair start has been made with some zoological collections; the aquarium, however, has proved a failure, and the vivarium labours under the disadvantage of never being reached by the sunlight. Several short and interesting papers are published with the report.

THE Russian Government has sent an official of the Education Department to Vienna to study the State commercial and industrial schools of Austria, these establishments being regarded as models, and the Russian Government intending to organise similar ones.

THE Fish Culture Department at the International Inventions Exhibition has proved a great success and attracted a large concourse of visitors. During the past week many important additions have been made, including a magnificent model of a Fish Culture Establishment exhibited by Mr. T. J. Mann, and a series of oyster beds, demonstrative of the process of breeding and fattening oysters. A special feature has been made of oysters this year in the Aquarium, where they are to be seen in numerous varieties imported from various quarters of the globe. In close proximity to them are exhibited various dredges and implements used in this particular fishery.

THE Count Lütke Medal of the Russian Geographical Society has been awarded this year to a work which deserves a special notice. It is Prof. N. J. Zinger's work on the determination of time by means of corresponding heights of different stars (translated in German by H. Kelchner, and published at Leipzig with a preface of O. W. Struve, under the title: "Die Zeitbestimmung aus correspondirenden Höhen verschiedener Sterne.") The determination of time with great exactitude, for telegraphic determinations of longitudes, by means of easily transportable instruments, has already occupied the Pulkowa astronomers. W. Struve and W. K. Döllen proposed very skilful methods of observations. The latter had proposed to determine the time by means of a special Repsold's circle from two passages of two stars in the prime vertical. The exactitude reached by this means was from 0·05 to 0·06 of a second; the circle had to remain in an unaltered position for no more than five or six minutes; but the whole observation took about forty minutes. Prof. Zinger's method, which is a further development of the work begun by Maupertuis, Olbers, Hauss, Delambre, and Knorre, consists in making two successive observations of two stars chosen for that purpose, at the same altitude, by means of any instruments which may not be divided with great perfection, but whose level would only show the changes the telescope may undergo when directed on two different azimuths. This method was met first with some coolness, on account of the difficulty of finding two stars which would culminate soon after one another at the same altitude. But M. Zinger has shown that even with a moderate telescope it is easy to have two stars easily found and pretty well seen at daylight which pass at the same altitude at an average of no more than nine minutes one after another. His tables render the task of finding such stars very easy, there being in moderate latitudes no less than 160 pairs of stars appropriate to that purpose. As to the ease and accuracy of the method, it is sufficient to say that time is determined with a probable error of no more than 0·04 of a second in no more than half an hour, without even making use of the divisions of the Repsold circle, and with only one reading of the microscope. For several years Prof. Zinger's method has been submitted to a very extensive test by Russian astronomers. So we learn from Gen. Koversky's analysis of it, published in the last "Annual Report" of the Geographical Society, that, when determining by means of light-signals the difference of longitudes between Pulkova and Parlovsk, and using a very plain instrument prepared by M. Brauer on M. Zinger's principles, the difference has been determined with an error of only one-fiftieth of a second. M. Pyertsoff, in Mongolia; Gen. Stebnitzky, in the Caucasus, who considers the determinations of time from corresponding heights of two stars quite as accurate as that deduced from zenithal distances taken with a Repsold circle, but far shorter and easier; the Russian officers in Bulgaria, who have determined with telegraphic signals the longitudes of thirty-seven places in less than seventy evenings, spending no more than three hours each evening for a determination which gave the longitude with an error of only 0·04 to 0·02 of a second; the measurements around Omsk in 1878; those of M. Gladysheff in the Transcaspian, and of M. Mionczyorski on the Ural in 1882–84—all these have been made on the same method of Prof. Zinger, which has now become the most familiar one with Russian astronomers. The measurements are usually made with a Repsold's circle, which is ready for work half an hour after the astronomer has arrived at the place whose longitude he proposes to determine; and in chronometrical expeditions five minutes to a quarter of an hour of a bright sky give the possibility of measuring the longitude with an accuracy quite sufficient for geographical purposes.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♀) from India, presented by Mr. James Fleming; a Common Badger (*Meles taxus*), British, presented by Mr. C. Ethelstone Parke; a —— Wild Ass (*Equus tæniopus* ♂) from the Island of Diego Garcia, Chagos Archipelago, presented by Mr. F. D. Lambert, jun.; a Common Squirrel (*Sciurus vulgaris*), British, presented by Mrs. G. A. Smith; four Red-faced Weaver Birds (*Foudia erythrops*) from South Africa, a Grenadier Weaver Bird (*Euplectes oryx*) from West Africa, presented by Mrs. Herman Kuhne; a Dominican Kestrel (*Tinnunculus dominicensis*), a —— Bittern (*Ardetta* ——), three Martinican Doves (*Zenaida martinicana*), two Moustache Ground Doves (*Geotrygon mystacea*), a Tuberculated Iguana (*Iguana tuberculata*) from the West Indies, presented by Dr. A. P. Boon; two Harvest Mice (*Mus minutus*), British, presented by Mr. G. W. Oldfield; two Demeraran Cock of the Rocks (*Rupicola crocea* ♂ ♂) from Demerara, presented by Mr. T. C. Edwards-Moss; two Mute Swans (*Cygnus olor*), British, presented by Mr. J. W. Gibson; a Horned Lizard (*Phrynosoma cornutum*) from Texas, presented by Master C. A. Greeven; three Common Vipers (*Vipera berus*), British, presented by Mr. W. H. B. Pain; four White-faced Tree-Ducks (*Dendrocygna viduata*), a White Gannet (*Sula piscata*) from Brazil, deposited; a Dark Green Snake (*Zamenis atrovirens*), South European, purchased.

GEOGRAPHICAL NOTES

THE following message from Col. Prjevalsky, dated Lob Nor, March 15 (probably O.S.), is published in the *Invalide Russe*:—"During the last autumn and winter we visited Eastern Zaidam as far as Lob Nor. The middle range of the Kuen Lun, hitherto unknown, has been examined with sufficient care. The ancient route leading from Khoten to China has been found and thoroughly explored. We have also discovered three enormous snow peaks, to which we have given the names of Muscovite, Columbus, and Enigmatical. The most elevated point of the first-named is Mount Kremlin, of the second Mount Djinri, and of the third the Crown of Monomachus, which are all of a higher elevation than 20,000 feet above the sea. The Thibetan plateau, skirting the middle Kuen Lun, has an average height of 4000 feet. No inhabitants were met with except in the Southern Zaidam. Further to the west the flora and fauna of the desert are extremely poor. In the month of December the cold was so intense that the mercury froze. We passed the month of February and the first fortnight of March at Lob Nor. We are just about to set out again, with the intention of crossing Cherchen, for the purpose of reaching Kiria, in the district of Khoten. During the three months of summer we shall traverse Northern Thibet, if the Chinese do not oppose us, and in the autumn we shall return to our own Turkestan. We are all in good health."

THE last issue of the *Izvestia* of the Russian Geographical Society (1885, 1) contains a very interesting paper, by M. Lessar, on "South-Eastern Turcomania," with a map, thirteen miles to an inch, of the region between Merv and Herat. This paper consists of a chapter on the occupation of Merv; a diary of the journey from Fol-otan to Penj-deh and in the Steppes; a geographical sketch of South-West Turcomania; and a translation of Sir Henry Rawlinson's note, by which M. Lessar's account of his first journey was accompanied in the *Proceedings* of the Royal Geographical Society, with a few remarks by the author. Capt. Abbot's remarks on South-West Turcomania and the Badhyz are also translated in an appendix. The geographical description of the region comprised between the oasis of Merv, the Murghab, the Borkhut mountains, and the Hari-rud, which region is described as "South-Western Turcomania," is especially worthy of notice, as a valuable contribution to the geography of the region.

THE Government of India has decided to appoint Mr. Ney Elias, one of the most distinguished of our Chinese travellers, and at present English Commissioner in Ladakh, to act as British Consul at Yarkand and Kashgar.

MR. HOLMAN BENTLEY sends to the *Times* news of the safe return of the Rev. G. Grenfell, F.R.G.S., in the Baptist Missionary Society's steamer the *Peace*, after a voyage on the Upper Congo River from Stanley Pool to Stanley Falls, a distance of 1060 miles. He has explored many of the tributaries on the way—the Mobangi to 4° 30′ N. lat., the Ukere to 2° 50′ N., and the Lubilanji to 1° 50′ S. The Mbura is navigable only for ten or twelve miles from its junction with the Congo, when cataracts bar the way. The Mobangi is a fine river, but the people are very wild.

IN a recent number of *Das Ausland*, Herr Habenicht, of Gotha, makes an important suggestion with regard to observations in Africa. He points out the dearth of accurate observations in latitude, longitude, and heights in the interior of that continent. For instance, with regard to the greater part of North Africa we are dependent on those of Vogel and Barth, while in South Africa those of Livingstone are almost the only ones we have. Even in the interior of the Cape Colony, the Orange Free State, the Transvaal, Namaqualand, the Kalahari desert, our knowledge of exact positions is still in the air. More is known of the central and lower Congo and the coast. To remedy these defects, Herr Habenicht proposes to geographical societies interested in African exploration that the field should be subdivided. Young men should be trained to make astronomical observations, barometrical measurements and itineraries, and two should be despatched on each route with separate sets of instruments. The routes suggested are the following: (1) Cape Town, through Stellaland, to the Zambesi; (2) Delagoa Bay to Stellaland; (3) Cape Town, through Namaqualand and Damaraland, to the Zambesi; (4) Loango to Zanzibar; (5) Zanzibar to the Egyptian Soudan; (6) the Lower Niger, through Darfur, to Khartoum; (7) the Gold Coast to Timbuctoo; (8) Morocco to Timbuctoo; (9) Tripoli to Socoto; (10) Bengazi, through Kufra and Borgu, to Kuka. All previous explorations, he says, would by these observations receive a sound scientific basis.

M. RADDE, the Director of the Natural History Museum at Tiflis, has been ordered by the Russian Government to investigate the mountain systems of the border-lands of Trans-Caucasia and Khorassan, between Ararat and Ala Dagh on the west and Elburz on the east.

FROM a report addressed by Col. Feilberg to the Argentine Minister of Marine on the subject of his mission to explore the Pilcomayo River, it appears that this stream is only navigable for eighty leagues from its mouth in the Rio Paraguay up to its confluent, the Rio Dorado. Five miles higher the rapids commence; there is then only two feet of water, the channel is narrow and very tortuous, and the current swift. The upper waters are lost in marshes, which the traveller crossed. On returning, the water had fallen considerably, and the journey was only accomplished with much trouble and after many accidents. During his stay on the Chaco he reports that he did not see a single Indian, although their tents were still standing in places. One of his officers had been sent with the chronometers to Corientes, to compare them by telegraph with the Observatory of Cordoba or Buenos Ayres. These comparisons are essential for the verification of the observations made, and as soon as they have been obtained, the maps which are to accompany the publication of the journal of the mission will be commenced.

ACCORDING to the *Colonies and India* a conference took place on March 31, by telegraph, between the Melbourne and Sydney branches of the Geographical Society of Australia, on the question of New Guinea exploration. It was decided to subsidise Mr. H. O. Forbes's expedition, to the extent of 500*l.*, on condition that the two Colonies receive copies of the explorer's diary and despatches, and duplicates of his collection of specimens. The Conference also decided to send an independent expedition from the Aird River, the whole expenses to be defrayed by the Society. The expedition will be placed under the leadership of Capt. Everell, who will be accompanied by Herr von Leudenfelt.

THE Report on the trade of Persia by our Consul at Teheran, which has just been laid before Parliament, contains some interesting statistics on the population of Persia, in order to judge how far the country has recovered from the effects of the great famine of 1871–72. The area of the dominions of the Shah is 1,647,070 square kilometres, and the population is estimated at 7,653,000, contained in 99 towns with a total population of 1,963,800, while the villages and rural districts contain 3,780,000, and the nomads are estimated at 7,909,800. It is curious to notice how the number of nomads are made up: the Arabs number 52,020; Turks, 144,000; Kurds and Leks, 135,000; Beluchs and gipsies, 4,140; Bakhtiaris and Lurs, 46,800. The statistics of the creeds are: Sheeahs, 6,860,600; Sunnis and other Mohammedan sects, 700,000; Parsees, 8,000; Jews, 19,000; Armenians, 43,000; Nestorians and Christians, 23,000. Of the Armenian population 52·8 per cent. are males and 47·2 females. Of the Mussulman population the mean proportion is 50·5 per cent. females and 49·5 males. The following is a list of some Persian towns with their respective populations:

Tabreez	164,630	Zenjan	24,000
Ispahan ...	60,000 to 70,000	Cazoin	40,000
Yezd	40,000	Resht (including adjoining villages) ...	40,000
Kerman	41,170	Astrabad	10,000
Shiraz	30,000	Nishapore	11,000
Shuster	under 20,000	Sebzevar	12,000
Dizful	25,000	Meshed	60,000
Burujird	20,000	Kashan	30,000
Kermanshah	30,000	Koom	20,000
Hamadan	30,000	Mianeh	7,000
Maragha	13,250	Mohammera	15,000
Soujboulak	5,000		

Mr. Dickson, taking the medium between the highest and lowest figures he has obtained, estimates the population of Teheran at about 120,000, while Col. Ross estimates that of Bushire at 70,000.

IN *Astron. Nachr.*, vol. cx., Prof. Dr. Auwers has published the results of his researches and calculations about the longitude of some places in Australia. Since these data will have to be altered by the result of the determination of the difference in longitude between Port Darwin and Banjuwangi (Java) we may omit particulars and only state that Mr. Auwers has found to be:—

	h.	m.	s.
Longitude of Sydney	10	4	49·75
" Windsor	10	3	20·92
" Melbourne...	9	39	54·32
" Adelaide	9	14	20·57

INFORMATION has been received in Berlin of the death, in the Cameroons, of Lieut. Tilly, the leader of another German expedition sent out to explore that part of Africa.

A PARLIAMENTARY paper just issued (Commercial, No. 5, 1885) contains an exhaustive report, by Vice-Consul Comberbatch, on the Dobrudja. Under the head of geography it refers to the name, limits, frontiers, area, topography, division, mountains, forests, mines, rivers, marshes, lakes, islands, harbours, and tides of the district. This is succeeded by sections on the climate, history, ancient remains, population, sanitary state, government, public works, religion, education, agriculture, commerce, industries, navigation, natural history, and principal towns. The report, which occupies fifty pages, is thus a short treatise on this district at the mouth of the Danube, of which much was heard in connection with political events a few years ago.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, *MAY* 24–30

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on May 24

Sun rises, 3h. 58m.; souths, 11h. 56m. 36·3s.; sets, 19h. 55m.; decl. on meridian, 20° 51′ N.: Sidereal Time at Sunset, 12h. 5m.

Moon (Full May 28, 21h.) rises, 15h. 16m.; souths, 20h. 59m.; sets, 2h. 33m.*; decl. on meridian, 5° 55′ S.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury ...	3 21 ...	10 21 ...	17 21 ...	11 3 N.
Venus ...	4 14 ...	12 19 ...	20 24 ...	21 47 N.
Mars ...	3 6 ...	10 29 ...	17 52 ...	14 56 N.
Jupiter ...	10 36 ...	17 50 ...	1 4* ...	13 25 N.
Saturn ...	5 19 ...	13 27 ...	21 35 ...	22 21 N.

* Indicates that the setting is that of the following day.

THE VALUE OF A MARINE LABORATORY TO THE DEVELOPMENT AND REGULATION OF OUR SEA FISHERIES[1]

It is a striking fact, to which attention has before now been drawn, that whilst the agriculturist, on whom we depend for a large part of our food supplies, has very largely availed himself of scientific knowledge in the treatment of crops and herds, the fisheries of our coasts, which provide an almost equally large amount of food to the people, have never been carried on with any regard to an accurate knowledge of the fishes on which they depend.

Agriculture is, in this country, a refined branch of chemistry; but there has been no demand for a knowledge of marine life which might enable the fisherman to pursue his calling to the greatest advantage. In fact, our fishery industries are still barbaric; we recklessly seize the produce of the sea, regardless of the consequences of the method, the time, or the extent of our depredations. In the same ignorant fashion as the nomadic herdsmen of Asia descend upon a fertile valley, and after exhausting it, leave it to time and natural causes for its recuperation, so do we treat the fishing-banks of our coast.

So long as fishing was relatively small in amount this method was not altogether objectionable. But with the increase of population, and the introduction of steam fishing boats and more effective instruments of capture, there is reason to believe that some at least of our coast fisheries are being destroyed, and that others may follow in the same direction.

Other civilised nations have perceived the necessity of attempting to regulate the various kinds of sea-fisheries on rational principles—that is to say, on principles based on an exact knowledge of the life and habits of the fishes which it is desired to capture. The French, the Norwegians, and above others, the Americans, have given attention to this matter.

There is reason to believe that the Romans had gained a special skill—now lost—in cultivating sea fish. Whatever that may have amounted to, it is certain that modern Europe has entirely neglected the cultivation, and even the care of sea fisheries. It has been the merit of the Fish Commission of the United States to make the first attempt in modern times to deal with sea fisheries in the spirit of civilisation, that is of men who are determined to understand and control, for the advantage of their race, the operations of nature, rather than to leave things to chance, the unknown development of physical causes.

The direct efforts of the American Commission, and the knowledge which scientific men have accumulated with regard to fishes, without designing aid in the regulation and development of fisheries, do not enable us at present to answer many of the questions with regard to different sea fishes which we urgently require to know if we are to deal like reasonable, practical men with our fisheries, so as to improve them, or even so as to prevent their extermination.

At the late Fisheries Exhibition Congresses, the universal cry, the one unanimous demand, was "more knowledge!" We cannot tell whether beam-trawling with steamboats is injurious or not to some of our most valuable sea fishes, until we have more knowledge. We have not sufficient knowledge to enable us to say that it would restore some herring grounds to their former richness, if the fishermen were kept off those grounds for a few years.

We do not know why soles are getting scarcer every year; we know nothing about soles, and so we can do nothing to remedy their constantly increasing diminution.

We do not know why oysters are scarce, or how to make them more abundant. A few hap-hazard attempts to cultivate oysters are now and then made, but have resulted in an immense loss of money rather than in gain, because we do not know all about oysters in the same precise and detailed way in which we know all about wheat, or all about pigs or chickens.

We do not know why some fishes swim in great shoals year after year at certain seasons near certain spots, and then to the dismay of the fishermen suddenly give up ever passing that way. We do not know whether we could hatch the young of soles, turbot, cod, and other valuable fishes, and stock the sea with them as we do our rivers with trout and salmon.

We do not know whether we could favour the increase of such fishes by cultivating in the sea their favourite food. In many cases we do not know what their food is.

We do not know whether we might increase these fishes by destroying their enemies.

In fact, we know exceedingly little about the minute details of the life of marine animals, and if we wish to deal with sea fisheries like rational men, we must find out these minute details, and gradually apply the knowledge so gained.

A laboratory on the sea-shore, provided with boats and fishermen, and having within its walls tanks for hatching eggs and watching sea fish, and conveniences for the work of naturalists trained in making such observations, is the way to meet the deficiency in our knowledge above noted.

This was perceived many years ago in France, and more recently various laboratories have sprung into existence on the Mediterranean and on the American coast.

There is not, as yet, any such place of investigation on the English coast, and it is this deficiency which the Marine Biological Association, of which my honoured friend, Prof. Huxley, is President, and H.R.H. the Prince of Wales is patron, proposes to meet by building and maintaining a really efficient and thoroughly organised laboratory and experimental aquarium on the shore of Plymouth Sound.

The Association does not propose merely to build this place, but to arrange for the carrying out there of most importan investigations on such questions as those I have a few minutes ago named. They have the hearty and earnest co-operation of all the naturalists in the United Kingdom, Scotch and Irish naturalists having united with their English brethren to form this institution.

Naturalists are glad to take part in the study of these practical questions, because the arrangements and the studies which are necessary to answer the questions of the practical fisherman, are also just those which are necessary to advance the knowledge of the order of nature which forms the single object of truly scientific investigation. They will systematically and eagerly join with one another in the operations of the Plymouth laboratory, to obtain thorough knowledge with regard to the habits, food, breeding, and life-conditions of all kinds of marine fishes, such

[1] Abstract of paper read at the Society of Arts, Wednesday, May 13, 1885. By E. Ray Lankester, M.A., LL.D., F.R.S., Professor of Zoology in University College, London, and Fellow of Exeter College, Oxford.

as will be not only valuable but actually indispensable to the practical fisherman; and in the reports of the work done in the new marine laboratory which will be published by the Association, I do not doubt that the basis for future legislation and for future methods of sea-fishery will be found.

I may here venture to mention some of the results obtained by the efforts of the naturalists who form the United States Fish Commission—at the head of which is Prof. Spencer Baird. I would, however, especially remark that the Commission has only been at work for ten years, and that very great practical results cannot be expected at once. A vast amount of knowledge has to be obtained before we can deal practically with all the various kinds of sea-fishes; and it is to me a proof of the wonderful sagacity and activity of the American naturalists that they have already been able to do what they have done in the practical direction.

Prof. Baird has especially attempted to artificially cultivate sea-fishes. It seems to him that it is better, if it be possible, to replenish the seas by stocking them with young fish, to take the place of those removed by fishermen, rather than to impose legislative restrictions and penalties upon the fishermen. The attempt to artificially cultivate sea fish is an admirable example of the relation of scientific knowledge—that is, thorough and cause-reaching knowledge—to practical commercial operations.

There are two distinct stages in this attempt at artificial cultivation. The first is the scientific. You must ascertain how, when, and where the fish naturally breeds; you must find out, experimentally, how to procure its eggs, fertilise them, and rear the young to a given size—on a small scale. That is the business of the scientific naturalist. When he has ascertained all the details of this operation—which differ entirely in the case of different fishes, and may take years to ascertain—then the second stage is entered on. The commercial man then comes forward, and in the light of the knowledge obtained for him by the scientific man, attempts the hatching of the fish on a large scale—not by the hundred, but by the million.

The American Fish Commission has undertaken both stages of the work, and the second is necessarily a very costly one. A very promising result has been obtained in the artificial breeding of codfish, and again in the case of the shad. [Details of these operations were here given by the author.]

Again, in dealing with the American oyster, the Commission has obtained what promises to be a very great success. [Details of this case were given.]

But there is an almost unlimited field of work before the American Commission.

Experiments and observations similar to those carried out by the American Commission, will be undertaken by the Biological Association at Plymouth. For example, the artificial cultivation of that most valuable of British fishes, the sole, will be at once taken in hand. At present absolutely nothing is known as to the spawning of the sole—the male fish is not even recognised. In the first instance the naturalists at Plymouth will study the eggs and the mode of spawning of the sole, and the way in which the eggs are fertilised naturally. Then the necessary conditions for the rearing of the young fish will be ascertained. After that it will be possible to hatch a vast number of young soles and turn them out into Plymouth Sound, and to determine in this particular area, which is admirably adapted by its natural delimitations for the experiment, whether the take of soles in the Sound has been increased by the operation.

Similar experiments will be tried with other fish; and also knowledge will be gained as to the food of various fishes, and the causes which determine their movements, their increase, and their diminution in the neighbourhood of Plymouth.

This knowledge will help us to form sound and reliable conclusions as to the supposed injurious effects of steam trawlers and other modes of fishing, and so lead on to sensible and valuable legislation in regard to the seasons and modes of fishing best suited to obtain the maximum benefit from the harvest of the sea.

The English oyster, though differing from its American congener, can no doubt be brought under control by a thorough-going knowledge of all the conditions affecting it at all periods of life; and this it will be a first duty of the Marine Biological Association to attain. [Suggested inquiries as to the oyster were here mentioned.]

Lastly, the subject of "bait" is one of great importance, which we shall be able to deal with effectively. Not only shall we find new and effective baits, at present neglected by our line fishermen, but we shall be able to direct the cultivation of such valuable baits as the mussel and the limpet.

There is no fact which gives one so vivid an idea of the immense commercial value of sea fisheries as the amount which is annually expended on mussels for use as bait in those fisheries. There are few statistics on this subject, or indeed on any matters relating to our sea fisheries, and it will be one object of the Marine Biological Association to collect such statistics. But there is a certain amount of information as to the use of mussels for bait. Thus between October, 1882, and May, 1883, twenty-eight boats engaged in the haddock fishery at Eyemouth, in the North of Scotland, used 620 tons of mussels (about 47,000,000 individuals), costing nearly 1800*l.* to the fishermen, that is to say, over a million and a half of mussels for the whole time, or about 7000 a day to each boat—at the rate of one penny for twelve mussels. The total value of mussels used for bait in the deep sea line fisheries of the British coasts must amount to many hundred thousand pounds in a year—and we can only roughly guess at the value of the fish caught by this large expenditure on bait. In spite of the great economic importance of the mussel, its complete history of reproduction and growth is not known, and though in France and Germany it is carefully and profitably cultivated, very few attempts have been made on the British coast to protect or to artificially favour mussel scalps so as to make them remunerative properties.

This is a subject with which a marine laboratory would enable us to deal in a very short time. The same general remarks, *mutatis mutandis*, apply to the second most important bait, viz, the limpet.

Before concluding this sketch of the work which lies before the managers of a marine biological laboratory, I may say a few words as to the nature of the buildings and equipment required for such an institution.

The most efficient scientific laboratory of the kind is that erected at Naples by Dr. Dohrn, a drawing of which is exhibited. The Naples laboratory, with its tanks, row boats, and steam launches, has cost about 20,000*l.*, and involves an annual expenditure of about 4000*l.* A staff of observers is paid out of this sum, and the efforts of the institution have hitherto been entirely directed to the obtaining of accurate scientific knowledge with regard to the fauna and flora of the Bay of Naples. It is justly regarded as one of the most important scientific institutions in Europe.

The United States Fish Commission have erected, from time to time, various small laboratories, and are now about to expend 10,000*l.* on a laboratory at Wood's Hole, and 20,000*l.* on building fish-ponds protected by piers of masonry. Since its commencement, the United States Commission has received from the Imperial revenue about 300,000*l.* In 1884 alone it received 70,000*l.* It must be remembered that these large sums cover the expense of very extensive operations in fish-breeding on a commercial scale, and are not solely for the purpose of preliminary investigation.

The Marine Biological Association proposes to proceed in a modest manner, arranging in the first instance for the carrying out of the necessary experimental inquiries. A site has been obtained on the Citadel Hill, at Plymouth, by permission of the authorities of the War Office, and here will be erected a laboratory, comprising on the ground floor large and small tanks, and above, a series of working rooms fitted with small tanks. Through all a stream of sea-water will be driven by pumping apparatus, from large tanks in the basement, containing several thousand gallons. These reservoirs will only be replenished two or three times in the year. Boats, including a steam-launch, will be required, and two or three fishermen, who will act as attendants. A resident superintendent, who will be a thoroughly qualified naturalist, will be appointed at a salary of 200*l.* a year, and will be lodged on the premises. Naturalists will frequent the laboratory at their own expense for the purpose of study, and from time to time competent investigators will be appointed to carry out particular inquiries. The latter will be paid for their work from special sources, not from the general income of the Association until that reaches a large amount. Great assistance will be afforded to the work of the Association by the local fleet of fishing boats, which is very numerous, and comprises some vessels of large size. It is estimated that a capital sum of 10,000*l.*, and the prospect of an income from annual subscribers, members of the Association and others, of about 500*l.* a year, will enable the important work which has been taken in hand to be commenced. The Council of the Association feel very great confidence that they will be able to obtain annually sufficient funds to keep the laboratory in efficient working order when once the capital sum of 10,000*l*. has been subscribed. Towards the latter amount they have already raised a sum exceeding 5000*l*. From Plymouth as a centre, in the course of future years, the operations of the Association will extend, and additional laboratories will no doubt be constructed hereafter by the Association on other parts of the coast of the United Kingdom, should the first one prove a success, and the work carried out through its agency meet with public approval and support.

Whilst the Marine Biological Association aims at obtaining, by the operations of its laboratory and experimental aquarium, that knowledge which is clearly necessary for the improvement and regulation of our sea fisheries, it must be remembered that its work will necessarily enlarge and advance the great science of biology, and that to many of us this is its surest promise of utility, for we cannot always directly govern the march of scientific progress. The whole field of knowledge must be cultivated, in the simple faith that the increase of knowledge is the greatest good which human effort can achieve. By adopting a thorough and comprehensive scheme of study of the problems connected with the life of fishes, we shall, as invariably happens in the history of science, obtain results which at present we cannot foresee, but which, we may feel assured, will yield in unexpected ways rewards and blessings to humanity.

METEOROLOGICAL INSTRUMENTS

THE Royal Meteorological Society recently held its sixth Annual Exhibition of Instruments at the Institution of Civil Engineers, 25, Great George Street, S.W. This Exhibition was devoted to sunshine recorders, and solar and terrestrial radiation instruments.

The first attempt at obtaining an instrumental record of the amount of sunshine was made by Mr. J. F. Campbell, of Islay, in the year 1853, when he mounted a hollow glass sphere filled with acidulated water, in the centre of a cup of mahogany, so arranged that the sun's rays were focussed on the interior of the cup and burned it. The lines of burning, therefore, indicated the existence of sunshine. Solid glass spheres have been substituted for the hollow ones, and cards in metal frames have replaced the wood; but in its principle the sunshine recorder of 1885 differs little from that erected on Richmond Terrace, Whitehall, thirty years ago. Other modes of recording sunshine are based on the action of the rays of the other end of the spectrum on the actinic instead of the heat rays. Among workers in this direction may be mentioned Marchand of Fécamp, Sir Henry Roscoe, and others. The most recent improvements in this direction are those by Prof. McLeod and by Mr. Jordan.

With regard to solar radiation thermometers, the successive stages in the assumed perfecting of these instruments have been as follows:—An ordinary mercurial thermometer acts as a spherical mirror, and reflects the rays which fall upon it. To lessen this the bulbs were first made with black glass; moreover, originally the degree marks were put upon the supporting slab, then they were put upon the tubes of the thermometers. It was then found that in a position where two thermometers with similarly coated bulbs were exposed to the sun, but one was exposed to more wind than the other, the indicated temperatures varied greatly. To avoid this it was proposed that the thermometer should be inserted in a glass shield exhausted of air. Various forms of mounting have been adopted, but the chief efforts have been expended in determining the influence of the amount of air left in the so-called vacuum. The next stage was that, inasmuch as black glass had a bright surface, there was still much light reflected, and therefore the surface was dulled with a coat of lamp-black—so that all heat falling upon the bulb might be absorbed. Subsequently, owing to the influence of the lower temperature of the unblackened thermometer tube, about one inch of it was coated like the bulb. As evidence of the degree of exhaustion, a small mercurial pressure gauge was attached to the thermometer, and by other makers platinum wires were soldered through the shield so that the stratification of the electric arc might indicate the amount of air still left.

With regard to terrestrial radiation thermometers, the pattern of instrument used has varied very little. The Rutherford minimum has almost always been used, but its sensitiveness has gradually been increased: the spherical bulb was replaced by a cylinder, the cylinder was elongated and bifurcated, and eventually, in order to strengthen the forks, they were united into what is known as a "link." Another plan was to flatten the cylindrical bulb into as thin a plate as possible, this giving a maximum of surface in proportion to the contents. The bulb was also made double, and thus we have the so-called "bottle" pattern, and then the tube was let into the side of the bottle, and both ends of the bottle were left open, and so we have the "open cylinder"—a remarkable specimen of glass-blowing. Then there have been two patterns of mercurial thermometers—Casella's and Negretti's. Difficulties have arisen from the degree marks being obliterated by the weather. To guard against this the tube has been inclosed in what are known as Leach's shields, and many attempts have been made to render the joint at the entrance of the tube watertight. This is not easy, because the thermometer is exposed to a great range of temperature, and the air inside the shield varies so much in volume that it forces its way through almost every joint. The object is, however, effected when the external jacket is sealed on the stem near the bulb.

In addition to specimens illustrating the various patterns of the above instruments, the Exhibition also included a number of new instruments, and many interesting photographs, sketches and diagrams. The photographs of clouds and lightning were very good.

At the meeting of the Society the President, Mr. R. H. Scott, F.R.S., read a paper giving a brief account of the various instruments and arrangements to be found in the Exhibition for the purposes of recording solar and terrestrial radiation and the duration of sunshine both in regard of its light and its heat, the last-named being obtained by means of the sunshine recorders, which are now pretty generally used. He exhibited twelve monthly maps showing the percentage proportion of hours of recorded sunshine to the hours the sun was above the horizon in the various districts of the United Kingdom. He stated that the features which strike any one on examining the maps of sunshine, which are for the most part for the five last summers and for the four last winters, excluding January to March, 1885, which has not yet expired, are:—First, the broad fact that the extreme south-western and southern stations are the sunniest, as has already frequently been pointed out. Jersey is undoubtedly the most favoured of our stations in this particular. Second, that in the late autumn and winter Ireland is much sunnier than Great Britain, Dublin having absolutely the highest percentage of possible duration of sunshine in November and December, and being only equalled by Jersey in January. The Dublin instrument is not situated in the city, but at the Mountjoy Barracks in the Phœnix Park, beyond the Vice-regal Lodge. The north-east of Scotland is also exceptionally bright, as the station, Aberdeen, lies to leeward of the Grampians. In April the line of 40 per cent. of possible duration takes in Jersey, Cornwall, Pembrokeshire, the Isle of Man, and the whole of Ireland except Armagh. The absolute maximum of the year occurs in May, and the amount rises to 50 per cent. (nearly to 60 in Jersey) over the district just mentioned as enjoying 40 per cent. in April. In June there is a falling off, which is continued into July and even into August in the Western Highlands. In the South of England, however, a second maximum occurs in August, the figure for Jersey rising to 50 per cent. This is mainly due to the exceptionally bright weather of August, 1884, in the southern counties of England. In September, Ireland shows a falling off, and the greatest degree of cloudiness is in Lincolnshire. In October, the Midland Counties of England are the worst off. In November the line of 40 per cent. encloses two districts, one Dublin, already mentioned; the other the Eastern Counties (Cambridge and Beccles). The absolutely highest monthly percentages in the period under consideration are in the month of May, 1882, in which St. Anne's Head, Milford Haven, had 62 per cent., while Geldeston (Beccles), Douglas (Isle of Man), and Southbourne (Bournemouth) show 61 per cent.

SCIENTIFIC SERIALS

THE *American Journal of Science*, April.—On the use of carbon bisulphide in prisms, being an account of experiments made by the late Dr. Henry Draper of New York. The results so far obtained by Dr. Draper in his investigations on the cause of the difficulties encountered in the use of carbon bisulphide in prisms seemed so valuable and so likely to prove useful to others engaged in photographing the prismatic spectrum that it was decided to publish them in the *American Journal of Science*.

With the assistance of Mrs. Draper, Mr. George F. Barker was accordingly requested to collect from Dr. Draper's copious notes the facts here detailed in connection with his experiments. Some supplementary measurements have also been made to test the efficiency of the apparatus.—The genus Pyrgulifera, Meek, and its associates and congeners, by Charles A. White. These molluscan forms, constituting the Bear River Laramic fauna of the author, are not found among any other North American fauna, either fossil or recent, but appear to have their congeners in a fauna still surviving in Lake Tanganyika, Central Africa, as well as in the Upper Cretaceous fresh-water deposits of Hungary.—On the occurrence of native mercury in the alluvium in Louisiana, by Ernest Wilkinson. Native mercury has recently been unexpectedly discovered at Cedar Grove Plantation, Jefferson Parish, Louisiana, where it is found disseminated in small globules in the mean proportion of 0·002934 per cent. throughout the alluvial soil. It also occurs elsewhere in the same region in such large quantities and under such general conditions that its presence can hardly be attributed to human agency. Yet no other explanation is offered of this curious phenomenon.—Remarks on the series of earthquakes that have recently devastated the southern provinces of Spain, by C. G. Rockwood, jun.—On the structure of the spores or spore-like bodies (*Sporangites huronensis* of Sir J. W. Dawson) occurring in the Devonian formations of North America, by J. M. Clarke.—Denudation of the two Americas, by T. Mellard Reade. In this paper the author follows up the calculations already made by him regarding the quantity of matter annually removed in river water from the surface in England and Wales and some of the river basins of the European continent. Here the Mississippi, Amazons, and St. Lawrence basins are dealt with, the results confirming the provisional assumption that about 100 tons of rocky matter are dissolved by rain per English square mile per annum throughout the world.—On Arctic Interglacial Periods, by Dr. James Croll. It is argued that the Polar Interglacial periods were more marked than the Glacial, and that they neither did nor could exist *simultaneously* in both hemispheres. In a concluding note the author remarks that this will probably be his last paper on questions relating to geological climate, advancing years and declining health obliging him to abandon the subject in order to finish some work in a different field of inquiry which has been laid aside for over a quarter of a century.—Notes on some apparently undescribed forms of fresh-water Infusoria, No. 2 (with Plate III.), by Dr. Alfred C. Stokes.—Palæozoic notes; new genus of Cambrian Trilobites Mesonacis, by Charles D. Walcott.

Bulletin de la Société d'Anthropologie de Paris, 4e Fascicule, 1884.—The sequel to the "Anthropology of California," by M. Ten Kate.—Observations on the anthropological character and social conditions of the M'zabites, by Dr. Charles Amat, who has added to the results of his personal study of the people a brief summary of their history, derived from the chronicle of Abou Zakaria, translated by M. Masqueray, while he is indebted to a brother officer, M. Motylinsky, for much interesting information regarding the language, which differs entirely from Arabic, and presents close affinities with the dialects of the Berbers. The people, who are a remnant of the ancient sect of the Karidjites, retain many traces of pre-Moslem usages and forms of belief, follow agricultural pursuits, and are the main purveyors of corn in the Sahara.—Notes, by Dr. Hyades, on the Fuegians, considered from a hygienic and medical point of view.—On the significance of the name of the Aryans, by M. Ploix, who attempts to prove its derivation from a Sanscrit root indicating "white." This hypothesis is very forcibly attacked by M. O. Beauregard, who, in a subsequent communication to the Society, brings forward strong evidence to show that the etymological meaning of the term is "noble" or "venerable."—A report on the project of instituting an official anthropometrical examination of the pupils in the primary schools of Paris, by M. Manouvrier.—On the influence of the American medium on the races of the Old World, by M. de Quatrefages.—Notes by M. Pietrement in support of his opinions regarding the age of iron, which had been called in question by M. Mortillet.—Communication, by M. de Rialle, of M. Macey's account of a grave, discovered near Saïgon, Cochin China, in 1882. According to the opinion of the few natives who are versed in local archæology, this grave, which was discovered twelve feet below the surface, dates back at least 400 years. From the lower of the two superposed coffins, besides a few vertebræ and the tibiæ, a cranium was extracted which presents a deep perforation above the right temporal that may be regarded as the cause of the death of the Annamite chief to whom the remains belonged.—Report, by M. de Ujfalvy, of the finds obtained from a Celtic cemetery near Rosegg, in the valley of the Drave. The tumuli, of which there are more than 300, resemble in structure and general contents those opened at Hallstadt and in Styria, but in addition they have yielded a large number of curious little leaden figures of wheels, birds, men on horses, &c., attached to the surface or margins of the various vases.—On some crania from the Merovingian graves at Fermes (Oise), by M. de Maricourt, with an extensive series of measurements, which, according to him, afford strong presumptive evidence of diseases having a scrofulous or syphilitic origin.—On the Gallic rock-tumuli of Port Bara (Quiberon), by M. Gaillard.—On an elephant's tusk found in the valley of the Drance (H. Savoie), by M. D'Acy. This find was obtained at 3000 feet above the level of the sea, and is believed to belong to a relatively recent representative of *Elephas primigenius*.—On the manufacture of fire-flints still existing in France, by M. P. Salmon. This industry is chiefly carried on near Percheriou (Loir-et-Cher), whence large numbers of flints are annually exported to supply the demand still existing for them among Central African and other savage tribes.—Communication, by Dr. Verrier, regarding the work of Dr. Engelmann, of Louisville, on the various modes of delivery prevalent amongst women of different races.—On the different powers of resisting cold shown by various races, by M. Maurel.—On a placental anomaly in a case of twin-delivery, by Dr. Verrier.—Notes on the crania of three idiots, by Drs. Doutrebente and Manouvrier.—Observations on the static and dynamic conditions by which man is enabled to stand erect, by Dr. Fauvelle.—Researches on the so-called "Maye" of Provence, by Dr. Berenger-Ferand. The paper is an enlarged exposition of an earlier notice, which appeared in 1883, on the Provenzal customs of our own times, in which the author sees a survival of the ancient worship of Maia—as are our own May queen, Florrie games, jack in the green, and other May festivals—the long ages of Christianity having modified but not obliterated the traces of paganism.

Rendiconti del Reale Istituto Lombardo, March 12.—Note on the kinetic theory of the gases and on the limits of the terrestrial atmosphere, by Prof. R. Ferrini.—On some geometrical, statical, and kinematic properties of articulated polygons, by Prof. G. Jung.—A comparison of the respective merits of Bellani's lucimeter and the English heliograph constructed by Negretti and Zambra, of London, by Giovanni Cantoni.—On some uniform representations in the higher mathematical analysis, by Prof. Giulio Ascoli.—On some remarkable features of the stratified rocks in the Valtravaglia district, North Lombardy, by Prof. Taramelli.—On the question whether rice should be considered as a contraband of war, by Ercole Vidari.

April 9.—Historical notes on the comet of the year 1472, by Prof. G. Celoria.—On the geometrical movement of invariable systems, by Prof. C. Formenti.—Remarks on the cholera bacilli observed and described by Pacini in his various medical publications, by Prof. L. Maggi.—Further observations on uniform representations, by Prof. Giulio Ascoli.—Note on the traces of Roman jurisprudence in the Longobard edicts, by Prof. P. del Giudice.—Critical examination of the proposed Italian penal code punishments, by E. A. Buccellati.

Bulletin de l'Académie Royale de Belgique, March 7.—A word on the two Balenopteræ cast ashore at Ostend in the years 1827 and 1885, by P. J. Van Beneden.—Observations of Wolf's comet made at the Brussels Observatory (0·15 m. equatorial), by L. Niesten.—Observations of Encke's comet made at the same observatory, by E. Stuyvaert.—On the early epochs of Flemish history, by Alphonse Wauters.—Note on Louis du Tielt, painter and engraver, who flourished at Ypres during the seventeenth century, by Ch. Piot.

SOCIETIES AND ACADEMIES

London

Royal Society, January 22.—"Observations on the Chromatology of Actiniæ," by C. A. MacMunn, M.A., M.D. Communicated by Prof. M. Foster, Sec.R.S.

The conclusions arrived at may in part be summed up as follows.—

(1) *Actinia mesembryanthemum* contains a colouring matter which can be changed into *hæmochromogen* and *hæmatoporphyrin*;

this is present in the other species mentioned above, and from its characters it is provisionally named *Actiniohæmatin*.

(2) It is not actiniochrome (a pigment found by Prof. Moseley in the tentacles of *Bunodes crassicornis*), as its band occurs nearer the violet than that of antiniochrome. Moreover, both actiniochrome and actiniohæmatin can be extracted with glycerin, in which the latter is convertible into hæmochromogen, but the former remains unchanged. Actiniochrome is generally confined to the tentacles, and is not respiratory, actiniohæmatin occurs in the ectoderm and endoderm, and is respiratory.

(3) A special colouring matter is found in *Sagartia parasitica*, different from either of the above, and this too exists in different states of oxidation. It is not apparently identical with that obtained by Heider from *Cerianthus membranaceus*.

(4) In the mesoderm and elsewhere in *Actinia mesembryanthemum* and other species, a green pigment occurs which alone and in solution gives all the reactions of *biliverdin*.

(5) *Anthea cereus*, *Bunodes ballii*, and *Sagartia bellis*, yield to solvents a colouring matter resembling chlorofucin, and all the colouring matter, which in them shows this spectrum, is derived from the "yellow cells" (= symbiotic algæ), which are abundantly present in their tentacles and elsewhere. It is not identical with any animal or plant chlorophyll, as is proved by adding reagents to its alcoholic solution.

(6) When "yellow cells" are present, there appears to be a suppression of those colouring matters which in other species are of respiratory use.

April 23.—"Magnetisation of Iron." By John Hopkinson, M.A., D.Sc., F.R.S.

The paper contains an account of the results of experiments which have been made on a considerable number of samples of iron and steel of known composition, including samples of cast iron, malleable cast iron, wrought iron, ordinary steels, manganese, chromium, tungsten, and silicon steels. The electrical resistance and the magnetic properties are determined in absolute measure. Amongst the electrical resistances the most noteworthy fact is the very high resistance of cast iron, as much as ten times that of wrought iron. The fact that manganese steel is almost non-magnetic is verified, and its actual permeability measured. The action of manganese appears to be to reduce the maximum magnetisation of steel, and in a still greater ratio the residual magnetism, but not to affect the coercive force materially. It is shown that the observed permeability of manganese steel containing 12 per cent. of manganese would be accounted for by assuming that this material consists of a perfectly non-magnetic material, in which are scattered about one-tenth part of isolated particles of pure iron. Some practical applications of the results are discussed.

April 30.—"Further Observations on Enterochlorophyll and Allied Pigments." By C. A. MacMunn, M.A., M.D.

In a paper read before the Royal Society in 1883, the writer described the spectroscopic and other characters of enterochlorophyll which was obtained from the liver or other appendage of the *enteron* of various invertebrates (hence the name). It is now shown that this pigment is *not* due to the presence of symbiotic algæ, or *immediate* food-products, but is built up by the animal containing it.

Taking the six bands[1] of vegetable chlorophyll in alcoholic solution described by Kraus, the first two and the fourth are coincident with those of enterochlorophyll in a similar solution; the third band is, however, frequently missing from the latter. The fifth and sixth bands belong to the yellow constituent, which Hansen shows to be a lipochrome; the corresponding bands in the case of enterochlorophyll also belong to a lipochrome, and are not always coincident with the lipochrome bands of plant-chlorophyll. This was proved by saponifying enterochlorophyll by Hansen's method (as described in NATURE, vol. xxx. p. 224). But saponification of vegetable chlorophpll changes it considerably, as bands of a solution, before saponifying, do not correspond with those of a similar solution after saponifying. Hansen's results were confirmed as far as the separation of "chlorophyll green" and "chlorophyll yellow" are concerned, and the crystals described by him obtained.

While the dominant band of "chlorophyll green" in solutions of plant-chlorophyll is moved much nearer the violet by saponifying, or split up into two in some cases, the corresponding band of enterochlorophyll disappears *in toto*, or remains in the same place. Another difference was also noted in the case of enterochlorophyll and in the case of *Spongilla* chlorophyll, namely, that it is impossible to bring about a *complete* separation of the constituents in most cases by saponifying and treating as Hansen directs.

All the bands of a solution of *Spongilla* chlorophyll are coincident with those of a similar solution of plant chlorophyll, as already proved by Prof. Lankester and Mr. Sorby.

From the enterochlorophyll of *Uraster rubens* crystals of "chlorophyll yellow" and "chlorophyll green" were obtained by saponifying.

Morphologically, enterochlorophyll occurs—as proved by the examination of fresh-frozen sections—in oil-globules, granules, and dissolved in the protoplasm of the liver cells; no starch or cellulose could be found in such sections after adopting the usual botanical precautions.

Hence enterochlorophyll is an animal product, and a chlorophyll, of which there are probably several occurring in animals.

[1] The five bands in a leaf, as described by Kraus, can be seen by using a micro-spectroscope of small dispersion and good substage achromatic condenser.

Geological Society, April 29.—Prof. T. G. Bonney, D.Sc., LL.D., F.R.S., President, in the chair.—James Backhouse, Percy Bosworth Smith, and James Shipman were elected Fellows of the Society.—The following communications were read:—On the structure of the ambulacra of some fossil genera and species of regular Echinoidea, by Prof. P. Martin Duncan, M.B. (Lond.), F.R.S., V.P. Linn. Soc. After noticing the general knowledge which exists about the structure of the ambulacra in the Cidaridæ and the elaborate investigations of Lovén on the Triplechinidæ, the author brought before the Society the results of his own work with and without the cooperation of his fellow-worker in the description of the Echinoidea of Sind, Mr. Percy Sladen, F.G.S., and which referred to the Diadematidæ and the Arbaciadæ of the recent faunas. Starting with the knowledge of the construction of the modern Diadematidæ, the author investigated the genera *Hemipedina*, *Pseudodiadema*, *Pedina*, *Hemicidaris*, *Diplopodia*, and *Cyphosoma*. The necessity for the re-establishment of the genus *Diplopodia* was shown, and a new genus, *Plesiodiadema*, was founded. *Pseudodiadema*, shorn of the forms included in these genera, remains and differs more from *Diadema* than has been believed. The method of the growth of the great plates of *Hemicidaris* was explained, and the comparison between the peristomial plates of some of the Diadematidæ and the universal structure of the ambulacral plates in *Pedina* was made. The author considered that there are six types of ambulacra in the regular Echinoidea, so far as the group has been investigated, there still remaining much to be done. These types are the Cidaroid, Diadematoid, Arbacioid, Echinoid, Cyphosomoid, and Diplopodous. In conclusion the succession in time of the structures which characterise these types was considered.—The Glacial period in Australia, by R. von Lendenfeld, Ph.D. Communicated by W. T. Blanford, LL.D., F.R.S., Sec.G.S. Although several previous writers have suggested that boulders and gravels found in different parts of Australia are of glacial origin, the evidence is vague, and no clear proof of glaciation has been brought forward. During a recent ascent of the highest ranges in Australia, parts of the Australian Alps, the author succeeded in discovering a peak which he named "Mount Clarke," 7256 feet high, and in finding traces of glaciation in the form of *roches moutonnées* throughout an area of about 100 square miles. The best-preserved of the ice-worn surfaces were found in a valley named by the author the "Wilkinson Valley," running from north-east to south-west, immediately south of Müller's Peak and the Abbot Range. No traces of ice-action were found at less than 5800 feet above the sea. The rocks showing ice-action are all granitic, and the fact that the surfaces have been polished by glaciers is said to be proved by the great size of such surfaces, by their occurrence on spurs and projecting points, by many of them being worn down to the same general level, and by their not coinciding in direction with the joints that traverse the rock. In conclusion the author briefly compared the evidence of glacial action in Australia with that in New Zealand.—The physical conditions involved in the injection, extrusion, and cooling of igneous matter, by H. J. Johnston-Lavis, M.D., F.G.S., &c. The great disproportion between the displays of volcanic activity in the same volcano at different times, and between the eruptions of different volcanoes, is a subject deserving the most attentive consideration. The violence of a volcanic outburst does not bear any relation to the quantity of material ejected. The union of water with lavas may be compared with the solution of a gas in water; but there is reason to believe that in their deep-seated sources lavas contain little or no water. If igneous matter be extruded through dry strata the eruption might take place without explosive manifestations. But if igneous matter be extruded through water-bearing beds, a kind of dialysis would take place between the igneous and aqueous masses. In this way the tension of the steam in the fluid rock may at last become so great that a fissure will be formed at the surface and volcanic action will follow. In this way the violence of a volcanic eruption will be determined by the quantity of water contained in the strata through which the lava passes in its passage to the surface, and by the temperature at which it reaches the surface. This theory explains the acknowledged sequence of volcanic outbursts of different degrees of violence, and the intervals which occur between them. It also explains the differences between the central and lateral eruptions of a great volcano and the phenomena attending its extinction. The structures of the igneous rocks, whether of basic or acid composition, are greatly modified by the presence in them of volatile ingredients. The succession of events indicated by the structure of Monte Somma and Vesuvius, Roccamonfina, Monte Vulture, and Monte Nuovo show that after a long cessation of volcanic activity we have an extensive production of fragmentary and scoriaceous material, and that this is gradually succeeded by the eruption of lava-streams. The water and other volatile substances, such as sulphates and chlorides, which are given off abundantly in volcanic eruptions, may act as solvents for the various minerals which constitute lavas.

Physical Society, May 9.—The meeting was held in the Physics Theatre of Clifton College, Bristol, in consequence of an invitation from the British Naturalists' Society, Prof. Guthrie, President, in the chair.—Messrs. E. Cleminshaw, E. F. Herrom, and A. L. Selby were elected members of the Society.—The following communications were read:—On evaporation and dissociation, by Prof. W. Ramsay and Dr. S. Young. The authors gave the results of a series of investigations undertaken with the view of determining how far the passage of a liquid into a gas resembled the dissociation of a chemical compound. For this purpose the relation between the pressure and temperature of several dissociating substances such as ammonic carbonate, chloral hydrate, and phthalic acid had been examined. The authors hope shortly to publish the full details of these experiments and the conclusions arrived at.—On a model illustrating the propagation of the electro-magnetic wave, by Dr. S. P. Thompson. The model consists of two sets of beads. Each set is composed of a number of beads fixed to the extremities of wires, and by a suitable mechanical contrivance each executes an approximately harmonic motion at right angles to the wires and the mean plane of the set. The phase of each bead differing by a certain small amount from the succeeding, the whole represents a wave-propagation. The two sets are coloured differently and are so placed that their harmonic motions are executed at right angles about the same axis which represents the direction of propagation of an electro-magnetic disturbance, one wave being the electrostatic and the other the electro-magnetic displacement.—On a self-recording stress and strain indicator, by Prof. H. S. H. Shaw. This instrument was designed for one of Wicksteed's 50-ton single lever machines lately erected in the Engineering Laboratory of University College, Bristol, and has been found very simple and effective. In this testing machine the stress is applied by moving a mass of 1 ton along a lever; this mass is connected by a cord with a vertical cylinder upon the indicator. This cylinder carries a paper wound around it, and turns upon its axis as the mass is moved towards the end of the lever. A pencil capable of a vertical motion bears against this, and thus horizontal distances upon the paper are measures of stress. The strain is measured by the vertical motion of the pencil, the position of which is controlled by a wire attached to the rim of a wheel above, upon the same axis of which are other smaller wheels, any one of which can be connected to a fine wire which is carried horizontally to the upper end of the test-piece passing over a pulley fixed to it, and is fixed to the lower end. Any extension of the test-piece can be multiplied at pleasure on the diagram by attaching the wire to a larger or smaller wheel.—Note on the so-called silent discharge of ozone generators, by Mr. W. A. Shenstone. Mr. Shenstone had arranged some apparatus by which this could be viewed. It seemed to have the characteristics of the Brush discharge.

EDINBURGH

Royal Society, April 20.—Robert Gray, Vice-President, in the chair.—In a paper on the effect of pressure on the temperature of minimum compressibility of water, Prof. Tait showed that the various results obtained admitted of easy deduction from theory.—A note on the variation by pressure of the melting-point of paraffin, &c., by Mr. W. Peddie; and a note on the thermal effects of tension in water, by Mr. G. N. Stewart, were submitted by Prof. Tait.—Mr. Hugh Robert Mill read a paper on the temperature of the water in the Firth of Forth, describing the work done at the Scottish Marine Station in this direction. The annual range of temperature, from summer maximum to winter minimum, was found to vary from nearly 40° F. at Alloa, where the river is fresh at low tide, to 20° at Queensferry, twenty miles seaward, and 10° at the mouth of the Firth thirty-five miles further on. The mean temperature of the water appeared to be the same—47°·5—at all parts of the estuary. From June to September the river was warmer than the sea, from October to May it was colder, the average rise or fall in temperature at any time along the Firth being 0°·07 per mile. During the summer period the surface-water had a higher, and during winter a lower, temperature than that beneath. The annual minimum was reached in February, the maximum in August, and there were indications of the period being delayed toward the open sea. Materials are unfortunately wanting for discussing the variations of temperature in the North Sea beyond the influence of land. Mr. Mill showed curves of the monthly mean temperatures of the water plotted by the use of polar coordinates. Each month was represented by an angle of 30°; the temperature being measured on the radius, equal values were shown as concentric circles. Temperatures so plotted appear as closed curves, and in several cases those for the water resembled a circle placed eccentrically to the circles of reference. This method of curve-drawing has several advantages over that by the use of rectangular coordinates where periodic phenomena are to be represented.—Mr. J. T. Cunningham, of the Marine Station, read a paper on the relations of the yolk to the gastrula in teleosteans and in other types.

Mathematical Society, May 8.—Mr. A. T. G. Barclay, President, in the chair.—Prof. Chrystal read papers on repeated differentiation, and on a process for finding the differential equation of an algebraic curve. Dr. Thomas Muir made a communication on integration formulæ, and gave a historical note on the so-called Simson line.—Mr. J. S. Mackay contributed several mnemonics for certain mathematical constants.

SYDNEY

Linnean Society of New South Wales, Feb. 25.—Prof. W. J. Stephens, M.A., F.G.S., President, in the chair.—The following papers were read:—On some reptiles from the Herbert River district, Queensland, by William Macleay, F.L.S., &c. Five new species are here described, *Hinulia picta*, and *Tetradactylus guttulatus* of the family Scincidæ, and of Ophidians *Nardoa crassa*, *Tropidonotus ater*, and *Hoplocephalus assimilis*.—Notes on certain Ceylonese Coleoptera, described by the late Francis Walker, by A. Sydney Olliff. In these notes Mr. Olliff, who had examined Mr. Walker's types in the British Museum, endeavours to clear up the synonymy of the Clavicorn families. The name *Asana* was proposed for the *Trogosita rhyzophagoides* of Walker, which cannot be referred to any known genus. In form it resembles *Lipaspis*, but is characterised by the presence of a scutellum.—On the flight of birds, by R. von Lendenfeld, Ph.D.

PARIS

Academy of Sciences, May 11.—M. Bouley, President, in the chair.—Remarks on the application of photography to the mapping of the stars by means of MM. P. and Pr. Henry's new objectives, by M. Mouchez. The first essays with an objective of 0·16 m. and a provisionary apparatus proved so successful, that a new instrument has been constructed with two objectives of 0·24 m. and 0·34 m. respectively. Although not yet completely regulated, this instrument has already yielded some remarkable results, fully justifying, if not exceeding, the hopes entertained by astronomers. It appears to have once for all solved the problem how to apply photography to the construction of a map of the heavenly bodies which shall include stars of the 14th and 15th magnitudes.—On the spontaneously reversible spectral rays, and on the analogy between the laws of their distribution and intensity with those of the hydrogen rays, by M. A. Cornu.—On the electric conductibility of solid mercury and of pure metals at low temperatures, by MM. Cailletet and Bouty. From numerous experiments made with mercury, silver, tin, aluminium, magnesium, copper, iron, and platina, the authors conclude that the electric resistance of most pure metals decreases regularly when the temperature is lowered from 0° to – 123°, and that the coefficient of variation is apparently much the same for all. It seems probable that the resistance would become extremely slight at temperatures lower than – 200°, although this point has not yet been practically tested.—Note on the action of aluminium on the chloride of aluminium, by MM. C. Friedel and L. Roux.—An inquiry into the reason which renders mechanical exciters incapable of bringing into play the excito-motor regions of the brain proper, by M. Vulpian.—Remarks on MM. A. F. Marion and G. de Saporta's "Evolution of the Vegetable Kingdom," by M. Duchartre.—On a method of reconnoitring the enemy's position at great distances with a description of the telemetrograph, an instrument invented for carrying out these operations (one illustration), by M. A. Laussédat.—On the cure of progressive myopy by the processes of iridectomy and sclerotomy, with remarks on the theory of this ophthalmic affection, by M. H. Dransart.—Note on the theory of the figure of the earth, by M. O. Callandreau.—Remarks on a new and accurate method of astronomic observation by means of a fixed lunette attached to the meridian, by M. Ch. von Zenger. By this simple process the angle of position and the distance of the double stars may be determined and measurements taken of the parallax of the sun or the stars. For simple observations a precision of 0"·02 may be relied upon which is considerably greater than that hitherto obtained by the use of the most accurate and powerful meridian lunettes.—Results of experiments undertaken at the national powder mills of Pont-du-Buis with the regulating apparatus of two turbines for the purpose of testing the conclusions deduced from M. Léauté's memoir on oscillations at long intervals in machinery set in motion by hydraulic agency, by M. A. Bérard.—On the polarisation of the metallic capillary tubes by the flow of fluids under high pressure, by M. Krouchkoll. When a conducting fluid is driven through a capillary metallic tube at a pressure of less than fifteen atmospheres, the tube and the fluid being placed in communication with the mercury of a capillary electrometer, no polarisation of the tube takes place. But if the pressure be raised, the author shows that the tube begins to become polarised, the polarisation increasing with the pressure.—Description of a new electric pile, at once simple and cheap, which has been named the "self-accumulator" by the inventor, M. Jablochkoff. For this pile it is claimed that it emits no odour, that it utilises the local currents which are so troublesome in ordinary piles, and especially that it supplies electric power at a very low price, for in it filings, cuttings, and other waste forms of metals may be employed.—On the tensions and critical points of some vapours, by MM. C. Vincent and J. Chappuis. The author's observations are here confined to hydrochloric acid and the chloride of methyl, the object being to show how the maxima tensions of a series of liquefied gases vary with the temperature, to determine the critical points of these products, and to compare the results obtained for the purpose of verifying the hypotheses advanced by MM. Nadejine and Pawlowsky. — Note on the oxychlorides of aluminium, by MM. P. Hautefeuille and A. Perrey.—On the apparent volatilisation of silicum at a temperature of 440°, by MM. P. Hautefeuille and A. Perrey.—Note on a method of preparing arsenical acid, and on the existence of combinations of arsenious and arsenical acids, by M. A. Joly.—On the limit of combination for the bicarbonates of magnesium and potassium, by M. R. Engel.—On a hydrochlorate of protochloride of chromium, by M. Berthelot.—A calorimetric study on the effects of the tempering and cold-hammering of cast steel, by M. Osmond.—Remarks on the mineralogical constitution of the Sierra Nevada of the Iberian Peninsula, by M. Guillemin-Tarayre.—On the liberation of carbonic acid and the absorption of oxygen by leaves kept in dark places, by MM. P. P. Dehérain and L. Maguenne.—Note on a new gutta-percha plant, by M. E. Heckel. As a substitute for the Isonandra gatta, Hooker, which is threatening to disappear, the author proposes the *Butyrospermum Parkii*, Kotschy, which possesses similar properties, and which is widely diffused throughout equatorial Africa, between Upper Senegal and the Nile basin.—A fresh contribution to the question of the origin of boric acid: analysis of the Montecatini waters between Florence and Pistoja, by M. Dieulafait.—On an arrangement enabling the observer to follow with the eye the phenomena presented by aquatic animals subjected to a pressure of 600 atmospheres, by M. P. Régnard.—On a new apparatus intended to detect infinitesimal quantities of blood wherever present in fluids or on solid substances, and named the "hema-spectroscope" by the inventor, M. M. de Thierry.—On pathological urines, by M. A. Villiers.—Note on a method for measuring the intensity of sensations, and especially those of colour, by M. Aug. Charpentier.—On the formation and development of the spores in *Cladothrix dichotoma*, by M. A. Billet.—A study of the Bacterium ureæ, by M. A. Billet.—Remarks on the cause of a new epidemic recently prevalent amongst the domestic ducks in the neighbourhood of Castres, Tarn, by M. A. Caraven-Cachin. This disease, which at one time raged with great violence, was ultimately traced to the leaves of the *Ailantus grandulosa*, Desf., or varnish of Japan, growing in the district and eaten by these birds.

Berlin

Physiological Society, April 17.—Prof. Busch spoke on anomalies in human teeth, and illustrated his observations in part by preparations laid before the Society, in part by plaster casts. In the first place he treated of anomalies of situations he had observed in teeth—the horizontal position of a wisdom tooth, which, pressing against the third molar, produced inflammation in the latter; the projection of teeth through the aveolar wall of the maxilla on the anterior or posterior side, an occurrence happening mostly in the case of permanent canine teeth which pushed their way through at a late period, when there was no place left for them in the jaw; the exchange of situation between the canine tooth and the first bicuspid in the order of the teeth. Another kind of anomalies respected the number of the teeth, especially of the incisors. Instead of the normal number of four in each jaw, five were now and again observed, and in a few, very rare, cases, as many as six. On the other hand, there were cases of only two incisors with a correspondingly large lacuna. The failure of the wisdom tooth was not a rare occurrence. Anomalies of dental structure the speaker illustrated by pieces of ivory, which presented very remarkable deviations from the normal course of their fibres. In human teeth there had to be considered under this head enamel pearls, that is, smaller or larger round drops of enamel adhering to the roots, and having no connection with the crown. Anomalies of size were very rare. The breadth of the physiological variations amounted to about 3 to 5 mm. Now and again, however, enlargements were observed as high as 10 mm., and diminutions as low as to 0·9 cm. In the latter case crown and root had each transformed itself into the shape of a cone. Enlargements affected the root more frequently than the crown. Anomalies of the root were sometimes seen in curves shaped like an S or hook, but more frequently in the increase or diminution of the number of the roots. More than five outspread roots, more or less perfect, had never been observed. Molars of the lower maxilla were not unfrequently found with three, and bicuspids with two separate roots. In incisors and canine teeth divisions of the tips of the roots were occasionally found with two pulps, or more or less deep segmentations. A diminution, as well as an increase in the number of the roots had also been observed; yet was the coalescence of separate roots of rarer occurrence than their increase by splitting. The frequency of the anomalies referred to was not great. Out of nearly 11,000 teeth examined, only about 100 anomalous specimens had been found. Still more seldom did swellings occur on the teeth. These were sometimes soft, and consisting of connective tissue; sometimes completely calcified without containing one of the tooth tissues differentiated; sometimes situated on the crown, sometimes on the root. These Odontoma, like the teeth themselves, were always to be found in particular grooves of the maxilla. No osseous coalescence of the teeth and maxilla had ever been observed. At the close the speaker produced casts of gums which showed very considerable variations in their curves, ranging from an entirely flat up to a highly arched form.—Prof. Christiani communicated briefly the results of experiments carried out by Herr Gnezda on the poison of the cobra di capello (*Naja tripudians*). The poison was obtainedin India by causing the snakes to bite into snails or mussels wrapped in gutta-percha and filled with water. The watery solution thus obtained was reduced by evaporation. Of its physical and chemical qualities it was to be remarked that the poison belonged to the class of propeptons. Experiments were instituted with representatives of all the vertebrata. They were all susceptible of the poison, and died when the dose of the poison amounted to 3mg. per kilogramme animal. The time when death followed a full dose of the poison was very various. Rabbits died after half an hour, pickerels after an hour, frogs later, then cats, and lastly pigeons. Stronger doses hastened death. Dilutions and the introduction of artificial respiration delayed death. The physiological effect extended principally to the central nervous system. The muscles and the peripherical nerves continued irritable, although paralysis set in very soon. Seldom were spasms and compulsory movements observed. The poison appeared to have hardly any effect at all on the heart.

Physical Society, April 24.—Dr. Kayser reported on a recent paper of Prof. Bunsen (*Wiedemann's Annalen*, 1885, Heft 3) in which the differences between the results of the speaker's experiments regarding the absorption of carbonic acid on smooth glass surfaces and those published by Prof. Bunsen two years ago received their explanation. While, namely, Dr. Kayser had found that the absorption of carbonic acid proceeded according to definite laws formulated by him, Prof. Bunsen had observed that this process of absorption did not terminate even after as long a period as three years, but still continued, even though at a reduced rate. In his most recent work Prof. Bunsen had now established that the glass threads, even after a current of dry air had been for a considerable time directed over them, still retained a layer of water which was thin in proportion as the temperature was high, but did not become entirely dissipated till the temperature reached as high as about 500° C. This layer of water it was which absorbed the carbonic acid, and all the more powerfully the denser was the layer of water. The density of the water, however, stood in inverse relation to its thickness. From these experiments Dr. Kayser concluded that the absorption of carbonic acid on the glass threads which Prof. Bunsen had observed continuing for so long a period was only an absorption of the gas by the adhering water and no absorption on the smooth glass surface, whereas in the speaker's experiments, in which the glass threads had in boiling oil been freed from all adhering matters, the carbonic acid had been absorbed by the smooth glass.—Dr. Less spoke of two curves placed before the Society, as markings of the barograph on April 22 and 23 during the time of the brief thunderstorm in Berlin. The two curves presented in general an analogous course, concurring, moreover, with curves which Dr. Less had observed last year during the severe July storm. Before the outburst of the thunderstorm the curves sank slowly, next rose steeply to a considerable height; with the attainment of the maximum of pressure coincided the stroke of lightning; the curve then maintained itself at a level for some time, throughout which the thunder-shower or hail was wont to fall; on the cessation of rain the curve of atmospheric pressure sank steeply to beneath the former minimum. In the two April curves a further sudden rise preceded the second weaker stroke of lightning, and there then followed several smaller jerkings of the curves coinciding with the time of the formation of clouds consequent on the short thunder-storm. In the curves of the July of last year during the severe storms so copiously charged with lightning, the apex of the curves after the sudden ascent was not straight, but consisted wholly of short indentations each of which appeared to correspond with an individual lightning stroke, so far as it was possible to fix the precise times. The sudden steep ascent of the curve on April 22 and 23 coincided with a sudden increase in the force of the wind, which soon, however, fell weaker, and at last sank almost to complete stillness. The speaker also reported the corresponding numerical values for the variations of atmospheric pressure marked by the barograph.

VIENNA

Imperial Academy of Sciences, March 5.—Contribution to a knowledge of Coniopterigidæ, by F. Löwe.—On a new morphological element of peripheric nerves, by A. Adamkiewicz.—On the sensibility to light and colours of some marine animals, by V. Graber.—On some propagatory organs of the fruits of Compositæ, by M. Kronfeld.—On the fauna of the Jurassic deposits of Hohenstein, Saxony, by G. Bruder.—On mannite lead-nitrate, by A. Smolka.—Note on Löwe's lead-nitrate and on Morawski's penta-plumbonitrate, by the same.—On the temperature of Vienna and its environs, with a study on the action of local influences on the mean temperature, by T. Hann.—On camphoronic acid, by T. Kachler and F. V. Spitzer.—On the daily and yearly course, and on the period of disturbances of magnetic declination at Vienna, by T. Liznar.

March 12.—On nerve-corpuscles, by A. Adamkiewicz.—On the use of boiling oxygen, nitrogen, carbon oxide, and atmospheric air as a freezing-agent, by S. von Wroblewski.—Contribution to a knowledge of the texture of hyaline cartilage, by E. Zuckerkandl.—On the Upper Italic flora of the Lunz strata and of the bituminous slate of Raibl, by Dr. Stur.

March 19.—Crystallographic researches on camphor derivates, by V. von Zepharovich.—Experimental studies on the determination of the constant of dielectricity of some gases and vapours, by T. Klemencie.—On the planes of solution of calcareous spar and arragonite, by V. von Ebner.—On figures obtained by corroding arragonite, by the same.—On a meteoric explosion observed at a distance of 1000 metres by R. Spitaler on March 15, by E. Weiss.

UPSALA

Society of Science, April 17.—The following paper, by Dr. K. B. J. Forssell, was accepted for insertion in the Society's *Journal*:—"Beiträge zur Kenntniss der Anatomie und Systematik der Gloeolichenen." Prof. Lilljeborg described a *Metridia armata* (Boeck) taken in the Antarctie Ocean (lat. 54°–5° S.), and suggests that it was probably found near both poles. It was taken by Capt. Schéele, of the Swedish barque *Monark*, an amateur scientist to whom the Society had lent instruments, vessels, and apparatus for deep-sea researches. He further exhibited *Pluroma abdominale* (Lubbock), also taken by Capt. Schéele in the South Atlantic. It was remarkable as having an appendicular eye on the side of the head.—Prof. Hildebrandsson spoke about the twilight phenomenon, specially with reference to some observations of the purple glimmer then prevailing, made by Dr. Gyllenskjöld.—Prof. Clason gave a lecture on the functions of certain parts of the brain.

THURSDAY, MAY 28, 1885

PRACTICAL INSTRUCTION IN BOTANY

A Course of Practical Instruction in Botany. By F. O. Bower, M.A., F.L.S., Lecturer on Botany at the Normal School of Science, South Kensington, and Sidney H. Vines, M.A., D.Sc., F.L.S., Fellow and Lecturer of Christ's College, Cambridge, and Reader in Botany in the University; with a Preface by W. T. Thiselton Dyer, M.A., C.M.G., F.R.S., F.L.S., Assistant Director of the Royal Gardens, Kew. Part I. Phanerogamæ-Pteridophyta. (London: Macmillan and Co., 1885.)

IT is with more than ordinary satisfaction that we welcome this volume. Apart altogether from consideration of its intrinsic excellency, its appearance is gratifying as a first product of the younger school of botanists in this country—a school which for some years past has been doing good work in oral teaching, though up till now it has not contributed to teaching literature—and it is time that its methods were put in a more permanent form and made more generally accessible. The inconsistencies and inaccuracies characterising, with few exceptions, our endemic botanical text-books and our dependence for reasonably safe handbooks with information up to date upon translated works, mostly of German authors, are a reproach for which every botanist would gladly see the cause removed. At last we have a prospect of this, and the volume now before us is an instalment of a work which will in great part do so. The names of Thiselton Dyer, Bower, and Vines on the title-page are a guarantee of its thoroughness and accuracy, and the book certainly bears out their reputation.

The book took origin, as Mr. Thiselton Dyer informs us in the preface, in the work initiated by him at South Kensington in 1873. It is no small merit to have started at that time a system of instruction which embraced the examination by every student of the leading morphological facts of every important type in the vegetable kingdom. And this programme, which Mr. Thiselton Dyer set himself and successfully carried out, has not only eventuated in what, with him, we hope will be permanent—the institution, in what is now the Normal School of Science, at South Kensington, of a lectureship on botany, but also, in what concerns us here—this volume.

"I had always," says Mr. Thiselton Dyer, "hoped to put together the results of the experience in teaching methods acquired at South Kensington in the form of a handbook, which should save teachers who wished to follow our example from much of the trouble and difficulty which I, and those who at different times have taught in this way, have had to face. But, in the meanwhile, I had been drawn off to administrative duties which left a steadily decreasing leisure for purely scientific work. Fortunately, my friend Mr. Bower was willing—and with far greater competence—to take up the task which I was unable to perform, and to him are entirely due the laboratory instructions for studying the different types selected. Dr. Vines has very kindly supplied the chapters on methods and on the morphology of the cell. But besides this he has at every step given the assistance of his own extensive experience in practical teaching." With this book before us we can understand the motive of success of the South Kensington course, for it is the most thorough introduction to the practical study of plant morphology which has yet appeared; the only book to be mentioned along with it is the recently published "Practicum" of Strasburger—(of which of course the inevitable translation is promised)—and that is laid down on somewhat different lines.

In the first chapter Dr. Vines gives an excellent account of methods and reagents, delightful in the clearness and conciseness of its language and bearing throughout evidence of the hand of one who is no mere compiler of instruction but who has himself tested and had experience of all that is explained. The manner of setting to work, of making preparation, of making cultures, of preparing reagents, is all set forth in such a way that any intelligent tyro may readily equip himself and do good work. And we must congratulate Dr. Vines on the wise selection of methods and reagents he has made for notice, and on their arrangement. The multiplicity of new methods—many with but questionable advantage to recommend them—and their technicalities even in connection with botanical work is, at the present time, somewhat appalling and it is satisfactory to have these sifted by so competent an authority.

Dr. Vines's second chapter, on the Structure and Properties of the Cell, is a very prominent and commendable feature in the book, and will prove an extremely valuable one to all practical students—the micro-chemical portion of it especially, which gives in summarised and terse form the fundamental reactions exhibited by the various elements in the plant body, which are the basis of all further laboratory work. The student finds here at once a guide for testing the dictums of the earlier chapter as well as a graphic code for reference in his future studies. A synoptical arrangement such as this, and so happily worked out, has not been attempted in any previous book.

Mr. Bower's more especial work, the morphology of the various types dealt with, is no less excellent. The examples selected for illustration appear to us particularly well chosen, being readily obtainable in any locality, and their characteristics, macroscopic and microscopic, are explained with precision and in great detail. We shall not dwell at any length upon illustration of the admirable character of this part of the book, but in evidence of its completeness will refer to the section on the vegetative organs of Dicotyledons. *Sunflower* is selected as the chief type for examination, and we have first of all a brief description of the embryo and germination; then its stem in the mature and young condition are gone over, macroscopically and microscopically; but as it shows only the herbaceous type, the arboreous type as seen in *Elm* is explained, and further, the aquatic type, as in *Mare's-tail*. Sections are next added on the stem of *Cucumber* and *Lime-tree* with a view to special illustration of the sieve-tube elements, and upon *Dandelion* and *Spurge* for laticiferous elements. In like manner the leaf is treated of, to that of *Sunflower*, which is the chief type, descriptions of *Cherry-laurel* and *Stone-crop* being appended. Again, in the case of the root, *Scarlet-runner* as well as *Sunflower* is described. Besides these forms we have mentioned, which are dealt with in detail, frequent references are made to other examples in which equally good or further illustration of special features may be obtained. Similar thoroughness runs through the accounts of all the types.

Every one perusing the volume must be impressed with the high standard of its educational value. Teacher and student in this country are alike to be congratulated upon its publication. The former has now a thoroughly trustworthy laboratory guide to place in the hands of pupils, and the latter has a handbook in his own language to which he can refer with confidence in his search after a sound knowledge of plant-morphology.

This is only the first part of the work, and deals with Phanerogams and Pteridophytes. May the succeeding portion not be long in appearing! It is regrettable that the original intention of the authors "to preface the directions for the study of each type with a short account . . . of its salient morphological facts" has not been carried out in this part; Mr. Thiselton Dyer assigns in the preface the reason for its postponement. We are convinced that the want of such brief epitomes will be universally felt. But as the book is certain of a full measure of success, we look forward, with the authors, to the realisation of their hope that "the original scheme upon which the work was planned" may be "carried out in a future edition."

We conclude as we began by heartily welcoming the volume. We envy a student commencing to work with such a guide, and we are greatly mistaken if its effect is not very rapidly felt in the botanical teaching of the country.

THE PENNATULIDA OF THE NORWEGIAN NORTH ATLANTIC EXPEDITION

Den Norske Nordhavs Expedition, 1876-1878. *Zoologie Pennatulida.* Ved D. C. Danielssen og Johan Koren. (Christiania: Grondahl and Sons, 1884.)

THIS is the twelfth part of the series of monographs contained in this fine work, the first part of which was published in 1880. The former parts have dealt with, besides the chemistry and physics of the expedition, the fishes, a part of the Mollusca, the Gephyrea, Annelida, Asteroidea, and Holothuroidea, the monographs on the last four animal groups being by the same indefatigable naturalists who have produced the present memoir on the Pennatulida. The work is a highly creditable one to all concerned.

The present part is illustrated by twelve excellent plates, two of which are coloured, and which are in the same style as those already published by the same authors in their well-known memoir on new Alcyonians belonging to the Norwegian fauna published two years ago.[1] Thirteen species of Pennatulida belonging to eight genera were obtained during the expedition, and of these eleven species and two genera were new. One of the new genera is Svava, a small sea-pen with rudimentary fins and devoid of spicules on the sarcosome, cells and polyps. There is a stripe of zooids on either side of the stem, and in the two lateral canals of the stem are developed the zonads on the mesenteries of these zooids. The zooids alone produce gonads, the fully-developed polyps being barren. They are viviparous, the larvæ escaping from their mouths, as in Corallium. The other new genus, Gunneria, is founded on a fragment of a single specimen, but it is characterised by the presence of an immense quantity of spicules on the bodies of the polyps, their tentacles, and the sarcosoma, which latter forms a regular calcareous crust on the walls of the cells; the spicules are so closely packed in several layers that it is difficult to separate them, even with caustic potash. In this respect Gunneria approaches the Gorgonidæ; yet it is, nevertheless, a true Pennatulid.

The main feature of the memoir is, however, the part which relates to the now famous deep-sea Pennatulid, *Umbellula encrinus*, to which more than half the letterpress and seven of the five plates are devoted.

The Norwegian Expedition obtained twelve specimens of *Umbellula encrinus* from different localities. Kolliker described eight species of the genus from the *Challenger* collection, but one of these, *U. magniflora*, is considered by the authors as referable to the old historical *U. encrinus*, as are also Lindahl's new species from the Swedish Expedition of 1871, viz. *U. miniacea* and *U. pallida*. The whole of the twelve specimens obtained by the Norwegian Expedition are here carefully described in all details. All of them differ from one another, displaying peculiarities in various ages and stages of development which might, were the series less complete, easily lead to the establishment of separate species. The largest specimen obtained was dredged from a depth of 763 metres. It is a giant indeed. The rachis and the polyps, of which there are forty in the bunch, are twice figured on the last two plates, of actual size, coloured and uncoloured. The bunch of polyps occupies with its breadth nearly the entire length of the folio plate. The plates are far the finest representation of Umbellula yet published. There are eight prominent lanceolate areas occupied by zooids which extend up between the lateral polyps on the calicle-like part of the rachis, and spread themselves inferiorly over the rachis generally. The zooids are described as having each a single protusible tentacle, the tentacle when not retracted looking like a pendent papilla. These tentacles sometimes, but not always, bear short lateral pinnules, which are hollow, their cavities communicating with those of the tentacles, and which can be retracted with them. Kölliker, in his account of the *Challenger* Pennatulids, described similar zooids each bearing a single tentacle as existing in *Umbellula Huxleyi* and *U. Carpenteri*, and in the latter species found the single tentacles branched. He figures them, but only on a very small scale. On looking at the figures here given of these zooids (Tab. X., Figs. 56, 57) it is very difficult to understand their structure: the position of the mouth is not shown in any one, and they are drawn as elongate and flask-like in form when expanded, squat and rounded when retracted. The tentacle seems when protruded to be a direct narrow prolongation of the entire body of the zooid, and it appears as if on retraction this prolongation were telescoped into the basal region of the body. The base of the single tentacle should abut on one side of the mouth, but no such mouth-opening is figured. In the enlarged view of a zooid (Fig. 57) the mouth is neither definitely indicated nor referred to in the description. The text is not at all clear on the point.

[1] "Bergens Museum. Nye Alcyonider, Gorgonider og Pannatulider tilhorende Norges Fauna." (Bergen, 1883.)

The polyps bear the gonads, and are apparently viviparous. Very interesting conclusions are arrived at by the authors by comparison of the various stages at their disposal as to the mode of growth and successive additions of fresh polyps to the colony around the terminal primary polyp, and these are at variance with those of Lindahl. A couple of lateral polyps appear on each side of the terminal polyp, then another pair of laterals are formed, and the rachis expands in breadth. The centrodorsal polyp is formed, and then the dorso-lateral are developed, whilst the lateral polyps become more numerous.

H. N. MOSELEY

OUR BOOK SHELF

A Flora of the English Lake District. By J. G. Baker, F.R.S., F.L.S. (London: George Bell and Sons, York Street, Covent Garden, 1885.)

IT is perhaps surprising that a "Flora" of the Lake district has not before been issued, considering the large number of botanists who have yearly rambled over its fells and dales. It has been left to Mr. J. G. Baker to do so, and with modesty he says "it does not seem likely at present to stand in the way of anything more complete." The limits of the "Flora" embrace parts of Cumberland, Westmoreland, and the whole of what is botanically called Lake Lancashire; but excludes "the northern half of Cumberland and the western slope of the Pennine Chain, through Cumberland and Westmoreland;" the exact boundaries are, however, not very clearly defined

One cannot help feeling, directly the book is opened, that it is the work of one used to generalise and deal with facts in a broad way: in no part more so than in the first fourteen pages, where, accepting Mr. H. C. Watson's definitions, he describes the distributive types, zones of altitude, temperature, &c., with a clearness coming of long and practical acquaintance with the subject, giving comparative tables of the types, &c., with those of Northern Yorkshire, Northumberland and Durham, and Britain, and making the Lake Flora about 900 species. It should, however, be remembered that this number is based on Mr. H. C. Watson's estimate of 1425 species for Britain as a whole.

Had that estimate to be made *now* by Mr. Watson, the result would probably be the accepting of a larger number, not alone by the discovery of species since made, but by a decided feeling on his part "that there were some species that would eventually have to be divided." It may well be asked *why* is there this comparatively large amount of difference demanded among our native plants to constitute a "species," and the little often accepted among newly-discovered "species" from distant countries; doubtless knowledge is progressive in the latter case, but still theories and generalisations are built up on them with as much apparent certainty as on floras long known and studied. Mr. Baker then enumerates the species constituting the flora, running up to 234 pages, numbering them according to the sixth edition of the "London Catalogue," showing also (but not numbering) the large number of doubtful plants that have at various times been reported from the district.

Perhaps the most striking fact brought out by this "Flora" is the scarcity of aquatic species compared with the numerous lakes and tarns, of which there must be between sixty and seventy, large and small. Whether in this particular district this is from the want of investigation, or from a real paucity of species or specimens, is difficult to say; but certainly our lakes and waters have not been sufficiently systematically searched, whether from the botanical, zoological, or chemical point of view. In this we should do well to emulate the Swedish naturalists; but in *our* case it may well be asked, "Where are we to look for help?"

How little we know of the life-histories of our aquatic plants! and it may well be suggested as a study for those botanists, who, while not being able to take up botany in the way so ably advocated lately by Prof. Bower in NATURE, still have some leisure from other occupations and duties, and could really advance the knowledge of our flora beyond mere collecting. It is only necessary to turn over the plates of Dr. T. Irmisch's work on them to understand what is meant and required.

AR. B.

The Fallacy of the Present Theory of Sound. By Henry A. Mott, jun., Ph.D., E.M., &c., Professor of Chemistry and Physics in the New York Medical College and Hospital for Women; Author of "The Chemist's Manual," "Was Man Created?" "Adulteration of Milk," "Testing the Value of Rifles by Firing under Water," "The Laws of Nature," "The Air We Breathe and Ventilations," &c. 12mo. (New York: Printed for the Author, 1885.)

THIS is a very curious book. Its author appends to his name recognised scientific titles, and seems to hold a responsible position as a teacher; but he has been led into a hopeless and inextricable muddle about wave-motion; and, starting with a misconception, he naturally obtains results so utterly at variance with common sense and experience, that it is remarkable he cannot see his error.

He begins by admitting that "to attack a theory which has been upheld for 2500 years, and which has been and is sustained by the greatest living scientists, is certainly a very bold undertaking." But he feels bound, nevertheless, "to come to the front and join Dr. A. Wilford Hall in exposing the fallacy." He fulminates, moreover, the following withering defiance at false prophets: "If Profs. Helmholtz, Tyndall, Lord Rayleigh, Sir William Thomson in Europe, and Profs. Rood and Mayer in this country, wish to retain the respect and confidence of thinking people, they will at once endeavour either to defend the theory of sound, or, like men, come boldly to the front and acknowledge that it is fallacious."

There can be no doubt that these various noblemen and gentlemen will at once proceed to adopt humbly the latter and safer alternative; because it is obvious that if they do not do so speedily, creation and nature will come to a premature end. This rather serious occurrence is thus predicted: "The lowest tone of an organ is stated by Prof. Blaserna to have sixteen vibrations to the second, and a consequent wave-length of 70 feet. It thus follows, says Dr. Hall, that in the sound of such an organ-pipe the air-particles (as a whole) are obliged to travel 35 feet and back sixteen times each second in order to pass from the space occupied by the centre of rarefaction to the centre of condensation and back. They would thus move with a velocity in one direction of 560 feet a second, or at the rate of 381 miles an hour, which would produce a tornado of more than double the velocity necessary to sweep a village into ruins. If there was the least truth in the wave-theory, the sound of a church-organ should get up a cyclone which would blow a cathedral into atoms."

This is truly very horrible! far worse than dynamite. Saddened by these reflections, we can bear with comparative equanimity the revelation that "the prong of a tuning-fork moves at the rate of only about one inch in four years," and "instead of swiftly advancing, as Tyndall says, sounds audibly when moving more than 25,000 times slower than the hour hand of a family clock, and more than 300,000,000 times slower than any clock-pendulum ever constructed, instead of very much faster, as Helmholtz teaches."

One more quotation is irresistible: "Imagine," says our author, who seems to have recovered wonderfully from the terrestrial cataclysm which he and the evil-doers above named have all but provoked, "imagine a locust stridulating in the centre of a mass of iron one mile in all directions" (*sic*). The idea is charming, countrified, bucolic, but perhaps rather cold for the poor insect! "It is admitted he could be heard, and about sixteen times quicker than in the air. . . ." (the steps of this grand calculation must perforce be omitted). "The mass of iron thus displaced" (*i.e.* by said locust) "would weigh not less than 729,749,050,612 tons, and would be so moved by the strength of the locust."

The thought is too tremendous! so, locust-like, I must cease to "stridulate," lest I bring down the solar system in ruins on the heads of innocent humanity.

W. H. STONE

Kryptogamen-Flora von Schlesien. Vol. III.: *Pilze.* Bearbeitet von Dr. J. Schröter. (Breslau: J. U. Kern.)

DR. COHN'S "Cryptogamic Flora" is already so favourably known by the portions which have appeared, that the announcement of any subsequent part is sure to be received with satisfaction. The first part of the Fungi, by Dr. J. Schröter, is just issued, and consists almost entirely of an introduction of nearly 100 pages, carefully digested and summarised, concluding with the order of classification adopted. The three groups or primary divisions are:—(1) Myxomycetes; (2) Schizomycetes; and (3) Eumycetes. The latter embraces the Chytridiei, Zygomycetes, Oomycetes, Protomycetes, Ustilaginei, Uredinei, Auriculariei, Basidiomycetes, and Ascomycetes, with an appendix for the incomplete Hyphomycetes, Tuberculariei, and Sphæropsidei. As the present part contains only a portion of the Myxomycetes, no opinion can be formed of the manner in which the foregoing skeleton will be filled up; but, as this portion is based upon Rostafinski's monograph, no exception can be taken thereto. The real difficulty lies further ahead, and whether the knot is to be untied or cut cannot be predicted.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

On the Terminology of the Mathematical Theory of Elasticity

I HAVE been greatly interested by the letters on this subject from Prof. K. Pearson (NATURE, vol. xxxi. p. 456) and Prof. A. B. W. Kennedy (vol. xxxi. p. 504), and I have looked forward with pleasure to further communications from other eminent "elasticians." As, however, no better qualified person seems disposed to continue the correspondence, and as I am practically interested in a definite settlement of elastic terminology, I venture to offer a few remarks on the subject.

(1) Nothing could be better than Prof. Pearson's term *state of ease* for the condition of an elastic body when capable of enduring a certain amount of stress, without showing permanent set on its removal. This is worthy of Clifford, and is sure to make its way.

Prof. Kennedy has extended this term by applying "maximum state of ease" to the condition in which the body may be strained to its elastic limit without set. Perhaps *ultimate state of ease* would be more significant, and *limited state of ease* might be employed to denote the intermediate stages. The ultimate state of ease of course corresponds to the "natural state" of the ideal perfectly elastic solid.

At the point B in Prof. Kennedy's figure we reach the *limit of perfect elasticity*, and enter the stage b of *elastic instability*. Prof. Kennedy's suggestion of "limit of stability" for the point C is inconsistent with the last. I would suggest *elastic crisis* as an alternative for "breaking-down point." We evidently here pass the critical point in the static equilibrium of the molecules.

Perhaps c' might be called the stage of *thermal inversion*.

At C_1 the bar enters the *plastic state*—divided by Prof. Kennedy into the *stage of uniform flow* from C_1 to the point D of *maximum load* and the *stage of local flow* from D to the point E of *terminal load* or (apparently) of *maximum stress*.

(2) I observe that Prof. Kennedy uses "load" and "external stress," apparently as alternative terms, and that Prof. Pearson speaks of "stress per unit area." Would it not be advisable to settle, once for all, that *stress* shall always, when it stands alone, mean a force per unit area? "Stress" and "intensity of stress" would then be identical terms, while the *force* across a given area due to stress would be known as the "total" or "resultant stress" across the area. This is all that is required to bring the terminology of *perfect* elasticity into exact correspondence with that of hydromechanics, in which pressure and total or resultant pressure have always stood in this relation to one another.

(3) Next as to "tension." The word was originally adopted from the theory of strings, and of bars used like strings to support weights, and was, I believe, invariably used (as it still is in the case of strings) to denote the load, or *total* longitudinal stress endured. Nowadays, however, it seems to be employed indifferently in this sense and in that of intensity of tensile stress. I would suggest that the term *traction*, which the modern French writers have freely adopted, should be invariably used to denote intensity of tensile stress, and that *tension* should be restored to its original signification of total or resultant traction.

"Traction" and "pressure" would then (according to the ordinary convention as to sign) be synonymous with "positive" and "negative" stress. Perhaps some elastician would suggest a convenient abbreviation for "total pressure" or "negative tension."

(4) Is it too late to protest on behalf of that much-abused term *viscosity* as applied to solids? The thoroughly-established sense of the word, as applied to fluids, implies—*not* the property in virtue of which they undergo permanent or continued change of shape under continued distorting stress (*i.e.* their *fluidity*); but that other property in virtue of which they are able to offer more or less resistance, by means of molecular friction, to instantaneous changes of shape under stress which is not continued. In this case, therefore, viscosity is a property distinctly opposed to fluidity, and, indeed, described in terms as a falling short of "perfect fluidity."

It is thus obviously false analogy to describe a metal in the state of plastic flow as *viscous*, or to "appropriate this name to that permanent set which may be produced by the application for a long period of a stress well within the limits of elasticity." The latter sense—at least as applied to ice (NATURE, vol. xxxii. p. 16)—has, no doubt, a classical authority in the great memoir of Forbes; but Sir W. Thomson has pointed out ("Enc. Brit.," Art. "Elasticity," § 31; and Thomson and Tait's "Natural Philosophy," § 741) that the properties of ice so described are included under the perfectly definite and convenient term *plasticity*, which is really analogous to fluidity.

On the other hand, analogy demands that the term *viscosity*, as applied to solids, shall be strictly confined to that frictional dissipation of energy which is always at work during rapid changes of strain, and which was first discovered during small vibrations within the elastic limit by Sir W. Thomson (*Proc. Roy. Soc.*, May 18, 1865, or the passages above cited).

That the viscosity of a ductile material is very greatly increased in the plastic stage is of course beyond a doubt, the amount of energy absorbed by it on sudden increase of the stress being so much in excess of that required to provide for the increased potential energy of the accompanying strain that the temperature rises to a sensible extent. But what I wish to make clear is that the true viscosity is not essential to or characteristic of the truly plastic state, but that, on the contrary, the viscosity of a ductile solid renders it *imperfectly plastic* in just the same sense as a viscous fluid is *imperfectly fluid*.

(5) Finally, I may perhaps be permitted to add that, next to the importance to all concerned of a definite and universal terminology, comes the importance to mathematicians at least of a uniform *notation*.

The effect of reading through, for purposes of comparison or historical record, the 100 odd *really important* treatises on this subject—in each of which a perfectly independent and generally quite different notation is employed—is simply infuriating! I would urge upon Prof. Pearson that he has now an unrivalled opportunity of fixing in the language of English (and perhaps foreign) mathematicians a really serviceable and significant system of notation.

The double-suffix notation for strain and stress, which is developed to perfection in St. Venant's French translation of Clebsch, has many advantages, but seems to be too cumbrous for English taste. Nothing perhaps could be more unmeaning than Thomson and Tait's notation for "stresses," independent as it is of all reference to the strain-symbols. Still I must confess (in common, I dare say, with most men who have derived their first inspirations from that mathematical epic) that it has secured too firm a place in my mental machinery to be lightly cast out, even in favour of a better. W. J. IBBETSON

Cambridge, May 12

The Colours of Arctic and Alpine Animals

MR. R. MELDOLA has maintained, in NATURE, vol. xxxi. p. 505, the idea that the white colour of some animals, Arctic mammals and birds, must be ascribed to the absorbent and radiating power of the same colorations in relation to the rays of the sun. He maintains also that to a similar cause we owe the seasonal polychromism of several mammals and birds of the Alps, and what would be for these animals a partial return to the characters of the Glacial epoch.

By an analogous theory the author explains the contrary phenomenon that is observed in many insects—that is, the darkening of the coloration, and he speaks principally on this point of the Lepidoptera.

Now I beg to make the following observations, and to indicate the following facts:—

(1) That a seasonal mutation of colour is observable in many mammals, now more, now less distinctly, and generally it concurs with the change of coat. Also not seldom in mammals strictly belonging to the Alps, as, for example, in the *Rupicapra europea*, and in the *Capra ibex*, the colour changes very little in the summer and in the winter, although the length, the thickness, and also the coarseness of the hairs were very different. In other cases, as, for example, in the *Cervus mandarinus*,[1] the coat is, in summer, light reddish yellow, with many round white spots, while in winter it is dark brown, and the round spots are less numerous and are light brown.

(2) As to the insects, it is observed that in *Coleoptera* the colours of the Alpine species are brighter than those of the warmer plains, as in the genera of *Carabus*, *Pterostichus*, &c. In several species of *Harpalus*, *Amara*, *Cicindelis*, &c., the individuals that we find at the greatest elevations of the Alps have often lighter colours.

(3) A darker colour and sometimes a whole melanism is observed in general in the insects of the deserts—for example, in that of Sahara. On the contrary, the mammals of these countries present in general a very light colour. It seems to me that this fact cannot be explained by the theory of radiation.

(4) A very remarkable melanism is also observed in several mammals, the Reptilia and Coleoptera that are in little islands, or upon rocks in the warmest regions, for example the *L. muralis*, &c., *Cicindela campestris*, in the island of St. Peter in Sardinia.[2]

(5) In the reptiles and in the Alpine amphibia we sometimes meet with some cases of darkening, but the cases of a remarkable brightening are not very rare, as, for example, in the *tadpoles* of *Rana muta*.

(6) A sensible difference is observed in the coloration between the Arctic birds and the Antarctic. In these last black is much more abundant.

Indeed, Australia, New Zealand, &c., are countries known for a remarkable darkening in the colours of many sorts of animals.

In the Carnivora, which are the mammals that chiefly present seasonal polychromism and white colour, is observed a tendency to this colour in several forms that, however, do not live either in Polar regions or in very cold places. As to this fact the colour of the genera *Zorilla*, *Meles*, &c., and also the very curious *Ailurus melanoleucus* of Thibet,[3] should be observed.

[1] Milne-Edwards, "Recherches pour servir à l'Histoire Naturelle des Mammifères," tav. 22, 22a. Paris: Masson.

[2] Si consulti L. Camerano, "Richerche interno alla Distribuzione dei Colori nel Regno animale." *Mem. R. Accad. Scienze di Torino.*

[3] Milne-Edwards.

The causes, I would say in conclusion, that intervene to modify the colour of animals, are very complicated; climate has amongst these a certain importance, but it does not seem to me that, although it be very attractive, Mr. Meldola's theory of radiation is sufficient. LORENZO CAMERANO

Zoological Museum of Turin

On Certain Stages of Ocular After-Images

IN a short note in the *Phil. Mag.*, 1872, vol. xliii. p. 343, Prof. C. A. Young has recorded a curious instance of "after-image," which seems to me to be of the same order as that observed by Mr. Shelford Bidwell, and recorded in NATURE, (vol. xxxii. p. 30). I quote from Prof. Young's note, which is named "Note on Recurrent Vision," a few lines, which will show what his observation was:—

"In the course of some experiments with a new double-plate Holtz machine belonging to the College (Dartmouth, America), I have come upon a very curious phenomenon, which I do not remember ever to have seen noticed. The machine gives easily intense Leyden-jar sparks from 7 to 9 inches in length, and of most dazzling brilliance, at the rate of seventy a minute. When, in a darkened room, the eye is screened from the direct light of the spark, the illumination produced is sufficient to render everything in the apartment perfectly visible; and, what is remarkable, every conspicuous object is seen *twice* at least, with an interval of a trifle less than a quarter of a second—the first time vividly, the second time faintly; often it is seen a third, and sometimes (but only with great difficulty) even a fourth time."

Prof. Young shows that it is a subjective phenomenon, and measures the interval between the first and second seeing of an object, giving as the mean of twelve experiments the interval 0·22 second for the case of his own eyes, and 0·24 second for that of another observer.

Five or six years ago I observed another instance of what I believe to be the same kind of "after-image," though at first I was inclined, being engaged upon experiments with a view to finding the cause of certain ocular "ghosts" due to multiple reflection inside the eye (*Proc. Roy. Soc.*, No. 223, 1883), to ascribe it to a different cause. It was seen in a room lighted only by the bright glow of coals in the grate. Whenever the eyes were suddenly flashed across the fireplace, and then fixed on some object 50° or 60° from it, there appeared a faint blue light, which seemed to flash from the object to the glow. This phenomenon was much more strongly marked at some times than others, and varied with some cause which I never further investigated. Later I came upon another instance of the same thing; and as this is the easiest to reproduce, and one by which one may best study the phenomena, I will describe it.

Let a match or a splinter of wood be made to glow, as for testing oxygen, and let it be observed in a dark room; the eyes should be fixed, and the glowing match moved about. I found that for purposes of rough measurement a most convenient curve of motion is a figure of 8 on its side in a vertical plane (∞). Also it is convenient to keep the period of the movement the same, and to vary the size of the curve if change of velocity is required. There are difficulties to be overcome in regulating the brilliancy of the light (Mr. Bidwell has pointed out the necessity of a certain degree of brilliancy in the case of the vacuum tubes), if a systematic investigation were undertaken; a glowing match becomes brighter the quicker the movement; the reverse is the case with a platinum wire carrying a strong current of electricity; and a small incandescent lamp is objectionable on account of reflection from its glass case.

I shall consider the "after-images" of the glowing-point as forming a trail, in which all the changes are set out at the same moment, and proceed to describe the trail for two cases. I should state that following descriptions refer to the trails as seen by me *in the evening*; for there are very considerable variations in the phenomena according as the eye is likely to be wearied or fresh. I may also repeat Mr. Bidwell's caution that it is by no means certain that a person new to the subject will at first be able to see the appearances described.

I arrange a metronome beating seconds, and move the glowing-point so as to describe the curve completely in two seconds. First, let the figure of eight be only as large as can be got into a rectangle 3 inches by 1½. In this case there comes after the glowing-point a dark interval in the trail, about an inch long; then a distinct blue-green ghost, about the same size as the glowing-point; again a dark interval follows, shorter than the first, and behind it a long strip with a dark core and very faintly bright edges; as one traces backwards, the edges appear to close in together gradually, so that, after about two inches, the dark core has collapsed, as it were, and the edges have come together to form a narrow and well-defined thread of a mauve tinge; this gradually dies away as we go further back along the trail, and by the time that the glowing-point has travelled over the whole curve once, it has nearly disappeared.

Secondly, let the figure of eight be as large as can be described in a rectangle 8 inches by 4. Here the phenomena are quite different. It now seems as if the dark intervals at either end of the ghost as described above were absent, and the ghost itself were drawn out into a streak which follows *immediately* upon the glowing-point. Its colour is now yellow-green. This gardually narrows to extinction as one traces the trail backwards, and is the positive after-image in its various stages. More probably this streak has no connection with the true *ghost*; but is quite distinct from it, whilst the ghost no longer appears, when the point moves with greater velocity. In fact, there is probably a limiting velocity of the glowing-point, beyond which the ghost is not formed. This coincides with Mr. Bidwell's observations as to the rate of rotation of the vacuum-tube. As the yellow streak disappears narrowing, one sees a faint blue haze on either side, separated from it by an interval of darkness. When one has traced backwards so far that the streak has vanished, one sees what was above described as a strip with dark core and faint blue or mauve edges. The edges close in and form a distinct mauve thread, which gradually dies out.

It is very beautiful to see the ghostly trail hanging before one; and, by suitable movement of the glowing point, one may fill the space, as it were, with a maze of wreathing lines. Perhaps the most striking part of the phenomenon, regarded from an æsthetical standpoint, is the *depth* of the figures so produced: one realises in the form of the trail that the glowing-point has been moving, not in one plane, but in space; and one sees that some parts are nearer than others. After a time the glowing-point seems to be forgotten, and the trail is the only thing observed. The position of the trail appears to change with any change in the state of accommodation of the eye; if the trail goes away from one the eye attempts to follow it, and exaggerates the movement. If there is any irregularity in the curve, as may often be the case from want of proper co-ordination of muscles—especially if the moving arm is at all subject to rheumatism—it is revealed in a terribly truthful manner by the trail.

A systematic investigation of the subject would, I think, be very valuable as throwing light upon the processes in the retina.

Both Prof. Young ("whatever the true explanation may turn out to be, the phenomenon at least suggests the idea of a *reflection of the nervous impulse* at the nerve extremities, as if the intense impression upon the retina, after being the first time propagated to the brain, were then reflected, returned to the retina, and, travelling again from the retina to the brain, renewed the sensation") and Mr. Bidwell ("the series of phenomena seem to be due to an affection of the optic nerve which is of an oscillatory character," &c) appear to incline to what I may call a *physical* view of the phenomena. The phenomena appear to me to point to some *chemical* action on the retina, and to depend in a great measure on the *rate* at which this action goes on. It would be of great interest to consider the phenomena in connection with Hering's theory of colour sensation; according to it these sensations are due to changes in a certain substance, in such a way that changes of a destructive or dissimilative character give rise to the sensations of white, red, and yellow, whilst those of a constructive or assimilative kind produce the sensations of black, green, and blue ("Zur Lehre vom Lichtsinne," Wien, 1878). It may be that this work has been already done; if so I must crave the indulgence of those who have made the subject a special study.

Crowthorne, Wokingham, May 18

"Speed" and "Velocity"

SOME of your "general" readers, like myself, may wish to see the distinction between "velocity" and "speed" more easily defined than by a reference to the calculus of quaternions, to which I believe the term "tensor" appertains.

"Speed" is not in the index to the new edition of Part II. of Thomson and Tait. Maxwell, at p. 26 of "Matter and Motion," says, "The rate or speed of the motion is called the velocity of the particle." Tate, in his "Properties of Matter," p. 52, writes about "water of motion; *i.e. Speeds.*" It seems thus:—

(1) Rate of motion is velocity (Maxwell)
(2) Speed of motion is velocity ,,
(3) Rate of motion is speed (Tate).

From (1) and (3) it appears as if velocity and speed must be the same, as indeed (2) seems to assert. But we are told this is not the case. Cannot the distinction between the two be made more generally intelligible than by saying that "speed" is the "tensor" of velocity.

SENEX

[When Maxwell introduced to junior students the *Diagram of Velocities*, he made velocity include the *direction* of motion as well as the mere *rate* of motion (*i.e.* speed).—ED.]

The Male Sole is not Unknown

IN last week's issue of NATURE is what is said to be an abstract of a paper read at the Society of Arts by Prof. Ray Lankester, in aid of a proposed marine laboratory, and, passing over what he stated generally requires elucidation, he gives one example of *what is not known among fishes*, and which in the first instance will be investigated at Plymouth. He is made to say "at present absolutely nothing is known as to the spawning of the sole—the male fish is not even recognised."

In times gone by the plaice was asserted to have ascended from a shrimp, but this, I think, is the first time that the existence of the male sole has been declined recognition. Omitting references to others, I will merely draw attention to the fact that in my collection of British fishes in spirit at the "Great International Fisheries Exhibition," and which is now deposited in the Economic Museum at South Kensington, is a fine example of the male sole, with the milt quite ripe.

I must apologise for pointing out the foregoing, but were such an error left unnoticed in a scientific paper, some practical fisherman will possibly direct attention to it, as the comparative rarity of the male to the female sole has been frequently observed upon in our weekly sporting journals during the last few years.

Cheltenham, May 23 FRANCIS DAY

The Aurora of March 15, 1885

NATURE for March 26 (p. 479) contains an account of a fine aurora observed at Christiania, Sweden, on March 15, by Prof. Sophus Tromholt. I would call attention to the fact that an aurora (a very unusual phenomenon at this place) was visible here on the evening of March 15. It was first seen at about 7 p.m.

At the above time several streamers were noticed ascending somewhat east of north: after a short interval these died leaving a white nebulous cloud of light at an altitude of about 10° near a point some 10° or 15° east of north. Shortly afterwards streamers appeared ascending some 10° or 15° west of north; these presently disappeared, leaving a mass of light similar to that left in the east of north. Several times feebler streamers made their appearance west of north. The rays did not attain a greater height than some 20°, and by 8½h. all was quiet, save an auroral glow along the horizon some few degrees east of north, which remained throughout the night. I have thought this might be interesting in connection with the Christiania aurora.

E. E. BARNARD

Vanderbilt University Observatory, Nashville, Tenn., U.S.A.

Catalogue of Fossil Mammalia in the British Museum. Part I.

IN reply to Mr. Lydekker's comments on the review of his work (NATURE, vol. xxxi. p. 597) I am glad to find that the author repudiates the Owenian system and its errors, though his recognition of the three upper premolars in *Vespertilio* as corresponding, respectively, to *pms.* 2, 3, and 4 of the typical series of four, and the minute anterior upper premolar of *Rhinolophus* as *p.* 3, added to the strange absence of any note on the presence of exceptions to the supposed rule that the premolars decrease in number by reduction from the anterior extremity of the series would certainly lead any one acquainted with the subject to believe that he had acted on it. The only clues afforded by the work which indicate that the Owenian system was not adopted in its entirety, now pointed out by Mr. Lydekker as existing at pp. 152, 174, would certainly escape the notice of any one who had not actually spelled through the work, as I feel sure whoever will take the trouble to refer to will agree with me.

There is no evidence whatever to support Mr. Lydekker's assumption that the two anterior premolars in *Vespertilio* and the anterior premolar in *Rhinolophus* correspond, respectively, to *pms.* 2 and 3 and to *p.* 3 of the typical series. On the contrary, the small size of the second premolar in *Vespertilio* points to reduction by loss from the middle of the series, as we find in the greater number of species of the closely-allied order, Insectivora, and, as we know, takes place in the mandible of several species of Chiroptera.

With reference to the wish expressed in the review that, instead of writing a mere catalogue of the fossil mammals in the British Museum, Mr. Lydekker had undertaken one of all the known species, and his objection, while regretting that the intended friendly estimate of his capability for such a work has been so hostilely received, I maintain that such should have been undertaken; but Mr. Lydekker's remarks show how necessary it is, and that the objection that new genera and species are being made almost daily (it is probable that they will continue to be be made to the end of time) might be applied with equal force on behalf of the birds by Mr. Sharpe, who nevertheless continues his excellent catalogue. It is only by the publication of such a work that we can hope to limit the manufacture of "empty names," such as Mr. Lydekker objects to, and to reduce to order the vast amount of scattered information and contesting opinions which encumber the study of the subject.

THE REVIEWER

THE ORCHID EXHIBITION

THE Exhibition held in the Conservatory at South Kensington on the 12th and 13th inst. in connection with the Orchid Conference of the Royal Horticultural Society, must have furnished to the least observant visitor some explanation of the fascination exercised by orchids over their cultivators. The beauty, the variety, the strangeness of the flowers of the Orchideæ attract and interest the least enthusiastic even of the lovers of nature. But the variation in flower, compatible with botanical inclusion in one family, is not more marked than is the difference in mode of flowering and of growth. Could there be in one natural order a stronger contrast than between the mode of growth and the gorgeous flowers of the genus Cattleya—essentially "flaunting flowers"—and those of the genus Masdevallia, where the conspicuous part of the flower consists of the three sepals, drawn out in many species into thread-like tails many inches long, and ranging in colour through every shade of orange, scarlet, and purple, down to an almost inky black!

While a larger array of specimen plants has often been seen than was shown at the Conference, there has never been gathered together in any country so varied and interesting a collection, nor one containing so many rare and curious plants. Great as was the interest for the cultivator, it was no less great for the botanist. Mr. Ridley, of the Natural History Museum, who, in conjunction with Mr. Burbidge, of the Dublin Botanic Gardens, has undertaken to draw up a report on the Conference Exhibition, found that sixty-one genera of orchids were represented. For the first time in the history of flower-shows there was a numerous collection of hybrid orchids, raised by artificial fertilisation, in flower. For the first time was there a large collection of orchids in fruit. The progress of hybridisation, greatly due to the energy and skill of Messrs. Veitch and Sons and their intelligent foremen, Mr. Dominy and Mr. Seden, has already been fertile in valuable results for the cultivator. An excellent little book lately published,[1] gives a list of eighty-nine hybrids already in cultivation, distributed among twelve genera, but thirty-seven of them belonging to the genus Cypripedium. Those who are privileged to enter the penetralia at Chelsea know that there are there and elsewhere great numbers and varieties of hybrids, which are slowly surmounting the dangers and delicacy of infancy and childhood.

But the labours of the hybridiser promise to be of great value to the botanist. Mr. Harry Veitch, in his very suggestive and interesting paper on the "Hybridisation of Orchids," read at the Conference, says: "How will these bigeneric crosses affect the stability of the genera as at present circumscribed?" It is well established already that the genera Lœlia and Cattleya cross freely with one another, and Mr. Veitch refers in his paper to two other bigeneric hybrids, which have already flowered, and to others which have been raised, but have not yet flowered.

Unfortunately it must be a long time before orchid cultivators generally can enjoy the results of hybridisation. Mr. Veitch gives the time the hybridist must wait to see the result of his labours, as follows:—

Genus.	Time from Germination to Flowering
Dendrobium	3 to 4 years.
Phaius	About the same.
Calanthe	
Masdevallia	4 to 5 years.
Chysis	
Zygopetalum	5 to 9 years.
Lycaste	7 to 8 years.
Lœlia	10 to 12 years.
Cattleya	

With the exception of the genera Dendrobium and Cypripedium, it is a long time before sufficient plants of a hybrid can be obtained for distribution, even under the most skilful cultivation. For this reason many of the more beautiful hybrids will probably remain scarce and valuable for years. The high prices paid by collectors for orchids in some cases have been a source of merriment to the uninitiated. Speaking generally, orchids were never so cheap or so plentiful. But if a collector must have a hybrid which has been raised by skilful hands and nursed into vigour by years of patient care—or, on the other hand, must have a beautiful natural variety which has been picked out of millions of plants—if he must have them, he must pay for them.

The Royal Horticultural Society is to be congratulated both on the botanical and the horticultural results of the late Conference. The Conference was a new idea, a new departure. It has demonstrated the great, widespread, and, better still, the intelligent interest taken in a singular and beautiful natural order, and the skill brought to bear on its cultivation.

The short scientific contributions of Prof. Reichenbach, whose absence was universally regretted; the paper on "Hybridisation," by Mr. Veitch, and the brief discussion which ensued, were listened to by a large and appreciative conference. The paper on "Cultivation," by Mr. O'Brien, was also interesting and valuable. The very difficult question of nomenclature, which is in so confused and unsatisfactory a state as to ill brook delay, was postponed. It could not be discussed with advantage at the tail of a long meeting, and will be referred, it is to be hoped, to a a scientific committee selected from botanists in and out of the Royal Horticultural Society. T. L.

WHEAT-PRODUCTION IN INDIA[1]

INDIA has recently exhibited her extraordinary powers as a wheat-producing area of vast extent. Up to the year 1877 the British wheat-grower looked upon the exhaustless prairies of the far West as his most formid-

[1] "Orchids: a Review of their Structure and History." Illustrated. By Lewis Castle. (*Journal of Horticulture* Office, 171, Fleet Street, E.C.)

[1] The Wheat-Production and Trade of India. Calcutta. Being a collection of correspondence in continuation of papers published in 1879.

able rival in the matter of wheat-growing. A short seven years has greatly altered his feelings in this respect, and we are probably right in considering that the far East is destined to do its part in forcing down the price of wheat to as great a degree as the land of the setting sun. The *brochure* before us is a thoroughly dry statement of facts composed of numbered despatches, letters, and tables, all bearing upon the capabilities of India as a wheat-producing country. The reader will not, however, obtain information as to extent or area, except in a more or less incidental manner. The principal matters dealt with are (1) the quality and comparative values of the various wheats grown; (2) the modes of cultivation pursued; (3) the nature of the soils on which wheat is grown; (4) the average yield per acre; (5) the effects of continuous wheat-growing in diminishing yield; and also other matters relating to the details of wheat-cultivation in India.

With regard to the quality of Indian wheats there is no room for doubt. The conclusions arrived at are based upon actual weight per bushel, value upon the Corn Exchange at Mark Lane, and an elaborate report upon milling and bread-making results furnished by Messrs. McDougall Brothers of 10, Mark Lane, London. From whichever of the above points of view we test the quality of the Indian wheat, the result is equally satisfactory, and the more so when we find that from year to year the samples and bulk continue to improve. Messrs. McDougall Brothers go so far as to sum up their experience by saying, "glancing at all the facts, it is evident that these wheats afford a larger margin of profit both to the miller and baker than any other."

The modes of cultivation adopted are of great interest. They usually exhibit vast pains, and are in this respect superior to the system of wheat-cultivation employed at home. Such elaborate cultivation would indeed astonish an English farmer accustomed to plough his lea land or turnip land once for wheat. The comparison is less fair if we take into consideration the fact that one thorough English ploughing may be worth half-a-dozen of those "ticklings" of the soil which, under Indian skies, are sufficient to make it "laugh." Under the head of Systems of Cultivation we read:—"Ploughed in July, and again six or seven times until October. Watered in November. Again ploughed twice, rolled, ploughed again, and the seed sown through a tube attached to a plough-handle. After twenty-five or thirty days, again watered; and this is repeated until the plants appear fortnightly where irrigation is by lift, and every twenty-five days where it is by flow. In February, when the ears have appeared, water is given weekly until the ears begin to mature." In Armritsar;—"Six months before sowing, the land is ploughed five to ten times. After sowing, the crops are watered not less than six or more than nine or or ten times." In Gujrat:—"Land is broken up and ploughed many times between May and September, manured and ploughed and levelled." The average produce per acre after this system of cultivation varies from seven to fourteen or even twenty maunds (nine to twenty-seven bushels of 61 lbs.), and yet it is calculated that it is grown at from 8*s.* to 11*s.* per quarter! Wheat-growing appears to be carried on upon all sorts of soils. Upon stiff loams, sandy loams, hard clay, and "every kind of soil." In reply to the question, Has the productive power of the soil begun to fail? the answers are usually in the negative, or that it is not apparent. Still, as might be expected, better crops are grown upon manured and irrigated soils and upon those newly broken up from pasturage.

After reading the details of wheat-cultivation in India and compared its results with those obtained in England with a fifth part of the labour, we are inclined to wonder greatly that this remote field should be able to compete with us. Why do they plough five to ten times? How is it that in that sunny land, and after all this expenditure of labour and irrigation, twenty-seven bushels should be a maximum return, while in some cases seven bushels is all that is reaped? A painstaking farmer in England hopes for from thirty-two to forty bushels per acre after once ploughing and pressing his clover leys, and yet he cannot make both ends meet, nor yet compete with the Indian Ryot.

JOHN WRIGHTSON

THE REPORTS OF THE UNITED STATES COMMISSION OF FISH AND FISHERIES FOR 1881 *AND* 1882[1]

THE Report for 1881 was presented to the Senate and Congress of the United States on March 17, 1882; it is to be regretted that so long an interval was allowed to elapse before its publication. The volume is a large one, three inches in thickness, and containing nearly 1200 pages. Scarcely any of this large quantity of letterpress is without interest and value, and we here give an account of the work described in it.

The Commission began the second decade of its existence in 1881, and the present report shows how greatly the organisation has extended itself, and what large results it has achieved in its first ten years. The central offices of the Commission are at Washington, and up to the year 1881 were confined to the private residence of its public-spirited chief, Mr. Spencer Baird, who devoted the greater part of his house to the State service without remuneration. In 1881 a building was erected next to the Commissioner's residence, at the public expense, to provide space for the increased administrative work. The stations where the varied operations of the Commission are carried on are scattered throughout the United States territory. These operations fall naturally under three heads: (1) Economical statistics and historical data concerning the fishing industries; (2) the applied science of regulating fish supply and distribution; (3) the pure science of marine zoology. The part of the work belonging to the first of these divisions is conducted partly at the central offices, partly at the seats of the industries in question. The two other fields of work are, of course, not always distinctly separate. Since 1878 buildings at Fort Wharf, Gloucester, Mass., had been occupied for hatching operations, but in 1881 they passed into the possession of a private firm, since which time only reports on the fisheries and records of ocean and atmospheric temperatures have been obtained from Gloucester. The principal site of the purely scientific work during the summer season was Wood's Holl, Mass., where the Commission possessed a sea-side laboratory. Researches on the artificial propagation of oysters, &c., were carried on at St. Jerome, Md., near the mouth of the Potomac. Cultivation of the land-locked or Schoodic salmon was practised on the Grand Lake Stream, near Calais, Me. The Penobscot or Atlantic salmon (*Salmo salar*) similarly received attention at Buckport, Me. Another station, where lake trout, brook trout, California trout, &c., were hatched, was at Northville. The principal hatchery for the Californian salmon was on the McCloud River, a branch of the Sacramento. Shad eggs were hatched at Battery Island, Md., at North-East River, Md., near the mouth of the Susquehanna, at the Central Station, Armory Buildings, Washington, at Washington Navy Yard, on the Potomac river-barges, and at Avoca, N.C. Carp ponds were maintained at Monument Lot and at the Arsenal, Washington. The Commission acknowledges valuable assistance received from almost all departments of the Government, but especially from the Navy Office, which, in compliance with decrees of Congress, has detailed steamers fully manned and equipped, lent launches, and executed work and repairs at the navy yards. Steam-

[1] Washington, 1884.

ship and telegraph companies have also aided in the work of the Commission.

Up till 1879 the Commission was not in possession of any vessel of considerable size: its explorations at sea were carried on by means of boats either hired or lent by the navy. In 1879 Congress voted money for the building of a steamer to be entirely devoted to the work of the organisation. This vessel was designed as a floating hatching station capable of being moved from place to place according to the season and the opportunities afforded, but she was not intended to go to sea in all weathers or to any great distance. She was named the *Fish-Hawk*, and was built at Wilmington, Del., from the designs of Chas. W. Copeland, consulting engineer of the Lighthouse Board. A very complete and interesting report is presented in the volume before us on the construction of the *Fish-Hawk* and the work performed by her in 1880; and another on her services in 1881. The *Fish-Hawk* is 156 feet long over all, 27 feet in the beam, and 7 feet 2 inches in draught at the stern. Her ordinary speed is about 9 knots an hour. The hull below the main deck is of iron, sheathed with yellow pine; above the main deck she is of wood. The hatching apparatus and machinery for working it are placed on the main deck immediately abaft the forecastle; the space thus set apart is 47 feet in length. On the after part of the main deck is the principal cabin, which contains the Commissioner's office. Above the main deck, extending from stem to stern, is a promenade deck, on which are the hoisting and reeling engine, the dredging boom, its heel attached to the foremast, and at the after end the naturalists' laboratory. The vessel is rigged as a fore and aft schooner, carrying a fore-staysail, a foresail and mainsail; she has four boats, the largest of which is a steam-cutter.

The *Fish-Hawk* has been found to fulfil admirably the purpose for which she was designed, viz. the economical and effective hatching of shad. But it had long been evident that the Commission required also a sea-going steamer to investigate the conditions and extent of the known, and to discover new, fishing-grounds, to ascertain the complete history of the migrations of food-fishes, to add, if possible, to the list of species available as food, and to study marine phenomena in general. The reward to be expected from this kind of work was indicated by the history of the discovery of the tile-fish, an entirely new species of which some specimens were brought in by a fishing-vessel in 1879. The *Fish-Hawk* made a trip to the place where the tile-fish was found, at the western edge of the Gulf Stream, and found that it was as abundant over a large extent of ground, as the cod is in other places. The area dredged over was found to be also in other respects a valuable fishing-ground, and extremely rich in all forms of life, many new and interesting species being discovered. The tile-fish has been found to be of great value as food when fresh, and to be as easily salted and preserved as the cod. In consideration of these facts Congress voted 103,000 dollars for the building of an ocean steamer for the work of the Commission, to be called the *Albatross*.

In 1881 the Commission began the publication of another annual volume in addition to its Report. It is called the Fish Commission Bulletin, and the first issue contained a memoir on the development of food-fishes, by John A. Ryder; one on the life-history of the eel, by G. Brown Goode; one on the salmon disease in English waters, by Prof. Huxley and S. Walpole; and other papers on fish-hatching and fisheries. Besides this were published in 1881 four census bulletins, and a volume of tables containing statistics of American fisheries, all prepared under the supervision of members of the Commission. In the latter part of the year a monograph on the oyster industry was issued by Mr. Ernest Ingersoll.

The results of the year's work in the three several departments already defined are given in three separate appendices to the Commissioner's report. Those belonging to the first department are contained in Appendix B, which consists of six memoirs, only two of which refer to American fisheries. The first of these is on the history of the mackerel fishery, by Messrs. Brown Goode, Collins, Earll, and Clarke, and occupies nearly a third of the whole volume. It begins with an account of the natural history of the fish, and of its geographical distribution, by Mr. Brown Goode. He finds that the species (*Scomber scombrus*) is confined to the North Atlantic. Its southern limit on the American coast is Cape Hatteras, lat. 35°; its northern limit, the Straits of Belle Isle, lat. 52°, though stragglers may occur further north. Its northern limit on the European coast is North Cape, lat. 71°; its southern, the Mediterranean. The mackerel appears in large shoals on the American coast every summer; as yet it has not been ascertained where it passes the winter. Prof. Hind, who is a Canadian, believes that the fish hibernates in the mud, near shore. Mr. Brown Goode, with much greater probability, argues that the shoals move out to the deep ocean in autumn. He distinguishes between the littoral and bathic migrations of this and other species, and concludes that this fish, like others of similar habits, is influenced in its movements chiefly by temperature, food, and breeding instincts. The mackerel only remains near shore while the temperature of the water is above 40° F. Off Cape Hatteras mackerel first appear about March 20; in the Gulf of St. Lawrence they are not abundant till June. The shoals disappear in October, though occasionally some are caught in December. The mackerel spawn in water of 15 fathoms and less, and while spawning do not take bait, or rise to the surface. The eggs are pelagic, and the young fish grow to 6½ or 7 inches in the first season, probably reaching full size in four years. The mackerel's food consists chiefly of pelagic forms, but not so exclusively as in the case of the herring. A great deal of space is given in this account to the evidence of fishermen as to the food of the mackerel, but as no scientific interpretation is given of their somewhat vague descriptions, the reader does not learn much from the discussion. We conclude that the food consists largely of copepoda, crustacean larvæ, schizopoda, and pteropoda. One paragraph dealing with the food question is, to an English reader, somewhat amusing. The author says that the food of the mackerel is called in England the "mackerel-mint," and consists of "sand-lants [*sic*] and five other species of fish." We are not sure, but we think "mackerel-mint" is a mistake for "mackerel-midge," which is the young of various species of rockling, but especially of *Motella tricirrata*. In the same paragraph it is said that mackerel have been seen to devour the swimming larvæ of tape-worms. The first chapter of the essay can only be regarded as a preliminary inquiry to serve as a basis for accurate investigation. It seems strange that Prof. Brown Goode and Mr. Baird should mention a mysterious membrane over the eye of the mackerel without giving the anatomical meaning of the membrane; and it is equally unsatisfactory to read an account of the dissection of a mackerel, quoted from Bernard Gilpin, in which the air-bladder and the aorta are mixed up. Next follows a history of the mackerel-fishery in the United States, from which we learn that since 1880 the purse-seine has come into general use for mackerel-catching. The mackerel fleet consists of 468 vessels, mostly of 60 to 80 tons, schooner rigged, and very fast sailers. The old method of hook-fishing is described fully in a historical chapter. Besides the purse-seine, gill-nets are also used in mackerel fishing at the end of the season, off the New England coast. The total catch of mackerel in 1881 off the United States coast is estimated at 294,667,000 fish.

Chapter III. of the essay contains an account of the legislation affecting the mackerel fishery. Even at the time of printing the Report in 1881, on account of the clamours of the inshore fishermen against the purse-seine, a Committee of Senate was appointed, which was likely to result in additional regulative enactments. The rest of the essay contains an account of mackerel-canning, statistics of the fishery in 1880, the inspection laws, a chronology of the history of the fishing, a list of vessels engaged in the industry, and a table of the catch by American vessels in Canadian waters.

A paper by Mr. Harrison Wright relates the history of the shad fishery in the Vale of Wyoming, on the north branch of the Susquehanna. The Indians caught shad there before white settlers came, about 100 years ago. The white people used shad seines with great success until 1830, when the construction of dams for a canal put an end to the fishery altogether. There were about forty permanent fisheries, some of which had an annual catch of 10,000 fish, weighing three to nine pounds each. It is suggested that the fishery might be restored by the construction of ladder-ways over the dams, and other improvements, together with a restocking of the river with young shad.

A translation is given of a report on the Loffoden fishery in 1880 by Lieut. Niels Juel, the chief of the police administration, which has charge of public order, &c., at the fishery. This report is very interesting, but we have scarcely space to summarise it: we can only give a few of the prominent facts. The number of boats engaged varied from 1000 to 5000; the total number of fishermen was about 27,000, of whom about 13,000 fished with gill-nets, 10,000 with long lines, and 3000 with hand-lines. The author believes that the water-temperature most suitable for cod is between 3½° C. and 4½° C. The total yield of the fishery in 1879 was 25,000,000 fish, valued at 5,000,000 crowns. In 1880 the yield was still greater, being only surpassed by that of 1877.

Another paper in this appendix gives extracts from the official statistics of the Norwegian fisheries in general, and another is a transcript, from the London *Quarterly Review*, of an article on "The Fish-Supply of London." In the latter the opinion of very high authorities is quoted that the fisheries of the North Sea, small as its area is, are practically inexhaustible, and that trawling does not tend to exterminate any species of food-fish.

Appendix D deals with the propagation of food-fishes. It contains twelve papers, which are, with one exception, reports on the work of the various stations of the Commission during the year. The exception is a paper on the "Repopulation of the Water-Courses of Belgium," by Baron de Selys Longchamps. This essay shows how the waters of the Meuse and Scheldt have been rendered barren by the construction of dams and the pollution from factories; and that it will be a matter of great difficulty to remedy this state of things by the construction of fish-ways and the purification of the rivers.

The whole work of the Commission, from its institution in 1871 to 1880, is reviewed in a number of statistical tables prepared by Chas. W. Smiley. In the period in question 43,000,000 shad were artificially hatched and released on the spot, 53,000,000 successfully transported; 15,000,000 of Californian salmon have been hatched and released on the Pacific coast, 31,000,000 transported to other States, and 4,000,000 sent abroad. Of the 31,000,000 transported, about 50 per cent. were successfully introduced into distant waters. In 1879 and 1880 61,000 carp were distributed.

Then follow seven reports on the work of the various hatching-stations, in which occur, here and there, interesting accounts of experiments and inventions connected with the hatching apparatus. At Wood's Holl experiments were made with a view to arranging an apparatus suitable for hatching cods' eggs; the experiments were only partially successful. It was at Wood's Holl that Prof. Ryder carried on his researches into the embryology of the cod. Experiments on the artificial hatching of the Spanish mackerel were made at Cherrystone, Va.

Lastly, we have to notice Appendix C, on Natural History and Biological Research. First, we have an account of the Annelida Chætopoda collected on the Massachusetts coast by the summer expedition of Union College. Three genera and sixteen species are described here as new to science. Of these Thaumastoma is said not to belong apparently to any known family. As far as we can judge from the figure of the head given, the genus is allied to the Nereidæ; but all the figures in the plates to this paper are rough and unsatisfactory.

Mr. Coutance records some experiments on the effect of saline solutions of the same strength as sea-water, but of different composition, on marine molluscs. In all cases the solutions were ultimately fatal; but it would be interesting to have these experiments repeated with some alterations: viz. the solution to be substituted for the sea-water gradually, instead of suddenly, and the natural conditions to be more nearly realised in all other respects save the composition of the medium.

Prof. J. A. Ryder contributes a paper on "The Importance of the Protozoa and Protophytes as the Primary Source of the Food of Fishes." He might have said simply Protophytes, since Protozoa are fed by these; and it is obvious, since a small proportion only of marine animals feed on littoral algæ, that marine life depends largely on pelagic Protophyta. The author reviews the evidence that most Entomostraca feed on Protozoa, and that these feed on diatoms, &c., while the Entomostraca constitute the food of vast numbers of fish. He gives evidence to show that the adult shad feeds while spawning, in fresh water, and that the newly hatched shad feed on exceedingly small and young Entomostraca. The paper is rather a popular essay than an original memoir.

S. A. Forbes finds that the earliest food of the young of *Coregonus albus* in Lake Michigan consists almost entirely of Copepoda of the species *Cyclops Thomasi* and *Diatomus sicilis*.

Prof. Ryder, in another paper, describes some successful experiments in retarding the development of shad ova. It was found impossible to develop them at 38° F. or at 45° F. Ova kept moist on flannel trays at 52° F. were killed by fungus, but the development proceeded at the rate of nine days for the embryonic period. In an experiment in which glass McDonald jars were used with water from the Potomac when the river was at the temperature of 51° F. to 57° F., development took place normally, and hatching was retarded till the thirteenth to the sixteenth day. The embryos were lost by accident, but the author thinks it would require about twenty-five days at this temperature to absorb the yolk, and thus, if the same success could be insured on board ship, there would be ample time to transport embryos to Europe.

Prof. Ryder's remarks at the end of this paper, on "The Rationale of Retardation" somewhat neutralise the satisfaction experienced in reading the account of his practical work. In the present state of science it is scarcely allowable to talk of the nucleus as a "directive dynamic centre," because the phrase has little definite meaning. It is not true that the division of a nucleus has been described by Flemming under the terms "systole" and "diastole"; that author's use of those words referred to certain alternating movements in a nucleus previous to its division. The division of the nucleus does not give us a complete explanation of the phenomena of retardation. It is a truism that retardation of development means diminution in the rapidity of the rate at which cell-divisions take place; but to talk of the *vis essentialis* of segmentation residing in the nucleus is about as instructive as an attempt to localise the horologity of a clock, the *vis essentialis* of a steam-engine, or the situponability of a chair.

The Report for the year 1882 was published at the end of last year, only a few months after the issue of the volume for 1881. In some respects this, the most recent annual Report, is the most interesting of the whole series, the year 1882 having been unusually eventful for the Commission. During that year the new ocean steamer *Albatross* was constructed, steps were taken towards founding a permanent station at Wood's Holl, the Armory Building at Washington was fitted up as the central station of the Commission, and the surprising fact came to light that the tile-fish, investigated a short time previously by the Commission, had been practically exterminated by unknown natural causes. Besides the history of these events the Report contains a long and elaborate memoir, by John A. Ryder, on "The Development of the Cod," which forms one of the most conspicuous features of the volume, and some interesting papers on the artificial propagation of the oyster: the rest of the volume is chiefly made up by the usual separate Reports of the various hatching-stations, and papers on American fishing industries.

The appropriation made by Congress for the *Albatross* in 1881 was too small, and it was not till March, 1882, that an additional grant was obtained, and the contract for her construction was signed. On November 11 the vessel was put into commission with Lieut. Z. L. Tanner, formerly commander of the *Fish Hawk*, as captain. On December 30 the *Albatross* left Wilmington, where she was built, for Washington, on a trial trip. Her total displacement is 1000 tons. A description of the vessel and of her equipment is promised in a subsequent Report. The arrangements for establishing the principal permanent seaside station of the Commission at Wood's Holl made some progress during the year, but were not completed. An agreement was made upon the conditions of the purchase of the requisite land, and all the necessary technical formalities arranged; but it was essential that there should be constructed within the great harbour of Wood's Holl an inner harbour, which would serve for a harbour of refuge as well as for the purposes of the Commission. An appropriation of 52,000*l.* for the new harbour was granted by Congress, but the President decided to defer action upon this and other new items in the harbour bill, and, consequently, the establishing of the Station was delayed for a time. Nevertheless, Wood's Holl was made the head-quarters of the general summer work of the Commission, and a large party were engaged there during July and August working at marine zoology and exploration. The *Fish Hawk* was stationed there during this time.

The central station at Washington was fitted up with shad-hatching apparatus, and was used as the centre from which all young shad hatched on the rivers Potomac and Susquehanna were distributed: the extreme limit of distribution was the Colorado river in Texas. The number of shad fry distributed was over 20,000,000.

The curious history of the tile-fish (*Lopholatilus chamæleonticeps*), into the distribution of which researches were made in 1881, is related in a report by Capt. Collins in Appendix B. At the beginning of Capt. Collins's paper an account of the fish itself is given, from which we learn that it belongs to the family Latilidæ, Gill, the representatives of which are mostly inhabitants of tropical seas and of shallow water. The ground where the tile-fish had been found lies between the latitudes of Hatteras and Nantucket, in long. 70° to 71°, about 100 miles off shore, at a depth of 90 to 125 fathoms. In March and April, 1882, vessels arriving at the principal Atlantic sea-ports reported the extraordinary occurrence of vast numbers of large dead and dying fish floating on the surface of the sea over the region where the tile-fish had been found. It was ascertained that a large proportion of these dead fish were tile-fish. In order to determine the extent of the destruction, a steamer was chartered by the Fish Commission, and sent out to the tile-fish ground in September. Not a single Lopholatilus could be obtained, but a new fish belonging to the genus Setarches was discovered, which promised to be of importance as a food-fish. An account of this exploring cruise was published in the Fish Commission *Bulletin* for 1882.

Prof. Ryder's memoir on the development of the cod is founded on researches made at Wood's Holl, Mass., in June, 1881, and at Fulton Market, New York, in February, 1882. On the former occasion an apparatus devised by Marshall MacDonald was used, and about 5000 young fry were set free at Wood's Holl, and 25,000 sent to Chesapeake Bay and liberated there; these were all the fry obtained from several millions of eggs artificially fertilised. The memoir is a long one, extending to more than 100 pages, and is illustrated by twelve plates of woodcuts. This is the first publication in which the development of the cod has been described in detail and figured; the description given by Sars in his report to the Norwegian Government some years ago having been rather general, and not illustrated. The facts are given in Prof. Ryder's paper for the most part with great accuracy and fidelity, although the appearance of the woodcuts is not very pleasing, and the more complicated of the figures are a little wanting in clearness. The theoretical part of the paper will not commend itself to those who have accepted the generalisations of embryology at present prevalent. For example, it is stated that in Teleosteans, at an early stage, the body-cavity and segmentation-cavity are continuous; but the evidence produced in support of this revolutionary proposition is not by any means conclusive. It cannot be said that the obscurities of Teleostean embryology, such as the invagination of the gastrula, or the development of the genital ducts, are much illuminated by Prof. Ryder's memoir: on the latter point no information is given.

Two other interesting papers are included in the Appendix for Natural History and Biological Research: one by Sidney J. Smith on the Decapod Crustacea from the dredgings of the *Albatross* in 1883, and the other by Prof. Verrill on the fauna of the tile-fish ground at the western edge of the Gulf Stream. The former of these is an extremely elaborate memoir, accompanied by ten plates of clear and well-executed woodcuts, illustrating species and structures which had not before been sufficiently figured. The paper contains a great number of new species and several new genera: each new species is described with wonderful minuteness, and, a long table of measurements being added to each description, no one having occasion to use this memoir will be able to complain of inexactness or incompleteness in the characterisation of specific distinctions.

The paper of Prof. Verrill is short, being simply intended to indicate the most interesting features of the peculiar area investigated. It was found in the operations of 1882 that the invertebrate fauna, discovered to be so unusually abundant in 1881, had, like the tile-fish, suffered great destruction in the interval between the two seasons. This was especially the case among the Crustacea, some species, which had been taken in thousands at a single haul, having become extremely scarce. Prof. Verrill believes the remarkable destruction of life had been caused by a very severe storm which occurred in the spring of 1882, and which probably forced out the cold coast water over the Gulf Stream slope.

The whole of Appendix D has reference to oyster culture. It contains six memoirs, two of which describe experiments on the artificial propagation of the American oyster, *Ostrea virginica*. Lieut. Francis Winslow studied the subject at Beaufort, N.C., and at Fair Haven, Con.; Prof. Ryder at St. James's Creek, Md. In both cases, though a fair amount of success was obtained in impregnating the ova and keeping the embryos alive in the free-swimming stage, no satisfactory method was discovered of obtaining a supply of attached spat with any certainty. Prof. Ryder and Col. MacDonald on one or two occasions found that their embryos had fixed themselves to the sides of their aquaria in large numbers, but they could not keep them alive more than a day or two after the attachment had taken place.

The growing extent of the piscicultural operations of the Commission, as indicated by the Reports in Appendix E, is marvellous. Statistics of the distribution of shad-fry during 1882 are given in a paper by Chas. W. Smiley; the total number distributed was over 30 millions. The total number of carp distributed was 259,000, of Penebscot salmon 1,716,000, of Schoodic salmon 1,482,000.

It would be extremely interesting to have some information as to the result of all this work, as to the effect produced on the supply of fish in the rivers, and on the productiveness of the fisheries. The Commissioner points out that it is of little use to put anadromous fish into rivers if the waters are obstructed by dams or made uninhabitable by pollution, and a new fish-way to remedy the former difficulty is described by Col. M. MacDonald in Appendix A. But all who are acquainted with the labours of the American Commission would be grateful if Mr. Chas. Smiley would apply his great power of handling statistics to exhibiting the economical results of the piscicultural work. J. T. CUNNINGHAM

NOTES

THE statue of Darwin will be unveiled in the great hall of the Natural History Museum, Cromwell Road, on Tuesday, June 9, at 12 o'clock, when Prof. Huxley, President of the Royal Society, on behalf of the memorial committee, will formally transfer it to the care of the Masters of the Museum, who will be represented by His Royal Highness the Prince of Wales. Places will be reserved for the committee and subscribers to the memorial, but the greater part of the hall will be open to the public during the ceremony. The statue, which has been executed by Mr. Boehm, R.A., is of marble, and seated, rather larger than life-size; it is pronounced by those who have seen it to be an admirable likeness as well as a fine work of art.

IT is now twenty-one years since the *Geological Magazine* was first issued. During all that time Dr. H. Woodward, F.R.S., has been an editor, and for almost the whole of it the principal editor, on whom the main burden and chief responsibility of the work has fallen. It has been a work which has not only cost him much time and labour but also has been practically unremunerative. His friends among geologists accordingly purpose to celebrate the "majority" of the *Magazine* by presenting to him a testimonial in appreciation of his services to science. A meeting was held last week, at which an influential committee was formed, a list of which will shortly be circulated. The treasurer and secretary is Dr. Hinde, F.G.S.

WE greatly regret to record the death of the Rev. Thomas W. Webb, Vicar of Hardwick, near Hay, Brecon, well-known for his writings on astronomical subjects. We hope next week to refer to the work he has done in astronomy.

THE death is announced of Mr. Peter William Barlow, F.R.S., the well-known engineer.

A CONGRESS on hydrology and climatology will, it is stated, be held at Biarritz during October next. The French Government has brought the matter to the notice of foreign Governments, in order that the latter may take the necessary steps to be represented at the congress.

ON April 13 the Leander McCormick Observatory attached to the University of Virginia was opened by public ceremony. The buildings are situated on a hill called "Observatory Mountain," because in 1825 Thomas Jefferson erected a small observatory there, which gradually fell into decay. They consist of residences for the director and assistant, offices, a small observatory for minor observations, and a large building for the dome. The observatory proper consists of a cylindrical building surmounted by a hemispherical dome forty-five feet in diameter, and a rectangular building used as a library and computing office. The walls are of brick, the circular portion being heavily buttressed, and bearing at the top a coping of Ohio stone. On this rests cast-iron rails, on which the dome revolves. The latter weighs 25,000 lbs., and is composed of a framework of steel covered with galvanised iron and lined with painted canvas, having three openings covered by shutters when not in use. It takes five seconds to open one of these, and a minute and a quarter to revolve the dome quite round. The telescope, which is mounted on a brick pier under the centre of the dome, is similar at the Washington Observatory. The clear aperture of the object-glass is twenty-six inches. Like so many other important scientific and educational institutions in the United States, this observatory is due to the generosity of a wealthy native of the State, Mr. Leander McCormick, from whom it takes its name. This gentleman presented both telescope and building to the University. The cost is stated to have been about 13,000*l.*, the telescope costing over 9000*l.* The directorship of the observatory, to which post Mr. Ormond Stone, director of the Cincinnati Observatory, has been elected, is endowed with a sum of 10,000*l.*, collected by public subscription; while Mr. W. H. Vanderbilt has given the University a further sum of 5000*l.* as an endowment to pay the salary of an assistant observer, the expenses of publication, &c. According to the founder's plan the observatory is not to be confined to purposes of the University alone, but for general scientific research, so that students from any part of the United States who desire to become professional astronomers may receive a thorough training there. In accordance with this plan the Professorship of Astronomy in the University is a wholly distinct post from that of Director of the Observatory. Prof. A. Hall. of the National Observatory at Washington, delivered the opening address, taking for his theme "The Instruments and Work of Astronomy."

FROM various publications which we have recently received from the Government of Hong Kong Dr. Doberck, the astronomer, appears to have lost no time in employing the new observatory. The last batch of observatory papers include observations on lunar transits across the meridian of Hong Kong, and on the height of Victoria Peak. As this eminence is the most important in the east (with the possible exception of Fuji-yama) in one sense—the sense in which Richmond Hill is more interesting than Mount Everest—it may be added that the mean height of the peak is 1710·6 feet above the Observatory, or 1818 feet above the mean sea-level. There is also a report on five-day means of the principal meteorological elements for 1884, constructed according to the recommendations of the International Meteorological Congress, and a complete weather report for the same year. With four well-equipped observatories (Tokio, Shanghai, Hong Kong, and Manila) at work, the meteorolgy of the China Seas will soon cease from being the sealed book which it practically is at present.

LAST year was a tolerably productive one for the collectors of prehistoric remains in Switzerland. The water of the lakes was almost constantly below the highest level, which is the most favourable state of things for explorations around the lake-dwellings. The remains discovered belong mostly to the Bronze period, and the chief localities in which they were found were Lake Neuchâtel and the settlement of Wallishofen near Zürich, the latter of which is the only station of the Bronze period yet know in Eastern Switzerland. Among the most remarkable articles discovered at this settlement in 1884 were a splendidly preserved bronze sword, several dozens of bronze hatchets, bracelets, &c. Of the remains of the Stone period discovered in the same year the most notable are those obtained at Robenhausen, including several pretty knife-handles made of yew, some excellent specimens of mechanical industry, such as thread, woven fabrics, fishing-nets, &c., and ears of barley and wheat, one being a specimen of the rare *Triticum turgidum*.

THE Zoological Society of Philadelphia, according to the Thirteenth Report of the Board of Directors, appears to have suffered during the past year, like many other institutions dependent on the public for support, from the general depression of trade. The financial balance shows a large reduction; nevertheless the Superintendent is able to report that the collection "presents to-day a greater and more typical variety of animal forms, in furtherance of the educational facilities which have been one of the chief aims of the Society, than at any previous period of the history of the garden." Among the principal additions during the year was a hippopotamus, the first obtained by the Society, a collection of European water-fowl, and a brush-turkey (*Tallegalla lathami*) of New South Wales. The specimen procured is a female, but it is hoped that a male may also be obtained, and that its extraordinary habit of hatching its eggs, by covering them with decomposing vegetable matter, may be shown in the garden.

IT seems that the experiments of Dr. Ferran in inoculation for cholera have been stopped by the Spanish Government.

THE Sanitary Congress at Rome has been engaged during the past week mainly in discussing quarantine regulations.

WE have received Prof. Theodore Gill's "Account of the Progress in Zoology" for 1883, from the Smithsonian Report—a substantial pamphlet of over fifty pages. The special discoveries recorded have been selected either on account of the modifications which the forms considered force on the system, or because they are or have been deemed of high taxonomic importance, or the animals *per se* are of general interest; or, finally, they are of special interest to the American naturalist. The arrangement of the account is as follows:—General Zoology, Protozoans, Porifers, Cœlenterates, Echinoderms, Worms, Arthropoids, Molluscoids, Mollusks and Vertebrates. Each of these divisions is sub-divided according to the discoveries to be noted. At the end, a brief bibliography of noteworthy memoirs and works relating to different classes is appended. "The statement," Prof. Gill says, "is not intended for the advanced scientific student so much as for those who entertain a general interest in zoology, or in some of the better-known classes. It is compiled for the many rather than the few, and hence, perhaps, zoologists cultivating limited fields of research may find omissions, as well as notices of discoveries of minor importance."

ON May 20 a terrific storm raged in Paris; a stupendous peal of thunder was heard at 11 a.m. It seems the lightning struck the top of a high furnace at St. Ouens, near Montmartre. It is supposed that it was attracted by a mass of lead which was placed at this elevated situation for some purpose. The peculiarity is that no trace of the lead was afterwards found

THE centennial celebration of Blanchard and Jeffries crossing the Channel in a balloon was celebrated on Sunday at Guine, Pas de Calais, where the two travellers landed.

SHOCKS of earthquake were felt at Wartberg and Kindberg, Austria, on May 20 towards 1.30 a.m. A sharp shock was felt at Smyrna at 7.15 p.m. on May 26.

PROF. DEWAR, F.R.S., will give a discourse on "Liquid Air and the Zero of Absolute Temperature" at the last Friday evening meeting of the season on June 5, at the Royal Institution.

A FEW years since the German Anthropological Society initiated an exhaustive investigation among German school children as to the proportion of those with dark and with fair complexions. This has been followed by similar investigations in Belgium, Switzerland, and Cislethian Austria, and these have supplied gaps in the German inquiry. The result was, according to *Die Natur*, laid before a recent meeting of the Berlin Academy of Sciences by Herr Virchow. In all, 10,077,635 children were examined as to the colour of the skin, hair, and eyes; 6,758,827 in Germany, 608,678 in Belgium, 505,609 in Switzerland, and 2,304,501 in Austria. The geographical boundaries were the Pregel and Dniester on the east to the Vosges on the west; the Baltic and German Ocean on the north, to the Adriatic and the Alps on the south. The following is the result:—Of pure blondes there were found in Germany 2,149,027; in Austria, 456,260; in Switzerland, 44,865; a total of 2,650,152, which, on a total of 9,468,557 (Belgium being omitted here) children examined, is rather more than one-fourth. The number of brunettes was: in Germany, 949,822; Austria, 534,091; in Belgium, 167,401; in Switzerland, 104,410; a total of 1,755,724, or about one-sixth of a total of 10,077,635. Hence more than half the school children of Central Europe are of the mixed type. The distribution of the pure types is very different. In Germany 31·80 per cent. is fair and 14·05 per cent. dark; in Austria the dark predominate, being 23·17 per cent., while the fair amount only to 19·79; in Switzerland the disparity is still greater, for the blondes are only 11·10 per cent., while the brunettes are 25·7; and in Belgium the blondes are 27·50 per cent. In Germany, therefore, the fair complexions predominate; but even here the proportions vary greatly, getting less and less as we go towards the south. In North Germany the proportion is between 43·35 and 33·5 per cent.; in Central Germany, about 25·29; and in the south, only 18·44; while, on the contrary, the proportion of dark children diminishes from 25 per cent. in South Germany, to 7 per cent. in the north. This appears to show the incorrectness of the theory of the French anthropologist that we must seek the real Germans in South Germany, and that North Germans are a dark race, a mixture of Finns and Slavs. The fair people are most numerous in Sleswick-Holstein, Oldenburg, Pomerania, Mecklenburg, Brunswick, and Hanover. That this should be the case in Mecklenburg—formerly a Slav district—is due, according to Herr Virchow, to a return-emigration of the Germans. Middle and Western Germany were especially the cradle of this emigration. Flemings, Dutch, and Frisians thus reached Holstein, Westphalia, Brunswick, Mecklenburg, and Pomerania. Saxony, Silesia, and Northern Bohemia were colonised through Eastern Franconia, Austria from Bavaria. The emigration of the German tribes took place at two different periods: the first, a movement from south to west, which ended with the foundation of the Frankish monarchy; the other a return to the last, which began with the Karolingian period, and is not yet concluded. The latter has led to a permanent colonisation, and to the formation of a new pure German people. The deep brown colour of the south and middle Germans, as well as of the Swiss, is traced by Herr Virchow to the Romans, Rhetians, and Illyrians, and especially to the remnants of the Celtic or pre-Celtic inhabitants, which have now become mixed with the Germans.

THE experiment of acclimatising the American Whitefish (*Coregonus albus*), lately tried by the National Fish Culture Association, has met with great success. Until now the attempts made were unsatisfactory, the utmost difficulty being experienced in finding suitable lakes for the reception of this valuable edible fish. The whitefish in question were incubated at South Kensington in March, and afterwards transferred to ponds at Delaford where they have thrived well ever since.

THE Naturalists' Societies in the East of Scotland have advanced an important stage. They have been established, have worked, and now have formed a union, the first report of which we have now before us. The union embraces the societies in the counties of Aberdeen, Fife, Forfar, Kincardine, Kinross, and Perth, and now consists of ten societies. The president, Dr. Buchanan White, of Perth, explained in his inaugural address the functions of the union as distinguished from those of the individual societies. Its main object of course is to carry on more effectually the work for which each of the societies that compose it has been formed, that work being the promotion of the study of natural science, especially of local natural science. Rivalry begotten of communication and connection, he argues, is as valuable to societies as to individuals; and while each society was isolated and worked independently in its own district, the sum total of the work done was necessarily imperfect because of want of uniformity in the matter of details; one subject has been thoroughly worked while another has been untouched, certain districts have been investigated, while others have been neglected, and the relations of one district to another have not been considered. Each society has toiled in a quarry in its own district, and has brought forth good stones, but they lie in an unsorted heap. The union undertakes the task of sorting and utilising them. On this broad principle the union started, and the president laid down in the opening address the programme of its work for the immediate future. The first step was to ascertain the present state of knowledge of the zoology, botany, geology, and meteorology of the six counties included in the union. For this purpose a uniform method of treatment was adopted. Each reporter in his own special subject states how far the subject has been investigated, what parts of it especially require investigation, both as regards the district and the subject, what the probable richness of the district is, what important works, if any, have been published on the subject and district, and, finally, what work should be taken in hand at once. These statements make up the bulk of this first report, and there are in all nineteen, covering almost every department of natural history. The union, it thus appears, directs and organises the work of its affiliated societies, and prevents waste of power.

THE additions to the Zoological Society's Gardens during the past week include a White-bellied Beaver-Rat (*Hydromys leucogaster*), a White-bellied Sea Eagle (*Haliaetus leucogaster*), two Stump-tailed Lizards (*Trachydosaurus rugosus*), a Great Cyclodus (*Cyclodus gigas*), a Diamond Snake (*Morelia spilotes*) from Australia, presented by Mr. E. P. Ramsay, C.M.Z.S.; an Australian Cassowary (*Casuarius australis*) from Australia, presented by Mr. T. H. Bowyer Bower; four Pucheran's Guinea Fowls (*Numida pucherani*) from East Africa, presented by Commander C. E. Gissing, R.N.; a Kestrel (*Tinnunculus alaudarius*), British, presented by Mr. C. A. Marriott; seven Striped Snakes (*Tropidonotus sirtalis*) from North America, presented by Mrs. A. H. Jamrach; a Common Viper (*Vipera berus*), from Epping Forest, presented by Mr. F. W. Elliott; two Lions (*Felis leo*) from Africa, two Pumas (*Felis concolor*) from South America, deposited; a Collared Fruit Bat (*Cynonycteris collaris*), four Upland Geese (*Bernicla magellanica*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN

DOUBLE-STAR MEASURES.—Nos. 2662–63 of the *Astronomische Nachrichten* contain the first division of a series of measures of double stars made by Herr R. Engelmann during the years 1882–84, preceded by a comparison of the differences between the observer's positions and distances of a number of stars, with those measured by Dembowski and Asaph Hall, and other particulars bearing upon his own results. For several of the more interesting binaries, the following epochs are given:—

		°	"
Castor	1882·88	234·3	5·56
ζ Cancri	1884·28	67·0	0·94
ω Leonis	1884·23	91·4	0·66
ξ Ursæ Majoris	1884·41	249·6	1·92
γ Virginis	1883·07	155·6	5·22
42 Comæ Beren.	1882·93	192·1	0·56
ξ Bootis	1884·45	266·6	3·65

MINIMA OF ALGOL.—The following Greenwich mean times of geocentric minima of Algol have been obtained after applying a small correction to the period given by Prof. Schönfeld in his second catalogue of variable stars, so as to satisfy more nearly the observations of the late Prof. Schmidt in 1882 and 1883:—

	h. m.		h. m.		h. m.
July 25	13 10	Sept. 3	16 29	Sept. 29	11 46
28	9 58	6	13 17	Oct. 2	8 34
Aug. 14	14 49	9	10 6	19	13 26
17	11 38	12	6 54	22	10 15
20	8 26	26	14 57	25	7 3

CENTRAL SOLAR ECLIPSES IN NEW ZEALAND.—It is well known to those who are interested in astronomical matters that the track of the central line in the total eclipse of the sun on September 9 next is almost entirely over the Southern Ocean, and that the total phase will only be observable on land on the shores of Cook's Straits, New Zealand. It would appear that no central eclipse has traversed those islands during the present century; an examination of the various ephemerides points to the annular eclipse of December 29, 1796, as the last which was there central. An annular, though nearly total, eclipse will take place near the north extremity of the North Island on January 3, 1927, while, on May 30, 1965, when the sun is barely risen to an altitude of 5°, he will be totally eclipsed on the east coast of the North Island, near its north extremity for about 2m. 20s.

It is true that in an old catalogue of eclipses which has been transcribed into several of our popular astronomical treatises those of December 12, 1890, and September 29, 1894, are mentioned as being central in New Zealand, but an examination of these eclipses upon more recent data shows that neither will reach that country. In the eclipse of 1890 the central line ends in about longitude 143° W., latitude 36½° S., totality with the sun on the meridian taking place in longitude 129½° E., latitude 54° south, and the line thus running south of New Zealand. In the eclipse of 1894 it ends not far from longitude 163° E., latitude 56° S.

THE DAYLIGHT-OCCULTATION OF ALDEBARAN ON MAY 22, 1868.—Mr. H. Sadler reminds us that the occultation of Aldebaran to which reference was lately made in this column, as having been pointed out by Mr. Newall in 1868, when the star was only some eight degrees from the sun's place, was observed by Prof. Asaph Hall. The observation is to be found in the "Washington Astronomical and Meteorological Observations" for 1868, p. 327.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, MAY 31 TO JUNE 6

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on May 31

Sun rises, 3h. 51m.; souths, 11h. 57m. 25·7s.; sets, 20h. 4m.; decl. on meridian, 21° 59′ N.: Sidereal Time at Sunset, 12h. 42m.

Moon (at Last Quarter June 6, 0h.) rises, 21h. 16m.*; souths, 1h. 43m.; sets, 6h. 10m.; decl. on meridian, 18° 21′ S.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	3 7	10 22	17 38	13 43 N.
Venus	4 14	12 28	20 42	23 8 N.
Mars	2 50	10 21	17 52	16 31 N.
Jupiter	10 13	17 25	0 37*	13 10 N.
Saturn	4 54	13 3	21 12	22 24 N.

* Indicates that the rising is that of the preceding and the setting that of the following day.

Phenomena of Jupiter's Satellites

June	h. m.		June	h. m.	
2	22 50	II. tr. ing.	5	22 43	I. occ. disap.
4	23 14	II. ecl. reap.	6	22 22	I. tr. egr.

The Phenomena of Jupiter's Satellites are such as are visible at Greenwich.

CHEMICAL NOTES

In a paper communicated by Prof. Mendeléeff to the last issue of the *Journal* of the Russian Chemical Society, being a reply to M. Avenarius, the Professor makes a very interesting comparison between his own formula of dilatation of liquids and the logarithmic formula of Waterston, supported in Russia by his opponent, M. Avenarius. He shows by analysis why both formulas express with sufficient approximation the expansion of ether within the limits of 0° and 104°, the observations beyond that limit having to be left aside until we have a more accurate knowledge of the laws of expansion of this substance at higher temperatures and under higher pressures. He demonstrates, moreover, that the logarithmic formula is as inapplicable to water as his own; and, developing both formulas into series, he shows why his own simpler formula ought to be considered as a first approximation to the law of dilatation of liquids until the true law is discovered. Though polemic in its first part, the paper is a masterly piece of scientific treatment of the controversy about so important a question.

Following on the lines laid down by Mr. H. B. Dixon in his experiments on the combustion of carbonic oxide in dry and in moist oxygen, Mr. H. Brereton Baker has recently described some very interesting results regarding the combustion of phosphorus and carbon in oxygen. When the elements in question were heated in oxygen which had been kept in contact with phosphorus pentoxide for some weeks, combustion occurred only to a very limited extent. The presence of a small quantity of water-vapour seems to be needed in order to start the combustion (*C. S. Journal*, *Trans.*, 1885, 349).

The influence of the relative masses of the reacting bodies on chemical changes has of late years received a good deal of attention. Urech has discussed the well-established data regarding the influence of dilution, and of the presence of excess of one or other ingredient, on chemical reactions (*Ber.*, xviii. 94). He points out that the diluent may act both physically and chemically. When it acts altogether as a diluent it does not, according to Urech, affect the rate of the chemical operation. Excess of either reacting body appears always to exert an influence on the rate of change. The causes of the variations in the rate of chemical change are probably very complicated; even the shape and character of the containing vessel may exert an appreciable effect.

Experiments are described by M. J. Thoulet (*Compt. Rend.*, xcix. 1072) on the effect of immersing various solid bodies in saline solutions, *e.g.* marble, quartz, &c., in aqueous solutions of sodium or barium chloride. In each case a portion of the dissolved salt was precipitated on the surface of the immersed solid. The conclusion is drawn that there is an attraction between the dissolved salt and the solid immersed, and that the amount of attraction is proportional to the surface of the solid.

Some time ago Mr. Bayley showed that when drops of various solutions are allowed to fall on to filter-paper, the salt which was in solution in many cases remains in the centre, and a water-ring extends around it. Mr. J. U. Lloyd has extended these observations (*Chem. News*, li. 51). He has observed the distances to which various substances in aqueous solutions extend on pieces of blotting paper, dipped into the solutions, before they are left behind by the water. Great differences were noticed in the length to which different salts thus travelled. Mixtures of salts were also examined; in some cases one salt passes on, leaving the other completely behind. Thus a solution of quinine and berberine sulphates was separated by the method described; the former salt passed on through the paper after the progress of the latter had quite ceased. Dilute sulphuric acid behaved similarly; pure water alone passed onwards. In the case of simple salts dissolved in water, the rule appears to be that the more dilute the solution, the quicker is the separation into salt and water.

Chemists are beginning to realise that the structural formulæ they have so long regarded as final expressions are, after all, very imperfect representations of chemical operations. The molecule of a compound has been treated as a structure built up of atoms; in their anxiety to learn the relations of these atoms chemists have almost forgotten that the molecule is itself a whole. Attention has of late been recalled to this aspect of molecular formulæ. Hartley's researches on "the relation between the molecular structure of carbon compounds and their absorption spectra" have led to results of much interest in this direction. In a paper communicated to the Chemical Society on May 7, Hartley brought forward a series of facts which lead to the conclusion that "molecules vibrate as wholes or units, and the fundamental vibrations give rise to secondary vibrations which stand in no obvious relation to the chemical constituents of the molecule, whether these be atoms or smaller molecules. Hence it appears that a molecule is a distinct and individual particle which cannot be truly represented by our usual chemical formulæ, since those only symbolise certain chemical reactions and physical properties, and fail to express any relations between physical and chemical properties."

Nasini (*Atti d. Acc. d. Lincei Rdct.*, 1885, 74) has been pursuing his inquiries regarding the "atomic refraction" of sulphur in various compounds, and has obtained results which lead him to conclude that the variations in the refraction-equivalents of sulphur compounds cannot be explained by the ordinary structural formulæ employed in chemistry. These variations appear to be connected neither with the valency of the sulphur-atom in the different molecules, nor with the nature of the other atoms which are associated with the atoms of sulphur. Changes in the structure of sulphur-containing molecules seem to be accompanied by changes in the refraction-equivalents of these molecules, but these changes cannot be regarded as due to variations in the valency, or arrangement, of the atom of sulphur they must rather be attributed to some cause which affects the molecule as a whole.

We notice a very interesting and important discussion raised in the *Journal* of the Russian Chemical Society (vol. xvii. 3) by Prof. A. Butleroff, with regard to Prof. Menshutkin's explanation of isomerism by "substitution." M. Butleroff very ably advocates the theory of "structure," *i.e.* of a combination of molecules, instead of atoms, and of compound molecules with atoms. The chief principles advocated by the author appear as follow:—We are right in speaking, as of a real thing, about mutual chemical relations between atoms and molecules; and it is only by admitting some differences in these relations (some differences in the manner of their "union") that we can explain the phenomena of isomerism. These differences are constant, permanent to the molecules; they are their inseparable characteristic attributes. These principles being admitted, the author deduces from them the following conclusions:—"(1) The scheme of substitution (advocated by Prof. Menshutkin) permits rightly to foresee and formulate isomerides only when the structure is supposed known; (2) it requires auxiliary hypotheses, and it is devoid of simplicity and lucidity; (3) the fundamental ideas, both of the theory of substitution as applied to organic bodies and of that of chemical structure, are the same; therefore the former gives nothing new which is not given by the latter; (4) being narrower and more one-sided, when applied to isomerism in organic bodies, the former—if it be applied alone—does not in many instances foretell certain phenomena which are simply and easily foreseen by the theory of chemical structure."

GEOGRAPHICAL NOTES

A British Mission from India is being sent to Cashmere in charge of Col. Lockhart, who is accompanied by Major Woodthorpe, Capt. Barrow, and Dr. Giles, and an escort consisting of two non-commissioned officers and twenty men. The chief object of the Mission is to obtain further geographical information concerning the countries on the northern and western frontiers of Cashmere. It will visit Chitral and the neighbourhood of that place, and will be absent for several months.

M. Leonardo Féa, of the Museum of Natural History at Genoa, has been despatched by the Italian Government on a scientific journey to Burmah. He is to make zoological collections, and also to make various scientific observations. He was provided with letters to the Burmese Government at Mandalay. The Geographical Society of Rome has received from Capt. Molinari reports of two journeys which he has recently made in the Shan States.

At the usual meeting of the Dutch Aardrijkskundig Genootschap on April 18, a general view of those parts of New Guinea was given to which the Society wishes to send an expedition. The Government has promised a grant not exceeding 10,000 florins a year, and under such circumstances the expedition is to be confined to geographical investigations. Particulars could not yet be given, since the proposals of the Society were still under consideration with the Government in the Dutch Indies. It was mentioned, however, that the expedition would probably go to Doreh or to Onin; many offers to accompany it have been made to the Society.

AT a recent meeting of the Paris Geographical Society, M. Romanet du Caillaud described the life and travels of Ordoñez de Cevallos, who was born at Jaen towards the middle of the sixteenth century, and who commenced his journeys all over the world at the age of seventeen. He visited various countries in Europe, and travelled several times to both Americas. He then became a priest, without, however, renouncing his dominant passion. He went as missionary to the Philippines, thence to Canton and Japan. From Japan he set sail for China again, but a storm drove him on the coasts of Tonquin. Having received permission to land, he went to the Court in 1590, and visited various parts of the Indo-Chinese peninsula, Malacca and India. He started then for Buenos Ayres, touching at the Cape of Good Hope, and endeavoured to go to the west coast of South America by the Straits of Magellan, but was prevented by an English fleet, which barred the Straits. He returned to Buenos Ayres, and in 1595 undertook a journey, similar to that in which Crévaux lost his life, by Tucuman, the Paraguay, Potosi, &c., preaching by the way to the savage tribes, whom he calls the Quixos, Omaguas, &c. He fought also agains the black Indian cannibals, called by the Spaniards the Gimarrons or Caribs. Ultimately he returned to Seville and became a canon. In 1607 the Bishop of Macao gave him a message from the King of Tonquin desiring him to return to that country, but he could not do so. The works of this indefatigable traveller are: (1) "Historia y Viage del Mundo"; (2) "Relaciones verdaderas de los Reynos de la China, Cochinchina, y Champaa" (Jaen, 1628); (3) "Triunfos de la Santissima Cruz"; (4) "Descriptio Indiæ Occidentalis," in the "Novus Orbis sive descriptio Indiæ Occidentalis" of Antonio de Herrera (Amsterdam, 1622).

A BLUE-BOOK just issued by the Foreign Office contains five maps referring to the Russo-Afghan boundaries. The first is a chart of the routes followed by members of the Boundary Commission from Kushan to Bala Murghab; the second is a reproduction in English of a Russian military map of the frontier; No. 3 is a copy of a map of South-Western Turcomania, produced in Russia; No. 4, which was prepared by M. Lessar, shows his explorations; while the last is a sketch map to illustrate the various zones and lines of frontier proposed at one time or other recently by Russia and England.

The Austrian Tourist Club has appointed a committee with the view of making experiments for the improvement of the natural drainage of certain parts of the Karst which are liable to periodical inundation. This celebrated region in the north of the Adriatic is remarkable for its underground rivers, which communicate with the surface here and there by vertical shafts. Through these openings the surplus waters escape to the surface when the underground channels are filled to overflowing, and in that way considerable tracts are periodically converted into temporary lakes. The well-known Lake Zirknitz is only one of dozens of such lakes that are formed in this district every year. The practicability of preventing these inundations by enlarging the underground channels has been discussed on several occasions in the Tourist Club, and now the first attempt to carry this scheme into effect is about to be made with the Pinka Jama, a natural shaft leading down to an underground channel about a mile and a half from the Adelsberg Cavern.

HERR GLASER, the Austrian explorer, is about to undertake a new journey in Southern Arabia. He will go first from Sanaa to Marib, and will then visit in succession Wadi-Davassir, Nedjd, Omaun, and Hadramant. In a similar journey which he made some time ago he brought back 276 inscriptions of the Sabeans, who were regarded in the time of the Ptolemys as the wealthiest people of Arabia.

CAPT. JENNINGS of the Royal Engineers, has returned to India (according to the *Pioneer*) after a successful exploration of South-eastern Persia, including the hitherto unknown Sarhad country. He carefully examined all the roads and the configuration of the country, and is said to bring back a mass of useful information with regard to this region.

THE last number (xx.) of the *Excursions et Reconnaissances* of Saigon contains, among others, two papers by that indefatigable student of Indo-China, Capt. Aymonier, one on Cambodian epigraphy, the other on a journey in Laos. Dr. Tirant gives the second part of his paper on the reptiles of Cochin China and Cambodia, and M. Hardouin concludes the account of a recent journey in Siam.

Petermann's Mittheilungen (No. 5, 1885) contains a paper, accompanied by an excellent map, on Kaffraria and the eastern boundary lands of the Cape Colony, by Herr Schunke, some observations on the sanitary features of the Upper Amu-Darya, and an account of the Geographical Congress at Hamburg.

A YEARLY AND A DAILY PERIOD IN TELEGRAPHIC PERTURBATIONS

SINCE July 1, 1881, all disturbing currents at forty-four telegraphic stations in Norway and Sweden regarding time, duration, force, direction, &c., have been at my request regularly recorded. These observations will of course first obtain real importance when a longer series is available; still, I believe it would be of interest at present to investigate whether for these telegraphic perturbations a similar yearly and daily period could be established, such as have been proved for the aurora and other terrestrial magnetic phenomena. My time being now rather limited, extensive researches are not possible; of the mentioned forty-four stations I have therefore selected four, and herewith present the results of my investigations.

The four stations are named and located as follows:—

Kistrand	70° 25′ N.	25° 13′ E.G.
Lödingen	68 24 ,,	16 1 ,,
Trondhjem	63 27 ,,	8 5 ,,
Bergen	60 24 ,,	5 20 ,,

My researches have been made for the three years from July, 1881, to June, 1884. As the Norwegian stations do not do night work, the observations could only be taken from 7 o'clock in the morning till midnight.

I have first noted the number of days for each month on which telegraphic perturbations have been observed, excluding those caused by thunderstorms. These numbers besider the totals for each month and year are shown in Tables I. to IV.

TABLE I.—*Kistrand*

Month	1881 to 1882	1882 to 1883	1883 to 1884	Total
July	1	2	8	11
August	0	12	3	15
September	7	12	11	30
October	14	20	6	40
November	10	22	3	35
December	13	8	3	24
January	5	7	0	12
February	7	10	9	26
March	13	16	4	33
April	25	6	12	43
May	19	4	3	26
June	14	5	5	24
Year	128	124	67	319

TABLE II.—*Trondhjem*

Month	1881 to 1882	1882 to 1883	1883 to 1884	Total
July	7	5	10	22
August	4	8	3	15
September	10	6	3	19
October	15	11	6	32
November	11	16	6	33
December	14	6	5	25
January	12	7	1	20
February	16	10	4	30
March	18	8	7	33
April	14	4	2	20
May	17	2	1	20
June	6	6	3	15
Year	144	89	51	284

The monthly totals for the three years are graphically represented in Fig. 1. Both the numbers and the figure show apparently that the yearly period for the telegraphic perturbations is identical with that of the aurora, *i.e.* its maximum coincides with both solstices and its minimum with both equinoxes. Of especial importance is the minimum at the time of the summer solstice, when the aurora, as is well known, ceases, on account of the brightness of the northern nights. The perspicuity with which the yearly course of the period is drawn in the four representations of Fig. 1 may even be called surprising, considering the material of observation only embraces three years.

Fig. 1.

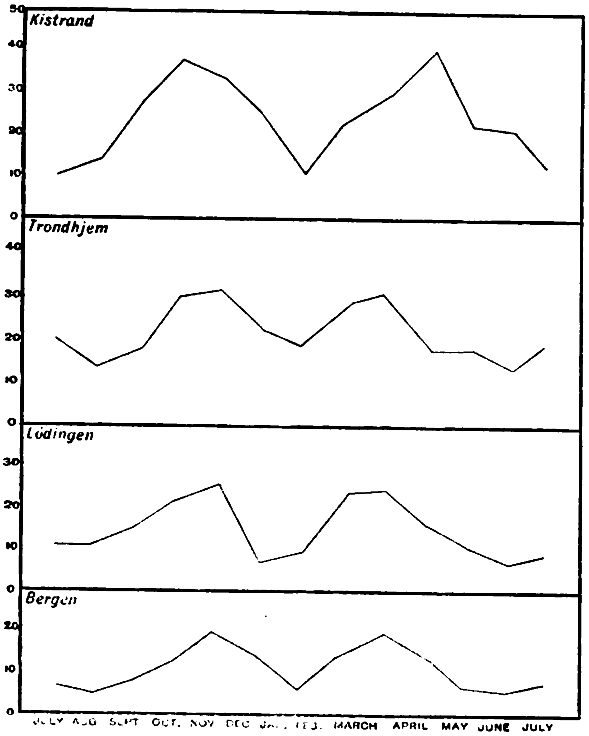

TABLE III.—*Lödingen*

Month	1881 to 1882	1882 to 1883	1883 to 1884	Total
July ...	3	4	3	10
August	6	3	1	10
September ...	9	3	3	14
October	8	11	1	20
November ...	8	14	4	26
December ...	2	5	0	7
January	5	4	0	9
February	10	10	3	23
March...	9	9	6	24
April ..	10	4	3	17
May ...	7	3	2	12
June ...	2	6	0	8
Year	79	75	26	180

TABLE IV.—*Bergen*

Month	1881 to 1882	1882 to 1883	1883 to 1884	Total
July ...	2	1	3	6
August	0	3	2	5
September ..	5	1	1	7
October	5	3	4	12
November ...	6	10	3	19
December ...	6	6	1	13
January	3	1	2	6
February	3	9	0	12
March...	10	4	4	18
April ...	9	3	1	13
May ...	4	2	0	6
June ...	3	1	0	4
Year	56	44	21	121

Tables I. to IV. will show the great frequency of these telegraphic perturbations in Norway compared with those of all other countries in Europe. In the totals of the years a constant decrease for all four stations is visible which decidedly coincides with the diminishing appearance of the aurora during recent years in this country. After some years it will probably be seen how the telegraphic perturbations have the 11-year period in common with the aurora.

In order to determine the daily period, I have investigated how often during the three years in every hour from 7 a.m. till midnight perturbations have been observed (excluding those caused by thunderstorms). Table V. shows the result :—

TABLE V.

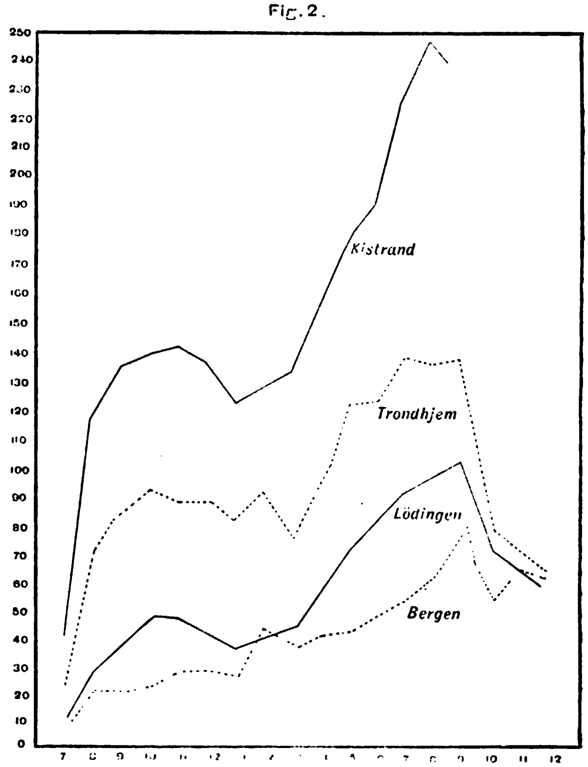
	7	8	9	10	11	12
Kistrand	42	117	135	139	141	137
Trondhjem	24	61	84	91	88	88
Lödingen	11	30	39	48	47	41
Bergen ...	9	23	23	24	28	29

	1	2	3	4	5	6
Kistrand	122	128	133	155	177	191
Trondhjem	81	91	75	93	120	123
Lödingen	36	41	43	57	70	80
Bergen ...	27	43	37	40	42	47

	7	8	9	10	11	12
Kistrand	227	247	238	—	—	—
Trondhjem	137	136	138	77	69	61
Lödingen	91	96	100	70	61	54
Bergen ...	52	61	77	51	61	59

Fig. 2 gives these numbers in graphic representation. It will

Fig. 2.



be seen that the telegraphic perturbations show a very prominent maximum in the evening, 8 till 9 o'clock. Intimations of a trifling maximum (with the exception of Bergen) 10 till 11 a.m., and a succeeding minimum 1 to 2 p.m. are also visible.

Other occupation taking up my time at present a more extensive and detailed investigation must be postponed.

Christiania SOPHUS TROMHOLT

A NOTE RELATING TO THE HISTORY OF THE AURORA BOREALIS

AMONG northern authors none has given the writers on the Aurora Borealis more to trouble than Peder Claussön Friis, 1566-1614, Minister at Undal, near the town of Mandal, in Southern Norway. This, for his time, very productive author, wrote, towards the end of the sixteenth century, a treatise, "About Greenlana." In a second edition (about 1600) he added some extracts from the "Kings-mirror,"[1] and among these, one about the Aurora Borealis. But here he has inserted a remark, which in a high degree has attracted attention and caused astonishment, and which, till now, has been inexplicable to the investigators of the Aurora Borealis. I give further on a translation of the description of the Aurora Borealis in the "Kings-mirror," and after it the version of Peder Claussön:—

Kings-mirror

"Such a nature and condition has the north-light, that the more obscure the night, the more brilliant it appears, and only in the night is it to be seen, never during the daytime, and especially in profound darkness, but seldom by moonlight. It appears as a large flame from a heavy fire seen from afar. Out of this flame protrudes, apparently up in the air, sharp points of unequal height, and very unsteady, so that now one, then the other is higher, and in such a manner this light is pendent like a luminous blaze. As long as these flashes are most intense and bright, such a keen light radiates from these streams of fire and rays, that outdoor people can find their way, and even go a hunting, if it should be necessary. Also, when people are in houses provided with windows, it is so bright inside that all present can recognise each other. But this light is so fluctuating that it sometimes seems to darken, as if a black smoke or a heavy nebulous cloud had been puffed into it, and then shortly again it seems as if the light were about to be smothered in this smoke, and almost become quite extinct. But as soon as this fog commences to dissolve, then this light brightens, and clears up for the second time, and it happens even that one would believe that heavy sparks emitted from it as from a red-hot iron just taken out of the forge. When the night declines, and with daybreak this light begins to decrease, and when the day has set in it seems entirely to disappear."

Peder Claussön Friis

"In Greenland a meteor and bright light is seen on the sky during the night, which appears in the following manner: the more obscure the night the more brilliant is the light; that is to say, the less the moon shines, *and when she is in her prime or wane, the more this light becomes visible in the sky, however, always towards the north,* AND NEVER SO HIGH IN THE SKY AS TO BE OBSERVED IN OTHER COUNTRIES THAN GREENLAND, ICELAND, AND THE NORTHERN PART OF NORWAY, *and for that reason it is called North-light.*

"It appears as a flame or a *darting fire,* and extends over the sky *like a tall and slender hedge,* and it rushes *up and down in a trice as if many organ pipes were posted one beside the other, and in the twinkling of an eye one shoots up and the other down, and where the flame darts clearest up and down, back and forwards,* it can grow dim and almost leave behind it a smoke; *but the next moment* light up again *on another spot, or catch fire where it just before seemed to be extinguished. Nobody who has not himself seen it, can imagine how quickly this light moves forwards and backwards, as if it were hopping and dancing with much agitation.* And when this light is most intense, people can perceive everything in the houses *as if the moon were shining.* At daybreak this northlight fades away."

The "Kings-mirror" was written about 1250, at all events before 1260, and probably later than 1240. The home of the unknown, but at all events Norwegian, author may be looked for, according to the sagacious reasoning of H. Geelmuyden (Christiania Observatory) between 64° 23′ and 64° 58′ N. lat. (not far from the town of Namsos). This description of the aurora is indeed unparalleled in the aurora literature of the past ages; the noble but unvarnished manner in which he describes the phenomenon has not a counterpart in the same or at a much later period. It is peculiar, however, that the aurora is mentioned in the "Kings-mirror" as a phenomenon chiefly characteristic of Greenland, and not even an intimation is given as to its being visible in Norway. This description indicates, nevertheless, quite plainly that it is based on the author's own observation of the aurora in his native country, and it is therefore beyond doubt that he was familiar with the phenomenon,[1] although he has considered Greenland—the country situated, according to the opinion of past ages, farthest towards the north—the proper home of the aurora.

In Peder Claussön's above quoted version of the aurora description in the "Kings-mirror" I have made the remarks and expressions differing from the "Kings-mirror" conspicuous by italics. It will be seen that his citation is rather free; many of these conspicuous expressions, if not all, point to Peder Claussön's knowledge of the aurora through his own observation. The more striking is the conspicuous remark that the aurora in Greenland does not appear so high in the sky as to be observed in other countries than Greenland, Iceland, and the northern part of Norway.

This remark has been inserted in many other publications, and all historians of the aurora from Mairan to Fritz have occupied themselves with the notable circumstance that, according to this remark, the aurora was not visible during the last half of the sixteenth century in Southern Norway. But nowhere in the whole history of the aurora is it so evident how much caution must be displayed in drawing comprehensive inferences from a single remark of an old author.

Peder Claussön has, in a single copy of his treatise on Greenland in the year 1604 or 1605, with regard to the aurora, added the following important "note," hitherto unknown to the investigators of the aurora:—

"This northlight was, as before said, only seen in past times in northern countries. But in the period of my infancy, about the year 1550, it was first seen by people who live in the southern part of Norway, however not higher on the sky than the Polar Star. But since the year 1570 it ascends to such a height that it appears to us in the south-east and in a southern direction, and I suppose that it is seen at present also in other countries."

Peder Claussön's relation is thus in downright contradiction with the interpretation given to his above-mentioned remark. It remains now to explain how he could write, in the year 1600, that the aurora was only visible in the extreme north of Norway. It may be seen that he had the opinion that the aurora, in "past times," was only visible in "the northern countries"; the silence of the "Kings-mirror" about this phenomenon in Norway has perhaps brought him to this conclusion. The remark "and never so high in the sky as to be observed," &c., therefore, in all probability describes the circumstances which, after his opinion, took place at the time when the "Kings-mirror" was written. The additional clause, "and for that reason it is called northlight," seems at the same time to intimate that he, by the previous remark, would explain why the author of the "Kings-mirror" uses the expression northlight (namely, because it is visible only in the extreme northern countries). SOPHUS TROMHOLT

Christiania

[1] The Kings-mirror (Konungs skuggsjá) is, of its kind, an unparalleled Norwegian work, in which an ingenious and noble man, who must have stood at the height of culture at his time, has expounded his philosophy and especially his views on State administration and ethics, in the form of conversations between a father and son. It is a book on good manners, social intercourse of the highest interest, because of the whole form of culture which it represents, and is written in elevated tone.

[1] The author himself never visited Greenland.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—Two studentships have been established at St. John's College on the foundation of the Rev. Mr. Hutchinson, late Senior Fellow. They are of the value of 60*l.* a year for two years and are tenable with a Foundation Scholarship. Any student of the College who shall be *bonâ fide* engaged in the pursuit of some branch or branches of physical or natural science or in the study of Semitic or Indian languages, and shall be of not less than nine and not more than eighteen terms' standing from the commencement of his residence in the University shall be qualified to be a candidate, and if there is no candidate belonging to the College of sufficient merit in these studies, the Council may elect a student engaged in any study, whether a member of the College or not. The Council may impose such conditions on the students as shall encourage genuine study after the best methods—*e.g.* they may require him to present in writing an account of his studies, to deliver lectures, &c. The election will take place in June each year.

It will be seen that a Hutchinson student may be free to work at biology in Naples, to join an Eclipse Expedition, to study Pali in Ceylon or Hebrew in Cambridge. We hope to hear of the Hutchinson students in the future.

The Senate has approved of the erection of a new Chemical

Laboratory according to Mr. Stevenson's design, and tenders are to be obtained as early as possible.

Mr. J. W. L. Glaisher, F.R.S., is to be Additional Examiner in Part III. of the Mathematical Tripos in January, 1886.

Prof, Bonney and Mr. J. J. H. Teall are appointed Examiners for the Sedgwick Prize to be adjudged next year.

Prof. Macalister will take a class in Osteology during the Long Vacation. There will also be an Introductory Practical Course in Anatomy, illustrated by that of the Dog, superintended by the Professor and Mr. Rolleston. The Demonstrator will take a practical class in Histology during the Long Vacation.

SOCIETIES AND ACADEMIES

London

Royal Society, April 23.—"The Essential Nature o the Colouring of Phytophagous Larvæ (and their pupæ); with an account of some Experiments upon the Relation between the Colour of such Larvæ and that of their Food-plants," by Edward B. Poulton, M.A., of Jesus and Keble Colleges, Oxford.

Abstract.

The Essential Nature of the Colouring of Phytophagous Larvæ.—Phytophagous larvæ are coloured by pigments derived from the food-plant, pigments proper to the larvæ, and tissues such as fat, which lend incidental aid to the colouring. The altered plant-pigments hitherto detected in larvæ are chlorophyll and xanthophyll, causing the colours green and yellow. The former is termed metachlorophyll, because of the difference between its spectrum and that of unaltered chlorophyll (in the leaf), and because of the chemical differences between its solution in larval blood, &c., and any known solution of plant chlorophyll. The evidence is at present insufficient to warrant the use of a separate name for the derived larval xanthophyll. Other colours hitherto examined are due to true pigments or tissues.

The following table indicates the situations occupied by the different causes of colour, and gives to some extent the historic order of their employment.

I. The internal tissues and organs with ready-made colour	*a.* Digestive tract. *b.* Fat. *c.* Dorsal vessel.
II. The passage of derived pigments through the walls of the digestive tract into	*a.* The blood. *b.* The subcuticular tissues.
III. The appearance of true pigment in	*a.* The hypodermis. *b.* The cuticle.

These causes explain larval and pupal colour, except such instances as the metallic tints of certain pupæ. The different stages of coloration mentioned in the table were not often mutually exclusive, but each new method was an additional resource. The derived pigments more often confer general resemblances, the true pigments special resemblances. In many cases the green colour is due to metachlorophyll in the blood only (many Noctuæ), while in other cases it is also placed in the subcuticular tissues (Sphingidæ). The former larvæ lose their colour locally on slight compression, while the swollen uncompressed part becomes of a deeper tint. When larvæ are dimorphic—green and brown—the colours of the former are mainly due to metachlorophyll, of the latter to true pigments. Such important differences in the causes of colour commonly occur among larvæ from the same batch of eggs, or in the life-history of a green larva, which becomes brown, or *vice versa*. The blood of brown larvæ, with transparent skins, is colourless except in very thick layers; in the brown *Chærocampa elpenor*, the blood becomes brown, but the bands of metachlorophyll and xanthophyll can be faintly seen. Hence these pigments are not destroyed beyond the point at which they cease to interfere with the changed colour. The derived pigments may exist unchanged in the blood after the larva has altered in colour, if the superficial pigments are completely opaque (many geometers). This persistence of the derived pigments may be very important to the organism. Thus the larva of *Ennomos angularia* is an opaque brown geometer, but pupates in a cocoon of loosely-attached leaves through which it can be seen. Before pupation the true pigment disappears, and the larva and pupa are coloured by metachlorophyll. Again, in many instances the derived pigments are retained in the blood of the pupa and segregated in the ova, when these are yellow or green, serving to tinge the newly-hatched larva before the effects of its first meal can become apparent. But after such a long period, and the alternation of solution in blood and deposition in tissue, the colour of the more stable pigment—xanthophyll—preponderates over the green of the metachlorophyll in the newly-hatched larva. The bands of xanthophyll are distinctly seen in an alcoholic extract of crushed ova taken from the bodies of moths which have been preserved for ten years or longer. In blown and dried larvæ the greens soon fade, while the yellows persist and the pigment can be detected after many years. The true pigments are also unaltered. In larvæ preserved in spirit the derived pigments quickly disappear, and the alcohol is yellow with xanthophyll, while the true pigments are unchanged. These facts are also true of phytophagous hymenopterous larvæ, as well as in the lepidoptera. Thus in *Nematus curtispina* the green colour is due to derived pigment, while the broad white dorsal band is due to fat collected on each side of the dorsal vessel (and it can be seen to move with the pulsations of the latter). In *Crœsus Septentrionalis* fat becomes the vehicle for a yellow colour. The few exposed pupæ of moths are coloured in the same manner as the larvæ (*e.g.* the *Ephyridæ* and *E. angularia*). In the Ephyridæ, dimorphic larvæ—green and brown—produce pupæ which follow the colour of their respective larvæ. Larval markings can often be seen upon the pupa immediately after pupation. Thus the pupa of *Sphinx ligustri* is marked by the oblique stripes of the larva. The pupæ of butterflies are nearly always protectively coloured, and often possess the derived pigments. In *Papilio machaon* the derived pigments of the pupa are segregated in a very remarkable chitinised (?) subcuticular layer, which is quite opaque, so that no effect is produced by the bright yellow blood (xanthophyll).

Methods of Investigation and Spectra of derived Pigments.—Zeiss's micro-spectroscope was always employed, with bright sunlight as the means of illumination. The blood is obtained by pricking the pupa or the larva in some situation remote from the digestive tract. Existing under pressure, most of the blood at once emerges as a clear bright green or yellow liquid (when the derived pigments are present). It is received into a tube-section, with one end cemented to a glass slide, and when full a cover glass is placed upon the open end, becoming fixed by the drying of the blood. In most cases the blood so prepared will keep for months. The spectrum of metachlorophyll is as follows (in the case of the bright green fresh blood of the pupa of *Pygæra bucephalus* in a thickness of 23 mm.):—

Chief band in the red, 71·–65·, continuous with a less absorption extending to 58·, darkest from 58·5–59·5; a broad band from 52·–48· with the dimmed blue and violet coming through 48·–42·, from which latter point the violet end is absorbed. There is no absorption of the extreme red. A Zeiss's scale is adopted in which 1· = 1/100,000 mm.

Comparing this spectrum with that of true chlorophyll, as seen in two fresh calceolaria leaves, the whole spectrum is shifted towards the violet end in the latter case, with the exception of the end absorption, which extends to 43·. The chief band in the red is 70·–64·5, and then the continuous absorption of metachlorophyll is replaced by two bands: 61·–63· and 57·5–60·, and if anything the former is the darker. The broad band is 47·5–51·, and the dimmed blue and violet 47·5–43·. The chief difference is the continuity of the three bands of the red end in metachlorophyll, and the fact that their darkness is in the order (1) (3) (2) from the red, instead of (1) (2) (3). A similar spectrum (as far as it could be identified by the use of a paraffin lamp) was observed in a clear green fluid from the digestive tract of the larva of *Phlogophora meticulosa*. In yellowish green blood (pupa of *S. ligustri*) the absorption at the violet end is aided by the xanthophyll present, which gives two bands if the thickness of blood be sufficiently small. In some cases a third band is also present. Thus the blood of *S. ligustri* in a thickness of 3 mm. does not give the band of chlorophyll in the red, but shows three bands in the more refrangible half of the spectrum: 48· 50·, 45·–46·25, and 42·–43· the violet end being absorbed at 41·. Between these areas of absorption the spectrum is dimmed. The three bands become less distinct in the above-mentioned order, and the third can only be seen under favourable conditions of light, and appears to be absent in some cases. Mr. Sorby states that a third band, due to another substance, is sometimes present in the xanthophyll spectrum. While the spectrum of metachlorophyll is very constant over a large number of larvæ and pupæ, in the living green pupa of *Ephyra punctaria*, a form of chlorophyll with a rather different spectrum was met with, in which the second band of true chlorophyll is present instead of the continuous absorption, while the third band could not be seen in the slight thickness obtainable. The term "ephyra-chlorophyll" is given to this pigment, which is dissolved in the blood of the pupa. Metachlorophyll, and probably xanthophyll, are united with a proteid in the blood. The addition of ether to green blood brings down the combined pigment and proteid in the form of a green coagulum, from which the ether does not dissolve the metachlorophyll, but gradually takes up the xanthophyll, becoming bright yellow. Alcohol, on the other hand, decomposes the combined proteid and pigments, the coagulum rapidly becoming decolorised, and the xanthophyll passing at once into solution, while the metachlorophyll disappears. Hence it seems that the latter pigment depends upon its association with the proteid for its extreme stability and permanence under the action of light. This permanence is necessary for the larva, since any colour due to derived pigments implies the penetration of light, and often the complete translucence of the whole organism, and, further, there are long periods (at the ecdyses), during which the pigments cannot be renewed, because no food is taken. Then there are the extreme cases of the green Ephyra pupæ, and the green pupæ of *P. machaon*, freely exposed to daylight during two-thirds of the year. It seems certain that the derived pigments are merely protective, and are of no further importance in the physiology of these organisms. Thus it is not probable that there are any marked differences between the physiological processes of the green and brown larvæ from the same batch of eggs, or in the processes of a green larva which has become brown, or *vice versâ*. The blood of larvæ seems to be always acid (and so with all pupæ examined, except *E. punctaria*, of which the blood was neutral, in the only instance in which the blood of this pupa was tested), but I have as yet been unable to obtain a sufficient quantity of blood to determine what acid is present. The blood forms a solid, black coagulum which is due to oxidation, and does not take place when the blood is preserved in the manner described above. The injured parts of larvæ which have healed are black. It is probable that the darkening of pupæ and of the cuticular pigment of larvæ is also due to oxidation. There is great variability in the amount of clot formed and in the rapidity of the process.

Historical.—Mr. Raphael Meldola, in the *Proc. Zool. Soc.* for 1873, and in the editorial notes to his translation of Weismann's "Studies in the Theory of Descent," Part. II., "On the Origin of the Markings of Caterpillars," &c., argues very convincingly for the use of plant-pigments by green larvæ He points out that internal feeders are never green unless their food contains chlorophyll, and that when this is the case (*Nepticula oxyacanthella*, &c.) they may be green, although the colour cannot be of any advantage to them. Pocklington (confirmed by Dr. MacMunn) found chlorophyll in the elytra of Cantharides, and Chautard seems doubtful about the same pigment in this situation (*Compt. Rend.*, January 13, 1873, and *Ann. Chim. Phys.*, 5, iii., 1-56). Dr. MacMunn found a band in the red which resembled chlorophyll, by concentrating light on the integument of the larva of *Pieris rapæ* and examining with a micro-spectroscope; but both he and Krukenberg refer the pigment to the larval digestive tract. (See *Reports* of British Association at Southport, 1883, and a letter by Dr. MacMunn to NATURE for the week ending January 10, 1885). It is very unlikely that the green colour of so thick and opaque a larva can be due to its digestive tract, and it is probable that the blood, with its dissolved metachlorophyll, was lost in the manipulation. From memory of the appearance of the larva, and from examining a blown specimen, I should certainly infer that there are also derived pigments in the subcuticular tissues.

The Relations between the Colour of Phytophagous Larvæ and that of their Food-Plants.—Entomologists have been long aware of the fact that the colours of many larvæ vary (within the limits of the same species) according to the colour of the plant upon which they are found. Complete references to the observations hitherto recorded upon this point occur in Mr. Meldola's writings (mentioned above). Among the most important of these is a paper by Mr. R. M'Lachlan (*Trans. Ent. Soc.*, 1865, p. 453) in which data are given as to *Eupithecia absynthiata*, which were yellowish when found upon *Senecio jacobæa*, reddish upon *Centaurea nigra*, whitish upon Matricaria. When nearly full grown they were all given *Senecio jacobæa* without altering the colour of the reddish and whitish varieties. From this Mr. M'Lachlan argued (1) that it was necessary for the larvæ to have fed on the one kind of plant from the egg to acquire the resemblance; (2) that the colour is not caused by the food showing through the somewhat transparent integument. Mr. Meldola quotes many instances in which the larva of *S. ligustri* has been observed to vary according to its food-plant (laurustinus, lilac, privet, ash). I have for many years known of the difference between the lilac and privet forms (the latter being of a brighter yellower green than the former, with brighter stripes). In 1884 I bred twelve larvæ from the egg upon privet, and the same number upon lilac. All the privet and six of the lilac larvæ reached maturity, and, without exception, showed the differences indicated above. A more remarkable instance is afforded by *Smerinthus ocellatus.* Mr. Meldola quotes Mr. E. Boscher as finding many yellowish-green varieties of this larva upon *Salix viminalis,* and many bluish-green varieties upon *S. triandra,* similar to those which are well known to occur upon apple. The former varieties possessed the rows of reddish-brown spots which sometimes occur on this variety of the larva. Upon another species of Salix he found instances of both varieties. In 1880 Mr. Boscher conducted some breeding experiments at Mr. Meldola's suggestion, feeding the larvæ from the egg upon *S. triandra, S. viminalis,* and apple, respectively. Only three of the third lot survived, and were all of the bluish-green form. I have also found (*Trans. Ent. Soc.*, Part I., April, 1884) that *S. rubra* and *S. cinerea* produce the yellowish variety, but *S. viminalis* the bluish form, according to my experience. In 1884 I fed five lots of six larvæ each, from the egg, upon apple, crab, *Salix viminalis, S. cinerea,* and *S. rubra,* respectively. On a few occasions *S. babylonica* and *triandra* were substituted for *S. rubra,* and ordinary apple for crab. The eggs were hatched July 15 to 18, and most of the larvæ were full fed by August 23, with the following results:—*Apple*: the five larvæ were typical bluish-green forms. *Crab*: the five larvæ were also typical bluish-green. *S. viminalis*: the four larvæ were not so whitish as the above-mentioned lots, but were almost intermediate. *S. cinerea*: the four larvæ were also intermediate. *S. rubra*: the four larvæ were yellower than any of the others, but were not much beyond intermediate forms. The yellowest was separated on August 14, and fed upon apple, becoming adult August 26, by which time it was rather whiter than any others of the same lot (*S. rubra*).

Thus there was no doubt about the effects produced, but there was a strong tendency all through towards the bluish variety, which the food-plant could only overcome to the extent of producing an intermediate form. The same conclusions were formed by a comparison of larvæ found in the field during 1884. Thus two nearly opposite varieties were found upon the same tree (? *S. ferruginea*, Anderson); an intermediate variety was found upon *S. rubra,* and a bright yellowish variety upon apple. At the same time the great majority of larvæ found were such as I should have anticipated.

Experiments were made upon the younger captured larvæ, which were fed upon food-plants tending towards a different colour. The results were similar to those indicated by the former experiments. Some effect could be produced in an intermediate variety by feeding it for some considerable time upon a food-plant known to have strong tendencies, but no such effect is produced upon a larva with a strongly-marked colour, *i.e.* one with strong tendencies itself, and corresponding with those of the food-plant. But the former experiments show that a very strong larval tendency may be counteracted to the extent of producing an intermediate form by feeding it from the egg upon a food-plant tending strongly in the other direction. When this latter effect has become manifest, it was proved that an appropriate change of the food at a comparatively late period may produce some considerable effect in the direction of the original tendency. The most probable explanation of the above-mentioned facts is that the effects of the food-plant are hereditary, and accumulate when the larvæ of successive generations feed upon plants with the same tendencies. Conversely feeding upon plants with different tendencies, and interbreeding, accounts for the irregularities observed. Thus in the larvæ fed from the egg, it is supposed that the previous generation (or generations) fed upon plants tending towards bluish-green larvæ. The yellowish larva found upon apple must have descended from a line fed upon *S. rubra,* or a plant with the same effects. The localisation of a food-plant would overcome both causes of irregularity, the liability to lay eggs on plants with different tendencies, and the chance of interbreeding between the two varieties.

This explanation is in accordance with the fact that the larvæ are of a very uniform tint upon apple trees in gardens, which are to a certain extent locally separated from the various species of sallow growing by the banks of streams, and in damp lanes and hedgerows. The strong effects produced upon the larvæ by apple, the usual proximity of many trees, and the sluggish flight of the Smerinthi, doubtless all conduce towards the uniformity between the larvæ upon this food-plant. On the other hand, there is the greatest facility for (the observed) irregularity in the results of sallow upon the larvæ, for many so-called species with various tendencies grow close together, so that there must be interbreeding and the deposition of eggs on various species of food-plants, even in the case of very sluggish insects. It is probable that certain conflicting statements as to the effect of the different food-plants upon the larva of *S. ligustri* are to be explained in the same way. As to the structural cause of the variability in these two larvæ, the main factor is a change in the relative amounts of the two derived pigments. Thus there is more xanthophyll in the blood of the pupa of a yellowish *S. ocellatus* than in the other case; and more chlorophyll with less xanthophyll, in the blood of the pupa of *S. ligustri,* from the greener larva fed upon lilac than from one fed upon privet. The result of this adjustment of the relative amounts of derived pigment is to produce a colour which harmonises with the part of the environment imitated—the undersides of the leaves in the case of *S. ocellatus,* the *tout ensemble* of the food-plant in the case of *S. ligustri.* In neither instance can the effects be due to the most direct and simple action of the food itself—the solution of its pigments in their normal proportion showing through the skin. This is disproved by the fact that *S. ocellatus eats* the whole leaf, but *resembles* the underside, and imitates in derived pigments an appearance largely due to texture; further, the effects do not at once follow a change of food, and a strong larval tendency may even cause the rearrangement of the derived pigments, so as to produce an effect *unlike* the leaf. The simple view allows no room for larval tendencies or for delayed effects. It has also been rendered very probable that the effects accumulate during successive generations. In the case of *S. ligustri* there is the additional difficulty that the larval pigment of the oblique stripes is affected by the food-plant as well as the derived pigments. Such effects cannot be explained by any simple theory of phytophagic effects, but it still holds good that phytophagic pigments play a most important part in larval coloration, and afford the chief material which is moulded by some influence—subtler than that which is implied by the term "phytophagic" itself—into likeness to a special part of the environment. The little we know of this influence points towards a nervous circle whose efferent effects are seen in the regulation of the passage of altered plant-pigments through the digestive tract into the blood, and finally the tissues, and in the colour of a certain amount of larval pigment, while the afferent part of the circuit must originate in some surface capable of responding to delicate shades of difference in the colour of the part of the environment imitated This interpretation is rendered unusually difficult by three facts: the gradual working of the process, often incomplete in a single life; the excessively complex and diverse results, and the special character of the stimulus (for it is only the part of the environment imitated which produces any effect —*e.g.* the *undersides* only of the leaves in the case of *S. ocellatus*). During the present year I hope to experiment further upon the subject, and I have a large number of living pupæ of *S. ocellatus,* with the life-histories of their respective larvæ carefully noted.

Chemical Society, May 7.—Dr. Hugo Müller, F.R.S., President, in the chair.—The following papers were read:—On some points in the composition of soils; with results illustrating the sources of fertility of Manitoba prairie soils, by Sir J. B. Lawes, Bart., LL.D., F.R.S., F.C.S., and J. H. Gilbert, Ph.D., LL.D., F.R.S., V.P.C.S.—Researches on the relation between the molecular structure of carbon compounds and their absorption spectra, by Prof. W. N. Hartley, F.R.S. In continuation of the author's previous researches (*Trans.*, 1881, 57-60 and 111-128; 1883, 676-678), measurements have been made of the wave-lengths of the rays absorbed by the following substances:—(1) Aromatic hydrocarbons: benzene, the three xylenes, and naphthalene. (2) Aromatic tertiary bases and their salts: pyridine, picoline, quinoline, and their hydrochlorides. (3) Addition products of tertiary bases and salts: piperidine, tetrahydroquinoline, and its hydrochloride. (4) Primary aromatic bases or amido-derivatives and salts thereof: ortho- and para-toluidine and their hydrochlorides. In the preparation of solutions, a milligram-molecule, that is, the molecular weight in milligrams, was dissolved in 20 c.c. of a diactinic solvent, and made up to a given volume, generally 20 c.c. In this way molecular weights were made to occupy equal volumes. Photographs of the absorption spectra were taken through definite thicknesses of solution. The lines of tin, lead, and cadmium were used as references; the positions of the bands were measured on the photographs by means of an ivory rule divided into hundredths of an inch, and those measurements were reduced by means of two curves to oscillation frequencies and wavelengths. As far as possible, the absorption curves are drawn to a uniform scale. These curves indicate the *molecular actinic absorption* of each substance. The following deductions are drawn:—When an atom of nitrogen is substituted for an atom of carbon in the benzene or naphthalene nucleus, the property of selective absorption is still retained. When the condensation of the carbon and nitrogen in the molecule of a benzenoid compound or tertiary base is modified by the addition of an atom of hydrogen to each atom of carbon and nitrogen, the power of selective absorption is destroyed. When the condensation of the carbon in quinoline is modified by the combination therewith of four atoms of hydrogen, the intensity of the selective absorption is reduced and is not destroyed. A very pure specimen of quinoline from coal-tar gave an absorption curve identical with that of quinoline prepared synthetically by Skraup's method. It may further be added that molecular actinic absorption of a salt is different from that of the organic base which it contains, although the acid exerts no absorptive power by itself. Sometimes the difference is very great, but the area included by the curve of the salt is always less than that of the base. Molecules vibrate as wholes or units, and the fundamental vibrations give rise to secondary vibrations which stand in no obvious relation to the chemical constituents of the molecule, whether these be atoms or smaller molecules. Hence it appears that a molecule is a distinct and individual particle which cannot be truly represented by our usual chemical formulæ, since these only symbolise certain chemical reactions and physical properties, and fail to express any relation between physical and chemical properties.—Researches on the action of the copper-zinc couple on organic bodies; Part x., benzyl bromide, by Dr. J. H. Gladstone, F.R.S., and Alfred Tribe.—On the selective alteration of the constituents of cast iron, by Thomas Turner, Assoc. R.S.M.—On the existence of nitrous anhydride in the gaseous state, by Prof. G. Lunge.—On the reaction between nitric oxide and oxygen under varying conditions, by Prof. G. Lunge. Experimental evidence is given for the following conclusions:—(1) That when nitric oxide is mixed in the dry state with an excess of oxygen they combine exclusively, or nearly so, to form N_2O_4. (2) Dry NO and O_2, with an excess of the former, yield a large proportion of N_2O_3 along with N_2O_4, both in the state of gas. (3) In the presence of water, NO in the presence of an excess of O_2 is altogether converted into HNO_3. (4) If NO and O_2 meet in the presence of concentrated sulphuric acid, neither N_2O_4 nor HNO_3 is formed, even with the greatest excess of oxygen; but the reaction is—

$$4SO_4H_2 + 4NO + O_2 = 4SO_2(OH)(ONO) + 2H_2O.$$

The bearing of these facts on the theory of the vitriol-chamber process is then discussed. The author considers that N_2O_3, and not NO as hitherto assumed, is the carrier of oxygen, and that as long as any appreciable quantity of SO_2 is present, no nitric oxide is formed, the following being the reactions whereby the sulphuric acid is formed:—

$$2SO_2 + N_2O_3 + O_2 + H_2O = 2SO_2(OH)(O_2N)$$
$$2SO_2(OH)(O_2N) + H_2O = 2SO_2(OH)_2 + N_2O_3.$$

Anthropological Institute, May 12.—Francis Galton, F.R.S., President, in the chair.—The election of R. Brudenell Carter, F.R.C.S., was announced.—The Earl of Northesk exhibited a collection of Maori worked jade.—Mr. Sepping Wright exhibited a portrait in oils of King Tawhiao, in native costume.—Mr. J. H. Kerry-Nicholls, F.R.G.S., read a paper on the origin and manners and customs of the Maori race. The origin of the Maoris and the date of their arrival in New Zealand is unknown. The natives refer to Hawaiki as the fatherland of their race, but there is no reliable evidence to show where that land was situated. The lecturer believed that the Maoris emigrated from the Tonga islands to New Zealand, and referred to the resemblance between the two races, and to the affinity of the two languages. The word *tonga* occurred no less than sixteen times in the Maori tongue. The natives of the two countries when they met could converse with but little difficulty. The Maoris are of Malay stock, and came with the gradual spread of that race through the eastern islands of the Pacific to the more southern groups. The race is greatly on the decrease. In Cook's time (1769) the whole native population was estimated to exceed 100,000. In 1859 it only amounted to 56,000. In 1881 the number had decreased to 44,099, of whom 24,370 were males and 19,729 females. Calculating at the same rate of decrease, about the year 2000 the Maori race would be extinct. The principal diseases conducing to this decay were phthisis, chronic asthma, and scrofula, the two first being principally brought about by a half savage, half civilised mode of life, and the latter from maladies contracted since the first contact with Europeans. The native religion still exercises a widespread influence over the people; it consists of a kind of polytheism, a worship of elementary spirits and deified ancestors. They have a vague conception of a Superior Being, and believe in a *Reinga*, or heaven, and a *Po*, or Hades. The Maoris are divided into tribes whose members are bound together by the strictest union. The ownership of the soil is by tribal tenure, and each tribe holds a commercial interest in lands, forests, cultivations, and fisheries. The tribes dwell together in villages, and each *hapu*, or tribal family, cultivates a portion of land sufficient to meet its immediate requirements. The Maoris own about 15,000,000 acres of land in the North Island, not yet alienated to Europeans. The ownership of the soil was secured to the natives under the treaty of Waitangi, made in 1840. The tribes are governed by hereditary chiefs. In 1858 a king was elected by consent of the tribes under the title of Potatau the First. He was succeeded by his son, Matutaera Te Pukepuke Te Paue Tu Karato Te-a-Botatau Te Wherowhero Tawhiao, or Potatau II. This was the king who last year visited this country.

EDINBURGH

Royal Society, May 18.—E. Sang, LL.D., Vice-President, in the chair.—The first instalment of a paper by Prof. Chrystal, on the Hessian, was read. The chief object was to contribute to the theory of the number of intersections of a curve and its Hessian at any one point as depending upon the nature of the singularity at that point.—In a paper on the distribution of potential in a thermo-electric circuit, open or closed, Prof. Tait detailed the various real additions to our knowledge of the subject in their chronological order. He showed what is at present the most probable arrangement of potential in the circuit, and what classes of experiments remain to be made in order to settle the point.—A paper by Mr. Broom gave numerical details of the percentage contraction of volume when a saturated solution of a salt in water is diluted with an equal bulk of pure water.

PARIS

Academy of Sciences, May 18.—M. Bouley, President, in the chair.—On the results of errors caused by defective instruments in the determination of certain astronomical elements, by M. M. Lœwy.—On the radiation of heat during the night in connection with the normal lowering of the temperature during the months of April and May, by M. J. Jamin. This lowering of the temperature, often so destructive to the spring crops, is rightly attributed by meteorologists to nocturnal radiation, which the author finds attains its maximum about the months of April and May.—Note on the prophylactic inoculation recently practised on Rio de Janeiro against yellow fever, by M. Bouley. This experiment, first introduced by Dr. Domingos Freire, has since been carried out on a large scale under the control of the Government. Since the month of March, 1883, as many as 1109 persons of all ages, nationalities and conditions of life have been subjected to sub-cutaneous injections with the attenuated virus cultivated for the purpose. In some cases the injections were administered in houses where the scourge had a few hours before proved fatal to some of the inmates. Yet no misadventure of any kind has followed, and this preventive measure seems so far to have been attended by the best results.—Anatomical study of the fœtus of a spermaceti whale, by M. Pouchet.—Note on the annular protuberance regarded as the prime motor of the cerebral mechanism, the focus or centre of localisation for speech, the reasoning faculty, and the will, by M. Bitot. From his studies in cerebrology the author concludes, against the generally accepted opinion, that the third left frontal convolution is not the seat or centre of speech, which he localises in the annular protuberance. In the same region he also considers that the intelligence and will are localised, so that even slight lesions of the central part of the annular protuberance destroy both the faculty of speech and of reason. He accordingly denies that the strictly psychic faculties are located in the cerebral cortex, which is the seat only of the organs of sense.—Note on the influence of the ship's motions (rolling and pitching) on the observations made at sea with the Renouf mercury level, by M. O. Callandreau.—Remarks on the observations of the planet Saturn made during the present year with the 0·22 refractor of the Meudon Observatory, by M. E. L. Trouvelot.—Note on the verification of the laws of vibration for elastic circular plaques, by M. E. Mercadier.—On the production of induction sparks at high temperatures, and on its application to the study of the spectrum, by M. Eug. Demarçay.—Composition and heat of combustion of a variety of coal from the Altendorf mines of the Ruhr Basin, by M. Scheurer-Kestner.—Note on the buccal membrane characteristic of the cephalopods, by M. L. Vialleton. From a microscopic study of this organ, the use of which has hitherto been unknown, the author infers that it should probably be regarded as a rudimentary arm.—A study of the chlorophyll action of plants as distinct from their respiration, by MM. G. Bonnier and L. Mangin. By "chlorophyll action" the authors understand the decomposition of the carbonic acid of the atmosphere by the green parts of vegetables in the light. This function they claim to have separated from that of respiration hitherto studied in connection with it, and here give the first results of their researches on the two physiological functions studied apart. — Note on the uric acid present in the saliva and in the nasal, pharyngial, bronchial, and vaginal mucus, by M. Boucheron. — On the influence of the lunar declinations on the displacement of the atmospheric currents, by M. H. de Parville.—On the earthquakes and volcanic eruptions which are of such frequent occurrence in Central America, by M. de Montessus. The author here communicates some of the results of a systematic study of these phenomena prosecuted for the last four years at San Salvador and neighbouring districts.—Note on some underground rumblings heard in the Island of San Domingo on August 28, 1883—that is, on the same day as the Krakatoa eruption, by M. Alex. Llenas.—Remarks on M. Gavoy's work on the "Morphology of the Encephalon," presented to the Academy by M. Larrey.

Berlin

Physical Society, March 8.—Dr. Kayser showed a new electro-dynamometer constructed according to the directions of Prof. Bellati. Hitherto dynamometers consisted of two spirals—an external one, fixed, and an internal, movable, with bifilar suspension, which, being both successively traversed by the currents to be measured, produced a deflexion of the movable spiral that was proportional to the square of the strength of the current. The technical difficulties attending the construction of these instruments were very great, and Prof. Bellati had therefore substituted for the inner spiral a bundle of annealed iron wires hanging to a cocoon thread inside the fixed spiral. Seeing the annealed iron wires possessed no residual magnetism, they were at once magnetised by any current and their deviation was likewise proportional to the square of the strength of the current. This dynamometer was highly sensitive with weak currents. An intercalated telephone, the membrane of which was feebly struck, gave deviations of from sixty to eighty parts of the scale—a sensitiveness which till then had been attained by no dynamometer. Dr. Kayser at the same time showed a globular dynamometer, after the design of Fröhlich, in which the inner spiral was coiled up like a ball, and a Siemens torsion dynamometer for strong currents in which the inner spiral was fixed, the outer movable, and the deviation read by a torsion apparatus. In the discussion which followed the speaker stated that the measurements hitherto taken had proved great precision on the part of Prof. Bellati's dynamometer.—Dr. Dieterici reported on the results of an investigation carried out by him in the last session into the electric residuum. The phenomenon had been experimentally examined by Prof. Kohlrausch, and theoretically treated by Riemann; but the formulæ set up by the latter did not correspond with the results of the experiments, and therefore the speaker undertook a new treatment of the subject. The experiments were carried out with a condenser, the lower plate of which was connected with the earth, the upper with a small mercury cup. A metal hoop led from the latter to a second mercury cup which on one side communicated through a metallic wire with one half of a quadrant electrometer, and on the other side through a second hoop with a third mercury cup. The second half of the electrometer and the third mercury cup were in permanent communication with the earth. The two hoops could alternately be raised out of the quicksilver by cords passing over a pulley or let down. If the first hoop were lifted up, the electrometer was conducted to the earth, the upper condenser plate, on the other hand, was isolated, and could now be charged. Thereupon the hoop was let down; the condenser now stood in connection with the earth and discharged itself. Finally, if the second hoop were raised, the condenser was connected with the electrometer, and both isolated. The residuum after the discharge could now be measured. The charge was effected by the highly constant dry Daniell cells (according to Herr v. Beetz), and in the different series of experiments the continuance of the charge was varied between five minutes and twenty-four hours, as the strength of the current was likewise varied. For each duration and strength of charge the residuum was determined in its course in respect of time in a series of individual determinations. The dielectric of the condenser was a paraffin plate and air. The experiments showed that under a charge of short duration—say, five to ten minutes—the residuum rose very rapidly with the time, and soon attained its maximum; so that its curve mounted very steeply and soon ran parallel to the abscissa of the time. Under a charge of long duration, again, the curve rose more slowly indeed; had, however, always greater values, and lay with more flat bend over the curve of short charge. On changing the strength of the current the electric residuum was always in proportion. Dr. Dieterici now treated the theory of the phenomenon, and briefly sketched the course of its theoretic investigation, which, under the assumption that the dielectric was infinitely thick—that is, neglecting the influence of the thickness—led to formulæ which very well explained the experimental results. The formulæ were, however, only empirical: they did not allow the determination of the constants of the phenomenon. In conclusion, the speaker dwelt on the analogy of the electric residuum to the phenomena of heat, which had also under theoretic treatment found its expression by application of heat-formulæ, and to the elastic after-effect which Prof. Kohlrausch had already pointed out.

Rome

Reale Accademia dei Lincei, March 1.—Fossil remains of *Dioplodon* and *Mesoplodon*, found in the Upper Tertiary in Italy.—Signor Capellini made a communication concerning a paper of his, in which he illustrates and describes the fossil remains of Ziphioids with elongated belemnite-shaped beak, found in various places in Italy. These remains belong to the following species:—*Dioplodon longirostris*, *D. gibbus*, *D. tenuirostris*, *D. bononiensis*, *D. medilineatus*, *D. senensis*, *D. laveleyi*, *D. meneghinii*. A few remains are ascribable to the genus *Mesoplodon*. The specimen described by the author add seven species of Ziphioids to the fossil cetaceans found in Italy; four of these being already known in the Upper Tertiary of Belgium and England, while the three others are entirely new. It must be remembered that before 1875 no fossil remains of Ziphioids were known to exist in Italy. From that time till now there have been discovered about ten species, some of the remains belonging to which are of great importance to palæontology and stratigraphical geology.—On the mineral volcanic *ejectamenta* found in the east of the Lake of Bracciano.—Signor Strüver communicated an abstract of a memoir, in which he explains how, after long and fruitless searches, there had been found within the last few years, in the region lying to the east of the Lake of Bracciano, numerous mineral *ejectamenta* similar to the bombs of Monte Somma, and the mineral aggregates of the Monti Albani, of Pitigliano, and of Lake Laach, in Germany. These *ejectamenta* are found between strata of tuff or *lapilli* and fragments of various rocks. Among the numerous minerals composing the aggregates, Prof. Strüver draws special attention to the sarcolite, a mineral hitherto found but rarely, and that only on Monte Somma. The *ejectamenta* in question present, in respect of the extraordinary diversity in their forms, great analogy to the aggregates of a like nature found in the other places mentioned, but nevertheless have a local stamp of their own, and their diversity is in correspondence with the position of the volcanoes from which they were ejected, and the rocks of the regions in which these volcanoes were active. Prof. Strüver draws attention to the fact that these aggregates must at one time have been united together and formed a single deposit, and shows how that excludes the hypotheses that they were formed in the place where they are now found, and that they are derived from deposits anterior to the period of volcanic activity.—On the relations between the maxima and minima of the solar protuberances, and the maxima and minima of the diurnal oscillation of the declination magnet. Prof. Tacchini, after giving an account of his own researches already published, on the maxima and minima of the sunspots and solar protuberances, referred to the observations of Prof. Schiapparelli on the values of the range of diurnal oscillation of the declination needle, and from the comparison of the two sets of observations, it appears that of late years the connection between the solar protuberances and terrestrial magnetism is more strikingly manifest. These and other similar observations, Prof. Tacchini added, corroborate the idea entertained by himself and some others, that electricity plays the chief part in the solar protuberances, and that electricity is able to produce corresponding magnetic disturbances on our globe. It may therefore be inferred with certainty that the phenomena of the sunspots, the solar protuberances, and terrestrial magnetism are closely connected together, and that by means of one of these sets of phenomena it is possible to determine with tolerable precision the epoch of the other two. In dealing, however, with phenomena of rather long period continuous observations for at least half a century are necessary to make our researches complete.—On the spectroscopic observations of the limb of the sun and the solar protuberances made in 1881 and 1884 at the Royal Observatory of the Capitol.—Prof. Respighi laid before the meeting some considerations of his own, based on observations made in his own observatory, and leading him to conclusions different from those of Prof. Tacchini. He maintains that the maximum of solar protuberances occurred towards the end of the third quarter of 1881. Holding that the sun-spots are due to partial cooling of the surface of the sun, and the protuberances to the escape of gases from the interior, Prof. Respighi believes that such perturbations are not of a nature to occur in periods, even though they retain a certain relation among themselves, and still less can he admit any connection between the maxima of the solar protuberances and the elements of terrestrial magnetism.—Meteorological observations made by Signor P. Orlandi, a physician of Rome, during the years 1809–1820. Signor Narducci called attention to a manuscript in the Biblioteca Angelica, containing some interesting medico-meteorological observations made by Signor Orlandi, a medical man belonging to Rome, between the years 1809 and 1820. These observations are copious and complete, having been made daily. They also include notices of movements of the earth's crust and inundations of the Tiber. Signor Narducci mentioned that Dr. Orlandi was a man of science and writer of great renown in his time. Large extracts from the observations of Orlandi are to be published in the *Annals* of the Central Office of Meteorology, and they will thus be able to be compared with those published by distinguished astronomers belonging to the same epoch.—On the last and recent maximum of sun-spots and solar protuberances. Prof. Riccò gave an account of his own observations made at Palermo on the phenomenon of the solar protuberances, which was so important on account of its coincidence in time with very singular manifestations of the solar maculæ. Prof. Riccò deduced from his own observations, harmonising, as they do, with those of Prof. Tacchini, that, starting from the last maximum in the period of eleven years, the number of the protuberances went on increasing till 1881, when a first maximum occurred. It was further verified that the absolute maximum fell between the end of 1803 and the beginning of 1804, and that on that occasion the maximum of protuberances continued beyond that of the sun-spots. Finally, leaving out of account secondary oscillations, Prof. Riccò asserted that a parallelism may be observed between the frequency of sun-spots and protuberances, the principal maxima and minima of both phenomena coinciding with one another.—On the relation between the maxima and minima of the sun-spots and the maxima and minima of the diurnal variations of the declination needle observed at Genoa. Prof. Garibaldi has made a comparison between the normal compensated series of groups of sun-spots observed by Prof. Tacchini during the period 1877–84 and the series of diurnal variations of the declination needle observed at Genoa during the same period. From the mirror-tracings of the author it appears that the two series agree perfectly. Hence, considering that the observation of the sun and its spots depends upon the clearness of the sky, while the magnetic influence of the sun can always act, and observations of magnetic changes can always be easily made, Prof. Garibaldi arrives at the conclusion that the epochs of maxima and minima of the sun-spots may be inferred from the indications of the declination needle when direct observations are not obtainable.—Action of nascent hydrogen on methyl-pyrrol. Drs. Ciamician and Magnaghi having already ascertained by previous researches that *pyrrol* is converted into an alkaloid called *pyrrolin* under the action of nascent hydrogen, communicated a preliminary notice of the experiments commenced by them with the view of increasing the number of bodies belonging to the pyrrolin series, experiments in which they studied the action of nascent hydrogen on other derivatives of pyrrol.—On a method for the electric calibration of a metallic wire. Dr. Ascoli, pointing out that in accurate measurements it cannot be assumed that the length and resistance of a wire stand in a constant relation to one another, described a very simple and easily applied method of his own by means of which a wire can be quickly and perfectly calibrated without the aid of special instruments and without accessory measurements. By the construction of a curve the resistance of the corresponding piece of wire is obtained from the area limited by the curve.—Other communications: Prof. Besso presented a first note on a class of differential linear equations of the fourth order and on the equation of the fifth degree.—Prof. Gomes-Teixeira furnished a paper on the determination of the algebraic part of the integral of rational functions.—Prof. Riccò made a preliminary note on the observations made by him on red glows.—Dr. de Franchis offered various considerations on some relations between the velocities of efflux, the specific heats, and the mean squares of the molecular velocities of gases.

THURSDAY, JUNE 4, 1885

THE DEINOCERATA OF WYOMING

Dinocerata, a Monograph of an Extinct Order of Gigantic Mammals. By O. C. Marsh. Monographs of the U.S. Geological Survey. Vol. X. (1884.)

ON the high plateau that lies to the west of the Rocky Mountains, along the southern borders of Wyoming Territory, the traveller who is moving westwards begins to enter upon a peculiar scenery. Bare, treeless wastes of naked stone, crumbling into sand and dust, arise here and there into terraced ledges and strange tower-like prominences, and sink into hollows where the water gathers in salt or bitter pools. Under the cloudless sky, and in the dry clear atmosphere, the extraordinary colouring of these landscapes forms, perhaps, their weirdest feature. Bars of deep red alternate with strips of orange, now deepening into sombre browns, now blazing out again into flaming vermilion, with belts of lilac, buff, pale green, and white. And everywhere the colours run in almost horizontal bands, the same band being continuous and traceable from hill to hill, and tower to tower, across hollow and river-gorge for mile after mile through this rocky desert. These parallel strips of colour mark the nearly horizontal stratification of the rocks that cover all this wide plateau country. They are the tints characteristic of an enormous accumulation of sedimentary rocks that mark the site of a vast Eocene lake or succession of lakes on what is now nearly the crest of the continent. These lacustrine sediments, in all somewhere about two miles in vertical thickness, were doubtless laid down during a slow subsidence of the lacustrine area, when the subterranean movements were in progress that finally gave the mountain-ranges and plateaux their present forms and altitudes. They represent a vastly protracted period of quiet sedimentation, in the immediate proximity of an extensive land-surface plentifully clothed with a tropical vegetation, and abounding in varied forms of animal life. They consequently offer to the geologist peculiar facilities for investigating the evolution of a fauna apparently exposed to the minimum of interference from changes in its environment.

It is now about fifteen years since the wonders sealed up within the sediments of these vanished lakes first began to be known. The wandering Indian, indeed, had long been familiar with the skulls and skeletons which, by the decay of the inclosing rock, looked out upon him from the side of *butte* and *cañon*. But he revered them as the bones of his ancestors, and left them untouched, to be disinterred by the ceaseless working of wind and rain. The earliest trappers, squatters, and prospectors brought back news of marvellous monsters grinning from the ledges of rock beneath which they camped. At last these tales attracted the notice of some of the enthusiastic naturalists in the eastern States. Prof. Leidy, of Philadelphia, obtained a number of bones from which he was able to bring to light an entirely novel, and now wholly extinct creature, to which he gave the name of *Uintatherium*. Prof. E. W. Cope likewise described some forms disinterred by him in the same region. But the earliest and most successful investigator of these remains is Prof. O. C. Marsh, who, as far back as 1870, began the search in the Green River basin, and who, after many years of most laborious research, both among the western deserts and in his wonderful collection at Yale College, has at last been able to publish this splendid monograph on the Deinocerata. No trouble or expense has been spared to obtain material for the study of these strange extinct creatures. One expedition after another has been despatched to the West, and many tons of bones have been deposited at Yale, where it is believed there are now represented more than two hundred individuals of the Deinocerata alone. Some of these remains are admirably preserved; indeed, had the animals been still living, the materials for a knowledge of their osteology could hardly have been more perfect than it is.

The Deinocerata form an order established by Prof. Marsh to include some peculiar and well-marked forms found in the lacustrine deposits of the Green River basin—a tributary of the Colorado River of the West. This order belongs to the Ungulates, some of the characters allying it with the Artiodactyls (*Paraxonia*), others with the Perissodactyls (*Mesaxonia*); while in others, again, it is linked with the Proboscidians. The points of resemblance, however, are usually, in the author's opinion, such general characters as seem to point backward to some ancestral ungulate, rather than to any near affinity with existing forms of these groups. The Deinocerata include three genera which occupy three successive stratigraphical horizons. The oldest, Uintatherium, found in the lower strata of the Eocene lake, appears to be the most primitive type; the youngest, *Tinoceras*, found at the highest level, is the most specialised; *Dinoceras* being an intermediate form. The number of species belonging to the order has not been satisfactorily determined, but about thirty forms more or less distinct have been recognised.

Comparing *Dinoceras* with the large living Ungulates, Prof. Marsh points out that in size and proportions it was intermediate between the elephant and rhinoceros, but had also features akin to those of the hippopotamus, while in its stature and movements it probably resembled the elephant as much as any existing animal. It presented certain striking peculiarities which at once marked it off from any form now familiar to us. The skull in particular wore an altogether extraordinary aspect. It was long and narrow, and on its top it supported three separate transverse pairs of high osseous protuberances or horn-cores, which may have been covered with bosses of thick skin, and were no doubt powerful offensive weapons. The canine teeth were enormously developed in the male, forming short, trenchant, decurved tusks, which were protected by a dependent process on the lower jaw. The nasal bones were so elongated as to form nearly half the length of the entire skull, projecting forward and overhanging the premaxillaries. There was probably no proboscis, for the neck was long enough to allow the head to reach the ground without it, but there is some evidence of a thick flexible lip, perhaps like that of the rhinoceros. The brain was proportionately smaller than in any other known mammal, recent or fossil, and even less than in some reptiles. In one species at least it was so diminutive that it apparently could have been drawn through the neural canal of all the pre-sacral vertebræ, certainly through the cervicals and lumbars. The limbs were massive and heavy, the bones, like those of the rest of the skeleton, being nearly or quite solid. The fore-foot was larger than the hind-foot, its component bones being comparatively short and massive, with five well-developed digits, as in Proboscidians, but the carpal bones interlocked with the metacarpals as in Perissodactyls. The feet, as in the modern elephant, were plantigrade, and were doubtless covered below with a thick pad.

We can picture these dull, heavy, slow-moving creatures haunting the forests and palm-jungles around the margin of a great lake. Into the quiet depths of that lake their carcases from time to time found their way, swept down perhaps by river-floods. Among their contemporaries were other forms whose remains have also been more or less abundantly preserved in the same deposits. Of these, two genera next in size to the Dinocerata were Perissodactyl ungulates somewhat larger than a tapir (*Palæosyops* and *Limnohyus*). Another interesting form is *Orohippus* —a four-toed ancestor of the living horse, while additional varieties of the ungulate type were related, though distantly, to the tapir and rhinoceros (*Colonoceras*, *Helaletes*, *Hyrachyus*). Two remarkable genera (*Tillotherium*, *Stylinodon*), nearly as large as a tapir, possessed characters resembling those of the ungulates, carnivores, and rodents, and have been embraced by the author in a new order called by him *Tillodontia*. Among the carnivores there was one (*Limnofelis*) nearly as large as a lion, and another hardly less in size (*Oreocyon*), while *Dromocyon* was somewhat smaller and *Limnocyon* about as large as a fox. There were likewise lemurs having some affinities with South American marmosets; also representatives of the Marsupials, Insectivora, Chiroptera, and Rodentia, but no true Quadrumana or Edentates. Reptiles abounded, especially crocodiles, turtles, lizards, and serpents, while fishes of many kinds swam in the lake.

The structure and history of the Deinocerata with their place and affinities in the animal kingdom are fully discussed in this important monograph. Like his previous work on toothed birds in the same series of memoirs, Prof. Marsh's present volume is an admirably executed and exhaustive research. Every bone is carefully worked out and drawn. Every available fragment of evidence is patiently collected, compared, and tabulated. Whatever may be disputable regarding the conclusions drawn, there can be no variety of opinion as to the actual data. No fewer than fifty-six lithographic plates, and nearly 200 woodcuts depict with singular fidelity every part of the skeleton of the Deinocerata as at present known.

But Prof. Marsh is much more than a comparative anatomist. It is not enough for him to describe the bones he has unearthed, and to point out their analogies in the living world. He is instinctively an evolutionist, and every extinct animal seems to propound to him the problem of its ancestry and its descendants. One of the most suggestive chapters in his present memoir is devoted to the genealogy of ungulate animals, and the place of the Deinocerata among them. He believes that from some primitive form, of generalised type, probably small in size, resembling generally an insectivore, and going back at least as far as Permian time, all the mammalian tribes have descended. Such a genealogical mammal, belonging to Prof. Huxley's group of *Hypotheria*, would possess all the general characters of the subsequently developed mammalian orders. But special characters, acquired in adaptation to conditions of environment, would be developed in the course of time, and would lead to the establishment of different modified types. The general characters would thus alone be a safe guide in tracing a community of ancestry, while those of a special kind need not necessarily indicate affinity, but may have independently arisen from the influence of the same surroundings in groups already quite distinct from each other. In the Cretaceous system, a well-marked group of mammals is found which is represented now by the living Hyrax, along what appears to have been the main stem of ungulate descent. From this stem, after the remarkable waning of reptilian life at the close of the Mesozoic ages, there diverged, in Cretaceous times, a branch which terminated in *Coryphodon*—a tapir-like form which, both in America and in Europe, probably quite equalled if it did not surpass in size and power any of the representatives of the fading reptilian types of an older creation. Another branch which may have been given off about the same time reached its full development in the Deinocerata, which were certainly the monarchs of the region where they lived. But nothing is more striking in the history of these and the other colossal mammals than the rapidity with which they appear and disappear from the scene. *Dinoceras* and its allies, so far as the evidence yet goes, appear to have been restricted to the middle part of the Eocene period. Their remains are not found in the earlier deposits of that period, and cease to occur before we reach the upper parts of the series. The cause of this speedy extinction is to be sought, according to Prof. Marsh, in the small brain of the animals, their highly specialised characters, and huge bulk, whereby they were unfitted for adapting themselves with sufficient rapidity to new conditions; and a change of surroundings brought about their extinction. But this is a point on which the geologist may not unnaturally claim to be heard when he demands some evidence of such change of surroundings. Had the supposed geological vicissitudes been sufficiently serious to cause the extinction of a whole tribe or sub-order of large mammals, they might have been expected to have left some palpable evidence of their passage in a corresponding change in the nature of the deposits accumulated in the lakes. But there is certainly nothing in the nature or succession of these deposits to suggest that any important modifications of topography or climate took place during the time when they were being deposited. On the contrary, they seem to point to protracted uniformity in the conditions of sedimentation. They afford no indication whatever that the successive appearance of *Coryphodon*, *Dinoceras*, and *Diplacodon* was accompanied, far less was determined by, any essential change of physical conditions. That such change actually took place is of course quite conceivable, but when it is demanded as an essential factor in mammalian evolution, some admissible proof may very fairly be demanded.

Like Prof. Marsh's previous memoir on "Odontornithes," the present volume may be regarded as a model monograph. It is complete without being overloaded, exhaustive and yet lucid and interesting from beginning to end. After reading it one feels that the Deinocerata are no longer extinct, vanished forms, but familiar acquaintances which one could not fail to recognise anywhere. Every part of their structure is methodically presented to view, and restorations are given showing the relations of the parts to each other and what is the author's conception of the general form of the animals. It has hardly ever been possible in the Old World to reconstruct the mammalia of so early a period from such ample materials as are now amassed at Yale College. Hence the restorations attempted have often been little more than more or less probable conjectures which might be conformed but were more usually corrected or even effaced by the progress of discovery. So full, however, is the evidence for Prof. Marsh's restorations, that there remains very little room for future emendation. He is still engaged in continuing these remarkable memoirs on the ancient life of the North American continent. A third monograph on the *Sauropoda* is approaching completion, and a fourth, on the *Stegosauria*, is far advanced. These large and profusely illustrated works are issued as part of the work of the United States Geological Survey. They reflect the highest honour on their indefatigable author, and on the Survey which undertakes their publication.

ARCH. GEIKIE

REMSEN'S "ORGANIC CHEMISTRY"

An Introduction to the Study of the Compounds of Carbon; or, Organic Chemistry. By Ira Remsen, Professor of Chemistry in the Johns Hopkins University. Pp. x., 364. (Boston: Ginn, Heath, and Co., 1885.)

THIS is chemistry. Of how few books professing to be books on chemistry can it be said that they teach us anything of the science. The student who begins the study of the carbon compounds has to suffer many things from the text-books. Some of them present him with dry bones in the shape of isolated facts and bold assertions regarding structural formulæ and the linking of atoms. Others lead him into speculations which he is unprepared to follow; he makes little flights into these and comes back fancying he is a chemist. Other books (there are not many of them) proceed on the true scientific lines; but very frequently their pages are encumbered with too many facts about more or less widely separated compounds, or they deal so much with groups of compounds, rather than with typical individual bodies, that the beginner soon loses his way, becomes perplexed, and is ready to abandon the pursuit.

Prof. Remsen has shown us a more excellent way than any of these. He leads the learner by degrees through the early difficulties; he places before him distinct and detailed accounts of a few typical compounds; he shows him how these compounds are mutually related; and then he takes him back to the beginning again and teaches him how each compound he has learned to know represents a group, and how, when he knows the properties of one member of the group he also knows much about all the members.

At the outset Prof. Remsen makes a few wise and pregnant remarks on the meaning of structural formulæ. These "enable the chemist who *understands* the language in which they are written to see relations which might easily escape his attention without their aid. In order to *understand* them, however, the student must have a knowledge of the reactions upon which they are based; and he is warned not to accept any chemical formula unless he can see the reasons for accepting it." The whole book is a practical sermon on this text.

In no other elementary book in the English language will the student find so many admirably chosen examples of the formation of structural formulæ. The important facts are noted; then the inference is drawn; then the hypothesis is ventured upon; analogous facts are recalled; the hypothesis is strengthened or weakened; suggestions are made; experiments are conducted; and all is finally summarised in the formula. But the book i more than a selection of examples showing ho.. ..ructural formulæ ought to be gained. It is a systematic although elementary treatise on organic chemistry. The student is first taught about the two paraffins, methane and ethane; then he learns how the halogen derivatives of these are prepared, and what relations they bear to the parent hydrocarbons. By this time he has had his first taste of isomerism. Then he proceeds to the oxygen derivatives of methane and ethane; he learns what an alcohol is; he becomes acquainted with ether, aldehyde, formic and acetic acids, some ethereal salts, and acetone. This method of studying a few simple compounds in detail is pursued until the student is more or less familiar with representatives of all the principal groups of compounds derived from the paraffins. He is now in a position to study these hydrocarbons as a group, and to deal in some detail with the questions of isomerism. When the paraffins and their derivatives have been thus studied, the more difficult subject of the benzenes and their compounds is approached. And here the author shows an admirable power of dealing with facts as facts, and with theories as theories. What could be better than the following remarks regarding saturated and unsaturated compounds?

"In the aldehydes and ketones, carbon is in combination with oxygen in the carbonyl condition. When they unite with hydrogen and some compounds, such as hydrocyanic acid, the relation between the carbon and oxygen is probably changed, the latter being in the hydroxyl condition. The changes are usually represented by formulas such as the following:—

$$CH_3.C\begin{cases}O\\H\end{cases} + H_2 = CH_3.C\begin{cases}OH\\H_2\end{cases},$$

$$\begin{matrix}H_3C\\H_3C\end{matrix}\!\!>C = O + HCN = \begin{matrix}H_3C\\H_3C\end{matrix}\!\!>C\!<\!\begin{matrix}CN\\OH\end{matrix}.$$

In the carbonyl group the oxygen is represented as held by two bonds to the carbon atom, while in the hydroxyl condition it is represented as held by one bond. The signs may be used if care is taken to avoid a too literal interpretation of them. There are undoubtedly two relations which carbon and oxygen bear to each other in carbon compounds. These relations may be called *the hydroxyl relation*, represented by the sign C—O—, and *the carbonyl relation*, represented by the sign C=O" (pp. 209-10).

How different this is to the crude, glaring statements that annoy the reader of the commonplace text-book written by the Philistine.

The fact that structural formulæ help us to understand the relations existing between the parts of specified molecules is strongly insisted on throughout this book. When we know nothing of these relations the author does not hesitate to tell us so. Thus, regarding the formula of benzene, as commonly written with successive double and single bonds, he says (p. 239):—"This formula, however, expresses something about which we know nothing, and concerning which it is difficult at present to form any conception. The simpler formula [*i.e.* the hexagon without any double bonds] leaves the question as to the relation between the carbon atoms entirely open, as it is in fact." And again, speaking of the structure of the molecule of ethylene, Prof. Remsen remarks (p. 213):—"As regards the relations between the two carbon atoms of ethylene we know nothing, save that it is probably different from that which exists between the carbon atoms of et[illegible]."

A most instructive example of the methods pursued in organic chemistry, and at the same time of the scientific method of inquiry, is to be found on pp. 318-321, where the reactions of phenol-phthaleïn are discussed. The facts are given, but they seem only facts until some light is shed on them by the appearance in one reaction of triphenylmethane, a substance already familiar to the student. The student is shown how "this suggests that all the substances [he has been examining] are derivatives of this fundamental hydrocarbon." And he is asked to note how easily, when this conception has once been formed, the interpretation of all the reactions follows.

Many other admirable illustrations of the scientific method of inquiry are to be found throughout the book. I would especially draw attention to the simple but thoroughgoing treatment of the "equivalency of the hydrogen atoms" in the molecule CH_4 (pp. 28-29), and in the molecule C_6H_6 (pp. 234-236). It is on subjects such as are discussed in the pages referred to that the chemical student so frequently suffers shipwreck. If he will use this little book by Prof. Remsen as his pilot, and will keep a good look out as he proceeds, he may hope to pass the shoals of the hexagon-formula, and the shallows of the ortho-, meta-, and para-derivatives of benzene.

The author of this book deserves the thanks of all chemical teachers who have tried to teach organic chemistry to beginners for the clear and short directions which he gives for preparing the more important compounds of carbon. The book may well be used as a laboratory guide, no less than as an introduction to the science of organic chemistry.

Prof. Remsen has already done good service to the science of which he is a student, by publishing his "Principles of Theoretical Chemistry;" he has now given us a book which must be of great use in advancing the study of organic chemistry; could he not supplement these by an elementary but scientific treatise on inorganic chemistry?

M. M. PATTISON MUIR

MINERALOGY IN CALIFORNIA

Fourth Annual Report of the State Mineralogist of California. By H. G. Hanks. 8vo, pp. 410. (Sacramento: State Printer.)

ALTHOUGH a systematic geological investigation of the State of California has been commenced at different times since 1853, the Legislature has generally got tired of providing the funds after a few years' continuance, and the work has been stopped. The most notable effort towards the provision of a complete geological description of the State was that made by Prof. J. D. Whitney, who, with a body of assistants, including men of the highest attainments in every collateral branch of natural science, carried on the survey from 1860 to 1873, when it was suddenly discontinued, to the great regret of scientific men both in America and Europe. No attempt to continue or supplement Prof. Whitney's work was made until 1880, when the author was appointed State mineralogist with the object of investigating questions more particularly connected with mining industry than with geology in the larger sense. The author during his period of office, which appears to be terminable and held for four years only, has founded a valuable mineral museum and library, more than 6000 specimens illustrative of the mineral deposits of the State having been collected and arranged. These do not, however, appear to be very sumptuously housed, as the author calls attention to the danger from fire, "as well as other inconveniences, such as the prevalence of ammoniacal and hippuric odours, and the disturbance of arranged specimens in the cases by the jarring made by the hoisting of hay by tackles attached to the underside of the museum floor. The California State Museum is well worthy of a good and thoroughly fireproof building." With the latter opinion our readers will no doubt heartily agree.

Besides the work of organising the museum the author has published annually a report upon some branch of mineral industry as carried out in the State—for instance, that for 1883 was largely devoted to the borax deposits of the mud lakes in the interior of the State. The present volume, described as the fourth and last report of the State mineralogist, is mainly devoted to a catalogue and description of the minerals of California as far as they are yet known. This is alphabetically arranged, and contains descriptions of the composition physical properties and uses of the different species, together with detailed information as to localities, and methods of working in the more important ones. Altogether 161 different species are described as having been found in California, but this number will no doubt be considerably increased by future explorers. At the present time, in addition to gold; mercury, petroleum, and borax are the chief products of importance, although as regards all of them the prevailing complaints of over-production and unremunerative prices appear to be as prevalent as in less favoured localities in the Old World. The condition of the gold-mining industry appears to be a very healthy one, for although the enormous annual yield, ranging from 10 to 13 millions sterling in 1850-55, has diminished to 3 and 4½ millions in the past four years; the increased facilities for working render it possible to handle at a profit rock not containing more than 12*s.* worth of gold in the ton; while in the earlier days 20 dollar (80*s.*) rock was not considered to be worth removal. The total value of the gold raised in California since 1848 is estimated at above 230,000,000*l.* in value, which if reduced to a single mass would be contained in a cube 14 feet 4 inches in the side.

Although the work is essentially a compilation, it is well arranged, and will be of great use to those interested in Californian minerals. A general introduction on the resources and industries of the State precedes the catalogue of minerals. This, though interesting matter, seems rather out of place. H. B.

ALGÆ

Rabenhorst's Kryptogamen-Flora von Deutschland, Oesterreich, und der Schweiz. Zweiter Band. Die Meeresalgen. Bearbeitet von Dr. F. Hauck. Nos. 7, 8, 9, 10. 8vo. (Leipzig: Ed. Kummer, 1883-1885.)

A Monograph of the Algæ of the Firth of Forth. By George William Traill. 4to. (Edinburgh: Printed for the Author, 1855.)

Notes on Marine Algæ. By Edw. Batters, F.L.S. (*Proceedings* of the Berwickshire Naturalist Club, 1884.)

THE concluding numbers of Dr. Hauck's work have recently appeared. To the description of species is added an appendix in which some new species are described. Then follow a comprehensive key to the genera; an index of families, genera, species, and synonyms; lists of illustrations, and of works on algæ, arranged alphabetically, according to the names of the authors; also the title-page, preface, and table of contents—all most useful auxiliaries to a scientific work.

To the favourable opinion of this work, already expressed in the columns of NATURE (vol. xxix. p. 341), it may be added that the later numbers, treating of the Chlorozoosporeæ and the Schizophyceæ, fully justify this opinion, and Dr. Hauck must be congratulated on the successful completion of what has undoubtedly been an arduous undertaking.

In turning over the pages of the work, one cannot but be struck by the variety of views which, in spite of the closest examination by competent observers with the aid of the best microscopes, still prevail among algologists as to the systematic position of certain algæ.

Not to multiply instances, it will be sufficient to mention the genera Porphyra and Bangia. By Dr. Berthold and Dr. Hauck they are classed with the Florideæ; while Dr. Agardh and M. Rosanoff place them among the Ulvaceæ. As to Goniotrichum, which Dr. Agardh relegates to the Ulvaceæ and Dr. Berthold includes in the Bangiaceæ, Dr. Hauck, in despair of discovering its affinities, places it at the end of the description of species, as of still doubtful position.

Although it may be doubted whether all Dr. Hauck's identifications of British Algæ will be admitted by our botanists, yet the work cannot fail to prove extremely useful in this country, and is, in fact, much needed.

Mr. Traill's work, entitled "A Monograph of the Algæ of the Firth of Forth," consists of an alphabetical list of the marine Algæ of this locality, with their habitats, time of appearance and of fruiting, and the names of the host-plants on which grow such species as are epiphitic. Each copy of the work is intended to be illustrated with some half-dozen herbarium specimens of the rarer Algæ. Those in the copy before the writer are in excellent condition, and are interesting from their rarity.

That Mr. Traill is a most patient and painstaking observer goes without saying. An analysis of the list will show how many species he has collected and observed, which are new, not only to the Firth of Forth, but to the British marine flora. He has watched the growth and development of these plants from their first appearance until their maturity. Among them will be found several Algæ which, though frequent in the south, have not previously been seen so far north; and he has also met with some arctic and northern species which are not only new to the British marine flora, but are not described in Dr. Hauck's work.

Among these northern species may be mentioned *Phlœospora tortilis*, which has a range in this country, so far as is known at present, from the Firth of Forth to Bamborough. While this plant is so abundant in the Baltic as to cause much inconvenience to fishermen by getting entangled in their nets, its existence is not recorded on the German shore of the North Sea. *Urospora penicilliformis*, one of the Algæ found by Dr. Kjellman on the coast of Spitzbergen, is another of Mr. Traill's "finds."

It will be observed that he mentions having obtained the cystocarps of *Rhodymenia palmata*. If he has really met with the true crystocarps of this plant he is fortunate, since Dr. Agardh, Dr. Harvey, Dr. Hauck, and other botanists have hitherto searched for them in vain. Harvey has shown ("Phyc. Brit.," Pl. 217) that bodies outwardly resembling cystocarps are common enough; probably these are what Mr. Traill has found. They are not, however, true cystocarps.

The establishment of the Biological Station at Granton, near Edinburgh, will certainly give a fresh impetus to the study of marine botany in that locality; and there is no doubt that Mr. Traill's work will be found extremely serviceable to local collectors of Algæ.

The *Proceedings* of the Berwickshire Naturalist Club for 1884 contain notes by Mr. Edward Batters on seventeen species of rare and little known Algæ found by him at Berwick-upon-Tweed. A short and clear description is given of each species, and the rarer kinds are illustrated by lithographic plates.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Ocular After-Images and Lightning

IT will no doubt be of interest to many of your readers to know that the curious optical phenomenon observed by Prof. C. A. Young, when working with a large Holtz machine, and referred to in Mr. Newall's letter (NATURE, vol. xxxii. p. 77), may be produced with very small apparatus.

I have in my possession one of the small Voss machines with 10-inch plates which are now so common. Upon the stand of this instrument I placed two ordinary Leyden jars, about 5½ inches high, in such a position that their tinfoil-covered bottoms touched the brass sockets in which rest the fixed condensers of the machine, while the rods connected with their inner coatings were in contact with the sliding electrodes; with this arrangement sparks of great brilliancy from 1½ to 2 inches in length could easily be produced at the rate of about six per minute. A copy of NATURE was set up against a dark background 4 feet distant from the machine, and at every discharge the paper appeared to be illuminated by two, or sometimes three, distinct flashes of decreasing brightness, which succeeded one another with great rapidity. Each flash was sufficiently powerful to enable the pictures on the cover to be clearly seen. By throwing the light upon a quickly rotating disk of zinc with a strip of white paper pasted across it, I convinced myself that the phenomenon was a subjective one: the successive images of the white strip always occurred in exactly the same position.

I think these experiments go far towards explaining a matter which must have occurred as a difficulty to many besides myself. Why is it that the illumination produced by a brilliant flash of lightning invariably appears to be of a quivering or intermittent character? We know that the actual duration of a single discharge is sensibly infinitesimal, and both reasoning and laboratory experiments would lead us to believe that a rapid series of discharges between two insulated bodies must at all events be of infrequent occurrence, and due to exceptional circumstances. Yet the quiver of the lightning-flash is proverbial. It would be interesting to ascertain by means of a revolving disk with a single white band across it, whether this is not in most cases a purely subjective phenomenon, due to a succession of after-images. SHELFORD BIDWELL

Wandsworth, June 1

Iridescent Crystals of Potassium Chlorate

WITH regard to the above crystals, described by Prof. Stokes in NATURE (April 16, p. 565), I should like to suggest, with some diffidence, that the colours may be due, not to a continuous hemitropic crystal-film, but to a series of fine tubular cavities ranged parallel to each other between the two main portions of the crystal, such as not unfrequently occur on a large scale in Iceland spar, and appear to be due to bad fitting (so to speak) of hemitrope-films on the rest of the crystal (see Groth's "Physikalische Krystallographie," p. 441).

The surfaces of these prismatic cavities, which may be of almost wave-length fineness, would form a series of furrows from which light would be reflected under the same conditions as from grooved surfaces like those of mother-of-pearl; and, according to the usual laws of interference, we should expect such phenomena to occur as are described by Prof. Stokes: *e.g.*, non-polarisation of the light, predominance of rays of a particular refrangibility in the reflected beam, and total disappearance of this beam at two azimuths differing by 180°, when the length-dimension of the tubes lies parallel to the plane of incidence.

I may mention that plates of opal—at any rate those portions which give a uniform colour—afford spectra extremely similar in character to those of the iridescent crystals: definite bright bands in the reflected light, and dark complementary bands in the transmitted light, changing their position in the spectrum with change of incidence. Now the iridescence of opal is pretty well known to be due to the reflection of light from the surfaces of rows of filaments imbedded in the mass (see Sir David Brewster's paper in *Brit. Ass. Reports*, 1844, part 2, p. 9).

The above hypothesis would also account for Prof. Stokes's observation that the iridescent crystals were best formed when the solution was gently stirred; the molecules then, like a harassed army, being too much disturbed to "fall in" as they should do.

I cannot say that I have yet succeeded in actually bringing out such rows of tubes under the microscope. It is easy to see with a $\frac{1}{4}$-inch power, when the illuminating beam is properly adjusted, a sort of wavy structure at the twin-film (like that seen in opal under the same conditions); but I have not yet made out such definite rows of cavities as would seem to be required to produce the singularly uniform sheet of colour. They may be beyond the power of a microscope altogether.

Eton College H. G. MADAN

P.S.—Since I wrote the above, Prof. Stokes has very kindly pointed out that opal spectra are fully described by Mr. Crookes in *Proc. Roy. Soc.*, xvii. 448. One opal micro-section which I have gives a spectrum almost exactly like No. 12 in that paper, but the band is slightly less refrangible than the D line at an incidence of 20°.

Pre-Existence and Post-Existence of Thought

To express any views on these subjects one might well have hesitated some years ago, as hereditary transmission, tolerated as a doctrine, chiefly with regard to the breeding of sheep and dogs, was held to be unphilosophical. Darwin has settled the matter in the domain of science, but perhaps without altogether disposing of prejudices. Mr. Galton and myself have long since dealt with less material aspects of heredity.

What I want to bring on the scene of consideration is the common notion of throwing the great-grandsire. Few now are inclined to doubt about this.

Throwing the grandsire in the case of man may be taken to represent a period of a hundred years of transmission until birth for three generations, and consequently such period of the pre-existence of a thought or habit, which is in one's self, and of which there may be an actual register. It is better to select the example of a man, and of a great-grandsire, rather than of a father, because it carries with it a period of remoteness.

Taking then a period of a century for pre-existence in the past, there comes the consideration of vitality of occurrence in the future, as we know of it from the past. Taking a generation for the birth of offspring, and adding to it three generations for a great-grandchild, we have, say, one hundred and fifty years. Adding together the two periods, we obtain an epoch of transmission in pre-existence and of possible existence of two hundred and fifty years.

One such epoch antecedently and another subsequently may be counted in round numbers five hundred years, and we shall see our way to a thousand.

Perhaps after all we know less in detail of the transmission of osseous peculiarities than we assume. There are the means in some cases of examining bony structures of epochs and intervals of 1,000, 2,000, 5,000, 10,000 and more years, and we can trace forms of development. What we further want is the power of witnessing the successive individual variations, which is attended with diversity from other beings, and constitutes identity. Though identity may to some extent repose in the process of a bone, in the way in which a vein or sinew has traversed, we have evidence of this rather collectively in a species or a variety, than in the mode in which it periodically or irregularly influences a series of individuals.

The transmission of physical peculiarities in the soft tissues is equally permanent, and can be better traced in the individual. There are good examples of it in well-known cases of family features, and of racial types.

We are now familiar with cases of the hereditary transmission of mental qualities, as in that of the Bernouilli family, though perhaps one of the most remarkable instances is that of the Ottoman dynasty, members of which for several hundred years have displayed capacity, and yet here we have only the male elements of transmission, as in the marriages there has been a great mixture of races. It may, however, be that the Turk, the so-called Circassian (sometimes a Daghestani), and the Georgian are more nearly allied than we have been disposed to consider.

The problem now before us may be treated, irrespective of what laws there may be of male or female transmission, as in breeding, the qualities of an ancestor on either side and of either sex may be reproduced, and it is this reproduction and transmission of mental qualities which is to be considered. The mental qualities must be distinguished from the osseous structure or the soft tissues in degree. There is a vast difference in extent, and probably in distinction, between the transmission of some feature and that of conscious or unconscious thought or even of a dream.

My own term of "unconscious thought" I prefer to "unconscious cerebration," because the main distinction between conscious and unconscious thought is chiefly, if not wholly, dependent on the quality of consciousness. One reason for retaining it here is with reference to dreams. Whatever may be the operation of recording other thoughts, dreams are certainly preserved during life as effectually as any kind of thought, although no organ of seeing or hearing is concerned.

If it is remarkable that purely physical properties should be preserved in the germ of a minute animal, it is much more so that any process allied to the operations of thought should be preserved—the influence of events, the influence of dreams, used age after age to constitute the mind of this day. It will be perceived that I am speaking very loosely and vaguely, to some extent of set purpose, to bring under consideration a general question of long time in the transmission of a mental process, whether connected with what is called instinct or unconscious thought, and without limiting the discussion more than is necessary with postulates or set definitions.

HYDE CLARKE

Long Sight

I WAS at school at Rossall, between Fleetwood and Blackpool, on the coast of Lancashire. One day, being on the sea-wall with Arthur A. Dawson, an Irish boy, we could see the Isle of Man as if it were ten miles away, and then to the south of the Calf of Man we could distinctly see on the horizon the summits of two mountains, which we pronounced must be in Ireland. Four years later I was staying at Blackpool with my mother, when we distinctly saw the same blue mountains just appearing above the sea. Being in the Isle of Man later on, I was at Port Erie, to the west of Castletown, and saw the same summits, and was told they were the mountains of Mourne. From there the mountains stood well out of the water, though we could not see the rest of the coast. The Mourne Mountains are 2798 feet high. They are 125 miles from Blackpool.

Museums

THE interest which the readers of NATURE in this country and in America take in the promotion of museums has induced so many of them to inquire of me for a paper recently noticed by yourself that, to spare their time and my own, I shall be glad if you will enable me to refer inquirers to your advertising columns.

THE AUTHOR OF "MUSEUMS OF NATURAL HISTORY"

A NEW EXAMPLE OF THE USE OF THE INFINITE AND IMAGINARY IN THE SERVICE OF THE FINITE AND REAL

GEOMETERS are wont to speak (it seems to me) somewhat laxly of "the line at infinity" as if there were only one such line in a plane; in a certain but not in the most obvious sense this is true—viz. there is but one right line of which all the points are at an infinite distance from all lines external to them in the finite region of the plane, and except these points there are none others having this property; but in the sense that there is but one line infinitely distant from all points external to it in the finite region, the statement is obviously erroneous, for it need only to be mentioned to be at once perceived to be true by any tyro in geometry that all rays passing through either of the two "circular points at infinity" (Cayley's absolute) are infinitely distant from any external point in the finite region; these two imaginary points may indeed without any reference to the circle be *defined* as the points which radiate out in all directions rays infinitely distant from the finite region; the "absolute" being, so to say, the common depository, *i.e.* the crossing points of all infinitely distant rays as the "line at infinity" is the locus of all infinitely distant points. Similarly in space: there is not one infinitely distant plane, "the plane at infinity," but an infinitely infinite number of such planes—viz. any plane touching "the circle at infinity" (an imaginary circle in the plane at infinity) will at once be recognised to be infinitely distant from any external point in the finite region, or, as we may say more briefly and picturesquely, infinitely distant from the finite region itself. It will give greater vivacity to this conception to imagine an axis through which pass planes in all directions, and to travel in idea this axis round "the circle at infinity" keeping it always tangential thereto; the complex or corolla of planes, so to say, thus formed (infinitely infinite in number) contains only planes of infinite distance from the finite region; and "the plane at infinity" is but one of them—viz. the one which passes through all the axes named, just as the line at infinity in a plane is the line which passes through both the centres of infinite distance. The infinitely infinite series of infinitely distant planes is of course the correlative of the infinitely infinite series of infinitely distant points whose locus is the so-called "plane at infinity."

The above statements have only to be made, to be accepted by the geometer, although I do not remember seeing them* anywhere explicitly given; but what I want to show is that, although supersensuous abstractions, so far from being barren they are capable of immediate application to the world of reality, and afford an instantaneous answer to a very simple practical question which has only just lately been mooted. The question is this: Suppose $abcd$ to be a given pyramid, and that perpendiculars are drawn from its four vertices, say A, B, C, D, to a variable plane, then it is easy to show that a certain homogeneous quadratic function of A, B, C, D depending on the form of the pyramid or relative lengths of its edges must be constant, and the question arises, What is this constant quadratic function, this quadric in A, B, C, D, expressed in terms of the edges of the pyramid exclusively?† Just so if we take a triangle, abc, in a plane there will be a constant quadratic homogeneous function of the distances of its three vertices from a variable line; and it is well known in this case that if A, B, C are the distances the constant quadratic function in question will be—

$$(ab)^2(A-C)(B-C)+(bc)^2(B-A)(C-A)+(ca)^2(C-B)(AB).$$

But if we had not known this fact it could have been found as follows:—Calling the above function F, when A, B, C all or two of them become infinite the relation between the ratios of $A:B:C$ will be such as would arise from making $F=0$; on no other supposition will this be the case.

Now, if we use trilinear co-ordinates with abc as the triangle of reference, and take as the co-ordinates of any variable point P, the areas aPb, bPc, cPa instead of the simple distances of P from ab, bc, ca, then every body knows that the line at infinity has for its equation—

$$(1)\quad x+y+z=0,$$

and will easily see that the circle circumscribing abc has for its equation—

$$(2)\quad (ab)^2xy+(bc)^2(yz)+(ca)^2xz=0.$$

Moreover, when such co-ordinates are employed the distances of any line $Ax+By+Cz=0$ (3) from the three vertices are A, B, C each multiplied by the *same* known quantity.

If then A, B, C become infinite this line must pass through one of the intersections of the line at infinity with the circle, or, in other words, the equations (1), (3), (2) must be capable of being satisfied simultaneously, and accordingly by a well-known algebraical law it follows that the determinant to (2) *bordered* by the coefficients of (1) and (3) must vanish. Consequently this determinant so bordered will represent the sought-for form F, *i.e.* the constant quadratic function will be represented by—

$$\begin{matrix} \bullet & A & B & C & \bullet \\ A & \bullet & (ab)^2 & (ac)^2 & 1 \\ B & (ba)^2 & \bullet & (bc)^2 & 1 \\ C & (ca^2) & (cb)^2 & \bullet & 1 \\ \bullet & 1 & 1 & 1 & \end{matrix}$$

On calculating this determinant it will be found to be the function of $A-B$, $B-C$, $C-A$ above given, except that each term is multiplied by the constant factor -2, which may of course be dispensed with.

Now let us apply similar or analogous considerations to the determination of the constant quadratic function of

* The statement concerning the circular point-pair at infinity being centres of pencils of infinitely distant rays I have since met with somewhere in Dr. Salmon's Conics, but stated in quite a casual manner. It may not be unworthy of notice that just as the distance between any two points in a ray passing through either point of the *absolute* in a plane vanishes, so similarly vanishes the area of any triangle drawn in any plane touching "the imaginary circle at infinity" in space.

† If l, m, n, p are the distances of the vertices from the opposite faces, and x, y, z, t from the variable plane, it is well known that

$$\Sigma\left(\frac{x^2}{l^2}-2\,\frac{yz}{mn}\cos m,n\right)$$

is constant, in fact is unity.

$A, B, C, D,$ the four distances on a variable plane from the fixed points a, b, c, d. I must promise that using quadriplanar co-ordinates x, y, z, t analogous to those employed just now for the plane—viz. such as will cause

$$x + y + z + t = 0 \quad (1)$$

to become the equation to "the plane at infinity," the sphere circumscribing the fundamental pyramid $a\,b\,c\,a$ takes the analogous form to that given for the circle from which indeed it may be deduced with a stroke of the pen —viz. the equation to this sphere will be—

$$(a\,b)^2xy + (a\,c)^2xz + (a\,d)^2xt + (b\,c)^2yz + (b\,d)^2yt + (c\,d)^2zt = 0 \quad (2).$$

Moreover the distances of a plane whose equation is—

$$Ax + By + Cz + Dt = 0 \quad (3)$$

from the vertices of the pyramid will be A, B, C, D each multiplied by the same known quantity.

The intersection of the plane at infinity with any sphere, and consequently with the circumscribing sphere named, is "the circle at infinity;" hence if F is the constant function required we may find it as the function of $A, B, C, D,$ which becomes zero when the plane (3) is tangential to the intersection of the plane (1) with the sphere (2), or, which is the same thing, when the intersection of the planes (1) and (3) is tangential to the sphere (2), and this function is well known to algebraists to be the determinant formed by bordering the determinant to (2) with the coefficients of (1) and (3), *i.e.* we may take as the constant function F the determinant following:—

$$\begin{array}{cccccc} \bullet & A & B & C & D & \bullet \\ A & \bullet & (a\,b)^2 & (a\,c)^2 & (a\,d)^2 & 1 \\ B & (b\,a)^2 & \bullet & (b\,c)^2 & (b\,d)^2 & 1 \\ C & (c\,a)^2 & (c\,b)^2 & \bullet & (c\,d)^2 & 1 \\ D & (d\,a)^2 & (d\,b)^2 & (d\,c)^2 & & 1 \\ \bullet & 1 & 1 & 1 & 1 & \bullet \end{array}$$

of which the developed value is easily found to be—

$$-\Sigma(a\,b)^4(C-D)^2 + 2\Sigma(a\,b)^2(a\,c)^2(B-D)(C-D) + 2\Sigma(a\,b)^2(c\,d)^2\left\{\begin{matrix}(A-C)(B-D)\\+(A-D)(B-C)\end{matrix}\right\}$$

This value of the constant function in its expanded form I some time ago found by a different method, and sent in the shape of a question to the *Educational Times*.* In a brief correspondence which ensued with Prof. Cayley, he wrote to me giving the equivalent determinant form which he arrived at by a totally different order of conceptions and in a very beautiful manner, as follows. We may regard the differences between A, B, C, D as equal to the differences between the distances of a, b, c, d from a fifth point, e, at an infinite distance, and may call $a\,e,\ b\,e,\ c\,e,\ d\,e$ equal to $A + K,\ B + K,\ C + K,\ D + K$ respectively, where K is infinite. Hence by his own well-known theorem regarding mutual distances of five points we shall have—

$$\left|\begin{array}{cccccc} \bullet & (a\,b)^2 & (a\,c)^2 & (a\,d)^2 & (A+K)^2 & 1 \\ (b\,a)^2 & \bullet & (b\,c)^2 & (b\,d)^2 & (B+K)^2 & 1 \\ (c\,a)^2 & (c\,b)^2 & \bullet & (c\,d)^2 & (C+K)^2 & 1 \\ (d\,a)^2 & (d\,b)^2 & (d\,c)^2 & \bullet & (D+K)^2 & 1 \\ (A+K)^2 & (B+K)^2 & (C+K)^2 & (D+K)^2 & \bullet & 1 \\ 1 & 1 & 1 & 1 & 1 & \bullet \end{array}\right| = 0$$

And by the ordinary well-known rules in determinants for combining lines with lines and columns with columns it may easily be shown that the above determinant is of the form $4F_1K^2 + GK + H$, where F_1 represents—

$$\begin{array}{cccccc} -\frac{1}{2} & A & B & C & D & \bullet \\ A & \bullet & (a\,b)^2 & (a\,c)^2 & (a\,d)^2 & 1 \\ B & (b\,a)^2 & \bullet & (b\,c)^2 & (b\,d)^2 & 1 \\ C & (c\,a)^2 & (c\,b)^2 & \bullet & (c\,d)^2 & 1 \\ D & (d\,a)^2 & (d\,b)^2 & (d\,c)^2 & \bullet & 1 \\ \bullet & 1 & 1 & 1 & 1 & \bullet \end{array}$$

Consequently $F_1 = 0$. This equation gives not only the form of the constant function but the value of the constant (F_1, when the element $-\frac{1}{2}$ is suppressed, being identical with my F).

On removing the line and column of capital letters the above determinant equated to zero expresses the condition of the points a, b, c, d lying in a plane—as proved by Cayley in days long past (and still ordinarily so proved) by a very artful manner of multiplying a determinant into a numerical multiple of itself; but this result follows as an instantaneous consequence of the reflexion that if a, b, c, d did not lie in a plane the above equation would mean that the circumscribing sphere was *touched* by the plane at infinity, whereas we know that this plane never touches but has the faculty of always cutting *every* sphere in a constant circle of imaginary points. Hence the existence of this equation implies the coplanarity of the four points $a, b, c, d,$ and the converse proposition may be shown by simple algebraical reasoning to follow from this.*

Postscript.—I have been led by what precedes to a rather interesting observation in universal geometry.

Suppose we form a determinant with the squared distances of one group of n points from another equinumerous group any or all of which may be coincident with those of the former one: and to each line and at the foot of each column of this determinant affix a unit; a determinant so formed we may agree to call the bordered determinant of either group in regard to the other. Thus *ex. gr.*

$$\begin{array}{cccc} a\,\alpha^2 & a\,\beta^2 & a\,\gamma^2 & 1 \\ b\,\alpha^2 & b\,\beta^2 & b\,\gamma^2 & 1 \\ c\,\alpha^2 & c\,\beta^2 & c\,\gamma^2 & 1 \\ 1 & 1 & 1 & \end{array}$$

is the bordered determinant of a, b, c in regard to $\alpha, \beta\,\gamma$. When the two groups are one group repeated we may call this determinant the bordered *self*-determinant of the groups.

My theorem is that the bordered determinant of two equi-numerous groups in respect to one another is a mean proportional to the bordered self-determinant of one of the groups, and that of the projection upon its *niveau* of the other group. [The *niveau* to a group of points means the homaloid (Clifford's flat) of the lowest number of dimensions which contains the group.]

We may regard a group of n points as the vertices of a figure whose squared content we know by Cayley's theorem above referred to is a sub-multiple of the bordered self-determinant of the group; it is in fact that quantity divided by $(-)^{n+1}2^n(1 \cdot 2 \cdot 3 \ldots n)^2$, so that we may vary the statement of the theorem and say that the product of the contents of the figures denoted by two equi-numerous groups into the cosine of the inclination of their *niveaus* is a known numerical sub-multiple of the bordered determinant of one group in respect to the other. Thus, keeping at first within the limits of conceivable space, we see

* If the differences between A, B, C, D be regarded as the minor determinants of the bilinear matrix $\begin{matrix}A & B & C & D\\ 1 & 1 & 1 & 1\end{matrix}$ any practised algebraist would at once recognise that my form becomes expressible as a determinant of the 6th order, and I think I could hardly have failed eventually to have made this observation, the more especially as I was aware of the connection of the subject with that of the section of any sphere with the plane at infinity—but as a matter of fact Cayley anticipated me, and was the first to actually write down the function under the form of a determinant.

In each method the concept of infinity appears, but in mine that of the imaginary as well; and although more far-fetched than the other, the latter possesses the advantage of yielding the result as the transcript of a mere mental process without involving the necessity for the performance of any work whatever of algebraical reduction.

* The equation in the text extended to the points $A, B, \ldots L, X$ assumes new importance and rises to philosophic interest when regarded as the *intrinsic equation to the niveau* of $A, B, \ldots L$, in which the co-ordinates of the variable point X in the niveau are the squares of $AX, BX, \ldots LX$; it is of course an equation of the second degree in these co-ordinates. The distances of either of two points from the other are the same in quantity but differ in sign. Hence the *square* of either is the natural measure of the interval *between* the two points.

that the cosine of the angle between abc, abd, the faces of a tetrahedron, will be the determinant—

$$\begin{array}{cccc} \bullet & ab^2 & ad^2 & 1 \\ ab^2 & \bullet & bd^2 & 1 \\ ca^2 & cb^2 & cd^2 & 1 \\ 1 & 1 & 1 & \end{array}$$

divided by sixteen times the product of the faces abc, abd.

Or, again, if ab, cd be any two non-intersecting edges of the tetrahedron, $\pm 2ab \, . \, cd \cos (ab, cd)$ ought to be equal to—

$$\left| \begin{array}{ccc} ac^2 & ad^2 & 1 \\ bc^2 & bd^2 & 1 \\ 1 & 1 & \bullet \end{array} \right|$$

and as a matter of fact the cosine between (ab, cd) is equal to $\dfrac{ad^2 + bc^2 - ac^2 - bd^2}{2ab}$.*

Again, if abc, def are any two triangles in space of 5, 4, or 3 dimensions the product of their areas into the cosine of their inclination will be a numerical multiple of the bordered determinant of the group abc in regard to def, and if they lie in the same plane their product itself will be that numerical multiple.

Similarly for two groups of four points lying in one space (as *ex gr.* that in which *we live, move, and have our being* †) the product of their bordered self-determinants will be equal to the bordered determinant of either group in respect of the other, because their *niveaus* coincide, and if we take two groups of five points each in ordinary space it again follows from the theorem that the bordered determinant between them must vanish, a statement which when the two groups coincide reverts to Cayley's condition concerning the mutual squared distances of five points in ordinary space.

Finally, there can be little doubt, I think, of the truth of the following theorem dealing with determinants (but unbordered) ‡ of which the general theorem we have been considering which deals with bordered determinants must needs be a corollary.

By $P : Q$ where P, Q are two groups of n points each, let us understand the determinant formed by taking the cosines of the angles which the n^2 lines connecting P and Q subtend at a point O equidistant, in space of the necessary number of dimensions, from each of the $2n$ given points, and let P', Q' mean the groups P and Q augmented by the addition of O to each of them, the theorem is that—

$$\cos (P', Q') = \frac{P : Q}{\sqrt{(P : P)(Q : Q)}}. \S$$

Thus for the case of n equal to 2 if O is the centre of the sphere passing through a, b, c, d, we ought to find the cosine of the angle between the arcs ab, cd equal to

$$\left| \begin{array}{cc} \cos ac & \cos cd \\ \cos bc & \cos bd \end{array} \right|$$

divided by a square root of

$$\left| \begin{array}{cc} \cos aa & \cos ab \\ \cos ba & \cos bb \end{array} \right|$$

into a square root of

$$\left| \begin{array}{cc} \cos cc & \cos cd \\ \cos dc & \cos dd \end{array} \right|$$

i.e. equal to

$$\pm \frac{\cos ac \, . \, \cos bd - \cos ad \cos bc}{\sin ab \, . \, \sin cd}$$

as is the case.

There ought also to exist analogous theorems applicable to non-equi-numerous point groups depending in some way upon the minors of a corresponding rectangular matrix.*

J. J. SYLVESTER

New College, Oxford, April 1885

* Obviously therefore we can express the squared shortest distance between two non-intersecting edges of a tetrahedron as a rational function of the squares of all six. The formula in the text is well known and easily proved for the case of $abcd$ being in a plane, which is enough to show that it must be true universally, for if we make BCD rotate about BC, the projection of C upon BD does not move, and consequently AC into the cosine of AC, BD is invariable.

† It would perhaps be more correct to say "*which has its being in us.*"

‡ From which it follows that every algebraical theorem regarding square matrices expressed in the umbral notation is immediately convertible into a proposition in universal geometry; the umbræ cease to be mere abstractions, and acquire a *local habitation and a name* as points in extension.

§ $\sqrt{P : P}$ is in fact the factorial of n divided by the nth power of the distance of O from each point in P into the content of (what I call) the *plasm* (of order n) denoted by P.

A *plasm* of the order 1, 2, 3 means a rectilinear segment, a triangle, a tetrahedron—whence it is easy to deduce and define in exact terms the meaning of a plasm of any order as a figure bounded by plasms of the order next below its own. The squared content of a triangle is equal to the sum of the 3 squared contents of its projections on mutually perpendicular planes in ordinary space: but also to the sum of the 6 squared contents of its projections on 6 such planes in extension of 4 dimensions and so on—and in general the square of the content of a *plasm* denoted by n points is similarly resoluble into a sum of $\dfrac{n(n-1)\ldots(n-i+1)}{1 \, . \, 2 \ldots i}$, such squares in extension of $(n+i-1)$ dimensions; as these squared contents are all expressible immediately by Cayley's theorem in terms of squared distances, the above statement gives rise to a far from self-evident theorem in determinants. What I have here termed *plasms* might with more exactitude be termed *protoplasms*, as being the elements into which all other figures are capable of being resolved.

* It may be objected that the theorems of the text applied in their full generality beyond the limits of empirical space cease to affirm a relation between two different things and therefore lose their efficacy as such and become mere *definitions* of the meaning of the inclination of two figures in supersensible space. To meet this objection it is sufficient to give a general method for determining algebraically the projection of a point in space of n dimensions on the niveau of ν points where ν is any number not greater than n; this it is easy to see may be effected as follows:—

(α) I observe that the niveau of any μ given points in a space of n dimensions may be expressed in Cartesian co-ordinates by means of equating to zero each of $n - \mu + 1$ independent minors of a rectangular matrix containing $n + 1$ columns and $\mu + 1$ lines, the formation of which is too obvious to need stating in detail.

(β) In order to project orthogonally a point whose n co-ordinates in a space of n dimensions are $x', y', \ldots z'$ upon a niveau (of the $(n-1)$th order) passing through n given points defined by the equation $Ax + By + \ldots Cz + L = 0$, we have only to write $x - x' : y - y' : \ldots : z - z' :: A : B : \ldots : C$, and combining the $(n-1)$ equations contained in this proportion with the given equation, the resulting values of $x, y, \ldots z$ determine the projection of the given point on the given niveau.

If now ν points are given in a space of n dimensions and the projection is required of a given point upon their niveau we may proceed as follows:—

(1) Find the $n - \nu + 1$ equations which define the niveau.

(2) On each of the niveaus of the $(n-1)$th order which correspond thereto respectively find the orthogonal projections of the given point.

(3) Through these $n - \nu + 1$ projections of the given points and the given point itself draw a niveau which will be defined by $(n+1) - (n - \nu + 2)$, *i.e.* $\nu - 1$ equations.

Finally, combining these with the $n - \nu + 1$ original equations we have n equations in all, and these will serve to determine the n co-ordinates of the projection required.

This method is not always the most compendious, but is always sufficient, and enables us to attach a definite meaning to the inclination of two spaces of any the same order to one another: thus *ex. gr.*, the content of the projection of $abcd$ on $efgh$ divided by the content of $abcd$ itself is the cosine of the inclination of the niveaus $abcd$, $efgh$, and the projections of the several points a, b, c, d on $efgh$ (say a', b', c', d') being found by the preceding method, the content of the tetrahedron $a'b'c'd'$ (and therefore the inclination of the two niveaus) is a known quantity.

GRESHAM COLLEGE

THE question of what is to be done with one of the greatest of existing London abuses, Gresham College, has again come up in connection with a letter from a "Londoner" in the *Times*. The *Times*, in a somewhat incomplete leader, animadverts strongly on the abuse, and urges its prompt remedying. Surely when the fact that London has no university in the true sense is attracting so much attention and the movement to supply the want is so powerful, it is absurd to allow the funds to be worse than wasted which represent the wreck of those which were originally intended for the maintenance of a real institution of this class. There were once 20,000 students at Gresham College, and when London does have a university, as it must have some time, even Gresham College will be without *raison d'être*.

"Topographically," the *Times* says, "the lecture-rooms are off the track of students. None of the apparatus of systematic instruction, in the way of examinations, accompanies the courses. Provision does not exist, or, at any rate is not employed, for the contact of the mind of the learner with the mind of the teacher. The lecturer ascends to his chair, recites or reads his stipulated discourse, and disappears with the mechanical routine of an automaton. The professorial staff, it might have been added, has as little internal unity as relationship to its classes. It is a concourse of atoms with no affinity except equality of stipends. To call the foundation a college is to use a manifest misnomer. It is as much a college as one at Oxford or Cambridge would be with the undergraduates and fellows suppressed, and the Master, Dean, Bursar, and Butler left to perpetuate the tradition. The Corporation of the City and the Mercers' Company are Sir Thomas Gresham's trustees, and derive very substantial advantages from his bounty.

"The inutility of the Gresham Lectures was recognised in the days of Dr. Johnson. Johnson lamented as bitterly as our correspondent that the able professors of Gresham College, which was 'intended as a place of instruction for London, contrived to have no scholars.' His explanation was that the professors lectured gratis, and grew indolent from the absence of pecuniary incentives to intellectual exertion. 'We would all,' he exclaimed with conviction, 'be idle if we could.' Permission to charge sixpence a pupil for each lecture would, in his opinion, have infused vitality into the institution; every professor would forthwith have grown 'emulous to have many scholars.' There could be no harm in administering his specific now. The good of a condition such as Gresham College has been reduced to is that any experiments may be tried upon it without excessive risk. But the failure of the foundation arises from deeper sources than those to which Johnson attributed it. Several of the present lecturers are notoriously of a temper and standing not to need a money bribe to urge them to do their duty. The Dean who is the Divinity Professor delights in occasions for ecclesiastical exegesis. He would rejoice to find a way of gathering five hundred receptive hearers to listen to the theological expositions he throws away on a meagre fraction of the number. Another Dean was Senior Wrangler, and is abundantly competent for the geometrical themes he has to discuss. The subject of civil law is committed to a most capable jurist. The Professor of Music is able elsewhere without any endowment to attract to his classes a large paying audience. The blame, as our correspondent concedes, does not lie with the lecturers, who only slumber in concert with their classes and their patrons. It must be imputed to the gross contempt which has been shown for all the conditions of educational success. Their founder intended his seven professors to be professors in a College which he did not survive to create. He died at the age of sixty, still immersed in public affairs, and before attaining the leisure for carrying out his idea of an 'epitome of a University in London.' Accidents for which it would be useless to condemn his trustees would have prevented them, had they otherwise been well disposed, from accomplishing his ambitious programme. His estate, so far as it was appropriated to the purpose, proved insufficient for the complete endowment of a College and its staff. A collection of lectures was left as it were in the air. For a time they appeared to have procured favour in spite of their disadvantages. In the nature of things they could not keep it permanently. They were without soil to take root and sprout in. The error of all concerned has been that the want was not supplied by incorporating either them in something else or something else in them. Last century was a period of educational, though not of intellectual, stagnation. Gresham College only languished in company with many other Colleges better furnished with the gifts of fortune. The present age has witnessed a revival of zeal for instruction by methods in which the Gresham foundation might have been turned to the greatest service, and has been turned to none. While London, and, most of all, the City, was careless of learning, it was no reproach to the managers of Sir Thomas Gresham's bounty that they converted it to no account. The absurdity is that for years the town, from its centre to its outskirts, has been crying out for educational appliances, and that Gresham College is suffered to remain as futile and superfluous as ever. Half-a-dozen institutions have been erected in or by the City to effect the objects for which Sir Thomas designed his foundation. For any one of them it would have been the most admirable nucleus; it would have afforded a starting point, and have bestowed the dignity of old descent. Thus it would have gained at last the reason for existence it has been craving in vain for a couple of centuries.

"Tastes of benefactors in distant ages do not always agree with the popular inclinations of the present. Reluctance on the part of trustees to deviate from the will of the men they represent is to be excused, though it cannot always be allowed to block the road to reform. When, however, a founder has let posterity into his confidence, and the application of his gifts clearly conflicts with his own views, it argues strange perversity or default of mental elasticity not to perceive where genuine respect for his wishes should lead. Without a framework in which they could be set and mutually co-ordinated, the Gresham Lectures cannot possibly do what the founder desired them to do. The public spirit of the City would not refuse to take up and finish the work which Gresham sketched out if it could be secure that his original instalment of beneficence was no longer wasted as now. Already it has been endeavouring to fill up the gap by its own exclusive exertions. The City of London College, the courses of the University Extension Society, lectures at the London Institution, the Technical College, Middle Class Schools, and not a few institutions besides, are spontaneous efforts of the past dozen years to work out the original idea of Sir Thomas Gresham. The proper City of London College is Gresham College. Around it as the centre all the other educational instruments of the City ought naturally to group themselves. Not the most punctilious conservatism could reprobate the Corporation and the Mercers' Company if they would use the authority they possess, and seek fresh authority, to aid in the promotion of that general result. Gresham College, as it is, has been for centuries, and is doomed to be, a burlesque of collegiate life. Its lectures must be equally dead whether delivered in a dead or a living tongue. Its choice is between becoming something more or something less than it is now. If it cannot develop, it had better cease to be."

ELECTRICITY AT THE INVENTIONS EXHIBITION

THE International Inventions Exhibition is intended to illustrate the progress of invention during the period that has elapsed since the last Great International Exhibition in this country in the year 1862. Accordingly we find under Group XIII. electricity ranged under twelve classes, entitled respectively, generators, conductors, testing and measuring apparatus, telegraphic and telephonic apparatus, electric lighting apparatus, electro-metallurgy and electro-chemistry, distribution and utilisation of power, electric signalling, lightning-conductors, electro medical apparatus, electrolytic methods for extracting and purifying metals, electrothermic apparatus. Under such a classification there is no doubt that the Exhibition might have been made thoroughly representative of the wonderful progress that has taken place in this branch of science, both in its theory and practice, during the last twenty-three years. The reason that it is not so is twofold: electricity has had of late years many exhibitions dedicated to itself—those of Paris, Vienna, and Sydenham; and it was quite impossible in such an exhibition as the Inventions, where so much has had to be compressed into so little space, to indicate the progress of invention in each class of each group. If, however, electricity is not represented in this way, it is in another way, and that is through the medium of one of its special applications—that of the electric light. Electricity thus forms the light and life of the whole Exhibition after sunset, and in this connection we would view it on the present occasion.

Those who visited the Health Exhibition last year will not notice any great change in the internal illumination beyond the more extensive use of the electric light and its greater steadiness, but will observe that an alteration has been made in the garden lighting, to a description of which we propose to confine this article. In place of the numerous attendants who, a little before darkness set in, were to be seen last year lighting one by one the little oil lamps which, in their coloured glasses, were scattered all over the trees and lawns, an observer discovers at half-past eight or a little later a gradual diminution in the darkness of the evening, and the eye becomes gradually sensible to the fact that the architectural features of the buildings are becoming clearly defined, and by degrees are actually illuminating surrounding objects, whilst at the same time the lawns and shrubberies, the parterres and trees, and even the ponds of water and waterfalls assist in the general illumination with light of every shade and colour. Where before all was darkness, there is a scene of bewildering enchantment: fountains play and throw up into the air, now high, now low, solid sheets of illumined water and spray of mingled water, dust, and light, at one moment of golden hue, at another of the loveliest magenta; while when the silver light of the electric arc alone illuminates the fountains, broken by some magic power below into waterdrops, all the prismatic colours of the rainbow are observable, and, revelling in the beauty, one wonders how it is all brought about.

In what is known as the tower, Sir Francis Bolton has before him a plan of the gardens with switches on it, enabling him to turn the lights on or off, or to increase or diminish their intensity at his will. One of the switches controls the effects in the upper garden, another those in the lower garden, a third commands the statue of the late Prince Consort, a fourth and fifth the illumination of the east and west quadrants and east and west arcades respectively, whilst a sixth controls the external lighting of the conservatory. Four switches on the lower portion of the switch board enable the operator to raise or lower the intensity of the light; the first altering it from $\frac{1}{4}$ to $\frac{3}{8}$, the second from $\frac{3}{8}$ to $\frac{1}{2}$, the third from $\frac{1}{2}$ to $\frac{3}{4}$, and the fourth from $\frac{3}{4}$ to full power.

One of the most interesting features of the illumination, and that which perhaps causes the most wonder and bewilderment, is the play of the fountains. Below the island in the fountain is a water-tight chamber, about 5 feet in height and 20 feet square, into which one obtains access by first descending a ladder from the diving apparatus-house into a low arched passage, from which one ascends into the chamber. The roof of this is covered with water-pipes which convey the water from the main in all directions, the supply being regulated by screw valves; the five large jets are fitted with plug valves and levers, by the manipulation of which the dancing motion and breaking up into water-drops of the columns of water are effected. The average quantity of water expended per hour during a fountain display is 70,000 gallons. Under the five large water jets are five skylights, fitted with thick glass, below each of which is placed a wooden box, containing a powerful arc-light with the carbons set horizontally. Over the top of the lantern is a holophote, such as is used in lighthouses, by means of which the rays of light are concentrated, and projected upwards into and with the column of water, whilst their colours are varied by drawing sheets of stained glass across the lantern. The water is supplied at a pressure of about 70lb. to the square inch, which is sufficient to carry it up to a height of 120 feet.

On one of the walls of the chamber is a board, on which are signalled the instructions from the tower, which are read off by an assistant to the staff. In this manner the various effects which more or less puzzle the spectators are telegraphed from the tower above, and carried out in the concealed chamber below.

The following are the number and distribution of the lamps, all of which are made by the Edison-Swan United Company, most of them being of 5 and 10-candle power, whilst a few of 20-candle power are used on the band stands and verandah of the conservatory:—

	Lamps
Conservatory	1418
E. and W. Quadrants	1584
E. and W. Arcades	1832
Upper Gardens	1550
Lower Gardens	2300
Albert Statue	336
Total	9020

There are fourteen miles of main and branch wires, nine miles of twin wire, and two miles of small connecting wire. On the buildings and on straight lines on the grass specially constructed wooden lamp-holders are used, in other places ordinary spring-holders. The current is generated by three Siemens B 13 self-regulating dynamos, each weighing about 11 tons, and each capable of maintaining 2000 (20-candle) lights at 300 revolutions per minute; the current of each being 500 amperes at an electromotive force of 250 volts, the weight of the armature being 3 tons. The dimensions of the machines are as below:—

	ft.	in.
Height including bed-plate	8	9
Length over all	8	0
Width	4	8
Diameter of armature	2	5
Length of armature	3	2

The four series coils, which are coupled in parallel, are wound with copper-wire 4-10ths of an inch in diameter, and the shunt coils, which are coupled in series, with wire of No. 9 standard gauge; the armature being wound with flat strips instead of wire. Each of the dynamos is coupled to a Goodfellow and Matthew's triplex compound engine of 200-h.p. indicated, two of the machines being easily capable of maintaining all the lights. The main current from the dynamos is led to a switch-board, in connection with which is an electro-dynamometer so arranged that there shall be no break of continuity. In each branch circuit is a fork working in the core of a solenoid, the prongs of the fork dipping into a pair of mercury contact cups. The solenoids are connected by wires with Sir Francis Bolton's room, and by their use he can raise or lower the fork out of or into the contact cups and thus turn the lights off or on as required. The return circuits enter into a single conductor, which is arranged with four sets of mercury cups and solenoids in series; around each set is a bye-pass containing a resistance of determined magnitude, so as to vary the brilliancy of the lamps as desired.

The works for the electric illumination of the gardens and fountains have been carried out by Messrs. Siemens Brothers, to the designs of Sir Francis Bolton. Considering that the instructions for the preparation of the machinery for illuminating the gardens were only given in February last, the result obtained at the Inventions Exhibition is evidence that electric lighting has now advanced to such a stage that orders may be given for very large installations and executed in a perfect manner in a very short space of time.

VESUVIUS

SINCE writing on May 3 Vesuvius has continued to pour forth a continuous stream of lava. From the lowering of the general level of lava in the main chimney no reflection could be seen at its mouth, as is usually the case. This state of things continued till the 6th, when the vapour could only escape in intermittent puff in consequence of the accumulation of *débris* from the crumbling edges of the inner crater edge. As these puffs escaped, they resembled balls of dark grey smoke, from which fell a shower of fine ash, the result of the grinding up of the fine materials that had fallen in as above described, and partially blocked the upper outlet. The crater plain was scattered over with ash and rounded fragments of lava from which that had been ground off. Soon after a faint glimmer was visible, which gradually increased each night until it came to a stationary point, since which little change has taken place. The lava still continues to flow with more or less regularity, but from the small quantity it only gutters and collects on the slope of the great cone. The whole series of events since May 2 is identical with what occurred under similar circumstances in December, 1881, and January, 1882, which I have already described in these pages. The whole sequence of phenomena are easily explicable on the most simple mechanical principles, and do not require that *vulcanological magic* which, even at the present time, is too often employed in describing volcanoes or earthquakes.

I may mention that the above estimate might seem too low as the surface of the streams moved quicker (about 1 m. in 17 seconds), but the lava was particularly viscuous on this occasion, and towards the edges it could not have progressed more than the above distance in two or three minutes. A similar retardation no doubt occurred wherever in contact with its channel, so that I think the estimate of 1 m. per minute is a very fair one. If we allow an average outflow of 5000 cm. during the last twenty-two days (*i.e.* from May 2 to 24), which I am sure many would think under-rated, we have the prodigious output of 110,000 cm.; the product of what would usually be called a very small eruption. But the flow has not stopped, and shows no indication of so doing.

This large amount of material, added to the surface of the great cone, is already making a difference in its outline, and should the outflow continue for nearly three years, as occurred after the December, 1881, outburst, the Vesuvian cone will have another gigantic hump of lava to spoil the graceful curves of its back.

Either as the result of bad writing or of printer's errors some obvious mistakes have crept into my last communication. For "*unattached* pyroxene crystals" read *unattacked*. For "*salbam*" read *salband*. Read for "about one metre per *second*," about one metre per *minute*.

Naples, May 24 H. J. JOHNSTON-LAVIS

THE RUAHINE RANGE, NEW ZEALAND

IN the summer of 1843, Mr. Colenso being at Hawke's Bay, first saw the Ruahine Range, looking sublimely grand under its crest of virgin snow. Hearing at this time of natives living secluded in the interior, in the country lying between this range and the famed central volcanic district, Tongariro, he determined to visit them, and he has lately published a most graphic and interesting account of several visits to and over the range, which were accomplished between the years 1845 and 1847. This narrative is, as would be expected from a botanist like the author, largely interspersed with valuable notes on the flora, and there are also some on the fauna of that region. It is also somewhat interspersed with quotations, for the most part appropriate ones, from the author's favourite poets. It is not necessary that we should make any comments on the fact that this little memoir does not appear in the *Transactions* of the New Zealand Institute, already so full of various important contributions to our knowledge of New Zealand forms from Mr. Colenso's pen, for the publishing Board of that Institute, having declined to publish more than an abstract of it, the memoir was, by request, returned to the Hawke's Bay Philosophical Institute, before which Society it had originally been read, and it has been by them laid before the scientific world with additional and copious notes. The first attempt to cross the range was made under great difficulties in February, 1844: the weather was bad, heavy rain flooded the rivers and mountain streams, and the guide had forgotten the route. Despite all disadvantages, many a rare and several new plants were found. On a Saturday night, after a slender supper amid the deepening gloom of the beech forest, we read: "Here, pendent from some of the trees, hung a most lovely species of Loranthus (*Loranthus flavidus*), while on many other trees that fine species *L. tetrapetalus* formed dense bushes, bearing crimson flowers in profusion, so that in some of the more open spots among the closely-growing trees the whole forest wore a reddish glare." At the very spot where they halted, a fine bushy composite shrub with hydrangea-like leaves was gathered, which has been since named by Sir J. Hooker, *Olearia Colensoi*. Fatigued with the day's work the party slept till 10 o'clock on the Sunday, and then awoke to find themselves completely invaded by a large "blue-bottle fly," which, it appears, inhabited the beech-wood in countless numbers, and was most teasing and audacious: their blankets and woollen clothing had been attacked, and were literally filled with the fly eggs, and the hair of the natives' heads had also similarly suffered. These blue-bottles spoiled the Sabbath day's rest; they had never before been met with by Mr. Colenso. We wonder if the species has been recognised by Baron Osten Sacken, who has recently been engaged in describing New Zealand Diptera. After two days' more fatigue, the party were obliged to descend without crossing the summit, being nearly starved into the bargain. But amid all these troubles, Colenso writes that he at least had some joys, certainly, under the circumstances, unknown to the natives, in that he discovered, on the return, several fine new plants (*Alsophila Colensoi*), several new species of Coprosma, some of which grew so compactly together that in some places it was impossible to get through them, and so they had to walk *upon* them. Here, but only in one spot, that beautiful fern, *Hypolepis millefolium*, was found. Many beautiful and new forms of Veronica, as *V. buxifolia*, *V. nivalis*, and *V. tetragona*, this last species in its barren state resembling much the branch of a Podocarpus. Here we venture to interpose a wish that Mr. Colenso would write an essay on the mimetic resemblances of the species of the genus. But this was not all: a little further up there were found "splendid Celmisias and Ranunculuses in countless numbers, intermixed with elegant Wahlenbergias and beautiful Ourisias, Euphraisias, Gentians, Dracophyllums, Astelias, and Calthas, and many others. Here were plants reminding one of those of our native land, with rare and little known novelties." After the first burst of surprise, the great difficulty of carrying off these prizes presented itself: no collecting materials were at hand. There was no time to lose. "First I pulled off my coat, and made a bag of that; then, driven by necessity, I added thereto my shirt, and, by tying the neck, got an excellent bag. Lastly the crown of my hat held a few. Fortunately the day turned out a fine one, and on returning to the camp the night was spent placing them among spare clothing, bedding, and books." Of this "find" drawings of nearly fifty were published by Sir W. J. Hooker, or Sir J. Hooker, in the "Flora Novæ Zelandiæ" or the "Icones Plantarum." The graphic account of that terrible plant, *Aciphylla Colensoi*, we must content ourselves by thus referring to; it is too long to quote, and too good to condense.

Two solitary tufts of two Alpine plants were also detected on this occasion. One, *Helichrysum Colensoi*, the edelweiss of New Zealand, was found on the edge of the top of a mountain composed entirely of dry shingle of various sizes, from big lumps to dust. The other, *Geum parviflorum*, grew near the former, but, unlike it, has been found on the South Island. This first attempt to cross the range failed, though its summit was reached; but a second attempt, made in February, 1847, was successful. A short sojourn was made at Matuku, the principal of the Patea villages; the route thereto was the long round-about by Taupo. From Matuku, on March 25, the ascent of the Ruahine was made, and the Mission Station at Waitanga was reached on March 3, after many hardships and difficulties. The narrative abounds in numerous records of great interest. The following is an account of one of the largest, we suspect, of flower visitors, honey-seekers, and one unknown to Darwin or Hermann Müller:—

"Close to the village, and even within its fence, were several very large Kewhai trees (*Edwardsia grandiflora*); these were covered with their golden flowers, and mostly without leaves. The sun was shining brightly, and the parrots (*Nestor meridionalis*) flocked screaming from the forests around to the Edwardsia blooms; it was a strange sight to see them, how deftly they managed to go out to the end of a long lithe branch (preferring to walk parrot fashion), and there, swinging back downwards, lick out the honey with their big tongues, without injuring the young fruit . . . For, seeing but very few petals falling (and those only vexillæ), I sent some of the boys to climb the trees and bring me several marked flowering branches, which had been visited by the parrots. I found that all of the fully expanded flowers had had the upper part of their calyces torn open, and the uppermost petal (vexillum) torn out; this the parrots had done to get at the honey. As the flowers are produced in large thick bunches, some are necessarily twisted or turned upside down; still it was always that peculiar petal and that part of the calyx (though often in such cases undermost) which had been torn away. Through this no injury was done to the young fruit inclosed, which would in all probability have been the case if any of the other petals had been bitten off. It cannot be said that it is owing to the vexillum being the largest petal (as it is in many papilionaceous flowers) that it is thus laid hold of and torn away by the parrot, such not being the case in this genus: for the long fruit runs down through the two carinated lowermost petals, that are often quite two inches long, and is further protected by the two side ones (alæ), which four, from their being closely imbricated together, form a much larger and firmer hold for the bird's beak.

"Further, as these parrots are large birds with huge bills, and as the flowers are always produced on the tips of the small branches, which bend and play about under the weight of their bodies, one cannot but suppose that it is no easy matter for the birds to get a bite at them at all, so as to make the proper openings whereby to insert their thick tongues and lick out the sweet contents without injuring the young immature fruits, especially when we further consider that the common practice of this parrot is to take up in its claws whatever it wishes to discuss. Of all the flowers I examined, only the upper part of the calyx and corolla had been torn, and on none was the young fruit wanting, nor did I notice any bunches which had had their flowers wholly torn off. What with the glistening snow, the sun shining, and the golden blossoms of those trees, the numerous parrots diligently and fearlessly at work so close to the village, yet often screaming, it was altogether a peculiar and interesting sight."

What delightful corners for the botanist are to be met with in this range the next paragraph will show. Many of the species are of the greatest interest—quite Alpine gems; and some few of them, or of closely-allied species, grow freely with us. We would be prepared to welcome them all.

"In the open ground, on two or three mound-like hills of peaty-looking soil, and near each other, on the west side, grew that remarkably fine Ranunculus, *R. insignis*. On my discovering it I was astonished at its size—its largest golden flowers being nearly 2 inches in diameter, its flowering stems 3 to 4 feet high, and some of its round crenated leaves measuring 8 to 9 inches across! Both Sir Joseph Hooker and his father were equally surprised and delighted, and as it was (then) by far the largest species known, Sir Joseph Hooker gave it that appropriate specific name—*insignis*. I only found it in that locality, but it was in great plenty; its principal neighbour was the notorious Tamarea plant (*Aciphylla Colensoi*), already fully noticed; and those splendid compositaceous plants *Celmisia spectabilis* and *C. incana*, which generally grew close together, forming large, dark-green, shining patches, and bearing a profusion of fine white flowers—a striking contrast to their leaves. At first sight I saw that this new Ranunculus was closely allied to *R. pinguis*, of Lord Auckland's group and Campbell's Island—then lately described in the "Flora Antarctica," of which work I had received an early part just before I left the station. Other plants of those far-off Antarctic islets were also found here, on the summits—notably *Oreobolis pumilio*, growing in dense tufts in exposed places; while the peculiar straggling *Cyathodes empetrifolia*, and the pretty little flowering-plants *Euphrasia antarctica* and *Myosotis antarctica* flourished in half-sheltered hollows with *Plantago Brownii* and the grass *Catabrosa antarctica*. With these last also grew, very closely intermixed (much as we have seen the daisies and buttercups among low turfy grasses in our English meadows), the curious plant *Drapetes dieffenbachii*; the little elegant *Ourisia cæspitosa*, abounding in flowers; a very small and new species of Plantago (*P. uniflora*); and a similar-sized botanical novelty, *Astelia linearis*, a tiny plant bearing a large orange-coloured fruit; a little Caltha (*C. Novæ Zealandiæ*), having pale, star-like flowers; two graceful Gentians (*G. montana* and *G. pleurogynoides*), and a very small, shrubby, prostrate Coprosma (*C. pumila*), together with several elegant, shrubby little Veronicæ. Two orchideous plants, *Pterostylis foliata* and *Caladenia bifolia* (of which I wished for better specimens), I also detected growing sparingly, and with them a couple of Carices, *C. acicularis* and *C. inversa*, and also two species of Uncinia, *U. divaricata* and *U. filiformis*; and with them several interesting Hepaticæ and Mosses. Only in one or two spots, in shady, sheltered places near the top, and just within the forest, did I meet with that pretty little plant, *Ourisia Colensoi*, but in those spots there were plenty of them, and always beautifully in flower; the plants of this species grew apart, as if they liked room—in this respect differing altogether from the other species of this genus I have seen."

The lover of flowers can easily judge from these extracts how interesting to them would be this memoir of the now venerable explorer; there is much more of the like nature throughout its pages, and we trust the Hawke's Bay Philosophical Institute will send some copies of this "In Memoriam" narrative to this country, on sale for their benefit.

NOTES

THERE will be a *conversazione* at the Royal Society on Wednesday next, June 10.

THE *conversazione* of Sir F. Bramwell, the President of the Institution of Civil Engineers, will be held in the International

Exhibition Buildings, South Kensington, to-morrow evening, from nine to twelve. The Society of Arts *conversazione* will be held in the same place on July 3 next.

A PUBLIC meeting has been held in Birmingham to make preliminary arrangements for the reception of the British Association for the Advancement of Science on its visit to Birmingham in 1886. The mayor, Mr. Alderman Martineau, presided, and there was a large attendance. After referring to the four previous visits of the Association to Birmingham, the last of which was in 1865, the mayor stated that the forthcoming visit would involve a large amount of preliminary work, for which arrangements had to be made by the appointment of local committees. The meeting would probably be under the presidency of Principal Dawson, of Montreal. A large local committee was appointed, together with honorary officers, and the meeting terminated with a vote of thanks to the mayor.

THE statue to Linnæus which was recently unveiled with so much ceremony in Stockholm, stands in the well-known park Humlegården. It represents the "flower-king"—as he is called in Sweden—at the age of sixty in a meditating attitude, holding the "Systema Naturæ" and a bunch of flowers in his left hand. It is surrounded by allegorical female figures representing botany, zoology, medicine, and mineralogy, and is executed by Prof. Kjelberg, the work having occupied five years.

A ZOOLOGICAL garden is being formed in Stockholm, at the well-known pleasure resort of Djurgården, which will be the first of its kind in Scandinavia. Most of the animals are being purchased in Germany.

THE Rede Lecture was delivered on Tuesday in the Senate House at Cambridge by Mr. G. J. Romanes, F.R.S., the subject being "Mind and Motion."

THE *Central News* has received a telegram from Bombay announcing that a fearful earthquake has devastated a portion of Cashmere. The first shocks were experienced on Sunday, and created intense consternation. The oscillation was repeated at intervals of about ten minutes, and the shocks still continued up to the time the despatch was sent off. A wild panic is stated to have seized upon the people, who ran to the rivers and lakes, and sought to escape by embarking upon floating craft of any description. The town of Srinagar seems to have suffered severely. A great portion of the city is stated to have been demolished by the most severe shocks. Later accounts state that although some severe shocks have occurred in Cashmere, the loss has been trifling.

A SMART shock of earthquake was felt in Cape Town and the surrounding districts shortly before midnight on May 10, but no damage was reported.

THE results of a series of observations carried out by the Hydrographical Bureau at Washington, in order to determine the length, depth, and duration of ocean waves, have been published. The largest wave observed is said to have had a length of half a mile, and to have spent itself in 23 seconds. During storms in the North Atlantic waves sometimes extend to a length of 500 and 600 feet, and last from 10 to 11 seconds. The most careful measurements of the heights of waves give from 44 to 48 feet as an extreme limit; the average height of great waves is about 30 feet. These measurements refer to ordinary marine action, and do not relate to earthquake action or other exceptional agencies.

A CORRESPONDENT to *Ausland* makes a communication regarding the present condition of the artesian wells in Sahara. It is well known that such wells have been in operation there from a very remote period, and in the Algerian Sahara additiona wells have been opened with considerable success by the French. Between Biskra and Tuggurt the 434 old wells yielded in 1879 64,000 litres of water per minute, the 68 French ones 113,000 litres. The number of palms had increased from 359,000 to 517,000, that of other fruit-trees from 40,000 to 90,000, the population from 6672 to 12,827. In December, 1881, the yield of water from the wells had risen to 209,000 litres per minute. But this success is confined to a narrow zone within which water can be reached within a depth of 100 metres, and even here the borings that have been made since 1881 indicate a diminution in the yield of water, making it appear as if the limit of production of the underground reservoirs had almost been reached. Many of the French borings, too, are getting stopped up by sand, and are of too small calibre to be cleaned out and restored ike the wider Arabic ones. It is believed that it will be absoutely necessary to set about the sinking of new wells with a wider bore.

DR. ANDRÉE, of Leipzig, discussed before a recent meeting of the Anthropological Society of Vienna the question whether iron was known in America in pre-Columbian times. Meteoric iron was certainly in use amongst certain Indian tribes and the Esquimaux, but Dr. Andrée thinks that they were wholly unacquainted with the art of forging iron. This conclusion is based on the fact, among others, that while there is ample proof that the Indians knew how to obtain and employ gold, silver, tin, copper, quicksilver, &c., we hear nothing of iron mines in the history of the civilisation of ancient America. The language itself proves this, for there is no expression for *iron*. Some writers, it is true, speak of the word *panilgue* as that for iron, but it really means metal in general. Moreover, in pre-historic, or rather pre-Columbian, graves, especially in the rainless regions of Peru and Northern Chili, ornaments of all kinds, weapons and implements are found, but no objects in iron have been discovered, although the Indians placed their most valued articles in their tombs. There is no reason, he thinks, to believe that the tools employed in the great masonry works of Peru, such as that at Tiahuanaco, were other than those in use in the rest of Peru, which were of *champi*, a species of bronze. The chisels found in Peruvian graves soon become blunted when used on the hard strut; but it is suggested that there was some method of sharpening them easily. Indians certainly have worked a hard stone like nephrite without iron; and there is no improbability, says the writer, in the theory that these chisels were employed, when we recollect the patient temperament of the Indians, who for generations were accustomed to the repetition of the same work, to indolently pursuing an uniform task, and also that *gutta cavat lapidem.*

BEFORE the last meeting of the Asiatic Society of Japan (reported in the *Japan Weekly Mail*) Mr. H. Pryer read a paper entitled "Notes on the *Mustela itatsi* and on the *Corvus japonensis*, Bonaparte." The paper was largely a criticism of views advanced by Dr. Brauns regarding the generic affinities of these animals, and published in the Society's *Transactions*. A series of comparative measurements of the beak, metatarsus and wing of the *Corvus corax* and *Corvus japonensis* were given, with comparisons of the tail, eggs, and larynx, which proved that they were not identical. It was suggested that Dr. Brauns' specimen of the *Corvus japonensis* was really a specimen of the *Corvus corone.*

THE *Johns Hopkins University Circular* for May contains the abstract of a paper by Mr. Donaldson, entitled "Observations on Temperature-Sense." Blix, of Upsala, and Eulenberg, of Berlin, have observed that there are definite points on the skin at which sensations of cold only are aroused; others, distinct from the first and equally definite, for the sensation of heat, while between these two sets of spots sensations of pressure only are aroused. These reactions were obtained by electrical and thermal stimulation of the skin. Mr. Donaldson, whose attention had previously been attracted to the subject, endeavoured to make accurate maps of these cold and hot spots. It was found that their distribution on corresponding parts differed in different individuals, that the distribution on symmetrical parts of the body was different, that the number of cold spots was greater than the number of hot spots, that the relative abundance of the two kinds varied in different parts of the skin, and that, roughly speaking, there are two grades of spots, viz. those which react almost always and those which react only half the time and with a comparatively faint sensation. The spots, as a rule, are less than a millimetre in diameter, and they are easily exhausted. The sensation roused by a single stimulus often lasts, however, for some minutes after the removal of the stimulus. As the thermally sensitive spots move about as the skin moves, it is clear that they are in the skin and not below. On being cut from the skin and examined, the spots showed no structures with which the sensations could be associated. The spots were found quite as sensitive on scars as on the sound skin. Using the radiant-heat method described by Pollitzer, the hot spots were found to respond from eight to forty times more quickly to a given stimulus than the not-hot ones. The explanation of any sensation of heat on the not-hot spots appears to be that there is conducting heat through the skin, so that the stimulus finally reaches a hot spot.

THE death is announced of Mr. Alexander Croall, Curator of the Smith Institute, Stirling, and a botanist of some reputation.

WE have just received Band v. of the *Verhandlungen des Vereins für naturwissenchaftliche Unterhaltung zu Hamburg*, 1878–1882; the title-page bears the date 1883; it appears to have been published in monthly numbers. Was Band v. actually published until 1885? There is no internal evidence against its appearance in 1883, but we fail to find any reference to certain papers in it in the published records for that year. This ambiguity as to date is awkward. The contents are varied and valuable, and embrace natural history in its broadest sense, as will be seen from the titles of some of the papers, such as "Die Umgestaltung unserer Gegend durch Wasser und Wind und die Abnahme des Wassers in unserem Gebiete;" "Die Variabilität der Schmetterlinge in ihren verschiedenen Entwickelungs-Stadien, und der biologische Werth von Form, Farbe, und Zeichnung;" "Die Entwickelung unserer Kenntnisse der Länder im Süden von Amerika;" "Hammer und Messer in der Sprachgeschichte;" "Haben auch in Deutschland gleichzeitig mit dem Mammuth Menschen gelebt?" "Die Insel Rotumah und ihre Bewohner;" "Mittheilungen über einen Taifun bei Jokohama und Jeddo," &c. Of the papers enumerated that on typhoons seems especially interesting on account of the analyses given of the reports of various ship-captains. There are several zoological and botanical papers, in addition to the one already quoted.

THE new annual report of the Canadian Minister of Agriculture to the Governor-General contains, for the first time, the report of the Dominion entomologist, Mr. James Fletcher. The Minister explains that as an acquaintance with the results of entomological science is a matter of necessity to every tiller of the soil, he took the step of appointing an official entomologist in order that the attention of those whose interests are materially affected might be called to the subject. As Mr. Fletcher was only appointed in June last year, his report is necessarily a preliminary one. He has succeeded in establishing a system of correspondence all over the Dominion, and from extracts of letters which are published in his report it is clear that he has ample work before him. In parts of Nova Scotia, for example, the cultivation of wheat has had to be abandoned, on account of the wheat-midge, or *Diplosis tritici*. In other places, clover, peas, roots, fruit and forest trees have suffered heavily by the ravages of various insects. The position of entomologists, therefore, is one with large possibilities of material benefit to the Dominion and its inhabitants.

A SERIES of photographs of lightning flashes were lately obtained at Berlin by Dr. Kayser, and are the subject of a paper to the Academy there (*Wied. Ann.*, No. 5). The lightning is shown (as previously) to have gone very often from one point to several, the aspect in the photograph being like that of a river with numerous tributaries (only the fluid takes the opposite direction). The weaker flashes did not so branch out. In one remarkable effect the stem consists not of one bright line only, but of four parallel throughout, the second being rather a band, and stratified transversely. The explanation Dr. Kayser offers is, that in this case there was an oscillating discharge. The first spark, in passing from cloud to earth, would leave a channel of heated air, which would be used by the next spark from earth to cloud, only it was meanwhile a little displaced by the wind; and so with the others. Such oscillatory discharges may sometimes be observed with the eye in violent thunderstorms if the oscillation be pretty slow. Dr. Kayser reckons the whole phenomenon in the present case to have occurred in less than half a second. The stratified appearance of the band he is unable to account for.

THE eels of the ponds in the woods of Vincennes leave them every spring in large numbers, making their way to the Seine or the Marne, several kilometres distant. They take advantage of rainy weather, when the herbage is wet, and their instinct guides them directly to their destination. New species have repeatedly been introduced into the lakes, but in vain; all seem to have this disposition to leave. Some have thought that the water of these ponds, having been brought by hydraulic engines, has undergone some change which drives the eels away. But the phenomenon of such migrations by eels and some other fishes is not uncommon. Thus in the marshes of Picardy eels are often found on the grass, going from one pond to another.

THE reports of the Aëronautical Society of Great Britain for the years 1883 and 1884 have just been issued together in a small volume. It is mainly occupied by papers read before the Society. Amongst these is one on the mechanics of flight and their application to flying machines, by Mr. H. Middleton; artificial flight attainable by Mr. Hollands; the possibility of man-flight, by Mr. Barry; on the methods of soaring birds, and the bearing of the facts connected with them, by Mr. J. Lancaster, of Chicago. Amongst the shorter papers are: a visit to the Aëronautical Exhibition at Paris, by Mr. Frost; a memoir of Mr. John Stringfellow, by Mr. Brearey; a light and economical motor for propulsion in air, by Capt. Griffiths; and conjoint gas and mechanical action as applied to flight, by Mr. Brearey.

AN aëronautical exhibition under the patronage of the Aëronautical Society of Great Britain is to be opened during the present month in connection with the International Exhibition at the Alexandra Palace. The objects for exhibition will be models of designs for the accomplishment of aërial navigation by mechanical means only, or partly by buoyancy and partly by mechanical means; objects which are capable of flight and carrying their own motive power; machines constructed upon a scale calculated to carry a weight equal to that of a man upon the principles advocated by the inventors; light motors; balloons, navigable or otherwise; balloon material; kites, or similar aërial appliances, for saving life at sea, or for traction; and other objects of interest connected with aëronautics. The large outdoor space will be made available for various competitions, such as the nearest approach to a given locality. The disputed question of aërial locomotion by the aid of buoyancy will also be conclusively tested.

THE scientific society, Isis, of Dresden, having recently attained the fiftieth year of its existence, has issued a special jubilee or festival number of its *Proceedings*. It was founded in 1834, at the end of which year it had 27 members, and in 1835 it was reorganised and called Isis. During the first thirty years of its existence the Society was fortunate in having in keeping a single president, Dr. Reichenbach, whose lectures were mainly instrumental in the formation of the Society. In 1860 the twenty-fifth anniversary of the founding was celebrated with much ceremony, and as the occasion was also Reichenbach's jubilee, the double event was commemorated by the establishment of a memorial fund which bore his name, and the income from which was to be devoted to the support of a Saxon student travelling for zoological investigation. A record was then issued of the work of the Society so far; the number before us carries on the story for another twenty-five years, thus completing the history of the half century. The 27 members of 1835 have swollen to about 465 in 1885, and progress in other directions has been in proportion. In addition to the secretary's record of the advances of the last quarter of a century, the *Festschrift* contains a paper by Prof. Stelzner on the development of the methods of petrographic investigation during the last fifty years, and one by Herr Töpler on the history of discoveries in electromagnetism and inductional electricity. Most of the remaining papers deal with local science, such traces of animals in the coal formations of Zwickau, and several others on subjects connected chiefly with Dresden and its neighbourhood. The Society starts on the second half of the first century of its existence with ample vigour and promise of an unlimited lease of existence and activity.

ON May 22, at about 6.30 p.m., a mirage was seen from Visby, on the island of Gothland, in the Baltic. It appeared out at sea, on the western horizon, and represented a town on both sides, surrounded by high forest-clad mountains, which seemed to be within a distance of only a few miles. A large vessel with three masts lay in front of the town. The mirage lasted a couple of minutes, when it suddenly disappeared.

ONE hundred thousand shad have been reared in the United States during the last year, to say nothing of other species of fish, the exact number of which it is impossible to compute. It will be remembered that the shad was once exceedingly prolific in the Thames, but owing to the impure state of the river their numerical proportions have decreased to a very large extent. The Fish Commissioners of America have acted wisely in acclimatising the shad to their own waters, it being a valuable fish and easy of cultivation.

A SHORT time since we commented upon the enormous quantities of rats which infested the Health Exhibition, but which entirely disappeared shortly after it closed. Soon after the present Inventions Exhibition opened, these pests commenced to reappear, and their numbers are daily increasing. The authorities would do well to check their movements before they assume gigantic proportions.

ALTHOUGH the Professorship of Anatomy and Histology at the University of Lund has been twice officially announced vacant no applicant has come forward. It will now have to remain unoccupied till 1886.

THE Mexican Government has at length determined to undertake a geological survey of the whole country, as far as practicable. 10,000 dollars have been assigned for preliminary expenses.

WE have received from Messrs. Theiler and Sons specimens of their Universal Pocket Microscope and their Demonstration Microscope. The former magnifies 50 diameters, while the latter, intended for "schools and the drawing-room," has three powers—30, 100, and 150 diameters. They are both very admirable contrivances, and should be in the hands of all young people. The definition and achromatism of the Demonstration Microscope are perfect.

THE additions to the Zoological Society's Gardens during the past week include two Javan Cats (*Felis javanensis*), a Marbled Cat (*Felis marmorata*) from Malacca, presented by Mr. Frank Swettenham; a Common Marmoset (*Hapale jacchus*) from Brazil, presented by Dr. L. Morgan; a Slender-billed Cockatoo (*Cacatua tenuirostris*) from Australia, presented by Mrs. E. H. Watson; two Tuatera Lizards (*Sphenodon punctata*) from New Zealand, presented by Prof. T. J. Parker; a Smooth Snake (*Coronella lævis*), a Common Viper (*Vipera berus*), British, presented by Mr. W. H. B. Pain; a Slender-billed Cockatoo (*Cacatua tenuirostris*) from Australia, thirteen Tuatera Lizards (*Sphenodon punctata*) from New Zealand, deposited; an Osprey (*Pandion haliaetus*), caught in the North Sea, purchased; a Darwin's Rhea (*Rhea darwini*) from Patagonia, received in exchange; a Hog Deer (*Cervus porcinus* ♂), two Four-horned Antelopes (*Tetraceros quadricornis*), two Prairie Marmots (*Arctomys ludovicianus*), two Long-fronted Gerbilles (*Gerbillus longifrons*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

THE OBSERVATORY OF PARIS.—Rear-Admiral Mouchez has issued his report on the work of this establishment during the year 1884. The completion of the re-observation of Lalande's stars has led to a new disposition of the meridian-instruments, one of which, on the proposal of M. Lœwy, is now occupied with the determination of a number of circumpolar stars on his new method; the great meridian-circle and the circle of Gambey are still employed for observations of the minor planets, and of comparison-stars for planets, comets, and nebulæ observed with the equatorials. The great telescope of 0·74 m. is still unmounted, no suitable position being available in the present state of the grounds of the Observatory. M. Mouchez mentions having received communications from the authorities in Algeria, referring to the possibility of obtaining from the local budget the greater part of the sum that would be required to mount the instrument at the Observatory of Algiers on the summit of the Boudjaréah—an exceptionally favourable situation, which might be visited by the astronomers of the Paris Observatory for special observations, but the Council of the latter institution have not availed themselves of the proposition, in the hope that the equatorial may yet be erected at Paris. Amongst the observations made with the instruments in the west tower and the Henry equatorial, are many of the satellites of Uranus and Neptune, the companion of Sirius, the belts of Uranus, nebulæ, and double-stars. MM. Henry have been occupied with astronomical photography during the year, and, as is well known, with great success; various clusters of stars have been photographed, and M. Mouchez appends to his report a reproduction by heliogravure of a plate of the great clusters in Perseus. A trace of the motion of the minor planet Pallas was shown after an exposure of thirty-five minutes. The important results obtained by MM. Henry in photographing very small stars in those crowded parts of the heavens where the Galaxy crosses the ecliptic have been already referred to in this column. Steady progress has been made both with the calculations and printing of the Paris Catalogue of Stars, and it is expected that the first volume of both series (star-positions as observed, and catalogue) will be completed by the end of the year. Vol. xviii. of the *Mémoires* is finished. The Report further details the personal work of the members of the Observatory staff. Amongst the additions to the Museum is a portrait of Pons, presented by M. Tempel.

The Report for the year 1884 is preceded by one which enters specially into the present condition of a scheme for removing the principal instruments in the Observatory to a site where not only greater steadiness can be secured in their mounting but where the objections of being surrounded by a great city will not exist. It appears that the Academy of Sciences have not, so far, favoured this scheme. M. Mouchez states very clearly his view of the question.

THE COMET TEMPEL-SWIFT (1869–80).—M. Bossert, of Paris, is engaged upon the determination of the orbit of this comet, which may be expected to reach perihelion again about May, 1886, the period of revolution being rather less than 5½ years. Since the last perihelion passage on November 8, 1880, the perturbations are not likely to have been material, and should the comet arrive at its least distance from the sun early in May the chances of reobservation will be very small indeed, the longitude of perihelion being in 43°, and the inclination of the orbit to the ecliptic less than 5½°.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, JUNE 7–13

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on June 7

Sun rises, 3h. 47m.; souths, 11h. 58m. 35·5s.; sets, 20h. 10m.; decl. on meridian, 22° 48′ N.: Sidereal Time at Sunset, 13h. 15m.

Moon (New on June 12, 23h.) rises, 0h. 56m.; souths, 7h. 3m.; sets, 13h. 22m.; decl. on meridian, 0° 41′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	2 59	10 34	18 9	17 10 N.
Venus	4 17	12 38	20 59	23 57 N.
Mars	2 34	10 14	17 54	17 58 N.
Jupiter	9 51	17 1	0 11*	12 52 N.
Saturn	4 31	12 40	20 49	22 26 N.

* Indicates that the setting is that of the following day.

Phenomena of Jupiter's Satellites

The Phenomena of Jupiter's Satellites are such as are visible at Greenwich.

June	h.	
11	1	Mars in conjunction with and 3° 51′ north of the Moon.
11	16	Mercury in conjunction with and 2° 47′ north of the Moon.
13	6	Saturn in conjunction with and 4° 3′ north of the Moon.
13	17	Venus in conjunction with and 5° 48′ north of the Moon.

GEOGRAPHICAL NOTES

The Pamir is the subject of another contribution, by M. Ivanoff, to the last issue of the *Izvestia* of the Russian Geographical Society. Several objections having been made to his views on the Pamir, already mentioned in Nature, and especially to his tendency of limiting the name of Pamir to the eastern part of the great Central Asian mountain mass. M. Ivanoff answers by a paper accompanied by a map of the Pamir, on which the whole of the region is represented; the chains of mountains being drawn, however, merely schematically, which circumstance is a great obstacle to catching on the map their real characters. He insists on the fact that the denominations "Great" and "Little Pamir," introduced by Messrs. Gordon and Trotter, are not known to those natives who are best acquainted with the region, and they lay altogether too much stress upon the names in use among Kirghizes. He thus limits the discussion as to what must be considered as the Pamir, which discussion had been so very well put by his former orographical papers on its proper ground—that of physical geography—where it obviously must remain. We notice in the same issue a paper by M. Wolter on the Prussian Lithuanians; and a preliminary report, by M. Sorokin, on his journey in Russian Tian-Shan.

The new and promising route to Central Asia from the Mortvyi Kultuk Gulf of the Caspian viâ the Ust-Urt to Kungrad is the subject of an interesting paper read by M. Belavskiy before the Russian Geographical Society, and analysed in the last issue of the *Izvestia* (xxi. 2). Until lately the Mortvyi Kultuk was considered too shallow for navigation, east winds being said to reduce its depth to 3·5 feet. Recent soundings proved, however, that, the usual depth being about 9 feet, no winds reduce it more than to 4½ feet; in fact, flat steamers freely navigate the gulf. Those which do not take more than 4½ feet of water approach the shores for 60 to 230 yards at Ayrakly. From that port, which has sweet-water wells, the route goes on to the Ust-Urt plateau. The Ust-Urt was formerly considered as quite dry, and as having a very severe climate. But this belief was exaggerated. Water is found at each 10 to 13 miles; there are also pasture-grounds, and neither the cold in winter nor the heat in summer is excessive. This last is moderated by winds. The *saksaoul*, brushes, and the excrement of camels give the necessary fuel. On the whole stretch, 270 miles long, from the Mortvyi Kultuk to Kungrad, there is no difficulty in crossing the Ust-Urt in carriages, and want of water is felt only near Kungrad. From this town steamers may ply on the Amu-daria; a steamer has already gone up the river to Khodja-Sala. Moreover, a route, available for carriages, runs along the left bank of the river. On the whole this new route has already proved to be more advantageous for the transport of merchandise from Bokhara to Russia than he old one viâ Orenburg.

From a communication to the Russian Geographical Society, made by Dr. Dybovskiy, it appears that the Commodore Islands—Behring, Copper, and two smaller ones—situated 300 miles east of Kamschatka, ought to be regarded in a better light than they have been hitherto. Behring Island is covered with excellent prairies, and Dr. Dybovskiy is sure that agriculture could be carried on it. The southern part of this island is hilly, and reminds one of the alpine regions of Kamstchatka. No forests, but only shrubs of the *Rhododendron Sorbus*, and so on, grow on the islands; but the explorer's experiments of planting forest-trees proved quite successful. The higher tracts offering excellent grazing grounds for reindeer, a number of these last were imported in 1882, and the experiment of acclimatising them on the island proved also quite successful. The narrow valleys of Copper Island are also considered quite suitable for agriculture. The islands are formed of crystalline rocks covered with Tertiary deposits; they contain copper ore and brown coal, of course unworked. Fuel is brought from Kamtschatka. The climate is far milder than on the peninsula, and while in May snow a yard thick lay at Petropavlovsk, vegetables are freely grown on the islands. Snow is altogether so scanty that horses brought on to Behring Island were feeding throughout the winter on the prairies. The fauna of the islands has been well explored by M. Dybovskiy. The flora is much like that of the alpine regions of Kamtschatka. The inhabitants, all Aleutes, 514 in number, live in wooden houses. They are all Christians, and can read.

The attention of geographers and men of science ought to be called to several numbers of the *Archiv für die naturwissenschaftliche Landesdurchforschung von Böhmen*, which have recently been issued (Prague: Franz Rzuonatz). The numbers of most interest to geographers pure and simple are those forming the first division of the third volume, and containing a list of the heights in Bohemia trigonometrically determined by the Imperial Institute of Military Geography in the years 1877–79. Numbers 2 to 6 of the fourth volume deal with the geology and botany of Bohemia, and numbers 1 to 3 of the fifth volume are also devoted to geology. The monographs composing this work are said to constitute a real treasury of information concerning the physical conditions and natural resources of the Austrian Crownland of which it treats.

At the last meeting of the Paris Geographical Society a communication was read from Capt. Sorensen respecting his visit last year to Spitzbergen. It contained numerous observations on climatology and the configuration of the coasts (especially in correction of the English charts). His remarks with regard to the state of the ice during the spring are of special interest. He found the ice around Spitzbergen very different from what he had observed in previous years. Usually the western side is accessible at the commencement of the season, viz., May and June. *Drifts* are to be met with, but they disappear about the middle of June, or, at the latest, in the beginning of July. Last year, on the other hand, the west coast was blocked by ice the whole summer through. No captain can recollect having ever encountered such a mass of ice on this coast. The Norwegians have observed that for three years past the melting of the ice has grown later year by year. On the east coast the sea is generally full of icebergs, but it was wholly free from them last year. Off Barentz Island also the sea was free from ice, and one of the captains who penetrated farther to the east discovered two islands. Capt. Sorensen suggests, therefore, that Spitzbergen and Franz-Josef Land form parts of a vast archipelago, and not two wholly distinct territories, as has hitherto been believed. He promises during coming years to continue his meteorological observations in his annual visits to these regions.

THE last number of the Royal Geographical Society of Antwerp (tome ix. 5e fascicule) contains a paper by M. van den Gheyn on the European origin of the Aryas, a discussion of recent researches on this subject, especially of the works of Schrader, Penka, von Löher, Roth, Geiger, and Ujfalvy. The author, while regarding the subject as open to discussion, thinks that the probabilities are in favour of an Asiatic origin. Dr. Haine writes on the manners of the Californian Indians, amongst whom he passed some time about 1850. M. August Thys contributes a brief account of an early Flemish navigator, Dietrich Paesschen, who made several voyages to the Levant about 1511; and M. Baguet describes Steinen's late journey on the Xingu. An instalment of the report of the commission to study the Scheldt concludes the number.

THE expedition which the Norwegian Government dispatches this summer to the coast of Finmarken, to which we have previously referred, has for its chief object to ascertain whether there are banks or fishing grounds far from the coast, a circumstance which has never been ascertained, but which would be of great value if proved. Hitherto all fishing has been confined to the shore, but, judging from what is the case further south in Norway, such a discovery is very likely.

ON May 27 the Arctic steamer *Alert* sailed from Halifax with a scientific expedition for Hudson's Bay, to examine its harbours and the facilities that exist for a trade route from the Western Territory to Europe.

ARTIFICIAL EARTHQUAKES

QUITE recently we noticed a paper by Prof. Milne, of Japan, which contained exhaustive records of nearly 250 earthquakes that occurred in that country in two years, and which was an earthquake history of Northern Japan during that period. We have now before us another paper from the same indefatigable investigator, also on earthquakes, but on a totally different branch, viz. seismic experiments—in other words, on artificial earthquakes. These experiments are so original in their inception, and in some respects so unexpected in their results, that they are worth describing at some length. The paper, which was read before two successive meetings of the Seismological Society of Japan towards the close of last year, covers over eighty octavo pages, and contains several illustrations; but it will be possible to extract its principal results in a comparatively short space. There were in all ten series of experiments, carried on over three years. The object was to study phenomena connected with earth-vibrations produced either by some explosive like dynamite, or by allowing a heavy weight to fall from a height. Each set of experiments involved several weeks' preparation; amongst the chief difficulties to be overcome were the procuring, transporting, and storing dynamite, putting the observing-stations in telegraphic connection, arranging the firing apparatus, making electric fuses, and the like, and doing all this in the midst of a populous city. These initial difficulties could never have been overcome but for the assistance of various departments of the Japanese administration, and it is pleasing to notice the help which Japanese officials freely render Prof. Milne in his interesting and important work in the field of seismic science. Nevertheless, he warns his readers at the outset that his experiments were such that it is hardly just to expect them to be carried out satisfactorily by a private individual; the trouble, expense, danger, and magnitude of the arrangements which they involve make them fitter undertakings for an army corps.

The only guiding data which he had when he commenced were the results obtained by the late Mr. Robert Mallet and by Gen. Abbot. These referred only to the velocity with which earth-vibrations were propagated, and in taking diagrams of earth-motion he was therefore entering upon new ground, and therefore continually encountered new results. Sometimes it was found that the instruments employed required modification before satisfactory records could be obtained; at other times the records which were obtained gave indications of new lines of investigation, to pursue which new apparatus would be needed, and so on. Hence many of his results, he observes, can only be regarded as provisional; for example, those which relate to the velocities of normal and transverse vibrations. The experiments were carried out, as far as circumstances would permit, in different soils, the chief agents employed being heavy weights of 1700 lbs. and upwards dropped from heights up to 40 feet, and different quantities of dynamite exploded in cavities of varying depths. The effects of these were observed with different seismographs. The observations thus made in the ten series of experiments are described with the utmost detail, illustrated by numerous plans and tables, under their appropriate heads. Prof. Milne sums up his results under a succession of heads, and the most important of them are given below. He observes, however, that in reading these conclusions it must be remembered that they only refer to experiments performed in certain kinds of ground.

Effect of Ground on Vibration.—Hills have but little effect in stopping vibrations, but excavations exert considerable influence on them. In soft, damp ground it is easy to produce vibrations of large amplitude and considerable duration; in loose, dry ground an explosion of dynamite yields a disturbance of large amplitude but of short duration, while in soft rock it is difficult to produce a disturbance the amplitude of which is sufficiently great to be recorded on an ordinary seismograph.

General Character of the Motion.—The pointer of a seismograph with a single index first moves in a normal direction, after which it is suddenly deflected, and the resulting diagram yields a figure partially dependent on the relative phases of the normal and transverse motion, which phases are in turn dependent upon the distance of the seismograph from the origin of the disturbance. A bracket seismograph indicating normal motion at a given station commences its indications before a similar seismograph arranged to write transverse motion. If the diagrams yielded by two such seismographs be compounded, they yield figures containing loops and other irregularities not unlike the figures yielded by the seismograph with the single index. Near to an origin the first movement will be in a straight line outwards from the origin; subsequently the motion may be elliptical, like the figure 8, and irregular. The general direction of the motion is, however, normal. Two points of ground only a few feet apart may not synchronise in their motions, and earthquake motion is probably not a simple harmonic one.

Normal Motion.—Near to an origin the first motion is outwards; at a distance from the origin the first motion may be inwards, the nature of the movement being dependent probably on the intensity of the initial disturbance and on the distance of the observing station from the origin. At a station near the origin the second or third wave is usually the largest, after which the motion dies down very rapidly in its amplitude, the motion inwards decreasing more rapidly than the motion outwards. Roughly speaking, the amplitude of normal motion is inversely as the distance from the origin. As a disturbance radiates, the period of oscillation increases, until finally it becomes equal to the period of the transverse motion. It may thus be inferred that the greater the initial disturbance the greater the frequency of the waves. A wave which appeared single at one observing station had split up into two by the time it reached the second. At stations near the origin the motion inwards is greater than the motion outwards; but at a distance the two motions are practically equal. At a station near the origin the period of the waves is at first short, but it becomes longer as the disturbance dies out. The semi-oscillations inwards are described more rapidly than those outwards.

Transverse Motion.—The laws governing the transverse motion are practically identical with those which govern the normal motion, the only difference being that in the case of normal motion they are more clearly pronounced. Near to an origin the transverse motion commences definitely but irregularly; the first two or three movements are decided, and their amplitude slightly exceeds that of those which follow, but it decreases as the disturbance radiates at a slower rate than that of the normal motion. The period increases as the disturbance radiates, and decreases as the latter begins to die out.

Relation of Normal to Transverse Motion.—Near to an origin the amplitude of normal is much greater than that of transverse motion, and as a disturbance radiates the amplitude of the latter decreases at a slower rate than that of the former, so that at a certain distance they may be equal.

Maximum Velocity and Intensity of Movements.—An earth-particle usually reaches its maximum velocity during the first inward movement, but a high velocity is sometimes attained in the first outward semi-oscillation. The value

$$V^2 = \tfrac{1}{2} g \sqrt{a^2 + b^2} \times \left(\frac{1 - \cos\theta}{\cos^2\theta}\right)$$

used by Mallet and other seismologists to express the velocity of shock, as determined from the dimensions of a body which it has overturned, is a quantity not obtainable from an earthquake diagram. It represents the effect of a sudden impulse. In an earthquake a body is overturned or shattered by an acceleration, f, which is calculable for a body of definite dimensions. As obtained from an earthquake diagram f lies between $\frac{V}{t}$ and $\frac{V^2}{a}$, where V is the maximum velocity, t is the quarter period, and a is the amplitude. The initial velocity given in the formula $V^2 = \frac{2a^2}{b}$ for horizontal projection used by Mallet as identical with V^2 in the first formula, are not identical quantities. The velocity calculated from the range of projection, when projection occurs, is identical with the maximum velocity as measured directly or calculated from a diagram. The values $\frac{V^2}{a}$ are those used by Prof. Milne in discussing the intensity of movement. The intensity of an earthquake at first decreases rapidly as the disturbance radiates, subsequently it decreases more slowly. A curve of intensities deduced from observations at a sufficient number of stations would furnish the means of approximately calculating an absolute value for the intensity of an earthquake.

Vertical Motion.—In soft ground vertical motion appears to be a free surface-wave which advances more rapidly than the horizontal component of motion. It commences with small, rapid vibrations, and ends with vibrations which are long and slow. High velocities of transit may be obtained by the observation of this component of motion, and this is possibly an explanation of the preliminary tremors of an earthquake and the sound phenomenon.

Velocity.—The velocity of transit decreases as a disturbance radiates; near to an origin it varies with the intensity of the initial disturbance. In different kinds of ground, with different intensities of initial disturbance, and with different systems of observation, velocities lying between 630 feet and 200 feet per second were determined. Mr. Mallet determined a velocity in sand of 824 feet, and in granite of 1664 feet per second. Gen. Abbot observed velocities of 8800 feet. These various determinations may all be strictly correct, the great difference between them being due partly to the nature of the rock, the intensity of the initial disturbance, and the kind of wave which was observed. In Prof. Milne's experiments the vertical free surface wave had the quickest rate of transit, the normal being next, and the transverse motion being the slowest; but the rate at which the normal motion exceeds the transverse is not constant. As the amplitude and period of the normal motion approach in value those of the transverse motion, so do the velocities of transit of these motions approach each other.

In stating the results, of which those given above are the principal, Prof. Milne refers to the particular experiments which support them, thus giving chapter and verse for his conclusions; but he thinks that if the investigations were repeated by himself or by any other investigator, although much of what he has recorded would be substantiated, more accurate results might be obtained by taking advantage of his experience. Finally he gives examples of investigations which have yet to be undertaken, and as these are valuable for others working in the same field, we append them here:—(1) An accurate determination of the rate at which the velocity of transit decreases as a disturbance radiates from its origin; (2) the relation between the velocity of transit and the intensity of the initial disturbance; (3) the determination of the rate at which the intensity of a disturbance decreases as measured at different distances from the origin. This might perhaps lead to the construction of a curve of intensities from which the absolute intensity of the initial disturbance could be learnt; (4) a more complete investigation of the vertical motion and of free surface waves; (5) an investigation of the inward motion of shocks. In Prof. Milne's experiments the movement of the ground from its neutral position *in* towards the origin of the disturbance has been performed so rapidly that he has been unable with the instruments at his disposal to measure its velocity accurately. As this is probably the most destructive element of motion, he regards its investigation as exceedingly important; (6) further investigations on the relationship between earthquake diagrams, and the overturning and projecting of various bodies; (7) a repetition of these and of all other experiments, on different kinds of ground.

THE INFLUENCE OF FORESTS ON CLIMATE

THE third number of *Petermann's Mittheilungen* for this year contains an article by Herr A. Woeikof on the influence of forests on climate. The commencement of a scientific investigation of this subject was made when the Bavarian forest meteorological stations were established, and when Prussia, Alsace-Lorraine, France, Switzerland, and Italy followed the example. As a general rule it may be laid down that in the warm seasons, as between forests and places close at hand which are treeless (1) the temperatures of the earth and air are lower in the former, (2) their variations are less, (3) the relative humidity is greater. After examining observations as to evaporations, Herr Woeikof states that the influence of forests in diminishing evaporation from water and the soil is so great that it cannot be accounted for alone by the lower temperature of the hot months, the greater humidity, or even by the shade. An important influence, which has hitherto been but little appreciated, is the protection from the wind afforded by the trees, and this the writer regards as more important than all the others together in reducing the degree of evaporation. With regard to the influence of forests on rain and snowfall, there is as yet only a single series of observations supplying comparative statistics, and extending over a sufficiently long period. These were taken in the neighbourhood of Nancy, and they show an important influence of forests in increasing the rainfall. It might appear that the effect of forests on rain in the climate of Central Europe in winter would be small, for the difference between the temperature and humidity of the forest and the open is very little, and the quantity of moisture in the atmosphere is small. But the observations show that it is at this time of the year that forests get much more rain. This the writer attributes to the clouds being lower, the resistance which the forest offers to the movement of the air, and to the moist west wind. Forests retain rain by the undergrowths of grass, moss, &c., much better than open ground, and let water off superficially only after a heavy rainfall; the remainder filters upwards slowly, and much of it is used for the evaporation of the trees. Although forests, especially thick, luxuriant forests, cannot exist without certain supplies of moisture, yet it is the same to them when the supplies come, for they retain what they get and use it over a long period. One example of this is the Lenkoran forest on the west coast of the Caspian, where the vegetation is more luxuriant than in any other part of Europe, yet very little rain falls in summer, but the rainfall in autumn and winter is great. The water is stored up by the forest, and is used in evaporation during the heat of summer. Humidity of the atmosphere, however, is not inconsistent with a high temperature, as the Red Sea shows; but in forests the humidity is due to the evaporation of the leaves—in other words, to a process by which heat is converted into work, and hence the coolness. Herr Woeikof then endeavours to ascertain the influence of forests on the climatic conditions of their neighbourhoods in the western parts of the Old World, between the 38th and 52nd degrees N. latitude, the places selected being in all cases in the open. Thus for the 52nd degree eight stations are taken between Valentia in Ireland on the west and the Kirghiz steppes on the east; for the 50th, Guernsey on the west, Semipalatinsk on the east, and thirteen stations, and so on for each two degrees of latitude to 38°. The general result of the observations in fifty-stations in six different degrees of latitude is that in Western Europe and Asia large forests have a great influence on the temperature of places near them, and that by their influence the normal increase of temperature as we travel eastward from the Atlantic Ocean to the interior of the continent is not merely interrupted, but they give places far removed from the coast a cooler summer than those actually on the sea. A striking example of this is Bosnia. An examination of the statistics shows (1) that in Bosnia the summer is 2°·5 to 4°·5 cooler than in Herzegovina; (2) even on the island of Lissa, in the full influence of the Adriatic Sea, the summer temperature is more than a degree higher than that of Bosnia, which is separated by lofty mountain ranges from the sea. Bosnia owes this comparatively cool summer to its great forests, while Herzegovina is almost disafforested. To sum up: forests exercise an influence on climate which does not cease on their borders, but extends over a larger or smaller adjacent region according to the size, kind, and position of forest. Hence man by afforestation and disafforestation can modify the climate around him; but it is an extreme position to hold that by afforestation the waste places of the earth can be made fertile. There are places incapable of being afforested, which would not give the necessary nourishment to trees.

ORIGIN OF THE CEREALS

RECENT numbers of *Naturen* contain interesting papers, by Prof. Schübeler, on the original habitat of some of the cereals, and the subsequent cultivation in the Scandinavian lands and Iceland of barley and rye more especially. It would appear that barley was cultivated before other cereals in Scandinavia, and that the generic term "corn" was applied among Northmen to this grain only from the oldest times, and that in the Norwegian laws of the seventeenth and eighteenth centuries wherever reference was made to the "*Kornskat*"—or standard by which land in the Northern lands was, and still is, rated in accordance with the corn it is capable of yielding—the term was understood to apply to barley. Proof of the high latitude to which the cultivation was carried in early ages is afforded by the Egil's Saga, where mention is made of a barn in Helgeland (65° N. lat.) used for the storing of corn, and which was so large that tables could be spread within it for the entertainment of 800 guests. In Iceland barley was cultivated from the time of its colonisation, in 870, till the middle of the fourteenth century, or, according to Jón Storrason, as lately as 1400. From that period down to our own times barley has not been grown in Iceland with any systematic attention, the islanders being dependent on the home country for their supplies of corn. In the last century, however, various attempts were made both by the Danish Government and private individuals to obtain home-grown corn in Iceland, and the success with which these endeavours were attended gives additional importance to the systematic undertaking, which has been set on foot by Dr. Schübeler and others, within the last three years, for the introduction into the island of the hardier cereals, vegetables, and fruits. As many as 382 samples of seeds of ornamental and useful plants, most of which were collected from the neighbourhood of Christiania, are now being cultivated at Reykjavik under the special direction of the local government doctor, Herr Schierbeck, who succeeded in 1883 in cutting barley ninety-eight days after the sowing of the seed, which had come from Alten (70° N. lat.). And here it may be observed that this seems the polar limit in Norway for anything like good barley crops. The seed is generally sown at the end of May, and in favourable seasons it may be cut at the end of August; the growth of the stalk being often 2½ inches in twenty-four hours. North of 60° or 61° barley cannot be successfully grown in Norway at more than from 1800 to 2000 feet above the sea-level. In Sweden the polar limit is about 68° or 66°, but even there, as in Finland, night-frosts prove very destructive to the young barley. In some of the fjeld valleys of Norway, on the other hand, barley may in favourable seasons be cut eight or nine weeks after its sowing, and thus two crops may be reaped in one summer. According even to a tradition current in Thelemarken, a farm there owes its name *Triset* to the *three* crops reaped in the land in one year! Rye early came into use as a bread-stuff in Scandinavia, and in 1490 the Norwegian Council of State issued an ordinance making it obligatory on every peasant to lay down a certain proportion of his land in rye. In Norway the polar limit of summer rye is about 69°, and that of winter rye about 61°; but in Sweden it has been carried along the coast as far north as 65°. The summer rye crops are generally sown and fit for cutting about the same time as barley, although occasionally in Southern Norway less than ninety days are required for their full maturity.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

THE Gilchrist Trustees have instituted a Scholarship of the annual value of 50*l.*, for three years, tenable at either Girton or Newnham College, Cambridge, to be awarded in connection with the Cambridge Higher Local Examination. The first award will be made on the results of the examination to be held in June. Further information may be obtained from the secretaries of the two colleges.

AT a recent meeting of the Senate of the Royal University of Ireland, two Fellows in the Department of Natural Science were elected. The successful competitors were the Rev. Marshal L. Klein, of the Catholic University College, and Mr. Marcus M. Hartog, Professor of Natural History, Queen's College, Cork. The salary attached to each of the Fellowships is 400*l.* a year.

SCIENTIFIC SERIALS

The Quarterly Journal of Microscopical Science, April, contains:—On the urinary organs of the Amphipoda, by W. B. Spencer, B.A. (plate 13).—The skin and nervous system of Priapulus and Halicryptus, by R. Scharff, Ph.D. (plate 14).—The eye and optic tract of insects, by S. J. Hickson, B.A. (plates 15–17).—A peculiar sense organ in *Scutigera coleoptrata*, one of the Myriopoda, by F. G. Heathcote, B.A. (plate 18).—The structure and development of Loxosoma, by S. F. Harmer, B.Sc. (plates 19–21).—A new hypothesis as to the relationship of the lung-book of Scorpio to the gill-book of Limulus, by E. R. Lankester, M.A.—A supplement number is announced to be published during May.

The Journal of the Royal Microscopical Society for April contains:—The Rev. W. H. Dallinger's address as President (plates 4–6).—The Lantern Microscope, by L. Wright.—On some unusual forms of lactic ferment; *Bacterium lactis*, by R. L. Maddox, M.D.—On a cata-dioptric immersion illuminator, by J. W. Stephenson.—With the usual summary of current researches in zoology and botany.

American Journal of Science, May.—Experiments undertaken to determine the modulus of elasticity of ice and the velocity of sound in ice, by John Trowbridge and Austin L. McRae. The average of all the observations was found to be 72×10^9 as compared with Bevan's absolute modulus 54×10^9. The velocity was determined at 2900 m. per second, or about nine times the velocity of sound in air.—Contributions from the Agricultural Experiment Station of the University of Wisconsin: digestion experiments, by H. P. Armsby. These experiments, made on sheep fed with hay, clover, malt-sprouts, and cotton seed-meal, yielded so many uncertain results that no satisfactory averages could be determined. Such averages may be made the basis of the calculation of rations in practice; but neither they nor the single results upon any given fodder can properly enter into any scientific calculation of the nutritive effect of a ration.—Chemical analysis of massive safflorite, by Le Roy W. McCay.—Application of photography to the study of electrical measurements (two illustrations), by John Trowbridge and Hammond Vinton Hayes.—On the production of alternating currents by means of a direct-current dynamo-electric machine, by John Trowbridge and Hammond Vinton Hayes.—Chemical analysis of a variety of topaz discovered in 1882 by Mr. N. H. Perry in the Stoneham district, State of Maine (two illustrations), by F. W. Clarke and J. S. Diller.—A notice of the relation observed by Dr. Weber between the residual elasticity and the chemical constitution of glass, by O. T. Sherman.—On the meridional deflection of ice-streams, as shown in the *moraines* of the extinct glaciers in the Mono Lake Valley, Eastern California (two illustrations), by W. J. McGee.—The pre-Glacial channel of Eagle River, Keweenaw Point, Lake Superior (one illustration), by Charles Whittlesey.—Note on the age of the slaty and arenaceous rocks in the vicinity of Schenectady, Schenectady County, New York, by S. W. Ford. These formations, usually referred to the epoch of the Lorraine shales, are regarded by the author as belonging to the Utica age. From them were obtained various fossils, including a species of Lingula which he considers to be the Utica species, *L. curta*.

The American Naturalist, March, contains:—Indian corn and the Indians, by E. L. Sturtevant.—The evolution of the Vertebrata, progressive and retrogressive, by E. D. Cope.—On the larval forms of *Spirorbis borealis*, by J. W. Fewkes.—Pennsylvania, before and after the elevation of the Appalachian Mountains; a study in dynamical geology, by E. W. Claypole.—Life and nature in Southern Labrador, by A. S. Packard.

April.—Why certain kinds of timber prevail in certain localities, by J. T. Campbell.—The evolution of the Vertebrata, by E. D. May.—Some new Infusoria (with illustrations), by A. C. Stokes.—Kitchen-garden esculents of American origin (I.), by E. L. Sturtevant.—The Lemuroidea and the Insectivora of the

Eocene period of North America (illustrated), by E. D. Cope. —On the Labrador Eskimo and their former range southward, by A. S. Packard.

Rendiconti del Reale Istituto Lombardo, April 23.—Some formulas for the calculation of the momenta of inertia in plain polygons, by Prof. G. Bardelli.—Some remarks on the functions which satisfy the differential equation $\Delta^2 u = 0$, by Prof. Giulio Ascoli.—Note on the morphological distinction between the various homologous and analogous organs of the different orders in the animal kingdom, by E. L. Maggi.—On a generalisation of the involute properties of complete squares and quadrilateral figures, by Gino Loria.—On a method of plain representation for the descriptive geometry of ordinary space, by Prof. F. Aschieri.—On the discontinuities in the secondary derived forms of the potential functions of a surface, by Dr. Paolo Paci.—Meteorological observations made in the Royal Brera Observatory, Milan, during the month of April.

Rivista Scientifico-Industriale, April 15-30.—Remarks on the velocity of the wind in connection with Prof. Archibald's experiments with Biram's anemometers, by the Editor.—Variations in the electric resistance of solid and pure metallic wires, according to the temperature (continued), by Prof. Angelo Emo.—Description of a new steam generator based on the principle of vortex circulation, by Prof. Annibale Riccò.—Note on the *Emberiza intermedia* discovered by Dr. Michaellis in Dalmatia is it a distinct species in this family of birds? by Dante Roster.

SOCIETIES AND ACADEMIES

London

Royal Society, May 7.—"Contributions to the Chemistry of Chlorophyll. Part I.," by Edward Schunck, F.R.S.

The paper treats of the products formed by the action of acids on chlorophyll. All who have worked with chlorophyll are familiar with the peculiar effects produced in solutions of chlorophyll by the action of acids. The colour is changed, and an absorption spectrum makes its appearance, which differs from that of chlorophyll. According to some, these changes are due to a simple modification of the chlorophyll, others consider they are caused by the formation of products of decomposition. The latter view seems the more probable.

On passing a current of hydrochloric acid gas into an alcoholic solution of chlorophyll, a dark green, almost black, precipitate is formed at once. The greenish-yellow liquid contains substances extracted along with chlorophyll by the alcohol, and not connected with the latter. The precipitate consists essentially of two colouring matters, phyllocyanin and phylloxanthin, bodies that had been previously observed and so named by Fremy, who, however, did not obtain them in a state of purity. They are best separated by Fremy's method, which consists in dissolving the mixture in ether, and then adding concentrated hydrochloric acid, when the liquid separates into two layers, a lower blue one containing phyllocyanin and an upper yellowish-green one containing phylloxanthin. It is immaterial what kind of leaves are taken for extraction, the products are always the same.

The paper deals only with the properties of phyllocyanin, which are very peculiar. After being purified in the manner described, it is obtained as a dark blue mass resembling indigo, and consisting of microscopic crystals which are generally opaque, but sometimes when very thin are translucent, and then appear olive-coloured. It stands heating to 160° without decomposition, but between that temperature and 180° it is decomposed without previously fusing, leaving a charred mass which, on further heating, burns away without residue. It contains nitrogen, but is free from sulphur.

Phyllocyanin is insoluble in water, petroleum ether, and ligroin, but dissolves in alcohol, ether, chloroform, glacial acetic acid, benzol, aniline, and carbon disulphide. The best solvent is chloroform. A minute quantity of the substance imparts an intense colour to any one of these solvents. It is only on diluting largely that the solutions lose their opacity. They then appear of a dull green or olive colour, and show the well-known and often described spectrum of so-called "acid chlorophyll," consisting of five bands, three of which are very dark, one of moderate intensity, and the fifth very faint.

By oxidising agents, such as nitric or chromic acid, phyllocyanin is easily decomposed, yielding yellow amorphous products, the solutions of which show no absorption bands. It shows a remarkable degree of permanence as compared with chlorophyll, when exposed to the combined action of air and light. A chloroformic solution contained in a loosely-stoppered bottle may be exposed for weeks, or even months, to alternate sunlight and diffused daylight before its peculiar colour and all trace of absorption bands have disappeared. When the process is complete a yellow liquid results, which contains several products, all of them amorphous, one being easily soluble in water, and exceedingly bitter to the taste. The decoloration of a chlorophyll solution under the same circumstances would take place in a day or two.

Phyllocyanin dissolves easily in concentrated sulphuric, hydrochloric, and hydrobromic acids, yielding dark blue solutions, which show spectra differing from that of phyllocyanin, and no doubt contain compounds of the latter with acids. These compounds, however, are unstable; for, on the addition of water to the solutions, phyllocyanin is precipitated unchanged. Phyllocyanin shows no tendency to combine with weaker acids, such as phosphoric, oxalic, tartaric, or citric acid.

Phyllocyanin dissolves easily in dilute caustic potash or soda lye. The solution gives precipitates of various shades of green with earthy and metallic salts, such as barium chloride, calcium chloride, lead acetate, and cupric acetate, and these might be called phyllocyanates. It seems, however, that by mere solution in alkali, phyllocyanin undergoes some change, for if acetic acid in excess be added to the solution, and it be then shaken up with ether, the precipitate dissolves in the ether, giving a solution which shows the bands of phyllocyanin; but if the whole be left to stand some time, the colour of the ethereal solution changes from green to brown, and it now shows a distinct and peculiar spectrum, characterised by two bands in the red and two fine but well-marked bands in the green, the third and fourth bands of phyllocyanin having disappeared, while the fifth still remains. The body yielding this spectrum has been prepared and found to yield microscopic crystals like phyllocyanin. A different product is formed when hot alkaline lye, or, what is better, boiling alcoholic potash or soda, is employed. It crystallises in small rosettes, which are green by transmitted, of a fine purple by reflected, light. Its solutions have a dull purple colour, and exhibit a distinct spectrum characterised by a broad, very dark band in the green. It may be identical with one of the products obtained by Hoppe-Seyler from his chlorophyllan with alkalis.

The concluding part of the paper treats of what may be called double compounds of phyllocyanin, into which metals and acids, especially organic acids, enter as constituents. Phyllocyanin seems to act the part of a weak base, uniting with strong acids and forming unstable compounds. In acetic acid it merely dissolves without yielding any compound. In like manner, when freshly precipitated cupric oxide or zinc oxide is added to a solution of phyllocyanin in boiling alcohol no combination takes place. A very different effect is observed when either of the two oxides is employed along with acetic acid. When cupric oxide is added to a solution of phyllocyanin in boiling acetic acid the solution acquires at once a deep greenish blue colour, and it no longer contains uncombined phyllocyanin, for its spectrum is different, and, on standing, it deposits lustrous crystals, which doubtless consist of a compound containing phyllocyanin, acetic acid, and copper. If zinc oxide be employed, a similar effect is observed: the liquid acquires an intense green colour like that of a chlorophyll solution, and now contains the corresponding acetate of phyllocyanin and zinc. The same phenomenon is seen when ferrous oxide, manganese oxide, or silver oxide is taken, liquids of various shades of green being obtained which contain phyllocyanin compounds; but no similar compounds are formed when potassium, sodium, barium, calcium, magnesium, or lead acetate is employed. Acetic acid is, however, not the only acid which yields the reaction. If palmitic, stearic, oleic, tartaric, citric, malic, or phosphoric acid be employed, it takes place just as with acetic acid, but in some cases time is required for its completion. Oxalic acid, however, seems to be without effect, and tartaric acid fails in some cases.

The behaviour of phyllocyanin towards zinc oxide in the presence of acids may serve to explain a peculiar phenomenon first observed by Prof. Church, and subsequently described by Tschirch. The former took chlorophyll that had become brown on standing, and, acting on it with zinc powder, obtained a body yielding green solutions, which he took to be regenerated chlorophyll. Tschirch acted on Hoppe-Seyler's chlorophyllan with zinc powder and observed the same phenomena, the conclusion at which he arrived being the same, viz. that chlorophyll is reproduced from chlorophyllan by reduction. It is probable, however, that what they obtained was in reality a zinc compound of phyllocyanin, and would have been formed just as well by using zinc oxide. Chlorophyllan is probably an impure substance containing some fatty acid along with phyllocyanin, so that by the action of zinc oxide it may yield a compound similar to those above mentioned. The experiment was tried with the crude product obtained by passing hydrochloric acid gas into a solution of chlorophyll. Some of this was dissolved in alcohol, and the solution was boiled with zinc oxide, when it gradually became of a bright green like a solution of chlorophyll, but its spectrum differed, being identical with that of the zinc compounds obtained directly from phyllocyanin.

May 21.—"Contributions to the History of the Pleiocene and Pleistocene Deer. Part I. *Cervus verticornis*, *Cervus savini*." By W. Boyd Dawkins, M.A., F.R.S., F.G.S., Professor of Geology and Palæontology in the Victoria University.

The numerous cervine remains which occur in the various collections in Britain and on the Continent have been studied by the author for the last twenty-five years, and in this communication two species, the one hitherto ill-defined, and the other new to science, have been described.

The first, or *Cervus verticornis*, Dawkins, remarkable for the singular forward and downward curvature of the first tine, is represented by a large series of skulls and antlers, which enable the author to define the changes in antler-form from youth to old age, as well as to relegate it to the division of deer with palmated antlers, and to establish its geological age to be Pleiocene and early Pleistocene in Norfolk and Suffolk.

The second, or *Cervus savini*, is represented by several skulls and many antlers, which present considerable modifications in form at varying ages. It also belongs to the section of deer with palmated antlers, and is probably the ancestral form of the extinct (*Cervus browni*, Dawkins) and living (*C. dama*) types of fallow deer. It has hitherto only been met with in the early Pleistocene forest-bed series of Norfolk and Suffolk.

Mathematical Society, May 14.—J. W. L. Glaisher, F.R.S., President, in the chair.—B. Hanumanta Rau, Madras, was elected a member.—Papers were read by Rev. T. C. Simmons, on an application of determinants to the solution of certain types of simultaneous equations; and by H. M. Jeffery, F.R.S., on binodal quartics, on the latter of which the President, S. Roberts, F.R.S., and the author made further remarks.—Mr. Tucker read part of a paper by Prof. J. Larmon on the flow of electricity in a system of linear conductors.

Zoological Society, May 19.—F. Du Cane Godman, F.R.S., in the chair.—A letter was read from the Rev. G. H. R. Fisk, C.M.Z.S., respecting the capture of a Sea-snake among the rocks at the entrance to Table Bay, which he believed to be referable to *Pelamis bicolor*.—A letter was read from Mr. B. Crowther, stating that he was about to send the Society a pair of Duckbills (*Ornithorhynchus paradoxus*), and giving some instructions as to the treatment of these animals in captivity.—Mr. F. Day exhibited and made remarks on a curious specimen illustrative of an extensive injury to the intestines of a Trout and its subsequent recovery therefrom. Mr. Day also exhibited a piece of the sifting-apparatus of the Basking-Shark, together with specimens of the food upon which it lives; and an example of the Vendace taken in Derwentwater Lake.—Mr. Osbert H. Howarth exhibited a specimen of coral of the genus *Dendrophyllia* attached to a brown stoneware bottle, which had been dredged up in the Atlantic, off Madeira, at a depth of about fifteen fathoms.—A communication was read from Prof. J. von Haast, C.M.Z.S., on *Dinornis oweni*, in which the author gave a detailed description of the bones of this recently-discovered new species of the extinct wingless birds of New Zealand, which was remarkable for its small size.—A communication was read from Dr. St. George Mivart, F.R.S., containing notes on the genetic affinities of the group of Pinnipeds.—Dr. F. H. H. Guillemard read the third part of his report on the collection of birds formed during the voyage of the yacht *Marchesa*. The paper dealt with the birds obtained on the island of Sumbawa, a locality hitherto almost unknown to ornithologists. During the *Marchesa's* short visit examples of thirty-nine species were collected. Of these, two (*Turnix powelli* and *Zosterops sumbavensis*) were new to science. The remaining species had been previously recorded from islands to the eastward or westward in the same group.—A communication was read from Dr. Hubrecht, C.M.Z.S., containing a description of a Pennatulid obtained by Capt. St. John in the Japanese Sea at a depth of seventy-one fathoms. A careful examination of the specimen in question induced the author to assign it to a new genus and species, which he proposed to name *Echinoptilum mackintoshii*.—Mr. Herbert Druce, F.Z.S., read a paper on some new species of Lepidoptera-Heterocera, founded on specimens obtained by the late Mr. C. Buckley in Ecuador, to which were added descriptions of some recent acquisitions of the same group from various other localities.—Mr. F. D. Godman, F.R.S., read descriptions of the Lepidoptera collected by Mr. H. H. Johnstone on Kilimanjaro. The collection contained examples of twenty-one species of the Rhopalocera and six of Heterocera. Of the Rhopalocera the author described three species as new.

Geological Society, May 13.—Prof. T. G. Bonney, D.Sc., LL.D., F.R.S., President, in the chair.—William Horton Ellis and Prof. J. Hoyes Panton, M.A., were elected Fellows; and Prof. J. Gosselet, of Lille, a Foregn Member of the Society.—The following communications were read:—On the Ostracoda of the Purbeck formation, with notes on the Wealden species, by Prof. T. Rupert Jones, F.R.S., F.G.S.—Evidence of the action of land-ice at Great Crosby, Lancashire, by T. Mellard Reade, F.R.S.—The North Wales and Shrewsbury coal-fields, by D. C. Davies, F.G.S. After discussing the origin of coal-beds, and the causes of their variation in structure and quality, the author proceeded to describe the North Wales and Shrewsbury coal-field, which consists of three parts: (1) The Shrewsbury field south of the Severn, exclusively composed of Upper Coal-measures; (2) the tracts north of the Severn, extending from near Oswestry to north of Wrexham; and (3) the Flintshire coal-field. The first and second are separated from each other by the alluvial plain of the Severn and Vyrmoy, and the second and third by the Great Bala and Yule faults. Some remarks on the scenery of the Welsh border-land followed, and then a general section of the Carboniferous system, as developed in the country described, was given, the Permian beds being included, as the author considered them the upper portion of one great division of Palæozoic time. The section was as follows, with the maximum thickness of each subdivision:—

	Thickness in yards	
1. Dark red Sandstone	210	Permian, 590 yards.
2. Ifton or St. Martin's Coal-measures	75	
3. Red marls with calcareous matter ..	180	
4. Green rocks and Conglomerates ...	125	
5. Upper Coal-measures	80	Coal-measures, 665 yards.
6. Cefn rock to Cefn coal	100	
7. Cefn coal to Lower yard-coal... ...	270	
8. Lower yard-coal to Chwarcle coal...	80	
9. Chwarcle coal to Millstone Grit ...	135	
	1255 yards	

A detailed description of the strata was next given, beginning with the lowest, together with details of each coal-seam as worked in various parts of the field. After describing the beds from the Millstone Grit to the Cefn rock in the North Wales coal-field, the author proceeded to notice the Upper Coal-measures and Permian strata in the Shrewsbury area, and showed that no break exists between the two, the former passing gradually into the latter. He then discussed the probability of Lower Coal-measures existing beneath the upper beds near Shrewsbury, and showed from sections that the existence of the lower measures might be anticipated. A similar inquiry as to the presence of the Coal-measures beneath the New Red Sandstone of the Vale of Clwyd should also, in the author's opinion, be answered in the affirmative. The organic remains found in the different beds were briefly noticed, and then the faults of the district were discussed at some length. The principal faults run north and south, with an upthrow to the east, but are crossed by lines of fracture running east and west. In conclusion, the correlation of the strata in the North Wales and Shrewsbury coal-fields, and especially of the coal-seams, with the beds found in other parts of Great Britain, was discussed, and a section was given to show the representation of the different measures in various coal-basins. The author was disposed to adopt four subdivisions rather than three only, as usually accepted, and pointed out some of the characteristics of each subdivision.

Royal Meteorological Society, May 20.—Mr. R. H. Scott, F.R.S., President, in the chair.—Dr. H. Dobell and Mr. J. N. Longden were elected Fellows of the Society.—The following papers were read:—The temperature zones of the earth considered in relation to the duration of the hot, temperate, and cold period, and to the effect of temperature upon the organic world, by Dr. W. Koppen, Hon. Mem. R. Met. Soc.—Velocities of winds and their measurement, by Lieut.-Col. H. S. Knight, F. R. Met. Soc. The author, after describing the various ways of ascertaining the direction and velocity of the wind, makes several suggestions for the improvement of Robinson's anemometer.—On the equivalent of Beaufort's scale in absolute velocity of wind, by Dr. W. Koppen, Hon. Mem. R. Met. Soc. The author refers to Mr. C. Harding's paper read before the Society in December last on the anomalies in the various wind velocities given by different authors as equivalents for the numbers in Beaufort's scale, and, as illustrating the point, calls special attention to the want of agreement between the velocities obtained by Mr. Scott and those subsequently obtained by Dr. Sprung, and confirmed by himself.—Note on a peculiar form of auroral cloud seen in Northamptonshire, March 1, 1885, by the Rev. James Davis.

EDINBURGH

Royal Physical Society, May 20.—Prof. Duns, D.D., F.R.S.E., President, in the chair.—The following communications were read, viz. :—On new Selachian remains from the Calciferous Sandstone series, by Ramsay H. Traquair, M.D., F.R.S., L. and E.—Observations on living Cephalopoda, and note on *Loligo forbesii* (Steenstrup), by W. E. Hoyle, M.A., F.R.S.E.—Note on ulceration of the skin of a fish, by G. Sims Woodhead, M.D., F.R.C.P.E.—Note on the presence of a double dorsal vessel in certain earthworms, by Frank E. Beddard, M.A., F.R.S.E., F.Z.S.—The north-west coasts of Sutherland and their bird-life, by John A. Harvie-Brown, F.Z.S., F.R.S.E.—Note on the contents of two bits of clay from the elephant bed at Kilmaurs in 1817, by James Bennie, H.M. Geological Survey. The Secretary (Mr. Robert Gray, V.P.R.S.E.) drew attention to several interesting birds that had been taken during the present month on the Island of May by Mr. Agnew, light-house-keeper, and forwarded to Mr. J. A. Harvie Brown, in whose collection they had since been placed. These were two specimens of the Ortolan bunting (*Embariza hortulana*) and others of the pied flycatcher (*Muscicapa atricapilla*), red-backed shrike (*Lanius collurio*). The Secretary remarked that these birds had occurred during their spring migration, and that in the case of the Ortolan bunting the captures proved that any Scottish specimens of the bird that had been recorded could not be said to be escaped birds, seeing that they had been in company with well-known migratory species, and were in all likelihood on their way to Scandinavia, where they were known to breed.

SYDNEY

Linnean Society of New South Wales, March 25.—Prof. W. J. Stephens, M.A., F.G.S., President, in the chair.—The following papers were read :—On a Devonian fossil, allied to *Worthenia* (de Koninck), from New South Wales, by F. Ratte.—On the Phoriaspongiæ (Marshall), by Dr. R. von Lendenfeld. Both species described by Marshall have been found by the author, who considers them, together with some new species discovered by himself, to be Ceraospongiæ, with flesh-spicules, and not, as Marshall had supposed, Desmacidanidæ, or Cianidæ, living in sand. There exist many sponges on the Australian shores with a skeleton consisting of arenaceous fibres, which form an irregular network, thus connecting the Phoriaspongiæ with the ordinary horny sponges. Eleven species of horny sponges, with fleshspicules, have been found in Australian waters. Their spicules are described and their relative position to other sponges discussed. The author upholds his previously published views on the relationship between Ceraospongia and Monactinellidæ, and discusses the hypothesis recently put forward by Vosmaer.—Synonymy of, and remarks upon, four species of shells, originally described by Dr. J. E. Gray, by John Brazier, C.M.Z.S., &c.—Notes on the Australian Amphipoda, by William A. Haswell, M.A., B.Sc., &c.—On the Toxoglossate Mollusca of New Zealand, by Capt. F. W. Hutton, F.G.S.—Notes descriptive of some rare Port Jackson fishes, by J. Douglas Ogilby, Assistant in Zoology, Australian Museum, Sydney.

PARIS

Academy of Sciences, May 25.—M. Bouley, President, in the chair.—After the formal proceedings, the President referred in the following terms to the late Victor Hugo :—"France is to-day widowed of one of her great writers, a man by whose works of genius the glory of our land has been spread furthest and widest during the present century. Victor Hugo is about to descend into the grave, but by the greatness of his writings he is himself saved from death. Years may henceforth roll on until they are reckoned by hundreds and thousands ; but in the series of future ages there never will be a time when André Chénier's lines on Homer will not also be applicable to our great poet :—

> " Trois mille ans ont passé sur la cendre d'Homère,
> Et depuis trois mille ans Homère respecté
> Est jeune encor de gloire et d'immortalité."

For the work of Victor Hugo belongs to that class which defies years and for everlasting ages secures the youth of glory and immortality to those by whom it has been accomplished. And now the five Academies of the French Institute must consider it a sacred duty to render like homage to this great memory. Our Bureau has the honour of asking you, in sign of mourning, to suspend your proceedings for to-day." The proposal having received general assent, the public meeting of the Academy was adjourned.—Account of an elliptical halo of unusual brilliancy, and evidently connected with the halo of 22° so frequently noticed for some weeks past, observed during the afternoon of Tuesday, May 19, by M. A. Cornu.—A contribution to the history of sulphur and quicksilver, by M. Berthelot.—Note on the algebraic integers of linear equations, by M. E. Goursat.—Demonstration of a particular property of geometrical curves of double curvature, by M. V. Jamet.—On the verification of the laws of vibration of circular plaques, second note, by M. E. Mercadier.—Remarks on the peculiar properties of the electric current generated by the rheostatic machine, by M. Gaston Planté.—On a method of determining and recording the charge of electric accumulators, by MM. A. Crova and P. Garbe. The authors claim to have discovered a means of determining and automatically recording the exact amount of energy stored in accumulators, and so regulating the discharge as to be able to ascertain the quantity still held in reserve at any given moment. The machines used in their experiments were of the Planté type modified by Faure.—Note on the phenomenon of crystalline superfusion of sulphur, and on the velocity of transformation from prismatic to octahedric sulphur, by M. D. Gernez.—Remarks on the composition of the persulphuret of hydrogen, and on the nacreous variety of sulphur, by M. P. Sabatier.—Note on the product of addition $PhFl^3Br^2$ obtained by the action of bromine on the trifluoride of phosphorus, by M. H. Moissan.—A synthesis of some specimens of anorthite recently obtained from the gas-works of Vaugirard, by M. Stanislaus Meunier.—Note on the microscopic anatomy of *Dentalium entale* from the Roscoff coast, by M. H. Fol.—On the Penian formations (red sandstones associated with clay-stone and felspar grit) prevalent in the secondary ranges of the Vosges Mountains, by M. Ch. Vélain.—The election of M. Laguerre as member of the section for geometry in the place of the late M. Serret was confirmed by the President of the Republic.

BERLIN

Physiological Society, May 1.—Dr. Raudnitz had subjected to examination, by new experiments, a statement advanced by Profs. Eulenberg and Landois, and which was controverted by several investigators, namely, that there was a vasomotor centre having its seat in the cortex of the cerebrum. For the measurement of the peripherical temperature he made use of mercurial thermometers, which he fastened into the paw of the animal. It was found, by preliminary experiments, that subcutaneously inserted thermometers, on stimulation of the nerves or of the central organs, yielded variations of temperature essentially different from, often opposite to, those fixed into the paw—a circumstance referable, no doubt, to the influence of the contraction of the muscles. Thermo-electric piles, again, were not suitable for application, for the reason that it was not possible to find for the second contact a medium that remained constant as far as 0°·04 C. Dr. Raudnitz had investigated a large number of conditions influencing the temperature of the skin, such as motion, the muscular rhythm, paralytic poisons, the situation of the paralysed animal, &c. Of the phenomena observed in the course of such investigation, the fact was specially striking that the difference in the situation of the investigated extremity was able to give rise to differences of temperature as great as 13° C. The results of the whole investigation went to show that it was not possible to demonstrate with certainty the existence of a vaso-motor centre in the cortex of the cerebrum. In the case of each epileptic attack resulting from stimulation of the membrane the change of temperature in the skin was induced in large part by the muscular movement, and in part also otherwise. Whether, however, the influence of the stimulation of the brain on the vaso-motor system was direct or indirect was a question not to be determined either by experiments of stimulation or by extirpation of the part of the cerebral cortex concerned. — Dr. Leo communicated his experiments on the formation of fat and conveyance of fat in the case of phosphorus-poisoning. Seeing that some physiologists ranged themselves on the side of the view that fat, and especially in fatty liver after phosphorus-poisoning, was formed in the body through decomposition of albumen, but others, on the contrary, held that the fat of the internal organs was derived from the alimentary fat, either directly conveyed to these organs, or transported from the skin, where it had been deposited, the speaker instituted the following experiments: two young guinea-pigs of the same litter, of very similar constitution, and of almost the same dry weight, were kept in a state of hunger for a considerable time; then one was poisoned with phosphorus, and after three days both were killed. On determining the fatty contents of each of the animals, it was found that the poisoned animal showed a very considerably larger percentage of fat than the other. It had now to be ascertained what amount of fat an animal experimented on had before, and what amount it had after the phosphorus-poisoning. For this purpose two rats were employed, living under precisely the same conditions. One of them, accordingly, was killed on the same day on which the poisoning of the second begun. After three days the latter was likewise killed, and an essentially smaller quantity of fat was found in the poisoned animal than in the former. Finally, experiments were made with eighteen frogs, of which six were killed before the poisoning, six after the poisoning, and at the same time with these, six control frogs were killed. The result was that the six poisoned frogs contained a larger per cent. of fat than the six killed before the poisoning, and than the six unpoisoned and in other respects similar frogs. In all experiments the fatty contents of the liver after the phosphorus-poisoning were considerably greater than in the case of the unpoisoned animals. The increase per cent. of the liver fat, in comparison with the dry substance, tended to show with great probability that fat was not only formed anew, but was conveyed to the liver from other quarters. According to present views fat was formed in the body of the animal only by decomposition of the albumen, and it was conjectured that the lecithin was an intermediate product of this transformation. The quantitative determination of the lecithin in the animals poisoned with phosphorus, and in the control animals yielded, however in both, like percentages, so that this conjecture was not confirmed by the experiment.

Rome

Reale Accademia dei Lincei, March 15.—The unthinkable; a logico-psychological note by Signor Bonatelli. In this note the author proposed to show that what is called the impossibility of thinking a thing is not really an impossibility on the part of the thinking subject to form any given thought, but rather either the absolute impossibility of imagining or the impossibility of the existence of the object. And in this fact there is found a confirmation of that philosophical doctrine which maintains the existence of the ideal. That which is absolutely unthinkable is out of all relation to our thought, and we can say nothing about it.—Concerning a vase found at Metapontum with a Greek alphabet of the Achæan colonies of South Italy. Signor Barnabei exhibited a vase found in a burying-place during the excavations now being carried on at Metapontum, and which may be considered one of the most important discoveries that have been made in recent times. The vase is in perfect preservation and shows by its form that it belongs to about 300 B.C. In the annular space surrounding the raised rim the letters of the entire alphabet are inscribed. Signor Barnabei, after citing the opinions of various authors on the origin of writing, showed that it could not be attributed to the Phœnicians, but that the art of writing was actually introduced into Italy by the Greeks.—On the distribution in latitude of the solar maculæ, faculæ, protuberances, and eruptions observed in 1884 in the Royal Observatory of the College of Rome. In this note Signor Tacchini explained at length the methods by which his observations on the solar maculæ, faculæ, and protuberances were made, and the tables relating to them drawn up, as well as the means taken to insure the accuracy of both. He defended, against the criticisms of Prof. Respighi, the conclusions which he had laid before the last meeting of the Academy on the strength of his own observations and those of other astronomers.—Resumption of the observations of red glows. Prof. Riccò communicated the conclusion of his previous note, in which he gave an account of all the observations made by him on red glows from December, 1883, to April, 1884. As some features of the phenomenon would induce us to admit the presence of an extremely fine dust at a great height in the atmosphere, Prof. Riccò wished to ascertain the fact as to whether fresh dust had fallen during and after the glows. But the examination of the dust collected at those times in rain-water or water long exposed to the air, showed no traces of fresh dust in the atmospheric deposits, and, in particular, no recognisable traces of volcanic dust.—Other communications:—Prof. Millosevich communicated the observations made by him on a new planetoid between Mars and Jupiter (245), discovered by Signor Borelly.—Drs. Ciamician and Silber explained the reactions by means of which they had succeeded in obtaining acetyl-pyrrol in a state of perfect purity without any trace of pyrrol-methyl-ketone. They also stated the result of their experiments with a view to obtain a sulphur acid from pyrrol-methyl-ketone: experiments which show clearly the analogy between pyrrol, pyrridin, and benzol.—Prof. Besso communicated a note by himself on trinomial equations, and in particular on those of the seventh degree.—Dr. Bianchi communicated a note by himself on the triple orthogonal systems of Weingarten.

Christiania

Society of Science, May 4.—The President, Prof. Guldberg, in giving an account of the working of the Society last year, stated that there had been eighteen meetings, and that fifty-two articles and papers had been presented by members.—The number of members is at present 112.—Prof. Lochman gave a lecture on biology in relation to life.

THURSDAY, JUNE 11, 1885

THE DARWIN MEMORIAL

IT is not often that the unveiling of a statue is attended with an interest at all comparable with that which characterised this ceremony as performed last Tuesday in the Great Hall of the Natural History Museum. If the greatness of a man is to be estimated by the measure in which he has influenced the thoughts of men it is scarcely open to question that the greatest man of our century is Charles Darwin. As Prof. Huxley remarked in the course of his singularly judicious and well-balanced address, Mr. Darwin's work has not only reconstructed the science of biology, but has spread with an organising influence through almost every department of philosophical thought. Yet it was not merely the greatness of the naturalist which invested the proceedings in the Natural History Museum with an interest so unique. It was known to the whole assembly that the man whom they delighted to honour was one whose moral nature had been cast in the same lines of simple grandeur as those which belonged to his intellectual nature. It therefore only needed a passing allusion from Prof. Huxley to enable the whole assembly to reflect that it was due as much to massiveness of character as to massiveness of work that within three years of his death Mr. Darwin's name should constitute a new centre of gravity in every system of thought. And it was this reflection which gave to the ceremony so unusual a measure of interest. Around the statue were congregated the most representative men of every branch of culture, from the Prince of Wales and the Archbishop of Canterbury, to the opposite extremes of Radicalism and freethought. Indeed, it is not too much to say that there can scarcely ever have been an occasion on which so many illustrious men of opposite ways of thinking have met to express a common agreement upon a man to whom they have felt that honour is due. The international memorial could not in any nation have found a more worthy site than the one in which it has been placed; but if anything could have added to the "solemn gladness" with which the personal friends of Mr. Darwin witnessed the presentation of this memorial, it must have been the evidence which the assembly yielded that among the innumerable differences of opinion which it represented, his memory must henceforth be always and universally regarded as a changeless monument of all that is greatest in human nature, as well as of all that is greatest in human achievement.

Concerning the statue itself, we have only to speak in terms of almost unqualified praise. It is, in the truest sense of the phrase, a noble work of art. The attitude is not only easy and dignified, but also natural and characteristic; the modelling of the head and face is unexceptionable; and the portrait is admirable. The only criticism we have to advance has reference to the hands, which not only do not bear the smallest resemblance to those of Mr. Darwin, but are of a kind which, had they been possessed by him, would have rendered impossible the accomplishment of much of his work. Although this misrepresentation is a matter to be deplored, it is not one for which the artist can be justly held responsible. Never having had the advantage of seeing Mr. Darwin, Mr. Boehm has only to be congratulated upon the wonderful success which has attended his portraiture of the face and figure; the hands were no doubt supplied by guess-work, and therefore we have only to regret that the guess did not happen to have been more fortunate.

The following is the address made by Prof. Huxley, in the name of the Darwin Memorial Committee, on handing over the statue to H.R.H. the Prince of Wales, as representative of the Trustees of the British Museum:—

YOUR ROYAL HIGHNESS,—It is now three years since the announcement of the death of our famous countryman, Charles Darwin, gave rise to a manifestation of public feeling, not only in these realms, but throughout the civilised world, which, if I mistake not, is without precedent in the modest annals of scientific biography.

The causes of this deep and wide outburst of emotion are not far to seek. We had lost one of those rare ministers and interpreters of Nature whose names mark epochs in the advance of natural knowledge. For, whatever be the ultimate verdict of posterity upon this or that opinion which Mr. Darwin has propounded; whatever adumbrations or anticipations of his doctrines may be found in the writings of his predecessors; the broad fact remains that since the publication, and by reason of the publication, of the "Origin of Species" the fundamental conceptions and the aims of the students of living Nature have been completely changed. From that work has sprung a great renewal, a true "instauratio magna" of the zoological and botanical sciences.

But the impulse thus given to scientific thought rapidly spread beyond the ordinarily recognised limits of biology. Psychology, Ethics, Cosmology were stirred to their foundations, and the "Origin of Species" proved itself to be the fixed point which the general doctrine of evolution needed in order to move the world. "Darwinism," in one form or another, sometimes strangely distorted and mutilated, became an everyday topic of men's speech, the object of an abundance both of vituperation and of praise, more often than of serious study.

It is curious now to remember how largely, at first, the objectors predominated; but, considering the usual fate of new views, it is still more curious to consider for how short a time the phase of vehement opposition lasted. Before twenty years had passed, not only had the importance of Mr. Darwin's work been fully recognised, but the world had discerned the simple, earnest, generous character of the man that shone through every page of his writings.

I imagine that reflections such as these swept through the minds alike of loving friends and of honourable antagonists when Mr. Darwin died; and that they were at one in the desire to honour the memory of the man who, without fear and without reproach, had successfully fought the hardest intellectual battle of these days.

It was in satisfaction of these just and generous impulses that our great naturalist's remains were deposited in Westminster Abbey; and that, immediately afterwards, a public meeting, presided over by my lamented predecessor Mr. Spottiswoode, was held in the rooms of the

Royal Society, for the purpose of considering what further steps should be taken towards the same end.

It was resolved to invite subscriptions, with the view of erecting a statue of Mr. Darwin in some suitable locality; and to devote any surplus to the advancement of the biological sciences.

Contributions at once flowed in from Austria, Belgium, Brazil, Denmark, France, Germany, Holland, Italy, Norway, Portugal, Russia, Spain, Sweden, Switzerland, the United States, and the British Colonies, no less than from all parts of the three kingdoms; and they came from all classes of the community. To mention one interesting case, Sweden sent in 2296 subscriptions "from all sorts of people," as the distinguished man of science who transmitted them wrote, "from the bishop to the seamstress, and in sums from five pounds to two pence."

The Executive Committee has thus been enabled to carry out the objects proposed. A "Darwin Fund" has been created, which is to be held in trust by the Royal Society, and is to be employed in the promotion of biological research.

The execution of the statue was entrusted to Mr. Boehm; and I think that those who had the good fortune to know Mr. Darwin personally will admire the power of artistic divination which has enabled the sculptor to place before us so very characteristic a likeness of one whom he had not seen.

It appeared to the Committee that, whether they regarded Mr. Darwin's career or the requirements of a work of art, no site could be so appropriate as this great hall, and they applied to the Trustees of the British Museum for permission to erect it in its present position.

That permission was most cordially granted, and I am desired to tender the best thanks of the Committee to the Trustees for their willingness to accede to our wishes.

I also beg leave to offer the expression of our gratitude to your Royal Highness for kindly consenting to represent the Trustees to-day.

It only remains for me, your Royal Highness, my Lords and Gentlemen, Trustees of the British Museum, in the name of the Darwin Memorial Committee, to request you to accept this statue of Charles Darwin.

We do not make this request for the mere sake of perpetuating a memory; for so long as men occupy themselves with the pursuit of truth, the name of Darwin runs no more risk of oblivion than does that of Copernicus or that of Harvey.

Nor, most assuredly, do we ask you to preserve the statue in its cynosural position in this entrance-hall of our National Museum of Natural History as evidence that Mr. Darwin's views have received your official sanction; for science does not recognise such sanctions, and commits suicide when it adopts a creed.

No; we beg you to cherish this Memorial as a symbol by which, as generation after generation of students of Nature enter yonder door, they shall be reminded of the ideal according to which they must shape their lives, if they would turn to the best account the opportunities offered by the great institution under your charge.

The following reply was made by H.R.H. the Prince of Wales:—

PROF. HUXLEY AND GENTLEMEN,—I consider it to be a high privilege to have been deputed by the unanimous wish of my colleagues, the Trustees of the British Museum, to accept, in their name, the gift which you have offered us on behalf of the Committee of the Darwin Memorial. The Committee and subscribers may rest assured that we have most willingly assigned this honourable place to the statue of the great Englishman who has exerted so vast an influence upon the progress of those branches of natural knowledge the advancement of which is the object of the vast collections gathered here. It has given me much pleasure to learn that the memorial has received so much support in foreign countries that it may be regarded as cosmopolitan rather than as simply national; while the fact that persons of every condition of life have contributed to it affords remarkable evidence of the popular interest in the discussion of scientific problems. A memorial to which all nations and all classes of society have contributed cannot be more fitly lodged than in our Museum, which, though national, is open to all the world, and the resources of which are at the disposal of every student of nature, whatever his condition or his country, who enters our doors.

CLAUS'S "ELEMENTARY TEXT-BOOK OF ZOOLOGY"

Elementary Text-Book of Zoology. Special Part: Mollusca to Man. By Dr. C. Claus. Translated and edited by Adam Sedgwick, M.A., Fellow and Lecturer of Trinity College, Cambridge, with the assistance of F. G. Heathcote, B.A., Trinity College, Cambridge. (London: W. Swan Sonnenschein and Co., 1885.)

THE first 109 pages of this volume are devoted to the Mollusca and Tunicata, and the remarks offered in NATURE (vol. xxxi. p. 191) in criticism upon Vol. I. apply equally well here.

The information imparted is fully up to date, and the Tunicate section may be taken, on the whole, as a type of that well-balanced and succinct writing indispensable in a work of this order.

The unqualified statement on p. 9 that the mollusca are "*bilaterally symmetrical*" is unfortunate, and typical of a general insufficiency and sketchiness, evident throughout the entire work, in the diagnoses given of the great groups. No better instance of this can be quoted than those relating to the birds and mammals, where characters so vitally important as the modes of articulation of the jaw-apparatus upon the skull are omitted, and, although mentioned elsewhere, are inserted without that emphasis demanded of *primâ facie* characters applicable to both the living and extinct forms.

It is disappointing to find the invertebrate digestive-gland still spoken of as a "liver," no mention being made of the researches of Weber, Barfurth, and others, into its structure and functions. It is highly desirable in a book of this kind that any statements made concerning animals, such as are likely to fall into the hands of the average student, should be absolutely reliable. It cannot be said (p. 52) that the shell of Aplysia is "covered by two lobes of the foot," and the beginner would soon find that Limax and Arion are not the only common Gasteropods in which the pedal gland is present, while, from the statements made on p. 27 he would never infer that the common Anodon shell is destitute of teeth. The Argonauta, although somewhat less commonplace than the aforenamed, is to be found in our museums, and no mention is made in this volume of the exceptional characters of its shell—in fact, the beginner would rather infer from the descriptions given that it is a normal Cephalopod shell. Less pardonable are the inadequate remarks devoted to the rest of the Cephalopod group, which are especially unfortunate in their reference to connecting-links with the extinct forms. The anomalous but characteristic Aptychi go without a mention.

Viewed in the light of Prof. Moseley's recent discoveries, the reasons adduced on p. 44 for the absence of the cerebral ganglia in Chiton are of some interest, as a caution against making too sweeping generalisations.

Under the head of Molluscoidea there is a bare mention of the genus Rhabdopleura, and we are at a loss to conceive why the reference to this important form printed in the original index should have been omitted in the translation.

Turning now to that portion of the work which follows, the fact that but 231 pages are devoted to the Vertebrata, exclusive of Tunicates, is sufficient in itself to raise suspicion, especially when we reflect that 115 pages of Vol. I. are given up to Tracheates alone. When Mr. Sedgwick published the first volume of this work it was patent to any one familiar with the original that nothing short of a complete revision of the Vertebrate section could justify that claim set up by him in his translator's preface. Having admitted his willingness to supplement the original where he "thought it necessary"—thereby, we presume, countenancing the weakness of the volume now before us—it is surprising to find how little he has carried that resolve into execution, the more so as he acknowledges the assistance and advice of others, some of whom are authorities. That this defect is not due to any want of intention on the translator's part is clear from insertions such as that on p. 167; but we look in vain for dozens of other similar modifications, connected with matters of infinitely greater importance than that just referred to. Similarly, why should the recent discovery of the meroblastic segmentation of the Monotreme's egg be inserted by the translators and referred to some two or three times when there is no mention whatever of the far more weighty characters of the skull of that group? Even were defects such as the above-named rectified, the book would still remain wholly insufficient and incompetent. The exclusive use of the old classification of birds—the dogmatic statements made concerning many of the most involved fields of Vertebrate morphology; for example, that of the auditory ossicles, where Reichert's views are alone given—the entire omission of any description of such a characteristic structure as the lizard's hind-limb and ankle-joint—the feeble and confused descriptions of the vertebrate skull, obvious throughout the entire work and ushered in on p. 118 by the barbarous "*os linguale*" and "*copulæ*"—the ambiguous statements made on p. 124 concerning the vertebrate diaphragm, which still (p. 250) finds its place among the respiratory organs of birds, are, to say nothing of other similar defects, sufficient in themselves to stamp the vertebrate portion of the Text-book as little short of a failure. That that section of the work falls short of the needs of the English-speaking student is certain, especially as it is so far behind other manuals current in the tongue. Errors, the bare enumeration of which would be superfluous, are predominant on all hands, and the retention of the "Cetacea Carnivora" and "Cetacea Herbivora or Sirenia" (*sic*) of the ancients, is, leaving the Hydrosauria with its sub-classes aside, certainly not creditable to any one concerned. We heartily recommend the invertebrate portion of the work to the student. He may find that which follows useful, but he need be no specialist to see that it is insufficient on all points, and absolutely inaccurate and misleading on many of vital importance. It but remains to enumerate certain of the more conspicuous defects, respecting which at least, should a second edition of the work be demanded, it is to be hoped that the translators will see fit to effect an alteration.

The cumbrous and fanciful method of accounting (p. 113) for the characters of the thoracic region of the vertebrate body is to be regretted, leading the beginner, as it does to suppose this to be the most modified region of the trunk—a conception the precise reverse of that which the properly-trained student will soon form for himself. The exclusion of the teeth from the list (p. 119) of dermal derivatives and the complete confusion between scutes and scales evident throughout, are but slight faults compared with such as we have already enumerated. On p. 127 we are introduced to a thorough mixing up of the urinary receptacle of fishes with the allantoic bladder of Amniotes—a serious error, and one which the translator ought to have been expected to rectify.

The above remarks apply more especially to the general part of the vertebrate section of the work; but, on passing to that treating of the special groups, we find a general feebleness nowhere more evident than in that portion devoted to fishes. The diagnoses of that group are meagre in the extreme, and descriptions of even their tails such as are given on p. 164 are wanting in accuracy. No wonder, then, that the "jugular" pelvic fin should be once more to the front, that there is a disregard of characters so important as are those of the maxillary apparatus of Teleostei, and that such genera as Albula, Cheirocentrus, Megalops, &c., go unnoticed. The treatment of the Sauropsida is no less unfortunate than the above. Reference has already been made to some of the more conspicuous defects of this section, barely less pardonable than which are the bad descriptions of the bird's manus (p. 237) and the bare mention of the structure of the avian lung.

We are told on p. 243 that birds possess a rudimentary "corpus callosum," no mention being made of that tract which may probably answer to it in Amphibia. The treatment of the Sauropsidian pelvis and of the bird's shoulder-girdle are miserably poor, and the student is informed on p. 196 that Crocodiles possess an "*abdominal* sternum," which is "composed of a number of ventral ribs (without dorsal part)"; he will learn a valuable lesson who—Prof. Claus's manual in hand—discovers for himself that the ventral sternal ribs and these abdominal splints coexist in Hatteria, skeletons of which are now to be found in our museums. Considering the above facts, it is not surprising that nearly all reference to important matters of affinity between living birds and reptiles should be overlooked. The characters of the mesotarsal joint and of the tarso-metatarsus are imperfectly defined, and those of the pelvis of Apteryx ignored; while among the extinct forms, the Dinosauria—several of whose features we are told on p. 220 "recall mammals, especially the Pachydermata"—the Ornithoscelida, and the Odontornithes, are all dismissed in a few lines. Little would the student, taking his text from this work, dream of the noble array of direct affinities to be found among even living birds and reptiles.

The translators have evidently realised that the statements reproduced on pp. 198 and 215, concerning the lizard's quadrato-jugal arcade are contradictory, and a supplemental paragraph of their own on p. 198 only serves to increase the perplexity. Chapter IX. is devoted to the Mammalia, but 69 pages of it starting with the assertion (p. 282) that the Monotremes' hemispheres are "still smooth," is poor fare. The cutting down of every group of mammals to a minimum would be in a sense pardonable, if only concise diagnoses were given such as should cover the broad lines of modification; but when, bearing in mind certain of the more glaring defects of this chapter referred to at the outset, we read (p. 306) that the Whales approach the Ungulates "through the Sirenia," and that the "Sirenia are intermediate, so far as their form is concerned, between the whales and seals" (p. 309), our faith is shaken in that which remains. There is the usual confusion concerning the position and movements of the hind-limbs of the Pinnipedia, the condition of the parts in the eared seals being entirely overlooked. In diagnosing a group of animals for purposes such as are here required, where the living and the extinct are both under consideration, it is but fair to assume that special attention should be paid to the hard parts, the teeth not excepted; but we look in vain for statements such as shall embody the extremes of modification of these parts in any one group of living mammals—for example, in dealing with the Rodents the utmost sketchiness prevails, the modifications of even the fibula are not hinted at, and while Hydromys is placed among the mice with grinders $\frac{2}{2}$, Heliophobius is not mentioned. No wonder, then, that Hyœmoschus should go unnoticed, that Hyrax should here be found under the order Proboscidea (with a caution, it is true), and that the Carnivora, Cheiroptera, Lemurs, and Primates should be treated with disrespect. We are told (p. 301) that the epipubes support the marsupial pouch, and there is no reference at all to the most important facts concerning the marsupial dentition. There is something so specifically English about gross vertebrate anatomy that we search in vain for bare mention, not to say recognition, of discoveries bearing upon the above, and many similar matters of first importance.

From what has been said it will be obvious to English students that the vertebrate section of Prof. Claus's manual is weakest where works on the subject already current in our language are strong; and, with all respect to our Continental cousins, we are of opinion that the market is becoming overstocked with translations such as that before us. Their period is past; the English student in earnest must sooner or later fit himself for access to the originals, and the repeated production of English versions serves only to prolong the fatal day. We cannot but regret, though reluctantly, the publication of this work in its present form, the more so as it threatens to encourage the growing tendency to under-estimate the value of gross vertebrate anatomy, a field of labour essentially English, but still the very backbone of zoological science.

Mr. Sedgwick has performed the task of translation with a thoroughness and skill deserving the thanks of his countrymen. Some few passages in the original, at best clumsy, might have been better rendered than they are; and settings such as the "above together," on p. 16, might be advantageously modified. The translators give in Vol. I. a list of English synonyms for the geological terms employed in the original, but these are not always adopted in Vol. II.; thus we find the Jurassic beds referred to again and again as the "Jura," a rendering certainly not that of English geologists. The original illustrations are for the most part excellent, and those which remain are admirably selected. That on p. 284, however, certainly does not illustrate the anatomy of the human ear, and the figures selected from the classic of Johannes Müller, in illustration of the anatomy of the lamprey's skull (p. 154) do scant justice to the work of a great genius, and he a German. G. B. H.

CLIFFORD'S EXACT SCIENCES

The Common Sense of the Exact Sciences. By the late W. K. Clifford. (London: Kegan Paul, Trench, and Co., 1885.)

ONCE more a characteristic record of the work of a most remarkable, but too brief, life lies before us. In rapidity of accurate thinking, even on abstruse matters, Clifford had few equals; in clearness of exposition, on subjects which suited the peculiar bent of his genius and on which he could be persuaded to bestow sufficient attention, still fewer. But the ease with which he mastered the more prominent features of a subject often led him to dispense with important steps which had been taken by some of his less agile concurrents. These steps, however, he was obliged to take when he was engaged in exposition; and he consequently gave them (of course in perfect good faith) without indicating that they were not his own. Thus, especially in matters connected with the development of recent mathematical and kinematical methods, his statements were by no means satisfactory (from the historical point of view) to those who recognised, as their own, some of the best "nuggets" that shine here and there in his pages. His *Kinematic* was, throughout, specially open to this objection:—and it applies, though by no means to the same extent, to the present work. On the other hand, the specially important and distinctive features of this work, viz. the homely, yet apt and often complete, illustrations of matters intrinsically difficult, are entirely due to the Author himself.

The Editor, in his *Preface*, tells us the whole story of the difficulties he had to face in completing the volume for press. All will sympathise with him when they find that he had to furnish one entire chapter, and large portions of two others, in addition to thorough revisal of the whole. For Clifford's style is here entirely *sui generis.* The track to his homely yet hardy expositions often lay in regions where but a single careless step would have led to the Inconsequent or the Ridiculous. And one who tries to imitate him successfully must possess not only his nerve, but also his wonderful agility and resource of every kind. We shall therefore say no more on the subject of the Editor's additions to the volume, than that his daring has met with comparative immunity from the more obvious dangers of his course.

The original title of the work was, we are told, *The First Principles of the Mathematical Sciences Explained to the Non-Mathematical.* There can be no doubt that the new title is much to be preferred. We do *not* believe that the Mathematical Sciences, even in their first principles, can be explained to the Non-Mathematical. Whosoever understands the explanation has, to that extent at least, *become* Mathematical in the very act of understanding. But this observation is made on the assumption that Non-Mathematical means "uninstructed in mathematics." There is another sense which the term may bear:—viz. "incapable of understanding mathematics." Among mankind there are none who more persistently claim the almost exclusive possession of the highest grade of human intelligence than do the (so-called) Metaphysicians. How many of these self-accredited possessors of all but superhuman acuteness have been able to cross the *Pons Asinorum?* How many have been able to understand even the *objects* (not the *processes*) of mathematical investigation? When the answer comes (it probably will not come, as it *can not* come in a favourable form) it will be time to comment on it.

The chief good of this book, and in many respects it is very good, lies in the fact that the versatility of its gifted author has enabled him to present to his readers many trite things, simple as well as complex, from so novel a point of view that they acquire a perfectly fresh and unexpected interest in the eyes of those to whom they had become commonplace. Surely this was an object worthy of attainment! But it is altogether thrown away on the non-mathematical, to whom neither new nor old points of view are accessible.

Considering the circumstances under which the book has been produced, it would be unfair to comment on the smaller errors. But there are a few very awkward statements, and one or two grave errors, which ought not to have escaped correction. We give an example of each class. Thus, p. 16, the following statement is quite unnecessarily puzzling:—

"If we can fill a box with cubes whose height, length, and breadth are all equal to one another, the shape of the box will be itself a cube."

This out-germans German itself in the displacement of the words from their natural position in English; and, at first sight, seems to be nonsense. Read it, however, thus:—

"If we can fill with cubes a box whose height, &c. . . . the shape of the box itself will be a cube,"

and the absurdity, suggested by the collocation, disappears.

Again, p. 66, what are we to make of the following, standing, as it does, without comment or explanation of any kind?—

"The statement that a thing can be moved about without altering its shape may be shown to amount only to this, that two angles which fit in one place will fit also in another, no matter how they have been brought from the one place to the other."

Several most serious qualifications must be imposed upon this statement before it can possibly be accepted as true.

The chapter on *Motion* properly forms a part of this work, so far at least as kinematics is concerned. But it seems to be a mistake to conclude it with a few editorial sentences on the *Laws of Motion.* For here we have a perfectly new subject, and one which would require at least a full chapter to itself. It is probable enough that, at some period of his life, Clifford imagined that it might be possible to get rid of the idea of matter as well as of that of force, and so to reduce Dynamics to mere Kinematics. He never so expressed himself to me. But purely physical subjects were, properly speaking, beyond his sphere; his ideas about them were always more or less vague, because always of a somewhat transitional character, and were much modified at times by the momentary turn of his philosophical speculations. We are told in a foot-note to the first page of the *Preface* that Clifford left his *Kinetic* (a companion volume to his Kinematic) *in a completed state.* Surely, keeping this in view, the introduction of Laws of Motion into the present work was superfluous.

This foot-note unfortunately strikes a jarring chord at the very first opening of the book. We are told that "more serious delay seems likely to attend the publication" of Clifford's *completed* MS.; this is followed by a mysterious species of protest or remonstrance. Clifford could never have written in this vein. He would either have kept silence, or have blurted out the whole truth. Mystery and insinuation were not weapons of his, and should not be employed in connection with his name.[1]

P. G. TAIT

OUR BOOK SHELF

New Commercial Plants and Drugs. No. 8. By Thos. Christy, F.L.S., &c. (London: Christy and Co., 155, Fenchurch Street, 1885.)

THE eighth number of Mr. Thos. Christy's "New Commercial Plants and Drugs" has recently appeared, and the contents are of a similar character to those that have preceded it, the most recently introduced commercial products derived from the vegetable kingdom being enumerated and what has been written about them brought together. The first plant referred to in the book is of course the Kola nut (*Cola acuminata*), as being one of the most important, or at least one that has attracted a very large share of attention during the past year. This article is illustrated by a coloured plate of the fruit and seeds of this species, as well as of the Guttiferous plant known as the Bitter Kola. Besides having the property of cleansing or purifying and thus rendering wholesome stagnant or foul water, it has also been used for clarifying beer and spirits. One of its most remarkable properties is in restoring the senses after partaking to excess of intoxicating drinks. The most recent application of the Kola nut, however, is in the preparation of a paste for mixing with cocoa or chocolate, which it is said to improve "both in strength and flavour to an astonishing degree." It is considerably more nutritious and strengthening; so much so indeed "that a workman can, on a single cup taken at breakfast time, go on with his work through the day without feeling fatigued."

In consequence of this and many other medicinal

[1] In NATURE, vol. xxxii. p. 4, Mr. Tucker intimated that Messrs. Macmillan and Co. would publish the remaining mathematical papers of the late Prof. Clifford.—ED.

virtues the Kola nut is considered to have a great future before it in European commerce, and is consequently strongly recommended to the notice of planters in our colonies for extensive cultivation. With regard to the preservation of the germinating properties of the seeds, Mr. Christy says he has received them in good condition, both in baskets and barrels lined with the leathery leaves of a tree known as the "bal tree." Some received in dry loam arrived as fresh as when they were gathered, and of some that arrived eighteen months since, the bulk is stated to be perfectly fresh and retaining still their beautiful red colour.

From a list of fifteen species of *Myristica*, the fruits or seeds of which are described, the value of the nutmeg genus is shown, especially as oil seeds. Seeds new to commerce are frequently arriving in the Liverpool and London markets, intended for the expression of oil and for the preparation of oil cake. Such seeds are of a very varied character and belong to widely different natural orders, and not long since those of *Myristica surinamensis* came into Liverpool under the name of African nuts. Upon analysis they were found to contain a large quantity of solid oil or fat with an agreeable taste, and but little, if any, odour, and when fairly pure it is said to resemble cocoa butter.

Amongst other important economic plants or drugs mentioned are the Coca (*Erythroxylon coca*), the medical effects of which have attracted so much attention of late; the Jamaica Chewstick (*Gouania domingensis*), which, it is stated, "has recently been introduced into this country by one of our leading London dentists for use in tooth powder and mouth wash," and also in the form of a fluid extract as a gargle for relaxed throat.

Of Papaine, the active principle of the Papaw (*Carica papaya*), some interesting records are given regarding its effects in treatment of diphtheria, croup, indigestion, dyspepsia, &c.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Ocular After-Images and Lightning

In reply to Mr. Shelford Bidwell's query whether the quiver of the lightning flash is a purely subjective phenomenon or not, I send the following extract from my note-book, made October, 1873:—"A flash of lightning consists of several separate flashes all occurring within a fraction of a second of each other. There was a very severe thunder storm at night, the thunder almost continuous. Drawing the curtain across the window so as to expose only a narrow slit of skylight, I observed this slit in the looking-glass which I kept moving rapidly backwards and forwards on its axis. Whenever a flash occurred, several images of the slit appeared, showing that there were several successive illuminations of the slit."

This was not the result I had expected, the experiment having been suggested to my mind in consequence of some experiments I had been making on the phenomenon of recurrent vision. The results of these experiments were published in the *Phil. Mag.*, December (supplement), 1872. One object of my experiments was to determine in what way the colour of the recurrent image depends upon the colour of the light producing it. By using a sliding shutter and a small window covered with different coloured glasses, I found that the colour of the recurrent image tends to be of a tint complementary to that of the light causing it, being, however, in all cases bluer than the complementary tint. I add the following extract from my paper:—"A recurrent image of an object may be produced without any apparatus whatever. To do this, place the right hand over the eyes so that the palm of the hand covers the right eye, and the fingers the left eye. If the middle finger be then raised for a moment, so as to admit light for as short a time as possible into the eye, a recurrent image of any light-coloured object held against a dark background may be seen. The effect is much better seen by twilight or gaslight than in full daylight. This method of producing a recurrent image is, however, much inferior to that in which a sliding shutter is used, owing probably to the illumination of the retina not being sufficiently instantaneous.

Cheltenham College, June 6 A. S. Davis

A Quinquefoliate Strawberry

In your issue for April 30 (vol. xxxi. p. 601) is an account of a quinquefoliate strawberry. In the garden of the New York Agricultural Experiment Station at Geneva we have some second year seedling strawberries, some of which are bearing three, four, and five leaflets on the same plant, the leaves all large and perfect. We have other plants in which the two extra leaves are borne half way down the petiole, and which attain fair size, and yet others where these stipulary-like appendages are reduced to hair-like bracts. The variety of strawberry introduced under the name "Mrs. Garfield" frequently has these bract-like appendages. While speaking of the strawberry, I would remark that seedling strawberries very frequently are unifoliate during their early growth, and it appears as if Duchesne's *Fragaria monophylla* may be regarded as an instance of arrested development in one of these one-leaved younglings.

E. Lewis Sturtevant

New York Agricultural Experiment Station, Geneva, N.Y., May 28

OBSERVATIONS OF THE TEMPERATURE OF THE SEA AND AIR, MADE DURING A VOYAGE FROM ENGLAND TO THE RIVER PLATE IN THE S.S. "LEIBNITZ"

Being obliged to proceed to South America at the beginning of this year, I took with me a thermometer and a hydrometer in order, if circumstances were favourable, to provide myself with occupation during the somewhat long and monotonous voyage. Thanks to the kindness and courtesy of Capt. Brown, of the s.s. *Leibnitz*, who took a lively interest, and assisted me greatly in carrying out my observations, the voyage was neither long nor tedious.

The *Leibnitz* sailed from Southampton on January 16, 1885, and made the passage direct, without touching at intermediate ports, to Monte Video, where she arrived on February 8, after a very favourable voyage. The route lay through the most interesting meteorological districts of the Atlantic, and my principal object at starting was to make as many observations of the temperature and the density of the surface-water along the route as possible. With these I combined observations of the temperature of the air, and frequently also of the wet-bulb thermometer. Observations were begun on January 21 in lat. 34° N., and continued up to the morning of arrival in the River Plate.

I have put together the simultaneous observations of the temperature of the air and the water with those of the wet-bulb thermometer, as they possess some interest of their own; the observations of density are kept for a future opportunity, as the reductions in connection with them are not quite finished.

The *thermometer* used for all the observations was divided into simple degrees of the Centigrade scale, and was of the ordinary form of German manufacture, with a paper scale. The degrees were 1·6 mm. apart, so that there was no difficulty in estimating tenths of a degree. Its zero was verified on board by immersing it in pounded ice, and found correct. The ice was well pounded in a clean towel, and a soda-water tumbler filled with it; the thermometer was then thrust into it and allowed to remain till sufficient ice had melted to fill up the interstices, producing a perfect magma of ice and water down to the bottom. The mercury remained constant on the zero line. The temperature of the air was 25° C.[1]

Temperature of the Water.—The water was collected in a small bucket, well clear of the side of the ship, and on the opposite side from that through which the condensing water of the engine is discharged. Its temperature was determined as soon as the sample was brought on board.

As the ship left the Channel in the middle of winter, and proceeded nearly due south, the temperature of the water rose rapidly at first. Observations were begun on January 21, in lat. 34° N., and between this latitude and lat. 10° N. the rate of rise was very steady, averaging 0·36° C. per degree of latitude. From lat. 5° N. to 15° S. the temperature is very uniform and high, averaging 26·86° C. After passing lat. 15° S. the temperature falls, and begins to show greater variations, as the shallow water on the Abrothes Bank is approached. The average temperature of the water over this bank was 25·56° C. After passing Cape Frio, and between the parallels of 25° and 30° of south latitude, the variations of temperature are considerable and often abrupt; the maximum observed in this part was 26°·7 C., and the minimum 24°·3 C. As the higher temperature generally accompanies a greater salinity, it is probable that these variations are due, not to any terrestrial source, such as large rivers, but to an oceanic cause, the less salt and colder water of the deeper ocean strata being thrown up against the coast, and mixing imperfectly with the hot and dense surface-water. In lat 30° S. the influence of the River Plate makes itself distinctly felt by a general rapid fall of temperature. As the ship got into soundings, with the change in colour and other properties of the water, the temperature fell rapidly to between 23° and 24° C., and to 22° C. in six fathoms off Flores Island close to Monte Video. The minimum temperature observed in this part was 20° C. at 2 a.m. between Lobos Island and Maldonado Point.

Excluding the latter part of the voyage between the River Plate and lat. 15° S., where the conditions are a good deal affected by purely local causes, the surface-water shows well-marked diurnal maxima and minima of temperature. From lat. 9° N. to lat. 2° N. the ship passed through the equatorial belt of calms and rains, which separates the regions of the north-east and the south-east trade-winds from each other. It is characterised by a calm sea, a cloudy sky, and heavy rains. Here the temperature was subject to very little diurnal variation (0°·3 C.) On approaching St. Paul's Rocks, a few miles north of the equator, the clouds cleared away completely, and there was a calm sea, a clear sky, and a very powerful sun. The result was a comparatively great rise of temperature in the afternoon; and yet the greatest difference between any neighbouring maximum and minimum in this region was only 1°·1 C.

The maximum temperature of the sea-surface observed during the voyage was 27°·4 C. (81°·3 F.) at 2 p.m. on January 31, in lat. 7° 35′ S., the Brazilian coast being about 100 miles distant. The temperature of the water will be further considered in connection with its density; at present its connection with the temperature of the air will be more particularly considered.

Temperature of the Air.—Along with the temperature of the water, that of the air during daylight was determined. It is probably very rare, in any part of the ocean, to find the mean temperature of the air agreeing accurately with that of the surface water, and in many places the differences are considerable. In order to be able to compare the temperature of the air with that of the water, it is necessary that both should be determined with equal accuracy. The temperature of the water is easily and accurately determined by agitating the thermometer in a bucket of it freshly collected. With the air it is somewhat different. Having only one thermometer with me, I was obliged to use it for all purposes, and I could not hang it up in a thermometer-box, even if I had had one, and had deemed it advisable to do so. On board ship, however, I am convinced that it is quite impossible to fix a thermometer-box in such a position as always to secure such an air-pressure as to justify the assumption that the indications of the thermometer may be taken as the true temperature of the air. Even on shore and under the most advantageous circumstances, the temperature of the thermometer in the atmosphere of the best constructed box is too much dependent on the temperature and capacity for heat of the material of the box for it to be assumed always to be identical with that of the air outside, at the moment of reading. I was obliged, therefore, to adopt the method of whirling the thermometer, at the end of a short string, in the air, in whatever part of the ship happened at the moment to afford the most favourable conditions, and reading it when it had assumed a constant temperature. The temperature of the air is thus determined in mostly the same way as that of the water, namely, by agitating a thermometer in it, and the comparison of the two is therefore likely to lead to trustworthy conclusions.

Temperature of Wet-bulb Thermometer.—The series of observations with this instrument is not so complete as that with the dry thermometer, but they possess some interest. The method of observation was the following:—The temperature of the air having been determined by whirling the thermometer in it, a bucket of sea-water was fetched and its temperature taken; the thermometer was then exposed, with its bulb still wet with sea-water, to the breeze in a proper part of the ship, and its temperature observed when it became constant. The exposure of the instrument requires some care. The bulb must be quite free from grease, which can be readily secured by washing it with soap and water. It is then dipped into the water and allowed to drip for a second. It is then held somewhat inclined to the direction of the wind and to the horizon, and rotated gently on its axis so that the bulb be kept covered with a continuous film of water which is locally thickened by gravity, which tends to form a drop on the lower side of the bulb. The reading of the thermometer is observed while it is being rotated. Had I intended from the beginning to make a series of wet and dry bulb observations, I should probably have used fresh water from the first. I began to expose the thermometer, merely in order to have an indication whether the atmosphere were saturated or not, and I expected, in the damp equatorial regions, to find the atmosphere so heavily saturated as to be incapable of producing any sensible lowering of the thermometer with damped bulb. For this purpose it seemed to be quite sufficient to expose the thermometer wet with sea-water. Having begun with

[1] Having plenty of pounded ice at my disposal, I poured off the water which had formed by melting, and replaced it by sea-water, containing 35·65 grammes salt per kilogramme, and then immersed the thermometer; it fell rapidly below zero, and remained constant at −1°·0. I then strained away the sea water from the ice and replaced it by a mixture of equal volumes sea-water and distilled water: the thermometer fell to −0·45, and remained constant for some time at that temperature. When the ice was mixed with distilled water alone, the thermometer again stood at 0° C. These experiments were made to verify some observations of Pettersson, quoted in his investigations into the nature of ice formed from waters of different degrees of salinity, in connection with the voyage of the *Vega*. He there says, referring to the melting temperature of different kinds of ice, that pure fresh-water ice, when immersed in sea water, melts at a temperature considerably below 0° C. Writing from memory, I think he puts the melting-point at from −1° to −2° C. Having both the ice and the sea-water ready at hand, I repeated this remarkable experiment. The result showed that Pettersson's observation is quite correct, and that the lowering of the melting-point is roughly proportional to the salt held in solution. When equal volumes of the sea-water and distilled water of the same temperature were mixed, there was no change of temperature. I do not remember if Dr. Pettersson furnished an explanation of this remarkable phenomenon, and I am unable to supply one myself, but it must necessarily affect the validity of conclusions as to the composition of sea-water ice drawn from its melting-point. When the *Challenger* was in Antarctic waters I made a number of observations on the melting-point of ice collected from broken pieces of the pack, and found it begin to melt a little below −1° C. I concluded that either it was one solid substance or a mixture of several solids. But if pure ice melts at a different temperature according to the medium in which it is placed, then this reasoning is faulty, for inclosed brine would have much the same effect as inclosed salt or crystalline hydrate.

sea-water the observations were continued with it. A few comparative observations were made in order to determine the effect of replacing the sea-water by fresh water. On February 2, after a shower, the temperature of the air was 25°·0 C. When wet with sea-water the temperature of the thermometer was 23°·5 C., and with rain-water 23°·1 C. Similarly, at noon on the same day, the following temperatures were observed: dry bulb, 26°·1 C.; wet bulb (sea), 24°5 C.; wet bulb (rain), 24°·2 C. The air, at this time, appeared, to the sensation, to be damper than at any other time, and yet, when suitably exposed, there was a difference of nearly 2° C. between the wet and dry thermometers.

There is an advantage in having the bulb of the thermometer wet with a continuous film of water, instead of being surrounded with damp muslin, namely, that it more nearly resembles the surface of the sea, which is exposed to the influence of the atmosphere. Observations with the wet thermometer were not made as regularly as those with the dry instrument, and no observations were made with either of them after dark, owing to the difficulty of securing proper exposure and reading the instrument with a lantern, without heating it.

The temperature of the air and of the water were taken generally every two hours from 6 a.m. to 6 p.m., but the intervals between the observations were not always the same. These observations showed that only on two days, January 31 and February 1, between lat. 6° S. and 12° S., did the mean *day* temperature of the air exceed that of the surface-water. On these days the temperatures were taken every two hours from 6 a.m. to 6 p.m., and the means of the groups of seven observations gave, on January 31: air, 27°·13 C.; sea, 26°·90 C.; difference, 0°·23 C.; and on February 1, air, 27°·26 C.; sea, 26°·96 C.; difference, 0°·30 C. These differences would have been reduced in amount if the observations had been carried on through the night, though, from the very high temperature of the air just before sunrise on February 1 and 2, they would not have been reduced to zero.

In the table (p. 129) all the simultaneous observations of temperature of air and water made during the voyage, except those of the last day, when approaching the mouth of the River Plate, are collected in small tables for each day. The time of day is given in hours, from 0 to 24; the temperatures are in Centigrade degrees; t denotes the temperature of the sea-surface, $t-T$ the difference between that of the temperature of the air, and $T-T$ the difference between the readings of the thermometer in air with its bulb dry and when it is wet with sea-water. At the head of each table is given the meteorological district of the ocean through which the ship was passing, as "north-east trade-winds," "equatorial calms," and the like; also the day of the month (1885) and the latitude and longitude at noon of the day. The means at the foot of each table are simply the arithmetical means of the numbers in each column; and their meaning and value are at once apparent on inspecting the column.

With the two exceptions above-named, the temperature of the sea was always found higher than that of the air, over the day, and only very seldom was it exceeded by that of the air at the hottest time of the day. Had the observations been carried on through the night, the contrast between the two temperatures would have been much greater. On January 31 and February 1 the conditions were somewhat exceptional. On the former of these days the ship passed into the northerly monsoon, which prevails all down the Brazilian coast during the southern summer. Like the similar monsoons in the northern hemisphere, it is caused by the proximity of a large mass of land, which gets intensely heated by the vertical rays of the sun. On January 30 the wind had been light south-easterly; during the night it fell calm, and at sunrise a light easterly wind sprang up, which gradually drew around towards the north and blew all day, with just sufficient force to travel exactly at the same rate as the ship (11½ knots); consequently, during the whole of the day the atmosphere on the deck was motionless, with a very powerful sun beating on it and heating up every thing, so that it was impossible to find any place where the air could be got, coming fresh on board, without having been exposed to the influence of the highly-heated deck and fittings. It is therefore certain that the air-temperatures are somewhat above the water.

It is probable that, when the true temperature of the air can be ascertained, it will be found to be usually below that of the sea-surface. The cause of this is, I think, to be found in the relative dryness of the atmosphere over the ocean. If the observations with the wet-bulb thermometer be considered, it will be seen that the least difference of reading between the dry- and the wet-bulb thermometers was 1°·0 C. on January 28, when the ship was in the middle of the equatorial belt of calms and rains. In this region perfectly saturated air might be expected, and with instruments exposed in the usual form of box I have no doubt that here, and in the very oppressive weather of the northerly monsoon, the two instruments would have given identical readings. The readings of the air-temperature on January 28 were perfectly trustworthy, as the sky was thickly overcast with dense rain-clouds all day; there was thus no risk of overheating; the readings with the wetted bulb were equally satisfactory, so that the results of the observations on that day may be taken to represent fairly the normal state of things in the "Doldrums." The temperature of the sea varied from 26°·3 to 26°·6 C., the mean of five observations during the day being 26°·42 C. The mean temperature of the air during the day was 0°·92 lower than that of the sea, or 25°·5 C., and the temperature of the wet-bulb thermometer 1°·3 lower still, or 24°·2 C. It will be seen that, on the two exceptional days, January 31 and February 1, the difference between the wet- and the dry-bulb thermometer is greater than would be expected from the oppressive damp feeling of the air; it is therefore all the more likely that the dry-bulb readings are too high as indicated above. However, it is important to observe that in all the regions passed through, whether in the westerly winds of the North Atlantic or the equatorial calms, or the monsoon of the South Atlantic, the temperature of the wet-bulb thermometer is always very markedly below that of the dry-bulb thermometer. In fact, such is the mobility of the atmosphere that it rarely has the opportunity of saturating itself; and if the effect which must be produced when this air meets the surface of the water be considered, it will, I think, afford some explanation of why at sea the temperature of the air, even by day alone, is usually markedly below that of the sea-surface.

If we consider the film of water immediately at the surface of the sea, having the atmosphere on the one side of it and the bulk of the water on the other, it is strictly comparable with the film of water surrounding the bulb of the thermometer, when exposed to the atmosphere in the way described above; and the air playing upon it must produce exactly the same effect in the one case as in the other. The evaporation lowers the temperature of the aqueous film, which proceeds to extract heat from the neighbouring bodies—namely, in the one case the air and the bulb of the thermometer and in the other case the air and the layer of water immediately below the surface film. If we imagine for a moment the surface film separated from the bulk of the water below it by a diaphragm impervious to heat, then exposed to the atmosphere so as to suffer evaporation and lowering of temperature, then on the removal of the diaphragm it would immediately sink away from the surface and its place would be taken by warmer, and therefore less dense, water from below. In the case of sea-water this effect would be slightly intensified by the concentration produced by evaporation. But

Table giving the Temperature of the Sea Surface (t), the Difference between it and the Temperature of the Air ($t-T$), and the Difference between the Readings of the Dry Bulb and the Wet Bulb Thermometers in Air ($T-T'$), at Different Hours of the Day

while the water below supplies some of the heat rendered latent by the evaporation of the water, the air above it supplies its share, and is cooled. In both cases the heat thus lost is made good by the direct radiation from the sun. Through a moderately dry atmosphere the rays pass with comparatively little heating effect, but are largely absorbed on entering the water. Consequently the loss of heat which the water suffers by evaporation at the surface of separation is made good more abundantly than that sustained by the air; and the difference in power of absorption of radiant heat exhibited by these two substances is thus sufficient to keep up a permanent difference of temperature between the water and the air immediately above it.

Starting with air and water at the same temperature, we may imagine the process taking place in three acts. First, the water at the surface evaporates, and the air on the one side, and the water on the other, are cooled; second, in order to make up for the heat thus rendered latent and lost, the sun shines upon both alike, but the water absorbs a larger proportion of the heat of its rays than the air does; and finally, a portion of this excess is then removed from the water by the simple contact of the air at its surface. The nett effect of these causes is to produce a permanent excess of temperature of the surface-water of the sea over that of the air above it, provided that that air is not completely saturated with moisture.

From what I have seen and experienced in the regions visited by the south-west monsoon in the east, I cannot doubt that there are often cases where the most carefully exposed wet- and dry-bulb thermometers would show identical readings, and the atmosphere is completely saturated with vapour of water. Thus it is probable that the temperature of the air would not be inferior to that of the water. Further, when, on the eastern coasts of Asia, the south-west monsoon blows out of the China Sea and penetrates far into the North Pacific, off the coasts of Japan it attains a latitude of naturally lower temperature than that from which it proceeded, so that much of the water with which it was laden, and which is held diffused through it as a mere gas, is condensed and remains suspended in it, producing a visible haze, which obscures the horizon and condenses on all solid objects exposed to it. Here the conditions are reversed, and instead of the air losing heat to evaporate the water, it receives the heat liberated by the condensation of the steam removed from waters of lower latitudes. Such conditions are, however, certainly exceptional, and there can be little doubt that, as a rule, the temperature of the surface-water of the sea is higher than that of the air. The temperature of the air depends on that of the water which tends to warm it and the degree of its own dryness, by virtue of which the water has a tendency to evaporate into it and, by extracting heat from it for this purpose, to cool it.

It is obvious that local circumstances such as currents may produce differences between the temperature of the air and the water, but such cases are not here under consideration. J. Y. BUCHANAN

Mendoza, March 18

THE REV. T. W. WEBB

BY the death of the Rev. Thomas William Webb, M.A., F.R.A.S., English astronomy has lost one of its most assiduous and accomplished votaries. Mr. Webb, who had reached the age of 79 years, passed a long life as the incumbent of two obscure Welsh livings, held by him in succession. At Tretire he may be said to have laid the foundations of those astronomical tastes which took their finished and best-known shape during the later years of his life whilst he was incumbent of Hardwick, in Breconshire. He was a genial and right-thinking parish priest, whose highest aim was the performance of his duty. For the sake of astronomy it was well perhaps that he obtained so little ecclesiastical advancement; for had things been otherwise it is probable that he would never have developed those scientific tastes which have made his name almost a household word. It was my privilege to make his acquaintance upwards of twenty years ago, and I look back with extreme pleasure to the many letters which have passed between us on practical matters connected with observational astronomy and the use of instruments. Whilst Mr. Webb in bygone years used to write a good deal in the current scientific magazines of the day, especially the *Intellectual Observer* and the *Student*, it was by his "Celestial Objects for Common Telescopes" that he became chiefly known in the astronomical world. This work, published in the year 1859, was designed to be a cheap popular abridgment in a modified form of Admiral Smyth's "Celestial Cycle," which had done right good service in providing English amateurs with information as to what to look for and how to find. By 1859 Smyth's work had become both out of print and somewhat out of date, and Mr. Webb's unpretending abridgment filled at once an undoubted void. It is indeed not wholly correct to speak of Webb's "Celestial Objects" as an abridgment of Smyth's older, larger, and more expensive volume. It was this; but it was also a good deal more, for whilst it offered to the possessors of small telescopes convenient lists of objects deserving of their attention, it also supplied an enormous amount of original information connected with the sun, moon, and planets, and the use of telescopes. This information, though no doubt suggested by Admiral Smyth's style, was no mere *rechauffé* of other people's work, but represented the personal experience of an intensely industrious and persevering man working under great difficulties through lack of instrumental means.

I shall never forget the feeling of blank astonishment which crept over my mind one day when (in, I think, the year 1864) Mr. Webb told me that the first edition of his book, and all his magazine articles up to that date describing double stars and clusters, were founded on studies pursued by means of a telescope set up in his garden and not equatorially mounted. This, I well remember, was not said in any spirit of boasting in the garb of mock modesty, but was the casual utterance of a simple truth disclosed without effort or intention. I do not think I ever came in the way of any student of nature of whom it could be so truly said that he was "without guile."

Mr. Webb was every inch a gentleman, and a philosopher in the highest sense of the word. Every line that he wrote contained either the record of some fact noticed by himself, or a sensible deduction from some other facts. When his facts had come to an end his pen ceased to pass over paper, and the result was that no one ever read a sentence written by him without learning something useful, set forth in the fewest possible words, often, indeed, in a form of concentration which erred on the side of inconvenient brevity; but in these days of penny-a-lining (and it may even be admitted that there is even such a thing as science penny-a-lining) Mr. Webb's habitual terseness cannot be described as a vice. His private letters show that, where necessary for the instruction of a young astronomer, he never grudged time and trouble for going into details. The highest praise that can be awarded him is that he not only did many useful things himself, but that he set an example of patient and industrious research which resulted in many young men all over the British Empire seeking to imitate his cheery and sensible style of work and thought.

G. F. CHAMBERS

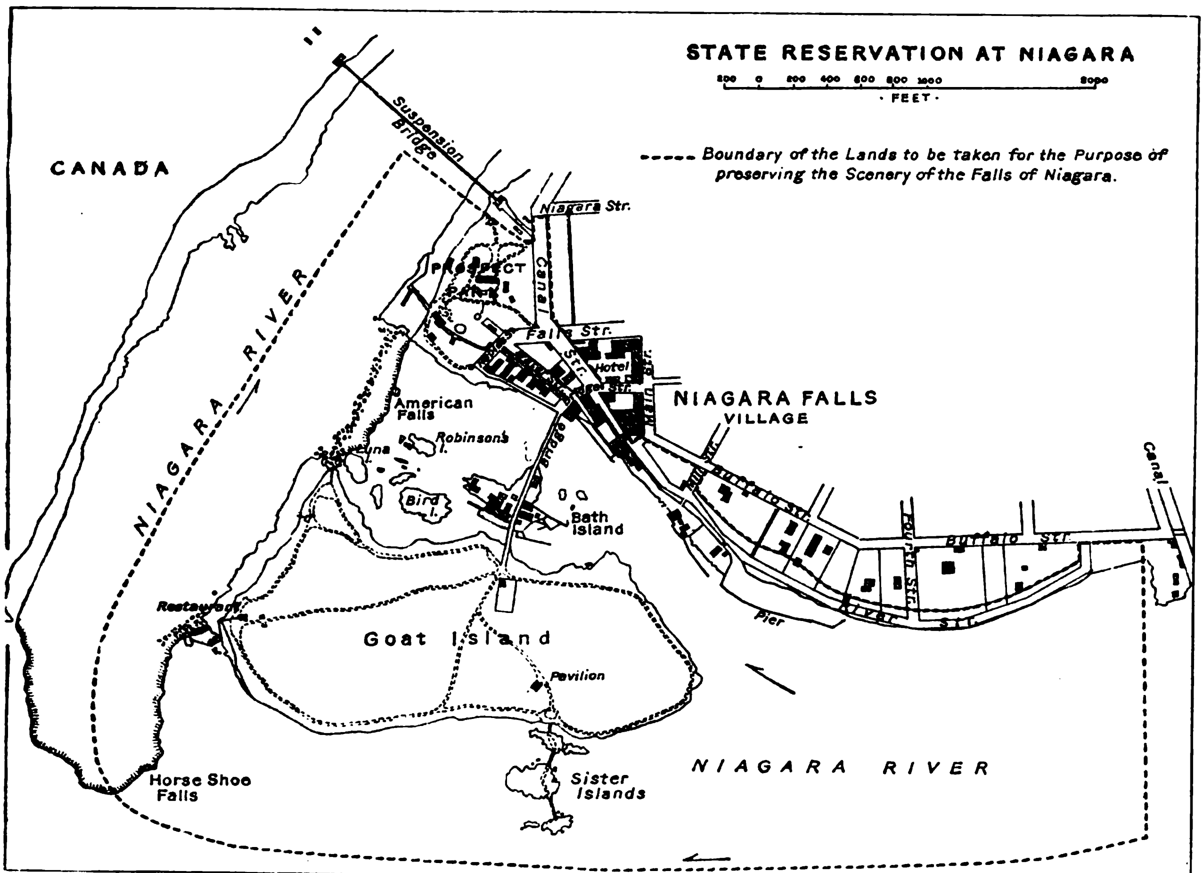
THE PRESERVATION OF NIAGARA[1]

NEARLY seven years ago Lord Dufferin, then governor-general of Canada, suggested to Gov. Robinson of New York that the governments of the province of Ontario and the state of New York should purchase such lands about Niagara Falls as would be required to give free access to the principal points of view, and serve to restore and preserve the natural scenery of the great cataract, beside securing to visitors freedom from those vexatious annoyances which now abound. Subsequently the governor-general called the attention of the government of Ontario to the matter, and recommended co-operation with the state of New York in accomplishing this purpose.

Later, in January, 1879, Gov. Robinson, in his annual message to the legislature of New York, presented this matter, and recommended the appointment of a commission to investigate the question, to confer with the Canadian authorities, to consider what measures were necessary, and to report the results to a succeeding legislature.

By resolution the commissioners of the State Survey were charged with the investigation. This commission included some of the most distinguished men of the state,—Ex-Gov. Horatio Seymour, Vice-President of the United States, W. A. Wheeler, Lieut.-Gov. Dorsheimer, President Barnard of Columbia College, and others.

With breadth of view worthy of such men, they state in their report that, "under this resolution, it became the duty of the commissioners to ascertain how far the private holding of land about Niagara Falls has worked to public



Stanford's Geogr Establ.

disadvantage through defacements of the scenery; to estimate the tendency to greater injury; and, lastly, to consider whether the proposed action by the state is necessary to arrest the process of destruction, and restore to the scenery its natural character." In pursuance of these objects, the commissioners instructed Mr. James T. Gardiner, director of the State Survey, to make an examination of the premises, and prepare for their consideration a project. He was assisted in this work by Mr. Frederick Law Olmsted, the distinguished landscape-architect.

The examination showed that the destruction of the natural scenery which forms the framework of the Falls was rapidly progressing: unsightly structures and mills were taking the place of the beautiful woods that once overhung the rapids; the fine piece of primeval forest remaining on Goat Island was in jeopardy from projects looking to making a showground of the island; and every point from which the Falls could be seen on the American side was fenced in, and a fee charged for admission. It was found that, owing to the topography of the main shore, it was practicable to restore its natural aspect by clearing away the buildings from a narrow strip of land 100 to 800 feet broad and a mile long, and planting it with trees which would screen out from view the buildings of the village. When these trees should be grown, and the mills removed from Bath Island, and trees planted there, the falls and rapids would be again seen in the setting of natural foliage which formed so important an element in their original beauty. Every point from which the Falls could be seen would also become free of access by the plan proposed. A map was made showing just what lands should be taken to carry out these purposes. The commissioners adopted the plan of Mr. Gardiner

[1] From *Science*.

and Mr. Olmsted, and recommended to the legislature of 1880 the passage of an Act to provide for acquiring title to the necessary lands by the exercise of the right of eminent domain, leaving it to a future legislature to consummate the purchase by appropriating the amount for the payment of the awards, if the sum should seem a reasonable price for the property. Such an Act passed the Assembly, but was defeated in the Senate, although the movement was supported by petitions signed by the most distinguished men of this and other countries. The report of the State Survey, with its complete descriptions, illustrations, and maps, then became the basis of a systematic effort on the part of a few determined friends of the Falls to educate and arouse public opinion to save the scenery of Niagara. Early in 1883 this movement ripened into the organisation of an association to promote legislation for preserving the scenery of the Falls of Niagara, Mr. Howard Potter of New York being president, and Hon. J. Hampden Robb, chairman of the executive committee.

Through the efforts of this Niagara Falls association an Act was passed, in 1883, providing for a commission, entitled "The commissioners of the state reservation at Niagara," and giving them power to proceed through the courts to condemn the lands needed. Ex-Lieut.-Gov. William Dorsheimer is the president of this board; and the other members are President Anderson of Rochester University, Hon. J. Hampden Robb, Hon. Sherman S. Rogers, and Andrew H. Green. With some modifications made necessary by changed conditions, they adopted the plan proposed by the State Survey. The lands selected were then surveyed, and their value appraised by a commission of very high character, appointed by the court, the total value of the lands being $1,433,429.50. The report of the commissioners of the reservation was made to the present legislature, and a Bill to appropriate this sum was introduced. The Niagara Falls association worked in every part of the state to arouse public opinion to the importance of making this appropriation, and the commissioners laboured most earnestly among the legislators and the people. The battle was a hard one against ignorance and narrow-minded selfishness; but the victory is complete. The legislature, by more than a two-thirds majority, has appropriated the $1,433,429.50, and the governor has approved the Act.

After six years of almost continuous effort on the part of the active friends of this enlightened project, it is secured by a law which declares that the lands are purchased by the state in order that they may be "restored to, and preserved in, a *state of nature*," and that every part of them shall be for ever free of access to all mankind.

NOTES

We understand that on the receipt by the Science and Art Department from the Foreign Office of a despatch from Her Majesty's Minister at Washington forwarding communications concerning the proposed change in the time for beginning the astronomical day, as recommended by the recent International Meridian Conference at Washington, the Lords of the Committee of Council on Education requested the following Committee to advise them as to what steps should be taken in the matter. Prof. J. C. Adams, F.R.S., the Astronomer-Royal, Capt. Sir F. Evans, K.C.B., R.N., the Hydrographer of the Navy, Gen. Strachey, R.E., C.S.I., F.R.S., Dr. Hind, F.R.S., and Col. Donnelly, R.E. In accordance with their recommendations copies of the Report of the Delegates to the International Prime Meridian Conference at Washington, together with the resolutions adopted by that body, have been sent to various departments of the State, and to the following Societies, &c. : Society of Telegraphic Engineers, Royal Astronomical Society, Royal Society, Submarine Telegraph Company, Eastern Telegraph Company (Limited), Eastern and South African Telegraph Company (Limited), Eastern Extension, Australasia and China Telegraph Company (Limited), Railway Clearing House. They have been informed that these resolutions of the Prime Meridian Conference appear to my Lords of the Committee of Council to be such as commend themselves for adoption. But before informing the American Government to that effect their Lordships would be glad to receive the opinion of the various societies on the subject.

The annual meeting for the election of Fellows of the Royal Society was held at Burlington House on Thursday, June 4, the President in the chair. The following were elected:—Major A. W. Baird, R.E., Philip Herbert Carpenter, D.Sc., Sir Andrew Clark, Bart., M.D., Andrew Ainslie Common, F.R.A.S., Staff-Commander Ettrick William Creak, R.N., Prof. Edward Divers, Henry Hicks, M.D., William Mitchison Hicks, M.A., Francis R. Japp, Ph D., Arthur Milnes Marshall, M.D., Prof. Henry Newell Martin, D.Sc., Cornelius O'Sullivan, Prof. John Perry, Prof. Sydney Ringer, Sidney Howard Vines, D.Sc.

The Davis lectures upon zoological subjects will be given in the Lecture Room in the Zoological Society's Gardens, Regent's Park, on Thursdays, at 5 p.m. The first was given on Thursday, June 4, the subject being "Rhinoceroses and their Extinct Allies," by Prof. Flower, LL.D., V.P.R.S. The others are:—Thursday, June 11, "Apes and Lemurs," by Dr. St. George Mivart, F.R.S.; Thursday, June 18, "The Structure of the Swan," by Prof. W. K. Parker, F.R.S.; Thursday, June 25, "The Domestic Cat," by J. E. Harting, F.L.S.; Thursday, July 2, "Recent Advances in Zoology," by Prof. F. Jeffrey Bell, M.A.; Thursday, July 9, "The Ancestors of Birds," by F. E. Beddard, M.A.; Thursday, July 16, "The Animals of New Guinea," by P. L. Sclater, F.R.S.

In the second edition of his work, "Sur l'Origine du Monde," M. Faye has promulgated the following hypothesis regarding the relations between the geological epochs and the stages of the terrestrial cosmogony. The history of the earth he divides into six stadia. The first is that in which the earth was a glowing ball. The second he calls the *Antezoic period*, in which total darkness supervened on the extinction of the earth's glow. The third is the *Primary period*, during which there was a feeble illumination from the sun, which was then just coming into existence. During the *Secondary period* the sunlight went on increasing as the sun itself grew larger and assumed its proper shape. In the fifth stadium, which is that of the *Tertiary period*, there was complete solar illumination, and the sun soon attained the maximum of its activity; while in the last stadium, that of the *Quaternary period*, there has been a slight diminution of the solar activity (rather surmised than demonstrated), accompanied by the diappearance of every cosmogonic influence and the establishment of perfect stability in almost all directions. Oscillations in the earth's crust and feeble volcanic manifestations are almost the only instances of cosmogonic change still observable.

We have received from MM. Fol et Sarasin a copy of a paper by them on the depth to which the light of the sun will penetrate into the sea. It will be remembered that in November last they recounted the results of their experiments on the same subject in the Lake of Geneva. The present paper describes similar experiments made in the Mediterranean off the zoological station and harbour of Villefranche. By means of photographic plates they have proved that in the month of March, in the middle of a sunny day, the rays of the sun do not penetrate beyond 400 metres below the surface of the Mediterranean. This is established by seven separate experiments, at varying depths and different hours of the morning. At 380 metres, shortly before 11 a.m., the impression on the plate was less than that which would have been left on exposure to the air on a clear night, without a moon. Between 1.20 and 1.30 p.m., at a depth of 405 to 420 metres, there was no trace of any impression whatever on the plate. Light clouds do not appear to cause any notable diminution in the depth to which the light penetrates. In the Lake of Geneva the writers also undertook a new series of investigations to determine the effect of the season on the penetration of light. They give 200 metres as the extreme limit for winter in the lake; but they found that there is as much light at 380 metres in the Mediterranean as at 192 metres in the Lake of Geneva; and by a comparison of these with previous experiments, it appears the light penetrates from 20 to 30 metres deeper in March than in September; in the month of August, perhaps the difference is a little more. Compared with the series of plates exposed in the lake, those of the Mediterranean are characterised by a slower and more regular gradation. This gives rise to the idea that while in the lake the light would be promptly intercepted by the deeper layers, more or less disturbed or muddy, in the Mediterranean the absorption proper to pure water would be the principal, if not the sole factor in arresting the luminous rays.

IN a communication to *Ausland* on the causes of the Andalusian earthquakes, A. Rzehak, of Brünn, maintains that they are clearly referable to the "tectonic" class of terrestrial disturbances—that is, those which are connected with the process by which mountains are elevated. Evidence of this connection is furnished by the manner in which the disturbed areas are influenced by lines of fault. The entire area of disturbance in the case of the earthquakes of December last is divisible into three zones: (1) the littoral zone in the south, where the shock was most severe; (2) Andalusia proper, which was likewise the seat of pretty severe disturbances; and (3) the central plateau of Spain as far as the Carpetena chain (a section of the Sierra Guadarrama), where, as already pointed out by M. Noguès (NATURE, xxxi. p. 417), the shocks completely died out. These three zones are separated by lines of fault. A great fault can be traced not only along the northern slopes of the Serrania de Ronda, but also further eastwards to the district lying north of Malaga. To the north of this line scarcely any places suffered greatly from the earthquake—except those which, like Antequera, Loja, and Archedona, lie close to or immediately beside transverse faults. Elsewhere the degree of shock was tolerably uniform as far as the fault of the Guadalquivir, which bounds the central plateau on the south. A third great fault passes along the south of the Sierra Guadarrama, and there the disturbance seems to have ended.

THE honour of C.I.E. has been conferred upon Mr. Francis Day, Deputy-Surgeon-General (Retired), Medical Department, Madras, and on Mr. J. B. N. Hennessey, late Deputy-Superintendent, Indian Survey Department.

THE Meteorological Society of Vienna has resolved to erect a meteorological station on Mount Sonnenblick, near Tauern, in the central range of the Tyrolese Alps, 3100 metres above sea-level, and thus the highest station of the kind in Europe.

THE Royal Institute of British Architects, on Monday evening, presented to Dr. Henry Schliemann, F.S.A., their Royal Gold Medal. In acknowledging the medal Dr. Schliemann said that our knowledge of prehistoric architecture was very deficient, for our sole informant was Homer, whose scanty information as to the construction and arrangement of the heroic palaces we did not even understand.

THE latest official report of the earthquake in Cashmere states that much damage was occasioned in the north western portion of the valley. The ground opened, and the villages of Dubgaon, Jamalapar, and Ovan were swallowed up, while sulphurous dust and hot water issued from the cracks. The fort at Gurais and the grain store-houses were buried. A telegram sent from Serinagur on Friday last says:—"The shocks continue every three hours, with much preliminary noise, but a comparatively slight motion." The great shock appears to have travelled in a southerly direction, and to have been felt at several places in Northern India, although it did no damage there.

THE death is announced, at the age of fifty-two, of Robert von Schlagintweit, Professor of Geography and Ethnology at the University of Giessen. He was the youngest of the three brothers Schlagintweit who, on the recommendation of Alexander von Humboldt, and under the special care of Lieut.Col. Sykes, were sent by the British East India Company to explore that country, and especially the mountain regions in the north-west. The results of their researches, which lasted for several years, are recorded in comprehensive works of the highest scientific value.

IMPORTANT experiments in aërial navigation are now being made by Mr. A. F. Gower, well known in connection with the Gower-Bell telephone. The operations being carried on are, it is understood, within the cognisance of the Government, and are more particularly directed towards the adaptation of balloons to war purposes. Several ascents have already been made, and in carrying out his arrangements Mr. Gower appears to have recognised the advantages offered by the position of the town of Hythe, which he has made the centre of his operations. On Sunday week the wind being favourable, one of the automatic pilot balloons invented by Mr. Gower, with appliances for giving out its own gas and ballast, one compensating for the loss of the other, was filled with 2300 feet of gas, and ascended at about 11 o'clock. In the car a written statement was, of course, placed, explaining the ownership of the machine and its object, with the result that it was next heard of at Dieppe, having made a rapid passage of about seventy-two miles in a straight direction and descended at 2.30 in the afternoon. On Monday, another pilot balloon, with a capacity of 4300 feet, was started, and immediately followed by Mr. Gower in his own balloon (containing 23,000 feet of gas). The object of Mr. Gower in ascending was to watch the action of the pilot; but the smaller machine made such rapid progress that it got out of his observation and came down in the vicinity of Paris. Meanwhile Mr. Gower, who ascended about noon, took the French coast at Boulogne at 2.15, and then taking a northerly curve travelled overland to Calais, where he made a smooth descent at 4 p.m. A still more important undertaking was, however, entered upon on Wednesday, when Mr. Gower, Capt. Lane, and Mr. Dale, the aëronaut, ascended in a balloon of 40,000 feet capacity. A good start was made, and the aërial voyagers sailed away in a northerly direction. After a journey of rather more than an hour, they were compelled to descend, owing to the wind taking a slight turn towards the North Sea, and with much difficulty landed on the Isle of Sheppey, having travelled twenty-three miles.

A VERY laudable effort at teaching the general public practical astronomy is being made in Christiania. An optician, Herr A. Olsen, has erected a great refractor in the Royal Park—in size said to be the fifth in the world—through which the celestial bodies can be observed by the public for a small fee, while explanations are given of their nature, &c. The interior of the pavilion in which it is mounted is hung with celestial charts and diagrams, as well as views of the planets, the sun, and the moon, for the purpose of facilitating the object in view. The cost of the instrument is very nearly 2000*l*.

INTELLIGENCE has been received at New York, June 9, stating that a waterspout has burst near Lagos, in Mexico. One hundred persons are reported to have perished, and it is feared that the loss of life will prove even greater.

A WATERSPOUT passed over a portion of the town of Hagenau (Alsace) on May 23 last, doing very great damage to houses and trees.

AT Stendal (Prussian Saxony) a Committee for the erection of a monument in memory of Dr. Gustav Nachtigal has been formed, and contributions towards this object are solicited.

THE Austrian Central Tourist Club has addressed a petition to the Assemblies of all Austrian alpine provinces to pass a law prohibiting the wholesale uprooting of *Edelweiss* now carried on. The petitioners point out that hundreds of thousands of the plants are dug up and sent abroad, even to America, so that there is a fear that the favourite plant of all lovers of the Alps will be totally exterminated, except in a few remote plac s. In Switzerland, it is stated, for several years past there have been stringent laws in the several cantons against uprooting and selling the *Edelweiss*.

THE *rôle* of wind in fertilising the ground is remarkably illustrated, according to M. Alluard, by the very fertile valley of Limagne, in Auvergne. The prevalent winds there are west and south-west, and traverse the chain of the Dômes, where are vast deposits of volcanic ashes. Much of this dust is thus carried to the Limagne valley, and settles there of itself, or is carried down by rain or snow. As it contains a large amount of phosphoric acid, potash, and lime, it is highly fertilising, and its very fine state favours rapid assimilation. From observations on the Puy de Dôme, M. Alluard estimates the annual deposit at 348 to 400 grammes per square metre.

WE have received the Calendar of the University of Virginia for the academical year 1884-85. The science department appears to be exceptionally strong and well organised.

ONE result of the recent visit of the Ameer of Afghanistan to India is that his palace at Cabul is to be lit by the electric light. He ordered the necessary apparatus when at Rawul Pindi, and three Cabulese have for some time past been studying its manipulation at Bombay.

WE have received a copy of a lecture by Mr. Thomas Fletcher, delivered before the Parkes Museum of Hygiene, on "Smokeless Houses and Manufactories." It deals mainly with the lecturer's personal experiences of the employment of gaseous fuel in his private residence and manufactory at Warrington, the appliances which he has used, a comparison of the cost with that of coal, the work done, &c. In reply to a question, Mr. Fletcher expressed the opinion that radiant heat is the only possible comfortable way of heating a living-room, and that it is therefore better to mix gas with air to prevent smoke, and heat as large a surface as possible to incandescence.

ACCORDING to a report by the Director of Public Instruction in Tunis, there are at the present moment twenty primary schools in the Regency—eight in Tunis, and twelve in other towns—Susa, Monastir, Sfax, Goletta, &c. In this number are included three schools of the Israelite alliance at Susa, Tunis, and Mehdia. The number of pupils is 3974, composed of 2291 boys and 1683 girls. The report states that there are in addition a certain number of primary schools in which the instruction is religious. Of these there are 113 in Tunis, and about 500 in the whole Regency. For secondary instruction there are three establishments, all in Tunis. These contain 23 classes with 38 masters, giving instruction to 416 pupils, of whom 78 are French, 27 Italian, 26 Anglo-Maltese, 74 Jews, 193 Arabs, and 18 of various nationalities.

A MEETING of the National Fish Culture Association was held on Thurday last to consider the question of instituting sea temperature observations with a view to gaining independent and fresh knowledge with respect to our marine food-fishes. The subject of marine stations was discussed together with other matters relative to log-books to be issued to suitable investigators.

THE additions to the Zoological Society's Gardens during the past week include a Squirrel Monkey (*Chrysothrix sciurea*) from Demerara, presented by Mr. T. C. Edwards-Moss; a Common Badger (*Meles taxus*) from Derbyshire, presented by His Grace the Duke of Devonshire, K.G., F.Z.S.; a Common Badger (*Meles taxus*) from North Wales, presented by Mr. T. W. Proger; two Common Hedgehogs (*Erinaceus europæus*), a Common Viper (*Vipera berus*) from Norfolk, presented by Mr. T. E. Gunn; a Chattering Lory (*Lorius garrulus*) from Moluccas, presented by Mr. H. D. Astley, F.Z.S.; a Red-crested Cardinal (*Paroaria cucullata*) from South America, presented by Miss Hyrzan; a White-tailed Eagle (*Haliaetus albicilla*) from Perthshire, presented by Mr. H. Tennent Tennent; a Manx Shearwater (*Puffinus anglorum*), a Puffin (*Fratercula arctica*), British, presented by Mr. W. Graham, F.Z.S.; an Egyptian Monitor (*Varanus niloticus*) from West Africa, presented by Mr. H. Denny; an African Lepidosiren (*Protopterus annectens*) from African Rivers, presented by Mr. Cornelius Alfred Malony, C.M.G.; two Slowworms (*Anguis fragilis*), British, presented by Mr. F. J. Guy; a Sharp-nosed Crocodile (*Crocodilus acutus*) from Jamaica, deposited; a Collared Fruit Bat (*Cynonycteris collaris*), an Axis Deer (*Cervus axis* ♀), a Hybrid Luhdorf's Deer (between *Cervus luehdorfi* and *Cervus canadensis* ♂), a Burrhel Wild Sheep (*Ovis burrhel*), two Triangular-spotted Pigeons (*Columba guinea*), a Variegated Sheldrake (*Tadorna variegata*), a Herring Gull (*Larus argentatus*), twenty Spotted Salamanders (*Salamandra maculosa*), thirty Pleurodele Newts (*Molge walti*), bred in the Gardens.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, *JUNE* 14-20

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on June 14

Sun rises, 3h. 44m.; souths, 11h. 59m. 59·9s.; sets, 20h. 16m.; decl. on meridian, 23° 18′ N.: Sidereal Time at Sunset, 13h. 49m.

Moon (at First Quarter on June 19, 14h.) rises, 5h. 46m.; souths, 13h. 38m.; sets, 21h. 25m.; decl. on meridian, 17° 37′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′

GEOGRAPHICAL NOTES

AFTER having lost, in December last, their director, Prof. W. G. Erofeeff, and in January one of their most active members, W. A. Domzer, the Russian Geological Commission has again sustained a heavy loss in the death of the distinguished G. P. Helmersen. According to the notice in the last issue of the *Izvestia* of the Commission he began his scientific career more than sixty years ago, at the Dorpat University, and when less than twenty-two years of age. Throughout his life he has had the opportunity of exploring nearly all the surface of Russia in Europe, from Olonetz to the Crimea and from Poland to the Ural, penetrating also into the Kirghiz Steppes in the Asiatic dominions of the empire. The results of his varied explorations are embodied in 130 monographs, some of which are bulky works. His first work of importance, the "Exploration of Southern Ural," was published in 1831, in connection with Hofmann. Five years later it was followed by a description of the Kirghiz Steppes and by a short paper on the Ural and Altay Mountains. In 1838 he began to publish the results of his explorations of the Baltic provinces, which were thenceforth continued throughout his life. In 1840 he studied the lake region of North-west Russia and of the Valdai Hills, and next year made the first attempt to embody all that was known regarding the geological structure of Russia by publishing the first geological map of the country. The coal-fields of the Moscow basin then attracted his attention, and in 1845 he published the results of his researches into the structure of the Ust-Urt and its slopes towards the Sea of Aral. In 1850 he published an interesting sketch of the Devonian Rocks of Middle Russsa. In 1857 there appeared his notice as to the rising of the Baltic shore and the action of ice and water on it, being the first of a series which led him afterwards to investigate the subject of boulders. After having spent four years in the exploration of the Olonetz region, he embodied the results of his observations in a work published in 1860. His researches into the physical conditions of St. Petersburgh, the artesian well bored in that capital, and the Alexander monolith, made his name popular even among unscientific readers. A work on Lake Peipus and the Narova river appeared in 1864, and completed his researches in the lake region of North-west Russia. Next year a second revised edition of his geological map of Russia, including the Ural and Caucasus, and a map of the Russian coal-basins, were published by the indefatigable geologist. The supposed drying up of the Sea of Azov was the subject of several papers and reports presented by him to the Academy of Sciences, as also the extension of the coal-fields from the Don, through Tula and Kaluya, to Courland and Eastern Prussia. In 1870 he published his "Studies on Boulders," the second part of which appeared only three years ago. In 1879 he issued a geological and physico-geographical description of the Aralo-Caspian region. A paper, written together with M. Yakovleff on the same subject, in 1883, was his last contribution to the Memoirs of the Academy of Sciences. In all these works, Helmersen appeared as a follower of the school of geologists represented by Leopold von Buch and Alexander Humboldt. Instead of merely describing the fossils of a given formation, and minutely studying its various stratigraphical and palæontological horizons, he tried to discover the leading physical and geographical features of the country he explored, and devoted great attention to dynamical geology. His works are as valuable to the geographer as to the geologist. For twenty-five consecutive years Helmersen was Professor at the Mining Institute of St. Petersburg, and since 1844 he was one of the most active members of the Academy of Sciences. In 1851 he was elected a foreign member of the Geological Society of London – an honour well bestowed on one of the most industrious and distinguished geologists whom Russia has produced.

THE last issue of the *Izvestia* of the Russian Geographical Society contains a map showing M. Potanin's last journey in China, from Peking to Kookoo-koto and Lang-tcheou (73° 30′ E. long.), to illustrate M. Potanin's letters dated Boro-balgasun and Lang-tcheou, September and November 13th, 1884. The Ordos, described with so dark features by Huc, looked more attractive than might have been expected. True, the whole of the country between the Yellow river and Boro-Balgasun is covered with sand; but moving sand is rare, the *barkhans* being usually fortified by vegetation. The *shiabyk*—a species of *Artemisia*—is the most frequent growth in the *barkhans*, the cavities between them being thickly covered with bushes of Caragana, *archa*, and *jashil*. Water is found wherever the subsoil appears from beneath the sand; numerous sweet water ponds make there their appearance, and they are surrounded with moist pasture-grounds. The dry grounds between the sands are covered with Steppe vegetation, the *Calimeris* colouring sometimes wide spaces in white. Sarrazin, millet, and hemp are cultivated on these dry grounds. Altogether, the eastern Ordos may be considered as a rich country for cattle breeding, if supported by some agriculture. Two old towns, now in ruins were passed on the borders of the Ordos. Boro-balgasun, too, was formerly a town, within the ruined walls of which there are now but a few Mongolian huts, and the house of the Belgian missionaries. In the Van principality M. Potanin visited the Edjen-khoro place, on the Tchamkhak river; it consists of two tents where the bones of Chengiz-khan are said to be preserved. On Sept. 22, the expedition left Boro-balgasun. They visited the salt lake Baga-shikyr, and for five days crossed a region covered with low hills and almost uninhabited, notwithstanding the good pasturage which spread between the *barkhans*, these last becoming more thinly spread than in the east. Ruins of Mussulman villages destroyed during the last insurrection are not uncommon. Lin-tcheou, on the Hoang-ho, is surrounded by fruit-gardens. South of it numerous villages extend for some fifty miles along a canal which runs parallel to the Hoang-ho and crosses on aqueducts its tributaries. Its banks offer an uninterrupted fruit garden, with a few rice-fields. All this richness is, however, of recent origin, the former gardens having been all destroyed by Chinese after the last insurrection. Altogether, the region bears traces of desolation; whole towns have been quite destroyed. The town Tsin-tsi-pou was the centre of the insurrection. South of this town, M. Potanin left the valley of the Hoang-ho, and crossed the series of flat ridges which reach towards the south, 6,000 feet to 7,000 feet above the sea-level. Still they have gentle slopes, owing to their covering of Loess which reaches a thickness of from 200 to 300 feet. The hills are formed of red sandstone, with some layers of pudding-stone north of the Tao-tsoui river, while south of Tsin-youang the ridge consists of silicious and clay-slate. The sandstone contains beds of salt, which impregnates also the soil and is worked to some extent; it is raised also from a number of small lakes. The Loess covers the whole of the country from Ping-yang-sia to Lang-tcheou, spreading also over the summits of the higher ridges. The population is of Turk origin, and though it has assumed Chinese customs it maintains its Mussulman religion. In the hilly tracts dwellings, and even inns, are dug out in the Loess. Lang-tcheou is a great city, picturesquely built on the right bank of the Hoang-ho at the foot of a high mountain ridge. A floating bridge crosses the great river. The plants collected for the herbarium by the expedition were but few, owing to the late season; but altogether in the whole region there are no trees excepting those which are cultivated; even the higher ridges are devoid of trees and but scarcely clothed with grass. From Lang-tcheou, where the astronomer, M. Skassy, remained with the scientific collection, M. Potanin went to the west to visit the Salors and Shorongols, who inhabit that region, while M. Berezovsky proposed to advance further south to Hoy-sian, situated on the water-divide between the Yellow and the Blue Rivers. The scientific results of the expedition promise to be very interesting. The astronomer, M. Skassy, has determined the position of fifteen places and mapped the route. M. Berezovsky has collected 140 samples of birds, and M. Potanin brings back collections of plants, insects, and reptiles, as also a geological collection.

A RECENT number of the *Japan Gazette* contains a series of notes on each of the islands forming the Kurile group, which stretches from Jeso northward to Kamtschatka, and which for the past ten years have belonged to Japan. The notes are arranged by Prof. Milne, from his own notes and those of Mr. Snow, who has spent many consecutive summers amongst the islands. They refer mainly to the numerous volcanoes among the Kuriles, but much information on other points relating to this little-known group is given. The name applied by the Japanese to the chain is "Chishima," or "the thousand islands," but there are really not more than thirty or forty. Of these, Iturup and Kunashiri, the most southern members of the group, are the largest. They "form the first links of the chain which volcanic agencies have built up whilst attempting to join Japan and Asia." Iturup is 113 miles long and 77 in greatest width; Kunashiri is 62 miles by 17. They are all very desolate, and sparsely populated in summer by Japanese and Ainos, who come to fish. In Iturup, between the coast and the mountains, there is a kind of jungle composed mainly of bamboo grass, which is impassable. The explorer has therefore to follow the bed of a stream or the bear tracks. Prof. Milne thinks it not unlikely that the Iturup bear may be a species new to science. From the specimens seen in cages it seems to resemble the grizzly bear of North America.

ANNIVERSARY OF THE ROYAL GEOGRAPHICAL SOCIETY

THE Anniversary Meeting of the Royal Geographical Society was held in the theatre of London University on Thursday, the Right Hon. Lord Aberdare, F.R.S., President, in the chair. In his address, Lord Aberdare referred to Mr. Keltie's report on the position of geographical education in England and on the Continent. The Report, Lord Aberdare stated, contains statements and recommendations of the highest interest and importance. Of the state of geographical education in Great Britain Mr. Keltie draws a very dismal picture. "There is no encouragement to give the subject a prominent place in the school curriculum; no provision, except at elementary normal schools, for the training of teachers in the facts and principles of the subject, and in the best methods of teaching it; no inducement to publishers to produce maps, globes, pictures, reliefs, or other apparatus of the quality and in the variety to be found on the Continent; while our ordinary text-books are, as a rule, unskilful compilations by men who have no special knowledge of their subject." This neglect is attributed to the "exigencies of examination." Geography, as a class-subject, "does not pay." It is not recognised at the Universities by either professorship or readership; it does not find a real place at any of their examinations; while in the Army and Navy examinations it is at a discount; and such geography as is given is of a very partial character, and is merely left to crammers. These unsatisfactory statements are justified by a large amount of evidence. In striking contrast to this picture is that which Mr. Keltie presents of the state of geographical education in Germany, France, Italy, Switzerland, and several other countries of Europe. Germany, as might be expected, takes the lead, and does its work most thoroughly. But the systematic study of geography is even there of recent creation. It prevails in twelve out of the twenty-one universities of Germany; and nearly all the twelve existing professorships of geography have been founded within the last twelve years. "The ideal aimed at, and being rapidly carried out, is to have one continuous course of geographical instruction from the youngest school-year up to the university." And Mr. Keltie deals with these ascending courses, showing in detail the teaching from the elementary to the higher schools, and in the universities. His examples of lessons he himself heard at some of these schools are most graphic, and suggest their high value in any course of intelligent education.

Lord Aberdare then briefly referred to the conclusions at which Mr. Keltie arrives. These, he stated, are clear, sensible, practical, but by no means encouraging. In all these European countries the curriculum is defined and imposed by the State, which, keeping the purse-strings, dictates the course of instruction. Except over our elementary schools, the State in this country exercises no such power, direct or indirect. We must be content to bring the force of public opinion to bear upon our schools and universities; for with them, and especially with our universities, rests the solution of this great question. Mr. Keltie's Report will be duly considered by the Council; it will doubtless be published; and means, Lord Aberdare ventured to prophesy, will be taken to bring home to our educational authorities, with fresh power and urgency, the necessity for not allowing Great Britain to lag behind our political and commercial rivals, our rivals in human culture, in the systematic study of geography. In the meantime, during the course of the autumn, an exhibition will be formed of the results of Mr. Keltie's labours in collecting specimens of the best text-books, maps, globes, diagrams, models, and other apparatus used in teaching the various branches of geography. This done, it remains for me, Lord Aberdare said, only to express the fervent hope that this latest effort of the Society to promote the studies which it was founded to extend, may meet with a large measure of success and tend to lay the basis of a sound and thoroughly national system of instruction in geography in all its branches, physical, political, and historical.

Lord Aberdare then gave a brief *résumé* of exploring work since his address in November last. He specially referred to the four years' explorations in Eastern Tibet of the Pundit Krishna, and to the geographical work done in connection with the Afghan Boundary Commission.

The preliminary map sent home by Major Holdich rectifies in many important points the erroneous topography in all pre-existing maps, and gives us a clear idea of the surface-configuration and physical condition of one of the most interesting districts in Central Asia.

Further east the indefatigable Colonel Prjevalsky has been recently again heard of from the centre of the continent, at Lob Nor.

In and around the Zhob valley, areas of about 5500 square miles of reconnaissance on the ¼-inch scale, and of 400 square miles of topography in the ½-inch scale are reported to have been completed; thus going far to fill in a reproachful hiatus in our present maps of Afghanistan. The ascent of certain peaks in the Himalaya by a member of the Alpine Club, Mr. W. W. Graham, an account of which was read by him at one of the Society's meetings in June last, has attracted considerable attention in India. The classical lands of Asia Minor have again this year been the subject of topographical investigation. In the winter of 1882–3 a fund was raised by public subscription in order to effect explorations that might throw light on the antiquities and early history of the region. Mr. W. M. Ramsay was entrusted with the execution of this scheme, and travelled with this view, May to October, 1883. He invited a scholar of the American School of Athens, Mr. J. R. S. Sterrett, to accompany him during great part of the summer. During that year's work the conviction grew up that no adequate study of the history of Asia Minor was possible till the ancient topography was better known and that no advance in the study of the ancient topography could be made till a better map of the country had been compiled. It was therefore found necessary, week by week, to pay a growing attention to the natural features of the country, the natural routes of communication, and the natural boundaries separating district from district. Lord Aberdare referred to the work done in New Guinea by Mr. Van Braam Morris, Dutch Resident at Tidore, who has examined this part of the coast, and ascended the Amberno, which had always been reported by passing navigators, on account of its numerous supposed mouths, to be a large river with an extensive delta, and to the journeys into the interior of the Rev. James Chalmers. Mr. Chalmers has visited many parts of this coast along a line of about 500 miles, and penetrated, at various places further inland, by land, than any other European, and his descriptions of the country and the habits of the vivacious, excitable, and pugnacious race of savages with which it is peopled, merit careful attention at the present time. An attempt is about to be made by the experienced traveller Mr. H. O. Forbes to penetrate to the summit of the ranges, or plateaux, which extend along the centre of this part of the great island. Since he left England on this arduous mission some weeks ago we learn that the Sydney and Melbourne branches of the Geographical Society of Australasia have offered to contribute to the expenses of this expedition, which is supported by grants by our Society, the Scottish Geographical Society, and the British Association. In other parts of Australasia the chief additions to our knowledge have been a survey of a large tract of new country in Central Queensland by Mr. C. Winnecke, and the exploration of the King Country in the northern island of New Zealand by Mr. Kerry-Nicholls, of which the explorer himself gave us an account at one of our evening meetings.

In Africa Lord Aberdare referred to the work done by Mr. H. H. Johnston at Kilimanjaro. Since then the brothers Denhardt, who had previously done excellent work in surveying the course of the River Dana, which flows from the southern slopes of Mount Kenia, have left again for East Africa. They have been commissioned, as we are informed by the German African Society, to take up a line of exploration similar to that adopted with so much success by Mr. Joseph Thomson, but to follow it much further to the north than the point reached by our English traveller, namely, to the reported great lake Samburu, north of Lake Bahringo. Further north still the year has witnessed the accomplishment of what may be termed one of the most interesting and difficult feats of all recent African travel. This is the journey of Messrs. F. L. and W. D. James, the authors of the well-known book on the "Wild Tribes of the Soudan," who with three English companions, Messrs. G. P. V. Aylmer, E. Lort Phillips, and J. Godfrey Thrupp, organised an expedition and started last December to cross the north-eastern angle of Africa from Berbera to Mogadoxo. The hostile disposition and uncertain temper of the Somali tribes who inhabit this wide region have hitherto offered invincible obstacles to its exploration by Europeans. Mr. James and his party, however, succeeded in penetrating 400 miles to the south, as far as Barri on the River Webbe, a point about 215 miles distant from Mogadoxo. The interior was found to be a plateau of an average elevation of about 4000 feet.

With regard to the more southerly parts of Eastern Africa, and more especially the region between the Mozambique coast and Lake Nyassa, our knowledge has lately increased by leaps and bounds. The increase has been principally due to the systematic explorations of Mr. Consul O'Neill. The general remark may be permitted that, thanks chiefly to Mr. O'Neill, we now have for the first time a fairly satisfactory knowledge of a region varied in its physical configuration, well watered, and fertile, which has hitherto remained a blank on our maps, notwithstanding the occupation of the coast by the Portuguese for nearly four centuries.

M. Giraud has returned this spring from his exploration of Lake Bangweolo and its outlet, and his unsuccessful attempt to cross Africa by way of the Upper-Congo; Mr. Arnot has crossed from Natal to the Bihé plateau by way of the Upper Zambesi; Mr. Montagu Kerr has crossed Matabele-land and the Zambesi, and penetrated by a new route to the south-western shore of Lake Nyassa; and Mr. Richards has reached from Inhambane the southern districts of Umzila's kingdom. In Western Africa further additons have been made to our knowledge of the Congo, chiefly by the publication of Mr. Stanley's long-expected book and the maps which accompany it, and by Messrs. Grenfell and Comber's careful survey of the middle course of the Congo and the Bochini tributary to the junction of the great river Kwango.

The members of the French Expedition on the Ogowé and the northern tributaries of the Congo have also been doing good work in the survey of the territories newly acquired by France.

In South America a striking feat of exploration has been accomplished since my last address; the supposed inaccessible summit of Mount Roraima, on the confines of British Guiana and Brazil, was reached in December last by Mr. im Thurn and his companion, Mr. Perkins, accompanied by a small party of Indians.

In conclusion Lord Aberdare gave the following brief summary of the Admiralty surveys of the year 1884, for which he was indebted to the hydrographer, Capt. Wharton, R.N.: The continuous prosecutions of marine surveys in different quarters of the globe has been well maintained during the past year. The two home-surveying vessels have been employed, one on the west and the other on the east coast of Great Britain. On foreign surveys 60 officers and 500 men have been employed in four steam ships of war and five other smaller vessels. These ships have been at work in Newfoundland, the Bahama Islands, Magellan Straits, South Africa, Red Sea, Malay Peninsula, coasts of China and Korea, north-west coast of Australia, and amongst the Pacific islands. The most important additions to our hydrographical knowledge are as follows:—The survey of the Little Bahama Bank will be shortly finished, and the same may be said of the southern shore of Newfoundland. The survey of the main strait of Magellan, to which reference was made in the last address, was completed early in the year. Many useful additions have been made to ports and salient parts of the coast of south-east Africa. In the Red Sea the intricate approaches to Sawakin have been well laid down. On the west coast of the Malay Peninsula, Penang harbour has been re-surveyed and the positions of the islands lying to the north-west and forming the eastern boundary of the ordinary route of vessels to Malacca Strait have been accurately determined. The unknown western shores of Korea, south of the approach to Seoul, for two degrees of latitude have been explored, and the main features of this island-studded shore laid down. New rivers and harbours have been entered, notably, the large river Yeun-san-gang, at the entrance to which stands the considerable town of Mokfo. There appears, however, to be little chance of immediate trade with Korea, in consequence of the absence of any valuable products and the scanty needs of the population. The southern approach to Haitan Strait on the Chinese coast, much used by British trade, has been re-charted. On the difficult shores of Western Australia such progress has been made as the small means at the disposal of the surveyors has permitted. In the Solomon Islands the Bougainville Strait has been charted. This Channel will in the future be most probably a highway for traffic between Eastern Australia and Japan. Many additions have been also made to the charts of various groups of other Pacific islands. The survey of the coasts of India carried on by officers of the Royal Navy and India Marine has been actively progressing. Surveys of Rangoon, Cheduba, and other ports in the Bay of Bengal, as well as harbours on the west coast of Hindostan, have been made. A re-survey of the great Canadian lakes has been commenced in Georgian Bay, where trade by water is on the increase.

Lord Aberdare then intimated his resignation of the Presidency of the Society, the Marquis of Lorne having been elected to succeed him.

PROF. REYNOLDS ON THE STEAM INDICATOR[1]

THE object of this paper was to define the causes and extent of the disturbances in indicator diagrams. The theory, as given, had been taught for several years in Owens College; but the publication had been deferred to enable an extensive series of experiments to be made. These experiments had now been carried out by Mr. A. W. Brightmore, Stud. Inst. C.E., late Berkeley Fellow in Owens College. In the first place it was shown that there were five principal causes of disturbance, namely: the inertia of the piston of the indicator and its attached weights; the friction of the pencil on the paper, and its attached mechanism; varying action of the spring; inertia of the drum; friction of the drum.

The effect of the inertia of the pencil and its attached mechanism presented a mathematical problem, by the solution of which it was shown that there were two disturbances from this cause: one, a general enlargement of the mean indicated pressure, depending on the weight of the moving parts of the indicator, the stiffness of the spring, and the square of the speed. The other disturbance was a vibration of the pencil. Every indicator piston vibrated when disturbed, so that the period of vibration depended on the stiffness of the spring.

The error which these oscillations caused in the area of the diagram depended on their magnitude, and, to a greater extent, on the smallness of the number in a revolution. But the evil of these oscillations was not so much an effect on the area as in the disfigurement and the confusion they produced in the diagram. So long as there were thirty of these oscillations in a cycle, the necessary fluid friction of the indicator piston would so far reduce them as to render a fair diagram possible, but when the number was as low as ten it was all the pencil could do to prevent them upsetting the diagram.

The friction arising from the pressure of the pencil always acted to oppose the motion of the pencil, and therefore rendered it too large during expansion and exhaust and too small during compression and admission, and thus the general effect was to increase the size of the diagram. This friction consisted of that of the pencil on the paper; and that of the mechanism, caused by sustaining the pressure of the pencil. The effect of the friction of the pencil was greatly reduced by the motion of the paper. The magnitude of these effects taken together on the area of the diagram depended on the construction of the instrument and on pencil-pressure. From numerous experiments it would appear possible to make a difference of as much as five per cent. in a locomotive in mid-gear by pencil-friction.

The couclusions, as regarded the motion of the pencil, were that the general effect of inertia and friction were both to increase the size of the diagram; that so long as the speeds were such that the number of vibrations of the pencil during a revolution of the engine was not greater than fifteen, the effect of inertia was less than one per cent., but that, if the number was greater than thirty, oscillations would show themselves unless the pencil-friction was increased. They might, by this, be kept down till the number of vibrations was equal to fifteen, but not farther, and then the necessary friction would affect the area of the diagram about five per cent. For the diagrams to be sensibly accurate, and free from oscillation, the speeds must not be greater than would make the number of vibrations equal to thirty. These speeds were given in the paper for Richards' indicators.

The effect of the inertia of the drum with an elastic cord was shown to be a nearly uniform elongation of the diagram. The result of the varying stiffness of the drum spring was a nearly uniform contraction. With Richards' indicator these two latter disturbances neutralized each other at a speed of 150 revolutions per minute. At other speeds the effects were apparent in the length of the diagram; but, except when the expansion was great and the connecting rod short, they did not affect the indicated pressure. The friction of the drum with an elastic cord caused the cord to be longer during the forward stroke than during the

[1] A Paper read at the Institution of Civil Engineers, May 19, "On the Theory of the Indicator and the Errors in Indicator Diagrams," by Prof. Osborne Reynolds F.R.S.

backward stroke, so that the diagram was distorted and shortened, the drum being uniformly behind its proper position during the forward stroke, and before its position during the backward stroke. This distortion diminished the area of the diagram according to the rate of expansion and the length and elasticity of the cord used. This was definitely expressed by a formula. This disturbance, the influence of which was very great in cases of high expansion, large engines, and ordinary cords, appeared to have been unnoticed. The circumstances on which it depended were the elasticity of the cord and the friction of the drum, and the question was how far these existed in the ordinary indicators. It might be said that the diagrams which led to the discovery of this effect were taken with an indicator which had been in constant use for several years. It was in apparently perfect condition, and the diagrams did not differ essentially from those which had been previously taken. The cord was one which had been supplied by the maker. The manner of the discovery was described: For years the author had pursued in the class the method of testing the vibrations of the indicator pencil by projecting them on to the crank-circle, and he had noticed that the first oscillation fell short, and shorter in the back diagram than in the front. The cause of this was not obvious, and it was partly with a view to determine this cause that Mr. Brightmore's investigation was commenced. A slight error in the reducing rod, which had a fixed centre and a slot in which a stud in the slide-block worked, was altered. This, however, did not get rid of the effect. A new cord was substituted for the old one, and the effect was found to be much enhanced, the new cord being more elastic than the old one. This reduced it to the stretching of the cord, but it was only after carefully working out the effect of the inertia of the drum, and it was seen this was to lengthen the first oscillation at the back end that the friction was examined. The indicator was taken to pieces, cleaned and oiled; then the effect was much reduced. Several new wires and cords were used, and eventually steel wire was adopted as the best. The test supplied by the oscillations could only be applied to diagrams taken at high speeds, and the test furnished by the influence upon area was vague. What was wanted was an independent means of determining the simultaneous positions of the drum and the engine-piston. As the best method of meeting this, it was decided to arrange an electric circuit through the pencil to the drum, with sufficient electromotive force to prick the paper, making the engine-piston close this circuit at eleven definite equidistant points in the motion backwards and forwards. This was successfully carried out, and the stretching of the cord during the backward and forward strokes was definitely ascertained. Taking the smallest results obtained with a cord, it appeared from these experiments that the least difference of stretching was to make this difference in inches 5 per cent. of the length of the cord in feet. Examples of this effect in diminishing the mean indicated pressure were given. Thus, in a locomotive cutting off at one-quarter it was 8 per cent.; in a condensing engine having 3·5 feet stroke, cutting off at one-tenth, 20 per cent.; and the same compounded, 10 per cent.

These would seem to be the smallest results that could have occurred in ordinary practice. The conclusion, however, that hitherto the normal indicated power from engines had been from 10 to 20 per cent. too small must wait for verification. Yet there were not wanting independent evidences of such an effect. In diagrams taken from engines at high speeds the admission line would not but for this effect be vertical. It would show a certain amount of detail, and the first oscillation would not have a sharp top. Moreover, it was commonly found that the expansion line, allowing for clearance, was above the true expansion line for the steam. This apparent rise in the curve of expansion was exactly what would result if the apparent cut-off was too early, and this was the result of the effect that had been considered. The author had tried several diagrams, and found that after correction the expansion line came out very close to the true curve.

In making these comparisons the explanation of another feature of diagrams became apparent. When the two diagrams were traced on the same card, there was sometimes a want of symmetry about them, and in this case the cut-off was shorter on the back than on the front diagram. This the author attributed to the friction of the drum when the cord for the back diagram was longer than that for the front. When this was the case the relative lengths of the cord were about 1 to 1·8. These observations were illustrated in a diagram from "Richards' Indicator." To test this diagram a tracing was taken, and reversed so that the front diagram was superimposed on the back. It was observed that the diagrams were of different lengths, and the difference was about the same as the difference in cut-off; that notwithstanding the apparent cut-off in the back diagram was to that in the front in the ratio of 2 to 3, the expansion line of the back diagram was the same shape as that in the front; and that if the diagrams were restored, supposing the lengths of the cords used to have been 5 feet and 9 feet, the diagrams became exactly similar, and, allowing 2 per cent. clearance, the expansion line came to be the true expansion line for that cut-off. The mean pressure was 14 per cent. larger than from the original diagram.

Such instances as these seemed to sufficiently establish a case against the blind faith which appeared to be at present placed in the accuracy of the indicator diagrams. But, in conclusion, the author stated that he should be very disappointed if anything in this investigation should have the effect of diminishing reliance on the indicator itself. He would have the instrument treated fairly, and instead of being the object of unthinking worship he would have it the object of careful study and experimental investigation, so that the limits of its wonderful perfection might be known exactly, and that reliance placed on it which sprang from knowledge.

THE VISITATION OF THE ROYAL OBSERVATORY, GREENWICH

THE visitation of the Royal Observatory took place on Saturday last, when, in spite of bad weather, there was a numerous attendance. The following extracts (condensed in some cases) from the Report of the Astronomer-Royal to the Board of Visitors indicate the work of the past year. It will be gratifying to all to know that a considerable increase in the optical power of the Observatory is in contemplation.

Transit-Circle.—A reversion-prism made by Messrs. Troughton and Simms has been used since last June in observations with the collimators as well as with the transit-circle to reverse the apparent direction of measurement or of motion, a movement towards the left (as in transits of south stars) being converted into a movement towa ds the right, or upwards, or downwards, according to the position of the plane of reflection of the reversion-prism. The collimation-observations show no sensible personality depending on the apparent direction of measurement; it has, however, been considered well, in order to eliminate any possible effect of the kind, to take half the measures in each determination of collimation with the direction of movement of the wire reversed as regards right and left. In the transits the practice is to observe on each day two clock-stars and also circumpolar stars with the direction of motion reversed. A comparison of the results from the reversed and ordinary observations of clock-stars shows sensible differences in the case of some observers, who, however, have probably not yet settled down into a definite habit of observing stars which appear to move in the reverse direction.

In order to determine absolute personal equations in the observation of slow-moving as well as of quick-moving stars of various magnitudes (whether the motion be from right to left or the reverse) and of limbs of the sun, moon, or planets, the Astronomer Royal has arranged, in concert with Mr. Simms, a personal equation instrument to be used with the transit-circle. In this instrument, which is on the point of completion, and was seen at work on Saturday, a vertical plate with a circular aperture, 6 inches in diameter, to represent the sun or moon, and several small pinholes, to represent stars of different magnitudes, is placed in the focus of an object-glass of about 7 inches aperture and of about 50 feet focal length (which is attached to the dew-cap of the transit-circle, when horizontal and pointing north), and is carried smoothly by clockwork from east to west or west to east at a rate which may be varied at will from that of a very close circumpolar star to three or four times that of an equatorial star by an ingenious but simple mechanical contrivance devised by Mr. Simms. The apertures in the vertical plate are illuminated by direct sunlight or moonlight reflected by a plane mirror towards the object-glass, and the times of transit of the artificial sun, moon, or stars, which are to be observed over the wires of the transit-circle, are also registered automatically on the chronograph by means of insulated platinum studs, corresponding to the artificial objects, which make contact with other studs, corresponding to the wires in the field of view of the transit-circle.

Since last October transits of the close circumpolar stars have been taken at the middle wire set to successive revolutions of the R.A. micrometer, thus virtually introducing a system of very close equidistant wires for the slow-moving stars. It is thus found that a larger number of separate observations can be obtained in a moderate time, a point of special importance in changeable weather. The equality of successive intervals of the R.A. micrometer-screw was tested last January for each revolution through a range of twelve revolutions, and also for every tenth of the three middle revolutions, and the errors of the screw appear not to exceed the errors of observation. The determination was made by means of the south collimator, the eye-piece of the transit-circle having been turned through 90°. The observations of close circumpolar stars have also been discussed with a view of testing the equality of successive revolutions of the R.A. micrometer screw, the results being very satisfactory. The screws of the microscope-micrometers also were examined by means of the south collimator on March 27 and following days, successive intervals being measured for each revolution and third of a revolution from -1^r to 6^r. Though there is evidence of considerable wear in the individual screws, which have been in constant use since 1875, the method of using them (the action of the spring being in opposite directions for the micrometers of each pair) entirely eliminates this effect from the mean, and the resulting errors (which are probably casual errors of observations) do not exceed 0″·05 at any part of the screws.

The subjects of meridian observations in the past year have been as usual the sun, moon, planets, and fundamental stars, with other stars from a working catalogue, which now contains about 2,750 stars. About 380 stars have been lately added to the list from the "Harvard Photometry," with a view of making the forthcoming Greenwich Catalogue of stars down to the sixth magnitude as complete as possible. It is hoped that all of these stars will have been sufficiently observed by the end of 1886, when it is proposed to form a Ten-Year Catalogue, epoch 1882·0. The annual catalogue of stars observed in 1884 contains about 1,370 stars.

The following statement shows the number of observations with the transit-circle made in the twelve months ending 1885, May 20:

Transits, the separate limbs being counted at separate observations...	5523
Determination of collimation error	299
Determinations of level error	376
Circle observations	5321
Determinations of nadir point, including the number of circle-observations	294
Reflection-observations of stars (similarly included)	619

The discordance between the nadir observation and the mean of the results from reflection observations of stars north and south of the zenith has recently become very small, the correction deduced for the first four months of the present year being only −0″·07. The mean correction indicated by the observations of 1884 was −0″·36, whilst those of 1883 gave the value −0″·45. The steady increase of this discordance from 1878 to 1883 and its subsequent decrease remained unexplained, no change having been introduced into the method of observation of the nadir point or of stars by reflection during the last two years.

The apparent flexure of the transit-circle, as found by means of the collimators, has again changed sign. From six determinations made on 1884 June 3, Sept. 9, Sept. 29, Oct. 5, Oct. 20, and May 20 (the reversion-prism being used on each occasion except the first) the resulting values (found by four different observers) are −0″·47, + 1″·00, + 0″·03, + 0″·10, and +0″·08, the mean of which is +0″·17, agreeing closely with the value + 0″·13 found by nine accordant determinations in the period 1879 to 1882, whilst the mean of five determinations by three different observers in 1883 gave the value − 0″·49. No correction for flexure (as distinct from the R − D correction) has been applied to the observations since 1879.

The correction for R − D, the error of assumed colatitude, and the position of the ecliptic, have been investigated for 1884. The computation of the geocentric and heliocentric errors for the planetary results is not yet complete.

The correction for discordance between reflection and direct observations of stars, deduced from observations in 1884 which extend from Z.D. 69° north to Z.D. 70° south is − 0″·02 + 0″·66 sin Z.D. The assumed formula $a + b \sin z$ represents the observations of 1884 satisfactorily throughout the whole range of zenith distance.

The value found for the colatitude from the observations of 1884 is 38°. 31′.21″·91, differing only by 0″·01 from the assumed value; the correction to the tabular obliquity of the ecliptic is + 0″·57; and the discordance between the results from the summer and winter solstices is − 0″·99.

The mean error of the moon's tabular place (computed from Hansen's Lunar Tables with Prof. Newcomb's corrections) is +0s·02 in R.A. and + 0″·29 in longitude as deduced from 104 meridian observations in 1884.

Altazimuth.—The observations with this instrument have been restricted to the period from last quarter to first quarter in each lunation, the total number of observations of various kinds made in the 12 months ending 1885 May 20 being as follows:—

Azimuths of the moon and stars	321
Azimuths of the azimuth-mark	181
Azimuths of the collimating-mark	192
Zenith-distances of the moon	178
Zenith-distances of the collimating-mark	196

Since last December a "reversion prism" has been used to reverse the apparent direction of motion in the observation with lamp right and in that with lamp left on alternate nights.

Clocks.—On Jan. 1 the public clock at the Observatory entrance and the other mean solar clocks were put forward 12 hours so as to show Greenwich civil time, starting at midnight and reckoning from 0h. to 24h., which would correspond with the universal time recommended by the Washington Conference. The change from astronomical to civil reckoning has also been made in all the internal work of the Observatory, and has been carried out without any difficulty. Greenwich civil time is found to be more convenient on the whole for the purposes of this Observatory, but its introduction into the printed astronomical observations has been deferred to allow time for a general agreement amongst astronomers to be arrived at. It is proposed, however, to adopt the civil day without further delay in the printed magnetical results, thus reverting to the practice previous to 1848, and making the time-reckoning harmonise with that used in the meteorological results, the reckoning from 0h. to 24h. being for the future adopted in both cases.

Reflex Zenith Tube.—The observations of γ Draconis for determination of the temperature correction have been continued, and about 45 transits over the 30 wires have been observed at temperatures ranging from 46° to 72°. Seven transits of θ Aurigæ were also observed last February at low temperatures ranging from 42° to 56°.

Equatorials.—The work on the Lassell equatoreal has occupied a great deal of attention during the past year, a number of repairs and alterations having been required in order to get the instrument into proper working order. The driving clock, which was found to drive the instrument at only three-fifths of the proper speed, has been altered, a slow motion in R.A. (to be worked from the observing stage) has been contrived, a new slide of improved construction has been made for gearing the driving-screw into the hour-circle, the teeth of the hour-circle have been re-cut, a firm declination clamp has been applied, an improved edge suspension for the large mirror (consisting of a steel band which encircles the mirror and is supported by brackets at six equidistant points of the circumference) has been contrived, a new and firmer mounting of the small mirror has been made, and the eye-piece has been mounted firmly on a plate which allows it to be tilted in any direction, for optical adjustment. The framed iron base which supports the instrument has been bricked up and filled with concrete, and this, with the other alterations, has greatly increased the stability of the telescope, which is now quite satisfactory. Difficulty is, however, still experienced from want of stability of the optical axis of the large mirror, which requires to be readjusted continually, as the telescope is moved. When the mirrors have been properly adjusted the definition appears to be very good, the companion to Vega being shown with remarkable distinctness without any trace of scattered light from the large star.

The south-east and Sheepshanks equatorials are in good order, as also is the Simms' six-inch equatorial mounted in the south ground.

With one or more of these equatorials, or with the altazimuth, 30 occultations of stars by the moon (19 disappearances and 11 reappearances, including 7 disappearances and 9 reappearances during the lunar eclipse of October 4), and 57 phenomena of

Jupiter's satellites, have been observed in the twelve months ending 1885 May 20, and the observations have all been completely reduced to the end of 1884. Comet (*c*) 1884 has been observed on four nights, the Lassell reflector or one of the other equatoreals being employed, and some measures of distances and position-angle of double stars, as well as a large number of observations for determining the value of 1rev. of the screw in different parts of the field of view have been made with the Airy double-image micrometer mounted on the Sheepshanks' or Simms' equatorial.

Micrometer measures of some of the satellites of Saturn (including Enceladus) were made on seven nights with the Lassell equatorial.

Spectroscopic and Photographic Observations.—The solar prominences have been observed with the half-prism spectroscope on only two days, the photographic reductions having pressed very severely on the spectroscopic assistant during the long continued maximum of sun-spots.

For the determination of motions of stars in the line of sight, 569 measures have been made of the displacement of the F line in the spectra of 47 stars, and 72 measures of the *b* lines in 14 stars, besides measures of the displacements of the *b* and F lines in the spectra of the east and west limbs of Jupiter, and of the east and west ansæ of the rings of Saturn, and comparisons with lines in the spectrum of the moon, or of the sky, made in the course of each night's observations of star-motions, or on the following morning, as a check on the general accuracy of the results for star-motions. The observations of the last twelve months confirm the change in the motion of Sirius, which now appears to be approaching the sun at the rate of about 20 miles a second. As there is great difficulty in the use of a pointer or cross-wires for measuring both the broad dark line in the star's spectrum and the narrow bright comparison line, Mr. Maunder has suggested the use of a reversion spectroscope (on the double-image principle) for these observations, and Prof. Pritchard has kindly lent the reversion spectroscope of the Oxford University Observatory, in order that the suitability of that form of instrument may be tested. The spectroscopic observations of all kinds are completely reduced to the present time.

In the twelve months ending 1885 May 20 photographs of the sun have been taken on 173 days, and of these 431 have been selected for preservation, the record being not so complete as usual, owing partly to the loss of several days during the adjustment of the instrument after the adaptation of the secondary magnifier, and partly to a failure of the supply of dry plates in July last during the absence of Mr. Maunder. There were only two days on which the sun's disk was observed to be free from spots.

The mean spotted area of the sun was slightly less in 1884 than in 1883 and slightly greater than in 1882, whilst the faculæ in 1884 showed a slight increase as compared with 1883, and a slight falling off as compared with 1882. It would seem that the maximum both of sun-spots and faculæ occurred about the end of 1883 or beginning of 1884.

For the year 1884 Greenwich photographs are available for measurement on 152 days, and Indian photographs filling up the gaps in the series on 159 days, making a total of 311 days out of 366 on which photographs have been measured. In 1883 the total number of days was 340, viz., Greenwich series 215 days, supplemented by Indian photographs received from the Solar Physics Committee on 125 days.

Magnetic Instruments.—The following are the principal results for magnetic elements for 1884:—

Approximate mean westerly declination	18°.8′.
Mean horizontal force ...	3·931 (in English units). 1·812 (in Metric units.)
Mean dip	67° 29′ 8″ (by 9-inch needles). 67.29.32 (by 6-inch needles). 67.30. 9 (by 3-inch needles).

In the year 1884 there were only five days of great magnetic disturbance, but there were also about 20 days of lesser disturbance for which it appears desirable to publish tracings of the photographic curves. It may be interesting to add the tracings for a few quiet and nearly quiet days in order to exhibit the characteristics of the ordinary diurnal movement.

Commencing with 1883 the magnetic diurnal inequalities of declination, horizontal force, and vertical force have been discussed by the method of harmonic analysis, the harmonic expressions for these inequalities being obtained for each month and for the year with arguments expressed in apparent solar time as well as in mean solar time.

Meteorological Observations.—The mean temperature of the year 1884 was 50°·7, being 1°·4 higher than the average of the last 43 years. The highest air temperature (in the shade) was 94°·1 on Aug. 11, and the lowest 24°·5 on Nov. 25. The mean monthly temperature was above the average excepting in the months of April, June, Oct. and Nov.

The mean daily motion of the air in 1884 was 286 miles, being 3 miles greater than the average of the last 17 years. The greatest daily motion was 891 miles on Jan. 23, and the least 78 miles on Feb. 8. The only recorded pressure exceeding 20 lbs. on the square foot in 1884 was 22·7 lbs. on Jan. 23, after which the connecting chain of the pressure plate broke, as mentioned in the last report. It is probable that greater pressures occurred afterwards on the same day, and also in the gale of Jan. 26, at which date the chain had not been renewed.

During the year 1884 Osler's anemometer showed an excess of about 25 revolutions of the vane in the positive direction N, E, S, W, N, excluding the turnings which are evidently accidental.

The number of hours of bright sunshine recorded by Campbell's sunshine instrument during 1884 was 1115, which is about 100 hours less than the average of the seven preceding years. The aggregate number of hours during which the sun was above the horizon was 4465, so that the mean proportion of sunshine for the year was 0·250, constant suushine being represented by 1.

The rainfall in 1884 was 18·0 inches, being about 7 inches below the average of the last 40 years.

Chronometers and Time Signals.—The number of chronometers now being tested at the Observatory is 151, and of these 103 (79 box-chronometers, 13 pocket-chronometers, and 11 deck-watches) belong to the Navy, 40 are placed here for the annual competitive trial, and 8 are on trial for purchase by the Austrian Government.

The first six chronometers in the competitive trial of 1884 were rather above the average of the last ten years as inferred from the trial numbers. As much difficulty is experienced in maintaining the chronometer oven at a nearly constant temperature, an apparatus has been procured from Mr. Kullberg which is designed to effect this automatically, by the action of a compensation-bar, which, as the temperature rises, gradually closes a small hole through which the supply of gas to the gas burners passes. The apparatus has not yet been brought into use, as the chronometer oven has been constantly required for testing chronometers since it has been received.

The automatic drop of the Greenwich time-ball failed on 6 days through the clock-train stopping. The ball was not raised on 3 days on account of the violence of the wind.

As regards the Deal time-ball, which is now dropped by current passing through the chronopher of the Post Office telegraphs, there have been fourteen cases of failure owing to interruption of the telegraphic connections, and on one day the current was too weak to release the trigger without the assistance of the attendant.

In connection with the establishment of hourly time signals at the Start or Lizard, which was long advocated by Sir G. B. Airy, I have received from the Committee of Lloyds', in answer to my inquiry, an assurance that that corporation would be willing to undertake the maintenance of hourly time-signals at any of their signal-stations, provided the Government would supply the necessary apparatus. After consultation with Capt. Wharton, it has been thought better that, before taking further steps, some preliminary trials should be made of a collapsible cone as an hourly time-signal, facilities for doing which exist at Devonport. As regards ball-drop or other time-signal, I would propose that it should be made automatically by a local clock, to be corrected daily by the help of a time-signal from Greenwich at 10 a.m., which should automatically start an auxiliary seconds pendulum, suspended freely just behind the clock pendulum. The attendant would then accelerate or retard his clock pendulum (by electro-magnetic action as in the Greenwich mean solar clock) so as to make it pass through the middle of its vibration at the same time and in the same direction as the auxiliary pendulum, and thus to indicate accurately Greenwich mean time. A return signal to Greenwich sent by the local clock at the next hour (11 A.M.) would show that this clock had been properly corrected, and would be a guarantee for the general accuracy of the time-signals. Preliminary trials have shown that the observation of coincidence of vibration of two pendulums can be made with great certainty, and Messrs. E. Dent and Co. are now arranging for the mounting of an auxiliary pendulum on one of the transit of Venus clocks, and for adapting it to give hourly time-signals.

The errors of the Westminster clock have been under 1s. on 50 per cent. of the days of observation, between 1s. and 2s. on 29 per cent., between 2s. and 3s. on 10 per cent., between 3s. and 4s. on 7 per cent., and over 4s. on 4 per cent.

During the past year the Observatory has lost the valuable services of Mr. Dunkin, who retired on August 25, after an honourable service of forty-six years, which has been throughout characterised by remarkable zeal and ability, and has contributed largely to maintain the credit of the Observatory. Mr. Dunkin has been succeeded in the post of Chief Assistant by Mr. H. H. Turner, B.A., of Trinity College, Cambridge.

The report concludes as follows:—

During the past year the various classes of work carried on in this Observatory have been somewhat extended. The meridian observations are more numerous than usual, and various subsidiary investigations involving considerable labour have been undertaken with a view to increase their accuracy. A large number of spectroscopic determinations of star-motions have been obtained, and the long continued maximum of sun-spots has made the photographic measurements and computations much heavier than in any previous year. Extensions have also been made in the magnetic and meteorological branch, which appeared very desirable, but which have pressed rather severely on Mr. Ellis and his staff.

Turning to the future, I wish to invite the attention of the visitors to the circumstance that an increase in our optical means is required to enable us to carry out satisfactorily the determinations of proper motions of stars in the line of sight with the spectroscope, a work which peculiarly belongs to this Observatory, as supplementing the determinations of proper motions from meridian observations.

The aperture of our largest refractor (12⅘ inches) is too small to allow of our observing successfully with the spectroscope any but the brightest stars, and though the Lassell reflector is somewhat more powerful, its mounting and clock-work are not adapted to carry a heavy spectroscope with the necessary steadiness and accuracy of motion. The firmness of the mounting of the south-east equatorial and the perfection of its clock-work would make it peculiarly suitable for this class of work if it carried a much larger object-glass.

After careful consideration of the conditions I have satisfied myself that an object-glass of 28 inches aperture and of 28 feet focal length could be mounted on the south-east equatorial, in place of the present object-glass of less than half that aperture; and I have ascertained that Mr. Grubb would be prepared to undertake the construction of such an object-glass with a tube suited to the special requirements of the case, so that the telescope would be equally available for eye-observation or for use with the spectroscope. With Mr. Grubb's assistance, I have prepared a model showing how this may be arranged.

While a large refractor is required specially for spectroscopic observations, it seems desirable also on other grounds that this Observatory should possess an equatorially mounted telescope comparable with those of other first-class observatories, so that we may no longer be prevented by deficient optical means from obtaining complete series of observations of comets and faint satellites.

VIVISECTION

A RETURN has been issued by the Home Office containing the reports of inspectors showing the number of experiments performed on living animals during the year 1884 under licences granted according to the Act 39 and 40 Victoria, c. 77, distinguishing painless from painful experiments.

The former of the two reports deals with England and Scotland, the latter with Ireland. They are as follows:—

"(1) The names of the 49 persons who held licences during any part of the year are given in the subjoined tables, in one of which are entered the names of those licensees who performed any experiments, 34 in number; and, in the other, the names of those who performed none.]

"(2) The total number of experiments of all kinds performed during the year was about 441.

"Of these, 140 were done under the restrictions of the licence alone, 78 under the same restrictions, but under certificates in column 1 (lecture illustrations); 145 under certificates in column 2; 76 under those in column 3; and 2 under a certificate in column 4.

"(3) With regard to the infliction of pain, as in all the experiments, except those under special certificates in columns 2, 3, and 4, the animals are rendered insensible during the whole of the experiment, and are not allowed to recover consciousness, no appreciable suffering would be caused if the provisions of the Act are faithfully carried out, as there is not the least reason to doubt they were.

"With respect to experiments under certificates in columns 2, 3, and 4, which dispense either wholly or partially with the use of anæsthetics, it should be stated:—

"(*a*) That of the 145 experiments performed under certificates in column 2, 99 consisted in simple inoculation with a morbid virus, in which no operation beyond the prick of a needle was required, and for which the administration of an anæsthetic would only have entailed needless annoyance and distress to the animal. In these experiments any appreciable suffering would be felt only in those cases in which the inoculation took effect, involving about the same amount of pain as ensues on ordinary vaccination, before the brief period the animals were allowed to survive. Of such cases, according to the returns I have received, about 16 occurred. Of the remaining 46 experiments under these certificates, 24 were performed for the purpose of medico-legal inquiries in cases of suspected poisoning, resulting in the death by tetanus of three frogs and six mice, which survived, however, only a few minutes; 10 other cases under the same head were experiments on the infection of fish with a species of fungus, very destructive in certain rivers and streams; and five on the effects of immersion of fish in distilled water, which proved fatal to about thirty minnows and sticklebacks. In none of these cases could it be said that any appreciable suffering was inflicted. In seven cases, in which salts of ammonia were hypodermically injected, two are returned as having suffered pain, but of a very trifling character.

"(*b*) Of the 76 experiments under certificates in column 3, 47 required a simple operation, but this being done under anæsthesia, was unfelt, and the after-effects, though in many of the cases resulting in partial paralysis, are reported as having been unattended with actual pain in any case. The remaining 29 were by simple inoculation, and none were attended with pain.

"(4) In conclusion, therefore, it may be stated that the amount of direct or indirect actual suffering, as the result of physiological and therapeutical experiments performed in England and Scotland, under the Act in the year 1884, was wholly insignificant. "GEORGE BUSK, Inspector

"The Right Hon. the Secretary of State."

"16, Harcourt Street, Dublin, May 17

"SIR,—In accordance with your instructions I beg to submit the following table, showing the licences in force in Ireland during the year 1884 under the Act 39 and 40 Vict., c. 77. No certificate has been allowed during the year.

"Several of the licences in force during the previous year have expired, and renewals have not been sought for.

"Under the licences in force thirteen experiments have been made; they were all painless. I am of opinion that the experiments in question were useful ones; eleven of them were intended to elucidate the actions of drugs, and the remaining two to assist the investigation of certain circulatory phenomena which have a bearing upon the treatment of disease.

"I have, &c.,
"W. THORNLEY STOKER

"To the Right Hon. the Chief Secretary for Ireland."

In each case the report is followed by a list of all persons who hold such licences, the places where they are permitted to make experiments, and the nature of the certificate held.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The Annual Report of the Museums and Lecture-Rooms Syndicate, recently published, contains the reports of all the professors, lecturers, and heads of departments connected with natural science.

Prof. Thomson (Cavendish Professor of Physics) reports that during the Lent term ninety students attended the demonstrations, and there were ten persons doing original work in the laboratory. Lord Rayleigh states that during the last five years about 2500*l*. has been spent on the Cavendish Laboratory in addition to the University expenditure. This has come partly from fees, partly from the apparatus fund raised by subscription.

The Chemical Laboratory has been much over-crowded and improvements are scarcely possible until the new laboratory has been completed.

The register of the mineralogical collections is completed. The number of students increases; fifteen attended Mr. Solly's demonstrations in the Michaelmas term and nineteen in the Lent term.

The department of mechanism has continued to grow rapidly. During the year two new woorkrooms and a new foundry have been added and have met the most urgent requirements. Upwards of 1000*l*. worth of new machinery has been added at Prof. Stuart's expense during the last two years to meet immediate wants; and during that time the pupils have doubled in number. The lecture-rooms have become over-crowded, and new ones are much wanted. Prof. Stuart urges that the University should now purchase the machinery and apparatus used in teaching, which is his property. The undertaking is now wholly self-supporting, paying interest on the capital involved, and providing an adequate sinking fund.

The classes of practical morphology and elementary biology are now much better accommodated in the new rooms. One hundred Zeiss's microscopes have been purchased. The Balfour library has been enlarged, and proves of great value to students. Seven demonstrators have been fully occupied in the classes, in addition to two ladies who have superintended the women students. In the May Term, 1884, in which two years of students were combined, 206 men and 12 women went through the course of elementary biology. In the Lent term of 1885, 128 men and 7 women attended. In Elementary Morphology there were 68 students in last October term, and 87 in the recent Lent term.

Prof. Macalister has utilised the services of seven assistant Demonstrators, in addition to Mr. Hill, whose labour has been unremitting. Subjects for dissection have been secured from a wide area. Prof. Macalister has presented a series of models of the viscera of the body showing their proper relative positions, casts of frozen sections, 26 crania, and 160 specimens of bones showing peculiarities. No department of University work is so badly housed as the Department of Anatomy; but much good work is done in the limited space.

In the Museum of Comparative Anatomy and Zoology 72 additional species from Dr. Dohrn's collection have been remounted and displayed. An extensive collection of marine invertebrata from the New England coast has been forwarded from the National Museum at Washington, through the kind offices of Prof. Baird. The work of the Curator in Invertebrate Zoology has been principally expended upon the MacAndrew collection of shells. Mr. Cooke has published two extensive papers, and progressed with the rectification of the nomenclature and the catalogue.

A fine adult Echidna from New Guinea has been presented by Dr. Guillemard. Both skin and skeleton have been mounted. A complete skeleton of the red deer in a sub-fossil state has been procured from Burwell Fen by Mr. W. Stubbings, Assistant in the Museum; a complete skeleton of an African elephant, shot by Mr. W. Heape near Port Elizabeth, has been presented. Many other interesting acquisitions are named in the report.

Dr. H. Gadow, the Strickland Curator, has been forming a manuscript catalogue of the skins of birds in the Museum. An exhibited series of specimens is being placed systematically, with the important anatomical parts, nests and eggs, in an educational series. Twenty maps have been placed in the cases to illustrate the geographical distribution of birds. The University collection now consists of 9653 specimens of 3290 species. The Strickland collection, in addition, contains 600 specimens of 3125 species; and, with Mr. E. Newton's collection, there are in all 17,000 specimens, representing probably 4500 species.

Prof. Foster reports that the number of students of elementary physiology has risen from 77 in the Easter term, 1884, to 141 in the recent Lent term, exclusive of women students. Twenty-eight have attended advanced lectures also. Several important additions, such as a gas-engine, a centrifugal machine, recording and other apparatus, have been made to the Laboratory, by the aid of a gift of 500*l*. by an anonymous donor. The inadequacy of accommodation, both for practical work and for lecturing, is severely felt.

Prof. Ray has been successful in organising extended practical courses, as well as systematic lectures. The *post-mortem* examinations at Addenbrooke's Hospital have been placed under his superintendence. At present the only laboratory space available is obtained by encroaching on Dr. Foster's already overcrowded rooms.

Prof. Babington reports that the arrangement of the general Herbarium is now complete. The plants have been placed in orders and genera, according to Bentham and Hooker. The arrangement of species has not as yet been attempted. Mr. Potter and Mr. Gardiner have commenced the formation of a small Botanical Museum similar to that of Comparative Anatomy. Mr. Vines finds the new rooms very suitable both for class purposes and for research. Last term there were 29 advanced and 30 elementary students working in the laboratory.

The Geological Museum has acquired a fine collection of fossils from the Oolites of Dorset, chiefly by the liberality of Prof. Henry Sidgwick. Messrs. Roberts and Small brought useful additions from the Jura. Mr. Marr has added largely to the Cambrian and Silurian series. Mr. Keeping has collected and restored many specimens from Pliocene and Pleiostocene deposits. Mr. J. Robarts has worked most energetically as Prof. Hughes' assistant, in the museum, in teaching and collecting. Work is much hindered by the want of a lecture room and class-room.

Mr. Walter Gardiner, whose original work in vegetable histology is so well known, has been elected to a Fellowship at Clare College.

SOCIETIES AND ACADEMIES

London

Royal Society, May 6.—"On charging Secondary Batteries," by William Henry Preece, F.R.S.

Mr. Preece said he had for some months past been experimenting with secondary batteries with a view of getting an efficient, uniform, and constant source of current for electric lighting his house. The cells are of the Planté type, manufactured by the Elwell Parker Company of Wolverhampton. Each cell contains fourteen plates of plain sheet lead 17" × 11", which are suspended in well-insulated wood boxes filled with diluted sulphuric acid in the proportion of about 1 to 19. These plates are grouped in two groups of seven, each group being soldered to a lead strip, forming alternately the positive and negative poles of the cell. The plates of the respective poles are prevented from touching each other by ebonite grids or separators introduced by Mr. Charles Moseley to prevent short-circuiting through the buckling of the plates. Each plate offers a surface of 1·3 square feet, so that the total surface of lead of each group opposed to each other is 9·1 square feet; that is, 9·1 square feet of peroxidised lead is opposed to 9·1 square feet of spongy lead. Mr. Preece employs 24 of such cells. The charging current varies from 3 to 3½ amperes per square foot, while the current of discharge used in lighting his house varies from 1 to 1½ ampere per square foot. The total weight of each cell is 120 lbs. The plates are prepared by the Parker-Planté process before insertion in the cell, those forming the positive pole being well peroxidised, while those forming the negative pole are well coated with spongy lead. This process consists in immersing for a few hours the lead plates in a solution of nitric and sulphuric acids in the proportions—

Nitric acid	1
Sulphuric acid	2
Water	17

before fixing in the cells. This not only chemically cleans the lead surfaces, but it favours the formation of sulphate of lead in such a way as to be readily converted into lead peroxide and spongy lead on the passage of a strong current through the cells. The formation of the cells is thus expedited. They are thus, when put together, prepared at once to be charged. If they are not at once charged, local action sets in, and lead sulphate is injuriously formed.

A hydrometer, having a scale graduated from 1·050 to 1·150, is used to indicate the density of the liquid while the cells are being charged and discharged. Mr. Preece puts into his battery a charge of about 120 ampere-hours twice a week. Hourly measurements of E.M.F. current and density of liquid have enabled him to know the condition of his battery at any period of charge or discharge. These measurements have been plotted out into curves, the ordinates showing volts, amperes, and specific gravity, and the abscissæ hourly observations. When each magnitude reaches its constant, bubbles of gas are freely given forth and energy is being wasted. The variation of the electromotive force and current strength is clearly due to the counter-electromotive force of the cells, which becomes a maximum only when the plates are fully formed. The counter-electromotive force partakes of the character of a higher resistance opposing the charging current, and increasing the proportion of the current through the shunt of the dynamo. Hence the changes of electromotive force are more marked than those of the current. Indeed, the changes in the electromotive force, as given by the voltmeter, are sufficient alone to indicate the progress and completion of the charge. They are more reliable than the evolution of gas.

The electrical leakage of Mr. Preece's cells is obviated by standing each cell on three porcelain supports, having cups half filled with resin oil on Messrs. Johnson and Phillip's plan.

Mr. Preece gives the E.M.F. of the battery at its terminals as—

When charging	2·25 per cell
When idle...	2·05 ,,
When discharging	1·90 ,,

and the internal resistance per cell as—

When charging	·0060 ohm
When discharging	·0017 ,,

But the latter is said to vary very markedly within the strength of current of discharge. This is shown by the following experiment, made with 23 cells of a smaller type than those described above, which are used in the Post Office :—

Current of discharge in amperes	Internal resistence in ohms
4·39	0·7608
7·25	0·4607
15·84	0·2816
25·07	0·1969

Thinking that this remarkable diminution of internal resistance might be due to the evolution of heat, Mr. Preece measured the temperature with a delicate thermometer.

Normal temperature of cell 12½° C. current of discharge :—

5 amperes	No alteration of temperature perceived
10 ,, ...	An exceedingly slight change
16 ,, ...	About 12¾°
20 ,, ...	Barely 13°

The current in each case was kept on for twenty minutes, hence the diminution, Mr. Preece says, is not due to heat.

Since the internal resistance varies in this way Mr. Preece now always takes the internal resistance with the same current, viz., 10 amperes.

The author of this paper asserts that the capacity of these batteries certainly improves with age, and up to the present time he has seen no sign of decay or deterioration.

M. Planté informed him that, though in course of time the peroxidised plate becomes very brittle, it is impossible to peroxidise it completely through ; there always remains a metallic core to give it strength. Mr. Preece finds that this is so. Up to the present moment he has made no careful measurements of the efficiency of his battery. He puts in about 240, and takes out about 200 ampere-hours weekly, and does not observe any change or fall in the electromotive force. When the electromotive force of these cells falls, it falls rapidly, indeed almost suddenly. Occasionally one plate of a group becomes inactive from undue local action, or from bad connection (shown by the colour). This plate is removed and put in a "hospital" cell, where it is brought into order either by a greater density of current or by reversal.

Reversing has a great beneficial action on a cell ; it not only improves its capacity, but it removes any cause of irregular working. It is advisable to do this periodically. Mr. Preece has two extra cells, which enables him to have two cells always under reversal by means of the charging current. It takes from 1,000 to 1,200 ampere-hours to reverse a cell, so that at this time of year it takes a month or more to complete the operation, and it will take a year to reverse the whole battery. Sixteen cells have been reversed during the past twelve months.

Chemical Society, May 21.—Dr. Hugo Müller, F.R.S., President, in the chair.—Messrs. E. G. Amphlett and E. G. Hogg were formally admitted fellows of the Society.—The following papers were read :—A colorimetric method for determining small quantities of iron, by Andrew Thomson, M.A. —On some sulphur compounds of calcium, by V. H. Veley. —Spectroscopic observations on dissolved cobaltous chloride, by Dr. W. J. Russell, F.R.S. The characteristic absorption-spectrum given by cobaltous chloride after dissolution in such media as pure and dry potassium chloride, sodium chloride, calcium chloride, alcohol, glacial acetic acid and in chlorhydric acid, is seen also in an aqueous solution. Hydrated cobaltous chloride gives an entirely different spectrum. If a somewhat faint indication of the spectrum of the chloride be taken as a standard, it is found possible to determine with tolerable accuracy when the amount of anhydrous chloride in solutions of varying strength and temperature is identical with that in the standard solution. A solution containing 4·18 grams of cobalt chloride in 10 c.c. of water at 0° C., when observed through a thickness of 7 mm., forms a convenient standard. If to 10 cc. of such a solution 2·9 cc. of water be added, then on raising the temperature to 33° an amount of anhydrous chloride is re-formed identical with that existing in the standard solution at 0° : this rise of temperature exactly counteracts the effect of adding 2·9 cc. of water. A series of determinations were made in this manner, and it was found that the number of c.c. of water added to the 10 cc. of standard being as given in the upper line, the temperature at which the spectrum appeared was as given in the lower line in the table :—

2·1		2·9		4·3		7·4		8·9
26°		33°		43°		55°		63°
	10·3		12·1		15·0		16·0	
	70°		75°		87°		95°	

Again, taking the most dilute solution, in which 16 cc. of water had been added to 10 c.c. of the standard solution, it was found that the same change was effected—*i.e.* that the chloride spectrum could be developed in it, by the addition to the solution of either 0·864 gram of hydrogen chloride gas. or 5·26 of sulphuric acid, or 2·47 of calcium chloride ; but that the addition of sodium chloride would not develop the bands, although on heating the solution after saturating it with this salt a temperature of 34·5° was sufficient, instead of 95°, to develop the bands. Zinc chloride was found to act in a different manner. Notwithstanding its power of combining with water, on adding it to the cobalt solution no banded spectrum shows itself, and even when added to a solution in which the spectrum is visible it causes its disappearance. The explanation is that it must have combined with cobalt chloride, forming a new and stable compound. On evaporating the solution this was found to be the case, and a new salt, a compound of cobalt and zinc, crystallised out. Cobalt bromide, both as a solid and in solution, gives a spectrum very similar to that given by the chloride, but the corresponding bands are nearer the red end of the spectrum. The salt is far more soluble in water than the chloride, and has a stronger affinity for water, as is shown by the much higher temperature required to neutralise the power with which water combines with it. The following determinations similar to those made with the chloride show the increase of temperature necessary to counteract the combining power of giving quantities of water with cobalt bromide :—

Standard 10 c.c.	+	Water	Temp. 0° C.
10 ,,	+	3·0	51
10 ,,	+	4·3	57
10 ,,	+	7·4	91

—The sulphides of titanium, by Prof. T. E. Thorpe, F.R.S.—Note on the formation of titanous chloride, by Prof. T. E. Thorpe, F.R.S.

Zoological Society, June 2.—Prof. W. H. Flower, V.P.R.S., President in the chair. Mr. Sclater exhibited drawings of and made remarks upon the specimens of various species of Coly living in the Society's Collection. Mr. Beddard, on behalf of himself and Mr. Treves, read a paper on the anatomy of the Sondaic Rhinoceros (*Rhinoceros sondaicus*) which had died in the Society's Gardens in January last. A communica- was read from Dr. Julius von Haast, F.R.S., C.M.Z.S., on *Megalapteryx hectori*, an extinct gigantic representative of the *Apteryx*, of which the remains had recently been discovered in New Zealand. Dr. Guillemard, F.Z.S., read the fourth and fifth parts of his report on the collection of birds formed during the voyage of the yacht *Marchesa*. The present communications treated of the birds collected at Celebes and on the Molucca Islands. Mr. J. Bland Sutton, F.Z.S., read a paper on the development and morphology of the human sphenoid bone, in which he attempted to show that the basi-temporals of the bird are not homologous with the *lingulæ sphenoidales*, but with the so-called pterygoid bones of the crocodile, and that the human *lingulæ* are homologous with the sphenotic of the bird.—Mr. Edgar A. Smith, F.Z.S., read a report on a collection of shells, chiefly land and fresh water, obtained by Mr. H. B. Guppy, R.N., Surgeon H.M.S. *Lark*, during a recent visit to Solomon Islands.

Paris

Academy of Sciences, June 2.—M. Bouley, President, in the chair.—Human locomotion: stereoscopic images of the trajectories described in space by a point of the body while walking, running, or otherwise moving (two illustrations), by M. Marey.—Remarks on the "Registres d'expérience," a collection of sixty-nine volumes in MSS. by Henry Victor Regnault, dealing with a great variety of questions in chemistry, physics, thermodynamics, hygrometry, &c., presented to the Academy by M. Reiset.—On the treatment of nervo-pulmonary asthma and cardiac asthma by inhaling certain vapours all containing a special substance known as pyridine (C_5H_5N), by M. Germain Sée.—Account of a species of anæsthesia unattended by sleep, and with the perfect preservation of the intellect, the voluntary movements, the senses and sensibility to the touch, by M. Brown-Séquard. From numerous experiments made on the dog, monkey, and man, the author shows that, under the influence of an irritation set up in the laryngeal mucous membrane, sensibility to pain may disappear or be diminished for many hours without the least disturbance of the mental faculties, the senses, or the voluntary movements in man and animals.—Remarks on M. Lucien Biart's work on "The Aztecs, their History, Manners, and Customs," presented to the Academy by M. de Quatrefages. It was stated by the Secretary that this volume forms one of a series entitled "The Ethnological Library," to be edited by MM. de Quatrefages and Hamy, and to comprise, besides a general history of the races of mankind, a number of monographs devoted to the detailed study of the various branches of the human family.—Observations of the solar spots, faculæ, and protuberances made at the Observatory of the Roman College during the first quarter of the year 1885, by M. Tacchini. Compared with the corresponding period of the previous year the spots appear to have been more numerous, but of relatively smaller size, while little difference was observed in the recurrence of the faculæ. The same peculiarity was again noted of a maximum of faculæ coinciding with a minimum of spots.—Remarks on the physical appearances of the planet Uranus in the months of March, April, and May of the present year, by Père Lamey.—On a method of measuring the magnetic rotatory force of solid, fluid, and gaseous bodies in absolute unities, by M. Henri Becquerel. The numbers determined in various ways by other observers correspond very closely with that of the author as shown by the subjoined table:—

Gordon	0'·0433
Lord Rayleigh	0'·0430
L. Arons	0'·0439
Becquerel	0'·04341

—An optical method for the absolute measurement of short distances, by M. Macé de Lépinay.—On the spectrum of bodies in "radiant matter," in which many substances emit a phosphorescent light, by M. W. Crookes.—On the velocity with which prismatic sulphur is transformed to octahedric sulphur, by M. D. Gernez.—On the presence of sulphurous acid in the atmosphere of towns, by M. G. Witz. From the analysis of the ozone made at Montsouris and elsewhere the author finds that sulphurous acid exists in the air of towns where coal is consumed, its presence causing a considerable diminution of atmospheric ozone, accompanied by the formation of sulphuric acid; further, that by the slow but continuous action of sulphurous acid, and under the influence of the frequent changes in the degree of humidity, the peroxide of red lead used in colouring certain placards, is destroyed and sulphated. At the same time the protoxide of lead thus liberated is transformed to an insoluble sulphite. This salt being easily analysed, a new and certain means is thus obtained for determining the condition of the atmosphere in large cities.—The arsenic present in the soil of cemeteries considered from the toxicological standpoint, by MM. Schlagdenhauffen and Garnier.—Classification and anatomy of the Tectibranchea, a family of mollusks abounding in the Bay of Marseilles, by M. A. Vayssière. Of this family twenty-two species are grouped under the sub-order Cephalaspidea, six under Anaspidea, and nine under Notaspidea. All belong to the order of Opistobranchea, the exceptions indicated by Hering being based on erroneous data.—On the spores and reproductive processes in *Sphærocarpus terrestris*, *Targionia hypophylla*, and other plants of the same order, by M. Leclerc du Sablon.—On the problem of repetitions and symmetry in the mineral kingdom (one illustration), by M. P. Curie.—On an apparatus adapted for the comparative study of opaque minerals, which cannot be easily examined under the microscope, by M. A. Inostrauzeff.—On a unique specimen of hydrous silex belonging to the quaternary formation of the Loing Valley, department of Seine-et-Marne, by M. Stan. Meunier.—On the upper Miocene formations of the Cerdagne district, a lacustrine basin on the southern slope of the Eastern Pyrenees, by MM. L. Rérolle and Ch. Depéret.—Description of a self-registering calorimeter adapted for recording the temperature of the human body, three illustrations, by M. A. d'Arsonval.—On electric alcoholic fermentation, by M. Em. Bourquelot. From his experiments the author finds that this fermentation, as originally determined by Dubrunfant, may be modified by the temperature, by dilution, and by the alcohol formed during the fermentation itself.—On the uniformity of the process of spermatogenesis in the order of mammals, by M. Laulanié.—Action of cocaïne on the invertebrate animals, by M. Richard.—A contribution to the study of antiseptics: action of the antiseptics on the higher organisms, iodide and chloride of mercury, by MM. A. Mairet, Pilatte, and Combemal.—Influence of the lunar declinations on the displacement of the atmospheric currents, a reply to M. de Parville, by M. A. Poincaré.

BÜTSCHLI'S "PROTOZOA"

Bronn's Classen und Ordnungen des Thierreichs. New Issue. (Leipzig: C. F. Winter, 1883-4 5.)

THE important work on the lowest division of the animal kingdom which Prof. Bütschli, of Heidelberg, has undertaken for the publishers of the well-known series of zoological treatises originated by the late Prof. Bronn, is so far advanced as to enable us to form some estimate of its merits and to call for an extended notice. The separate parts of Prof. Bütschli's work which have appeared at intervals during the last two years have now accumulated so as to form a large octavo of 900 pages and 50 plates. The whole of the Protozoa have been discussed with the exception of the Ciliata, the Dino-flagellata (formerly called Cilio-flagellata), and the Acinetaria. The work does not comprise in its scope the Mycetozoa, which should, in the opinion of the present writer, be included in the animal kingdom. This is the less to be regretted, since an excellent work on this group has been recently published by Dr. Zopf, of Berlin, in the "Encyklopädie der Naturwissenschaften," and may be obtained separately of the publishers, Trewendt, of Breslau.

That the Mycetozoa are to be considered as animals rather than as plants is the opinion of no less an authority than the botanist De Bary, who has done more than any other observer to elucidate their life-history and structure.

Bütschli divides the Protozoa into classes as follows—the Sarkodina, the Sporozoa, the Mastigophora, and presumably the Ciliata and the Tentaculifera, though of the last two he has not yet written.

The Sarkodina are divided into the sub-classes Rhizopoda, Heliozoa, and Radiolaria.

The class Sporozoa contains the sub-classes Gregarinida, Coccidia, Myxosporidia, and Sarcosporidia.

The Mastigophora are grouped in sub-classes as Flagellata, Choanoflagellata, Cystoflagellata, and Cilioflagellata (now altered to Dinoflagellata).

Each of the sub-classes is treated of in turn in the thoroughly systematic and comprehensive manner which the readers of Bronn's "Thierreich" know so well and have so long appreciated. The treatment commences with a "Historical Review of the Development of our Knowledge of the Sub-class," which is no formal repetition of familiar commonplaces, but a really critical statement of the share contributed by various earlier naturalists to the building up of our present conceptions on the subject. This is followed by a wonderfully complete list of memoirs and papers relating to the group—under the heading "Literature." We have in many instances tested the completeness of these lists, and have found that even short papers in obscure periodicals which happen to contain facts of real importance have been duly hunted up and recorded by Prof. Bütschli.

Then follows a "Short Survey of the Morphological Characteristics of the Sub-class and its Chief Divisions," and after this each prominent morphological factor is taken separately and its variations in the group very thoroughly discussed, references being given to the widely scattered writings of the numerous microscopists who have advanced this or that view or added this or that quantum of fact to our knowledge. Thus in the portion of the work relating to the Rhizopoda we find—

(1) The shell-structure of the Rhizopoda. A. Material of the shell—(*a*) chitinous shells; (*b*) calcareous shells; (*c*) shells built up of foreign particles; (*d*) siliceous shells. B. The morphological structure of the Rhizopod shell—(*a*) homaxonic shells; (*b*) monaxonic shells; (*c*) polythalamous shells; (*d*) abnormal shell-formation.

(2) The structure of the soft body of the Rhizopoda—(*a*) general characters of the soft body; (*b*) properties of the protoplasm of the Rhizopod-body in general; (*c*) differentiation of the protoplasm into special zones or regions; (*d*) coloration of the protoplasm; (*e*) peculiar bodies enclosed by the protoplasm, namely, non-contractile vacuoles, gas-bubbles, and peculiar products of metabolism, contractile vacuoles, nuclei; (*f*) pseudopodia, movement and inception of nutriment in the Rhizopoda; (*g*) gelatinous investment of the soft body.

(3) Relation of the soft body to the shell and formation of the shell by the soft body.

(4) Reproductive phenomena, colony-formation, and encystment of the Rhizopoda—(*a*) reproduction by simple division or budding; (*b*) colony-formation in connection with the division or budding of the Rhizopoda; (*c*) encystment in connection with or without reproduction; (*d*) copulation and conjugation in the Rhizopoda; (*e*) review of the attempts made to prove the existence of a sexual reproduction in the Rhizopoda.

(5) Biological relations of the Rhizopoda—(*a*) habitat; (*b*) nutrition; (*c*) dependance on external life-conditions.

(6) Taxonomy of the Rhizopoda—(*a*) historical development; (*b*) review of the system of the Rhizopoda, with brief characterisation of the divisions, inclusive of genera.

(8) Geographical distribution of the Rhizopoda.

(9) Palæontological development of the Rhizopoda.

This exhaustive discussion of the Rhizopoda occupies about 250 pages and 13 plates, in which the most important forms are figured: the figures being selected from all sources, and showing not only shell-structure but all that is known with regard to the protoplasmic body.

In the same thorough manner the subsequent groups of Sarkodina, of Sporozoa and Mastigophora are dealt with.

One point, however, to which we have not yet alluded gives Prof. Bütschli's work an altogether exceptional value. From what we have hitherto said it might appear that the work is simply a well-digested and critical survey of other men's work. This is not the case; the discussion of each group possesses a special value and importance from the fact that Prof. Bütschli has made very extensive researches himself in regard to the Protozoa, and has especially given attention to doubtful points, so that he is able to speak with the authority of a specialist in nearly every case. Portions of these researches, for instance those on the Radiolaria, on the Gregarinida and Myxosporidia (Psorosperms), and on the Flagellata have been already published from time to time during the past five years by Prof. Bütschli in various scientific journals. They have everywhere excited the greatest interest and have been recognised as most important additions to knowledge. In the present work they appear in due place aad enable Prof. Bütschli to give a decisive opinion upon many points on which authorities have hitherto differed. Many of the illustrations in the admirably engraved plates are also original.

We may perhaps remind our readers that it is to Prof. Bütschli that we owe the first important paper in the recent development of our knowledge of the karyokinetic figures of dividing cell-nuclei. It is his investigation which demonstrated the identity of the changes in the nuclei of Ciliate Infusoria with the curious fibrillation of normal tissue-cells when in course of division, and more than any others have given a wide basis to the recent generalisations on this subject.

Our author is not only extremely fair and scrupulous in citing all discoverable authorities for the facts which he sets forth as to the structure, &c., of Protozoa (our English microscopists of all ranks will find themselves cited and fairly considered), but he exhibits admirable judgment, temper, and caution in his treatment of vexed questions. He has wisely withheld his full discussion of the classification of the Radiolaria until such time as Haeckel's *Challenger* work on the group is published. In the meantime his analysis of the various forms of skeleton which occur in that group is a masterly essay on a very difficult subject.

With regard to the question of the chlorophyll corpuscles of some Protozoa—considered by Brandt as parasitic Algæ—we gather that Prof. Bütschli leans to the acceptance of that view; but we shall look for a more definite judgment from him in relation to that question when he has to discuss such forms as the Ciliata, *Stentor*, *Bursaria*, and *Ophrydium*.

It is noteworthy that Prof. Bütschli includes the Volvocina and the "Protococcus" forms in the Flagellata, being convinced of their relationship here in spite of their "holophytic" nutrition.

It would be impossible here to point out the numerous new views of importance which are advanced in Prof. Bütschli's work. It must be sufficient to say that the book is absolutely invaluable to every student of microscopic life, and is perhaps the most remarkable attempt yet made by a distinguished original observer to coordinate and render available for use the entire series of works of his predecessors in a large and important field of study.

E. R. LANKESTER

PHÆNOLOGY

Resultate der wichtigsten pflanzen-phänologischen Beobachtungen in Europa, nebst einer Frühlingskarte. Von Dr. H. Hoffmann, Professor der Botanik in Giessen. Anhang, Dr. Egon Ihne, *Die Norwegischen, Schwedischen, und Finnländischen Beobachtungen.* (Giessen: J. Ricker'sche Buchhandlung, 1885.)

THIS work, the results of forty years' labour, forms a most important contribution to the literature on the subject of phænology.

The work begins with an introduction, in which is explained the importance of phænological observations, particularly with regard to comparative climatology and biology. Then follows an investigation of the degree of accuracy to be obtained by this kind of observation, succeeded by a discussion as to how many years such observations ought to be continued for obtaining useful and trustworthy information for comparative investigation. A table is then given of those plants and their phases which the author, after forty years' observations, thinks the most proper for adoption with a view to international reception. The number is fifty-three, and they are arranged according to the calendar, to facilitate observation; which system appears with regard to accuracy preferable to an alphabetical arrangement.

A short notice follows of the most important general results of the work with respect to climatology and biology, abstracted from the observations from the whole of Europe. At the end of the introduction the author points out the next tasks for phænological researchers.

The remainder of the book contains an alphabetical list of all phænological stations throughout Europe (about 2000), with the geographical situation and elevation above sea-level. Under each station are given in an alphabetical arrangement the mean dates of the simple phases known from the place, with the number of years of observation.

It is to be seen that from a great number of these but one or two years' observations have been published, whereas others extend to above thirty years. These dates are to be employed for comparing any single place with all the others. The mean dates are given as completely as possible, because such comparisons are the chief object of the author for publishing this work. They are extracted and calculated from a vast number of lists published in a great many periodicals and works of all nations.

With regard to spring flowers, the author himself has followed the plan of comparisons, giving under each station an indication of the number of days the single species open their flowers, sooner or later than at Giessen, the residence of the author, from which place, generally speaking, the most comprehensive observations have been published. In a "spring map" of Europe at the end of the book the results of these investigations are entered, by which the mean progress of spring through different countries may be seen at a glance.

OUR BOOK SHELF

Louis Pasteur, his Life and Labours. By his Son-in-Law. Translated from the French by Lady Claud Hamilton. (London: Longmans, Green, & Co., 1885.)

THE name of M. Pasteur, owing to his many brilliant and eminently practical discoveries, has been for some years so prominently before the general public that a popular and connected account of his life and labours cannot fail to be interesting and instructive reading to every educated member of the community. In this respect the present volume must be considered a signal success and a valuable addition to popular scientific literature. But the importance of the book reaches a step further, for it gives to the scientific world an authentic account of the development and progress of M. Pasteur's discoveries, since it is written by one who has been and is still living with M. Pasteur in the bonds of intimate friendship, and who has received his information directly from M. Pasteur himself. While to the general reader the achievement of a discovery is the only and great point of interest, to the scientific reader it is only one of many, the history of a discovery being one of them, and not the least important one, for it reveals methods and manner, and it gives us a true insight into the working of the mind, more so than the contemplation of the actual results. Looking at the book in this sense, we must consider it of inestimable value to every worker in the same field of research.

The many and great researches of M. Pasteur—amongst which may be mentioned his discoveries that every one of the many kinds of fermentations depends on the growth and activity of a definite and specific microbe; his long-continued controversy and final refutation of the doctrine of spontaneous generation, his immensely practical discoveries on the silkworm diseases, on the attenuation of the virus of splenic fever and of hydrophobia are described with great lucidity and their history and progress rendered in a very spirited and fascinating manner. Reading the volume, one does not know what to admire more in M. Pasteur's life and labours — the way in which a problem is stated, worked, and solved in all its theoretical and practical bearings; the energy and perseverance with which he forces nature to yield up her secrets; the fertility and resources of his genius, or the ready way in which he goes to work to set at rest by direct experiment all objections and to remove possible sources of error. His is a truly grand life and his labours grander still!

The translator is to be congratulated on the admirable way in which she has fulfilled her task. Prof. Tyndall's preface forms an interesting and valuable part of the book. E. KLEIN

The Microtomist's Vade-Mecum. A Handbook of the Methods of Microscopic Anatomy. By Arther Bolles Lee. (London: J. and A. Churchill, 1885.)

IN the preface the author tells us that the aim of the book is to put into the hands of the instructed anatomist "a concise but complete account of all the methods that have been recommended as useful for the purpose of microscopic anatomy," and also "that it is to serve as a guide to the beginner." After a perusal of the book we venture to say that, although the book will prove useful, it is neither a concise, still less a complete, account of all the methods, nor will it serve as a guide to the beginner. As far as we can see, it is a collection of formulæ, published by various authors in various journals and archives, and particularly reported in the *Journal* of the Royal Microscopical Society. The formulæ are more or less promiscuously given, and without an attempt of intelligible selection. For many formulæ references to their authors are given, but in some places these references are incomplete, in others they are wrong, since methods discovered by one are ascribed to another. Nor can we see the use of describing a host of minute and sometimes quite insignificant modifications of a certain method, as A's, B's, C's, &c., method.

As regards the beginner, we venture to say that the book will fail to come up to the expectations of its author. What the author for this purpose ought to have done is to give us a list of ready methods which he himself has tried and found useful in the examination of the various tissues.

The important branch of the examination of living issues, the methods used for the application of reagents, heat, gases, electrical currents, &c., on fresh and living tissues are not included in the book; their treatment, and a few illustrations of apparatus used in microscopic *technique*, would prove a useful addition. E. KLEIN

LETTERS TO THE EDITOR

The Late Prof. Clifford's Kinetic

PROF. TAIT, in his notice of Clifford's "Common Sense of the Exact Sciences" (NATURE, vol. xxxii. p. 124) has brought so prominently forward the statement made in Prof. Pearson's footnote—"the manuscript of the 'Kinetic' was left in a completed state," that I think it is fitting I should somewhat anticipate what will ultimately be stated when the manuscript in my hands has been printed. All the manuscript bearing upon the "Dynamic," after having, I think, passed under Mr. F. Pollock's eyes, was handed over to me, and with it Mrs. Clifford gave me, for use,[1] nine German text-books in case I should need them to fill up any gaps in the manuscript. It is needless to say that there have been "reasons" why this manuscript has not hitherto seen the light; suffice it now to say that the *continuous* portion has been received by Messrs. Macmillan, and the printing is to proceed forthwith. But of what does the *continuous* part consist? I have a draught before me of the work as originally contemplated by the author: Books i., ii., iii., form the "Kinematic"; Book iv., entitled "Forces," is broken up into ten or eleven sections. It is this portion which is *continuous*, and which takes up about forty pages of manuscript. Book v. was to treat of "Stresses;" Book vi., of "Heat;" and Book vii., of "Waves and Vibrations." Of these latter books I have only stray leaves here and there. It is said "Fools rush in where angels fear to tread." I certainly do not propose to try to supplement Clifford's work, but what I do propose is to get out all the *continuous* part in continuation as approximately as I can of the "Kinematic" and to relegate the odds and ends to an appendix. If any mathematician thinks some other course preferable, I shall be glad to let him see the "slips," and will hope to profit by his advice. I am in the receipt of letters from distinguished teachers which express a hope that the lectures I referred to (NATURE, vol. xxvii. p. 4) may see the light; but this point is still, I believe, under consideration. R. TUCKER

University College School, June 13

[1] These books are to be presented to University College Library after I have done with them.

Sky-Glows

A MAGNIFICENT display of red sky-glow has been seen here. The last observed was in September last (the 17th, the 27th, and the 28th), and only feeble ones have been noticed since up to June 11. At that date the sky glowed with a magnificent grayish pink on the whole of the northern horizon until 9 o'clock p.m. Yesterday the glow was still brighter, and at 9 15 p.m. it extended over the whole of the northern and north-eastern horizon. It was brighter than even last year, but acquired its maximum of brilliancy at a later hour than last summer.

Clairvaux-sur-Aube, France P. K.

Flying Fish

AN excellent opportunity of observing the aerial means of propulsion in the flying fish was afforded me during a six days' calm lately when crossing the Bay of Bengal. This must be my excuse for again touching this subject. I watched day by day some hundreds rise under the bows of the ship. The water surface was a glassy calm. As each fish rose it spread its wings at once, apparently beating the surface with them two or three strokes before they steadied out. I say apparently, for it was not a definite beat so much as a struggle to rise. The tail which, of course, under water was in rapid motion, to escape from the ship, now gave ten or a dozen rapid beats, which could be counted by the ripples on the still surface, and the fish was off in aerial flight. As each fish lost the impetus of the first rise, which generally happened at about forty yards, the binoculars showed us the anal fins, which had till now been fully extended, drooping to feel the water. As soon as the surface was felt the tail was quickly introduced, and five or six smart strokes, also indicated by ripples, brought the impetus up again and carried the fish about another thirty yards, when another droop sent it on again, and so forth, some of the older fish travelling in this way 400 to 500 yards. The younger fish frequently fell awkwardly in this attempt to regain impetus. Where waves are running it requires a clever fish to gain impetus by a few judicious strokes on the crest of a wave, and many a fish tumbles over in the attempt.

I once saw a fish rise close to the ship's quarter, and it flew parallel with the ship, pursued below by a dolphin or bonita. The latter followed every sway of the flying fish, keeping almost under it. At the first dip of the tail the pursuer made a dart forward, but missed it, and again dogged its pray by keeping just under it. On the second dip the tail went into its pursuer's mouth, and there was an end of the flyer. It always struck me that it seemed a strain on the fish to keep the wings extended.

May 15 ALFRED CARPENTER

THE UNIVERSAL MERIDIAN[1]

AFTER some preliminary historical matter Dr. Janssen proceeded:—The question as to which of all the meridians encircling the earth ought to serve as the starting line in the general numeration of the longitudes, is the question known as that of the *prime meridian*—a famous question oftentimes taken in hand, never definitively settled, and which the Congress of Washington was charged to decide. Such was at least its intention.

The ancients, who had just ideas in all matters, perfectly understood that a prime meridian ought to be placed at the origin of the lands to be measured. Marinus of Tyre, and after him Ptolemy, chose quite naturally, as the point of departure for their longitudes, the extremity of the world which was best known to them. What was this extremity? It was the islands which navigators encountered beyond the pillars of Hercules in an enchanting climate, where the inhabitants, freed from every toil, lived in peace and happiness on the abundant spontaneous fruits of a prodigal soil, the Fortunate Isles, as they were called, which people pleased themselves with assigning, as a final resting place (Elysian fields) to the souls of heroes!

Homer, Hesiod, Pindar, Plutarch, speak to us of these Fortunate Isles, which were then regarded as the extreme limit of the western dependencies of Africa. Afterwards they were the unknown solitudes of the ocean.

It is from these isles, then, that the great heir of the geography of the Greeks starts his numeration of longitudes. Here again, however, the ignorance of the ancients in the matter of measures did not allow the maintaining of so natural a point of departure. The indifferent knowledge of the position of the Fortunate Isles damaged the whole system, and people later on were compelled to revert to the continent where the measures were less uncertain.

Following Greek science came the middle ages, when the scientific idea disappeared, and was replaced by a religious or political idea. The first line of longitudes was taken anywhere. People took their meridians from capitals, or remarkable places; every one chose his own centre, and the confusion grew to be intolerable. It is noteworthy how it was France which gave the signal for the resuscitation of the scientific idea in this question, and that it is to the great Richelieu we owe it.

It is, however, a false idea of Richelieu's action to consider it as directed by a pure intention of scientific reform, and by the desire alone of serving the general interests. Richelieu is above all a political spirit, and political interests dominate his preoccupations. At the same time, however, he is a unifying and innovating genius, who feels the necessity of order and serves that necessity by general, great, and elevated measures, for such is the form of his spirit.

What, in fact, was the point of departure of a reform such as science disengaged from all personal interest would alone dictate at the present day? A jealous quarrel among maritime nations in reference to commerce!

At the commencement of the seventeenth century France made a trial of commerce in distant parts, particularly in the Indies and America.

The navigation and traffic of these countries were then in the hands of the Spanish and Portuguese, who, however little they agreed on the division of these rich spoils among each other, were nevertheless wonderfully united when there was a question of interdicting others from sharing in them. The French ships appearing in the seas either of the East or West Indies were, in point of fact, chased by the Spaniards and the Portuguese! Awaiting the time till he had rendered the French navy strong enough to dispute with these nations a property which on the whole was the right of all the world, Richelieu sought to draw around France a maritime zone of protection. He accordingly negotiated and obtained that on this side of the prime meridian fixed on this occasion and to the north of the tropic of Cancer every French ship, whencesoever it may have come and whatever its cargo, should be safe from the pursuit of foreign vessels. Beyond these limits the argument of the strongest was to have force. France was at peace with Spain and Portugal on this side, at war on the other. A curious state of affairs, recalling to some extent the word of Pascal: "Vérité en deçà, erreur au delà!"

And yet have we really the right at this day to look on an arrangement of this kind as such a strange one? Have we not now what the casuists of international law call the *état de représailles*—a state in virtue of which one may blockade the ports of a nation, burn its arsenals and destroy its armies, without being in declared war, and without ceasing diplomatic relations with it?

The object of the great Minister was evidently to secure a refuge for our marine till such time as it was able to contend with others—a goal for which he laboured with such admirable success that before his death our navy was constituted and the basis laid of that colonial greatness which came with Louis XIV. and Colbert.

Such, then, was the political motive at work. But in pursuing this question of colonial commerce the mind of Richelieu was for a moment turned to geography. He needed a pure line of demarcation, not liable to be disputed, and found it in the ancient meridian of the Canaries. He resumes the geographical idea of Marinus of Tyre and of Ptolemy. He places his meridian as far to the west as possible in the archipelago of the Canaries—in the island of Ferro, and the longitudes are to be counted east of it. All the other meridians of the continent are excluded.

Accordingly, and I insist on the fact, all the qualifications of a universal meridian, such as science might be able to establish at this day, were combined in Richelieu's meridian.

(1). It is universal and fit to be so, seeing it personifies no nation, but is, on the contrary, the determination of a purely geographical idea; namely, the position farthest to the west of the ancient world.

(2). The numeration of the longitudes is very natural. It brings the numerical augmentation of the longitude into harmony with that of the local time. It sets forth no negative longitude—a system which, in our opinion, is defective, when there is a question of universal numeration of longitudes.

(3). It places the first meridian in the sea, as geographers have always desired.

The appointment of Richelieu had but one fault: it was in advance of its time—not in respect of its utility and urgency, but of its means of realisation.

In order to establish a meridian at any point it is necessary to be able to connect this point exactly with all well-known points which are to be brought into relation to it. Now, by reason of various circumstances, chief amongst which was the state of war then prevailing, the longitude of this island of Ferro was not known till a century later, when P. Fouillée, astronomer and naturalist, proceeded to the Canaries by order of the King and the Academy, and there made observations on the occultations of the satellites of Jupiter, whence he determined the position of Orotara in Teneriffe, and consequently, by means of a triangulation, the position also of the island of Ferro.

[1] Lecture by Dr. Janssen at the Paris Geographical Society.

In the meantime a conventional position had been arranged for the island of Ferro. In fact, at the beginning of the seventeenth century our geographer Delisle is found placing the meridian of the island of Ferro on his maps 20° W. from Paris.

The grand geographical idea of Richelieu was, accordingly, not maintained in its integrity. Paris, in fact, gave the point of departure.

Delisle was a geographer of very great merit, and accomplished a real reform in the science by always seeking to establish astronomical determinations as the basis of geography. Delisle and d'Anville placed France in the seventeenth century in the front rank in geography. Be it added that, while France had thus an undisputed superiority in geography, she at the same time took the initiative in inventing hydrographic methods, and producing the most beautiful hydrographic works, as I had occasion to call to remembrance at the Congress.

In thus speaking of the labours of France shall we not be allowed to recall our present activity in the branches which engage us? I shall say but a word in passing. But in fine, are we not accomplishing great things even at the present day? The creation of the port of Rochelle, established on new and profound scientific principles; the geodetic junction of Spain and Africa; the great geodetic labours of France resumed; the publication of the astronomical and nautical ephemerides, the most complete and perfect in existence; the fair series of determinations of longitude of high precision, undertaken under the auspices of the Bureau of Longitudes; those sublime cosmogonical theories which are being elaborated at this very moment; finally, and without passing beyond the domain of geography, let us not forget the great enterprises of our president, who everywhere vindicates the genius of France, and whom age seems to spare in the interest of our glory—have we not in all that a sum of sterling substance, and is it not proper to call it to mind at a moment when every one is putting his claims forward?

These preliminary explanations made, we may now, with your permission, address ourselves to an analysis of the labours of the Washington Congress.

This Congress, assembled by the zeal of the United States Government, was formed by the diplomatic and scientific representatives of the different States invited. It was officially charged with the task of studying the question of a universal meridian and of cosmopolitan time, and of formulating propositions, which, it is true, were not to be binding on the Governments represented, but were yet to serve as a basis for further negotiations and definitive resolutions.

When the invitation of the American Government reached the Government of France, the latter applied to the Academy to name the delegates which should represent France scientifically at the Congress. This step was followed by the appointment of a Grand Commission comprising representatives of all the sciences and services interested, and in which the Academy of Sciences was largely represented.

This Commission, presided over by the Dean of our Astronomical Section, held numerous meetings, at which they discussed with the greatest care and with high authority the questions composing the programme of the Washington Congress. The resolutions which this Commission adopted, formulated in a remarkable report of M. Gaspari and fully accepted by the Government, formed the basis of the instructions given to the French delegates.

The Congress opened on October 1 in the Diplomatic Hall of the Department of State.

On the formal demand of the French delegation the Congress allowed that the motions and speeches delivered in the English language should be translated into French, and that the *procès-verbaux* should be drawn up in the two languages. To secure the accuracy of the French version M. Janssen accepted the duties of secretary.

The Congress invited certain learned men present at Washington to assist at the sittings, and to take part in the discussions. Among them may be named Messrs. Newcomb, Asaph Hall, Sir William Thomson, and Prof. Hilgard.

On examining the composition of the assembly it will be seen how largely England and America were represented, and yet, to add to the force which such a numerous and eminent representation was calculated to give them in the discussion, there was joined to it, under the form of invitation, the support of the most eminent men of learning of America or England present at Washington.

Finally, without at all wishing to call in question the independence of any one present at the Congress, it is yet difficult not to be struck by the fact of invitations being addressed to all the small States politically allied with the United States.

Such was the arena on which France was called to defend her interests.

Luckily, however, we had no personal interest to contend for. The France of the nineteenth century does not, any more than the France of the eighteenth and seventeenth centuries, deem herself entitled to consider national interest in questions of a scientific and universal character.

In conformity, therefore, with the spirit which ruled the institution of the metrical system the French representation at the Washington Congress solely maintained the principle of a meridian such as science would designate and such as would be most advantageous for the general interest.

At the opening of the sittings a member of the American delegation, expressing, no doubt, the sentiment of his colleagues, at once proposed the meridian of Greenwich as the international meridian. If this proposition had been adopted the main question which called the Congress together would have been decided, and that, so to say, without discussion, and without the questions of principle and general interest, which we wished to defend, being so much as entered on.

The delegate of France raised his voice against this summary and inadmissible method of procedure. He pointed out that, before proceeding to choose any meridian in particular, it was necessary to come to a decision on the question as to whether a universal meridian should be fixed upon or not, and, if this question were settled in the affirmative, according to what principles they should choose this meridian.

The legitimacy of this demand was evident. It was accepted, and the proposition of the American delegate was temporarily withdrawn.

The question of fixing a single meridian of departure for all nations having been submitted to the Congress, it was unanimously agreed to choose such a meridian.

It next remained to be decided according to what principle this meridian should be chosen—whether, namely, the choice should be made among the observatories already existing, or whether the choice should be made with a view exclusively to geographical conditions, and to the service which the meridian was destined to render.

On this question the French scientific delegate begged permission to speak, and delivered the following discourse:—

"If after so many fruitless attempts recorded by history to arrange a single universal system of longitudes this question is now again resumed, then in our opinion it has no chance of definitive success unless it is established on a purely geographical basis to the rigorous exclusion of all national rivalries.

"We do not, therefore, come here to support a candidature, we put ourselves completely outside the arena of debate, and are consequently infinitely freer to express our opinion and discuss the question from the one point of view of the interests of the projected reform.

"The history of geography shows us very numerous attempts at the unification of longitudes, and on searching into the causes of the failure of those attempts, many of them very happily conceived, one is struck by the fact that they seem reducible to two main causes, one of a scientific, the other of a moral nature. The cause of a scientific nature lies in the inability of the ancients to determine exactly the relative positions of points taken on the globe, particularly in the case of an island removed from a continent, where the distance between the two was not determinable by itinerary measures.

"It was thus, for example, that the first meridian of Marinus of Tyre and of Ptolemy, placed in the so-called Fortunate Islands, could not continue to be used, notwithstanding the advantage belonging to the choice of a position in the extreme west of the then known world, on account of the uncertainty attaching to this point of departure.

"This very regrettable reverse served to give a wrong direction to the question. People were obliged to revert to the continent. Instead of regarding a common origin of longitudes indicated by nature, people took their first meridian from a capital, from remarkable places, from observations. The second cause to which I referred, the cause of a moral kind—namely, national jealousy—led to the multiplication of geographical origins, whereas the nature of things would have demanded their reduction to one single origin.

"In the seventeenth century Cardinal de Richelieu, seeing this confusion, wanted to resume the idea of Marinus, and assembled at Paris learned men of France and foreign countries. The famous meridian of the island of Ferro was the result of their conferences. Here is a lesson which we ought not to lose sight of: the meridian of the island of Ferro, which had at first the purely geographical and neutral character alone able to render it, and maintain it as, a first international meridian, was displaced from its primary position by the geographer Guillaume Delisle, who, to simplify the figures, placed it in round numbers 20° west of Paris. This unhappy simplification completely changed the principle of impersonality. It was no longer an independent meridian, but the meridian of Paris disguised. Nor were the consequences slow in making themselves felt. The meridian of the island of Ferro, from that time regarded as a purely French meridian, wounded national susceptibilities, and thus lost the future which was certainly in store for it had it remained true to its first intention.

"This was a real misfortune for geography. Our maps in their process of improvement ought to have maintained the unity of departure, instead of confusing it ever more and more.

"If from the time when astronomical methods were sufficiently advanced to allow the fixing of relative positions with the degree of precision required for general geography (a state obtaining from the end of the seventeenth century), the idea of Marinus of Tyre, so just and so geographical, had been resumed, the reform would have been effected two centuries sooner, and we should now have been in the full enjoyment of it. But people fell into the error of losing sight of the very principles of the question, an error to which the foundation and multiplication of observatories at that time greatly contributed. Furnishing relative positions, as they of course did, with great precision, each of these establishments was chosen by the nation possessing it to give it a point of departure for longitudes, so that the intervention of astronomy in these questions of a geographical nature—an intervention which, properly understood, should have been so advantageous—served only to remove us further from the object to be attained.

"The study of these questions leads us to establish a very necessary distinction between the meridians of a geographical or hydrographical nature, and the meridians of observatories.

"The meridians of observatories must be regarded as essentially national. Their office is to enable observatories to depend on each other for the unification of their observations. They also serve as a basis for geodetic and topographical labours executed in connection with them. Their functions, however, being of an entirely special character, ought in general to be limited to the country possessing them.

"The first meridians in geography, on the other hand, do not require to be fixed with a precision quite so delicate as that exacted by astronomy; but in return their domain ought to be comprehensive, and while it is serviceable to multiply observatories, it is necessary to reduce to the utmost the origins of longitude in geography.

"It may further be said that if the site of an observatory ought to be chosen under considerations of an astronomical description, a meridian of departure in geography ought to be fixed on grounds of a geographical description.

"Have these two so different functions always been well comprehended, and a distinction of such vital moment properly observed? By no manner of means.

"Seeing the observatories, by reason of the labours of high precision executed by them, furnish admirable data, each nation in a position to do so has assigned to its principal observatory not only the geodetic or topographical works undertaken at home—a task very proper to it; but likewise the general works of geography or hydrography executed abroad—a confusion of functions comprising in it the germs of all the difficulties under which we now labour.

"In proportion, therefore, as cartographic labours accumulated, the necessity of establishing unity in all that relates especially to general geography became more and more felt. This explains how the question of a single meridian of departure has been so often raised in recent times.

"Among the assemblies occupied with this question that principally deserving our attention is the one held at Rome last year. For many even of our colleagues the conclusions adopted by the Congress of Rome settle the matter. Those conclusions must, therefore, very particularly engage our attention.

"On reading the reports of the sittings of that assembly I was struck by the fact that in a meeting embracing so many men eminent for their learning and speculations, it was the *Utilitarian* side of the question which was especially considered, and which finally dictated the sense of the resolution taken.

"Thus, instead of laying down the great principle that the meridian which should be offered to the world as a point of departure for all the longitudes of the earth ought, above everything else, to have an essentially geographical and impersonal character, the question was simply asked, which among the meridians of observatories was the one possessing—permit me the expression—the largest following (*la clientèle la plus nombreuse*).

"In a question of a geographical, much more than of a hydrographical, interest, as almost all mariners confess (seeing that, in fact, there exist but two prime hydrographical meridians, Greenwich and Paris), a primary meridian is taken, the dominating character of which is marine. And this meridian, instead of being chosen according to the configuration of the continents, is claimed for an observatory. That is to say, the prime meridian is chosen for a mere chance spot on the globe, and one which, moreover, is very inconvenient, for the function the meridian is intended to perform. Instead, finally, of profiting by the lessons of the past, an element of national rivalry is introduced into a question which ought to unite the votes of all interested.

"Well, I say that considerations of economy and of use and wont ought not to blind us to the principles which should govern this question, and which can alone render its settlement universally acceptable and permanent.

"But further, this argument of economy, and use, and wont, which is advanced as a reason of determinative force, has validity, it is true, for the majority for whom it is brought forward, but for them alone, and leaves for us exclusively the burden of change in habits, publications, and maps.

"Seeing the report holds us of so light account in the balance, allow me briefly to recall the past and the present of our hydrography, and for this purpose I cannot do better than cite a few passages from a work communicated to me, and emanating from one of our foremost hydrographers. 'France,' says he, 'created more than two centuries ago the oldest nautical ephemerides in existence. She was the first to conceive and execute the great geodetic operations having for their object the construction of maps civil and military, the measure of meridional arcs in Europe, America, and Africa. All these works were and are regulated by the meridian of Paris. Almost all the astronomical tables which the astronomers and mariners of the entire world make use of at this day are French, and calculated in reference to the meridian of Paris. As regards oceanography, more particularly marine surveying, the precise methods employed at the present day by all the nations are of French origin, and our maps, all based on the meridian of Paris, bear names such as those of Bourgainville, La Pérouse, Fleurieu, Borda, d'Entrecasteaux, Beautemps Beaupré, Duperrey, Dumont d'Urville, Daussy—to mention but a small number of those who are no more.

"Our existing hydrographical collections count more than 4000 charts. Deducting from this number those which the progress of exploration has rendered no longer available, there remain about 2600 charts in use.

"Of this number more than a half represent original French surveys which foreign nations have in great part reproduced. Of the remainder the general maps are the result of the labours of discussion carried out at the marine depôt where all documents, French as much as foreign, were utilised, and relatively few of them are the expressions pure and simple of foreign labours. Our surveys are not limited to the coasts of France and its colonies. There is hardly a region on the globe for which we do not possess original labours: Newfoundland, the coasts of Guiana, of Brazil and La Plata, Madagascar, numerous points of Japan and China, 187 original charts relative to the Pacific Ocean. We must not omit mentioning the fine work of our hydrographical engineers on the West coast of Italy, which was honoured by the International Jury with the grand medal of honour at the universal exhibition of 1867. The exclusive use by mariners of the meridian of Paris is grounded on considerations of a past of 200 years such as we have briefly recalled.

"The adoption of another prime meridian would involve a change in the graduation of the 2600 charts of our hydrography, would involve a similar change in our maps for nautical instruction numbering over 600, and would of necessity entail a corresponding change in the *connaissance des temps*.

"These are considerations deserving to be pondered. Well, if under these conditions the projected reform, instead of being inspired by the high principles which should govern this subject, is to take for its basis simply a regard for the use and wont of the largest number and their exemption from all sacrifice, reserving for us exclusively the burden of change and the abandonment of a dear and glorious past, are we not, then, justified in saying that a proposal formulated in this sense would not be acceptable?

"When at the end of the last century France established the metre, did she proceed in this way? Did she, as a measure of economy, and not to change anything in her habits, propose her foot-rule to the world? You know the facts. The truth is, we turned everything at home topsy-turvy—habits and material. And the measure chosen related, as it is, only to the dimensions of our globe, is so well disengaged from every French tie that in future ages the traveller who will trample on the ruins of our cities will be able to ask himself by what people was invented the metrical measure which his feet may chance to light on.

"Permit me to say that it is in this way a reform is established and rendered acceptable. It is by setting oneself the example of self-sacrifice and by completely effacing oneself in his work that resistance is disarmed and that a sincere love of progress is attested.

"I hasten to say that I am persuaded that the proposal voted at Rome was neither made nor suggested by England, but I doubt whether, if accepted, it will render a true service to the English nation. An immense majority of the sailors of the globe navigate with English charts, it is true, but it is a homage of fact rendered to the great maritime activity of this nation. The day, however, when this supremacy, freely accorded, is changed into a supremacy official and imposed, it will undergo the vicissitudes of every human power, and this institution, which by its nature is of a purely scientific order, and to which we desire to assure a long and peaceable future, will become an object of keen and jealous rivalry among the nations.

"All this shows how much wiser it would be to take for the origin of terrestrial longitudes a point determined by purely geographical considerations. On our globe nature has so distinctly separated the continent on which the great American nation are now developing themselves that from a geographical point of view there are but two possible solutions, both very natural.

"The first solution would consist in returning to the solution of the ancients with a little modification, by placing our first meridian towards the Azores; the second in relegating it to the immense straits separating America from Asia, towards the confines of the north, where the New World reaches out a hand to the Old.

"These two solutions may be discussed, as they have often and again quite recently been by one of our ablest geologists, M. de Chancourtois.

"Each of these meridians unites in it the fundamental conditions required by geography, and on which people have always been agreed, when national meridians were eliminated from the debates. As to the determination of the point adopted, the astronomical methods which are now so perfect would furnish it with as a great a degree of exactness as geography would require.

"But what need of a special and costly determination of longitude for a point which may be placed arbitrarily provided it is comprised within certain limits, such as to satisfy the condition, for example, of passing by a strait or traversing an island? It is enough to mark out approximately the point adopted. The position thus obtained will be referred to each of the great observatories, which will be related to one another and chosen for this purpose, and this list of relative positions will constitute the definition of the first meridian. As to a material sign on the globe, should such be wanted, a point by no means necessary, it will have to be placed in conformity with this definition, its place would have to be shifted till such conformity was obtained.

(*To be continued.*)

GUESSINGS AT TRUTH

I.

OLD SPENSER, in his wondrous Allegory, tells us—

"... he, that never *would*,
Could never :—"

We are constantly reminded that we must creep before we can walk. So that we cannot look coldly or sarcastically on

"... budding Genius' earliest essàye,"

provided always that we are sure of the earliness. For there often is a strange resemblance between the erratic first flights of the scientific fledgeling and the habitual evolutions of the time-hardened Paradoxer or of the Paper-Scientist.

Besides the mere dozen or so of really successful Physicists, all that the world seems able to produce at any one time, even in these later years, and whose efforts can at the best be rarely called more than *Guesses*, there is an untold multitude whose *Guessings* are irrepressible. These, unlike some at least of the former, never hide their light under a bushel. From week to week we view with curious awe the increasing piles of pamphlets under which our shelves and table sag, groan, and crack! Let us make an effort, and get rid of some of them. Not to the waste-basket—at least not at once—for there is something in almost every bundle of hay (in the Soudan it is not needles, but bricks and slag), and this is usually worth searching for, were it only in the interests of justice to those who have thus (unconsciously?) hidden them. We take the bundles as they come; many are rotten and can be tossed aside at once, others require more careful scrutiny.

The first we light upon is by our particularly modest contributor John O'Toole.[1] [He does not seem to be aware of the powers of Peroxide of Hydrogen, which (though we did not proclaim the fact) enabled us on a former occasion easily to penetrate his *incognito*. But his secret is safe with us.] His present work is a singularly quaint protest against the modern abuse of elementary dynamical terms, and as such is well worthy of careful perusal. There can be little doubt that, of all physical subjects, as presented in an elementary form to the beginner, Dynamics is the most repulsive. And it stands at the very threshold. Mr. O'Toole shows the natural working of a clear, logical, mind in the middle of the present chaos. His pamphlet is one which should be read by all; for, though he hits all round and sometimes attacks the very giants of Science, he invariably hits fair as well as hard. It would take a whole article to discuss fully the questions he raises: suffice it to say that the root of the confusion which he so justly exposes is that little, but much-abused word *Force;* and to quote the following pregnant sentence as showing his point of view :—

"When we behold . . . a group or sequence of phenomena, we *insert* force among them of ourselves, because we know from experience that if our organism were substituted for the acting or resisting body, we should have the sensation of pressure."

Next we take a couple of smaller, but more ambitious, pamphlets[2]:—in each of which the Past, Present, and Future of the Universe are promptly settled, though the terms of settlement are by no means identical. When we find, however, that Herr Zehnder, in the second sentence of his pamphlet, says that insuperable objections can be raised against the hypotheses of Helmholtz as well as against those of Kant, Herschel, and Laplace, *because they take too little account of the existing laws of mechanics*, we begin to understand him; and we have only to turn over a few pages to find him thoroughly revealed. His bugbear is the Dissipation of Energy:—and he informs us that the "Eternal Circulation of Matter"—in virtue of which all aggregations such as the sun will ultimately explode into their former nebulous condition, to recommence their condensation, &c.,—is an immediate consequence of THE PRINCIPLE OF THE CONSERVATION OF LIGHT!

Our rival author sums up *his* Kreislauf as follows :—

"... life, matter, and all things, are the necessary and inevitable outcome of the existence of Space. Space or Room, in any form whatever, must of necessity be a form of force or energy, and all things are just phases or manifestations of the working of this force or energy; the Earth is dissolving in Space like a lump of Salt in Water, but New Worlds are being formed in Suns; this dissolving and forming process will go on for ever; and consequently life will be eternal; . . ."

This is a step in advance even of Descartes, with whom Space and Matter were the same. We leave to the reader to judge which of the two has the more grotesquely grinned through the horse-collar, the German Swiss or the Scotsman.

Our next step is a large one, no less than from the Universe to the Atom.[1] The work now before us is a very curious one. The author has hunted widely for his materials, and (very naturally) selects such only as suit his theory. So long as he can utilise Sir W. Thomson or Clerk-Maxwell he does so; but, when he finds their statements incompatible with his theory, he has no difficulty in picking up what he wants from Zeuner, Rühlmann, Deschanel, &c. He seems, however, not to be acquainted with the elaborate work of Athanase Dupré. This is unfortunate, for in it he would have found little difficulty in obtaining whatever he might require. The object of the essay, briefly stated, is to frame a theory of the liquid and solid states, somewhat on the lines of the kinetic gas-theory:—only it seems we must have a mutual force between particles, whose law is something between the inverse 4th and inverse 5th powers of the distance. But somehow the law itself seems to vary with the distance; so that "we must apply the theory of probabilities to determine the potential at any centre due to the surrounding atoms." As a striking instance of Mr. Whiting's extensive range of quotation, we note that he refers, for the sum of a common series (given everywhere in elementary text-books of Trigonometry), to no less august an authority than Riemann in his *Partielle Differentialgleichungen!* We do not venture farther to criticise the work of a writer who can, as a matter of course, invoke such irresistible authorities.

We now come to a whole series of memoirs, tracts, letters, and pamphlets:—usually of American origin:—which deal specially with the vexed question of the Sun's temperature. From these we select one only, as the work of the most persistent, if not the most lucid or successful, of the many mere guessers on this subject.[2] For the others consult Van Nostrand's *Engineering Magazine, &c., passim*. Something, if not very much, has been done in this matter in Europe. Pouillet, J. Herschel, Crova, Rosetti, Violle, and others have at all events gone to work in a scientific way:—though (as is obvious from the results of Prof. Langley recently given in our columns) the values obtained by them can be but very rough approximations. A few of Mr. Ericsson's weightier sayings will pretty well show the value and character of his treatise. At p. 58 we are told that

"... the actinometer merely shows the thermometric interval of solar intensity on Fahrenheit's scale, without reference to the position of that interval on a scale which commences at the accepted 'absolute zero.' I regard this absolute zero, however, as an *ignis-fatuus*, retreating as fast as we approach it."

[1] *A New Theory of Cohesion*, &c. By Harold Whiting. (Cambridge, U.S., University Press, 1884.)

[2] *Solar Heat (an Extract from a work on "Radiant Heat")*. By John Ericsson. New York, 1885.

The little kinematical, or rather quasi-corpuscular, *excursus* to which pp. 71–74 are devoted, is one of the richest pieces of *paradoxing* (in De Morgan's sense) that we have ever met with. Here is a little bit of it:—

"Pouillet, having ascertained the number of thermal units imparted to the water in his pyrheliometer of 3·93 ins. diameter, imagined that he had measured only the energy of the rays contained in a pencil of 11·9 square inches section; whereas, in reality, he had, at the end of his experiment of five minutes' duration, subjected his instrument to the action of the entire number of rays contained in a passing pencil or sunbeam, the section of which we ascertain by multiplying the orbital advance of the earth during five minutes, 28,836,000 ft., by the diameter of the pyrheliometer, 0·305 ft."

Thus it is the *number* of rays, not the time of exposure to one ray, which determines the result!

One more quotation, a very short one, must be given. It is from p. 136, and we put two words in italics:—

"In view of the fact that projectile force *diminishes inversely* as the square of the depth of the medium penetrated. . . ."

It is not easy to fix on the exact meaning of this very curious statement. Hence we must take it literally, whatever be the consequences. Discussion of penetration would obviously be useless in such a case, for the whole projectile force (even were it infinite) would be gone before penetration had commenced!

The immense expense which has been lavished on this volume, and on its truly wonderful illustrations, is calculated to produce reflections even more painful than those evoked by the perusal of the text itself. From the materials here given, *something* may yet be made, but certainly not on the lines chosen by the author.

We hope, shortly, to return to our store, and to select for the instruction and warning of our readers a few additional specimens, by no means inferior in quality to those just dealt with. G. H.

PROFESSOR FLEEMING JENKIN, LL.D., F.R.S.

ON Friday last, most unexpectedly and greatly to the grief of all his friends, died Prof. Fleeming Jenkin at Edinburgh, at the age of fifty-two. He had been in somewhat delicate health for a considerable time, but was, as usual, personally directing the engineering operations in connection with telpherage in London and Sussex, and seemed to have greatly gained in health and strength when he started for Edinburgh some days before his death. But blood-poisoning succeeded a slight surgical operation, and his death rapidly followed.

He was born in Kent in 1833, and was the son of the late Capt. Charles Jenkin, R.N. His school-days were spent at Jedburgh, Edinburgh, and Frankfort-on-the-Maine, while he took his M.A. degree at the University of Genoa, and began his engineering career in Marseilles, thus acquiring a wide knowledge of languages and of peoples which was most valuable to him afterwards in his scientific and social life.

In 1851 he returned to England, and was apprenticed to Messrs. Fairbairn's in Manchester, from which time his progress was rapid. We hope that the interesting and highly creditable history of his subsequent introduction as a well-trained mechanical engineer to submarine telegraphy (then in its extreme youth) and to Sir William Thomson, which led to his soon taking charge of the testing of the first Atlantic cable in 1858, and to a friendship and partnership with Thomson and Varley, will yet be told by some one who can do full justice to it. Our grief at Varley's loss is yet fresh, and we deeply sympathise with Sir William Thomson at the close of this partnership, the existence of which has been synonymous with the progress of submarine telegraphy.

On the appointment of the Committee of the British Association on Electrical Standards Jenkin's services were solicited, and the good work that he did as a member of this Committee is amply shown by his large contributions to the Reports on Electrical Standards, and which contain an account of his absolute measurement of the capacity of a condenser, the first such determination ever made; and the chapters that he wrote in connection with these Reports on the subject of "Absolute Units" formed the only available text-book for the student of mathematical electricity before about the year 1872. Appended to these reports are the Cantor lectures which he delivered on the construction, laying, and testing of submarine cables, and these lectures showed as wide an acquaintance with the practice of electrical science as do the other chapters referred to with the theory of the subject.

In 1865 he was elected a Fellow of the Royal Society and Professor of Engineering in University College, London, and in 1868 he became Professor in the University of Edinburgh, where he created a School of Engineering to which considerable numbers of prominent Engineers and Professors of Engineering acknowledge their indebtedness. In the following year the Royal Society of Edinburgh elected him a Fellow, and subsequently he became a Member of the Institution of Civil Engineers, having been made an Associate of that Institution as early as 1859. In 1883 the honorary degree of LL.D. was conferred on him by the University of Glasgow.

Jenkin's book on Electricity and Magnetism, published in 1873, was a revelation to non-mathematical and even to many mathematical men, of the ideas which had until then been wrapped up in the mystery of mathematics or in the practice of the submarine cable testing-rooms. Sir William Thomson had been publishing many detached papers on electricity in the mathematical journals, and had been applying his knowledge in practice, so that an exact science of electrical quantities had been growing up among submarine cable engineers; but the electricity of the text-books remained as unscientific and primitive as of old: the knowledge of the practical men had become indeed far more scientific than the knowledge of the schools.

Fully recognising this, Prof. Jenkin made in his book a totally new departure, and presented electricity and magnetism for the first time in a text-book as subjects capable of quantitative study. To understand the great effect produced by this book, which has now passed through many editions, it must be remembered that neither Clerk-Maxwell's treatise, nor Thomson's reprint of his Mathematical Papers appeared until 1873, and that at that time "electric potential," which to-day has its commercial unit, was to every one, except the engineers of submarine telegraphy, a mere mathematical function.

In 1882 a lecture was delivered at the Royal Institution on Electric Railways, and the system devised by Profs. Ayrton and Perry for effecting an absolute block, and thus enabling any number of electric trains to be run without the employment of drivers, guards, or signalmen, was described and exhibited by a working model. An account of this was read by Prof. Jenkin, and he at once saw that it contained the solution of a plan that he had been thinking over for doing on a large scale by electricity what had previously been done on a small scale with pneumatic tubes. *Telpherage*, or the automatic electric transport of goods, was the outcome, and the development of practical methods of running carriers electrically along a steel rod suspended in the air from wooden posts, occupied him, with the other two inventors, during the last three years of his life, the system being one which needed new invention in every one of its details. His inventive power is described by his assistants as wonderfully active and prolific, and he had energetic characteristics which only seldom accompany inventive genius, and which made his cooperation invaluable to the other directors of the Telpherage Company. It is deeply to be regretted that, having busied himself so actively in the long series of telpherage experiments carried out in Hertfordshire, he did not live to see the completion of the first commercial "telpher line" now being erected at Glynder in Sussex.

The building of houses on sanitary principles interested him largely, and the Sanitary Protection Associations in Edinburgh and in London owed their existence to his initiation, and their success was largely due to his constant exertions. His article on "Bridges" in the "Encyclopædia Britannica," his book on "Healthy Houses," and his primer on "Magnetism and Electricity," are well known to scientific readers, but not perhaps to the readers of his numerous articles in the quarterly reviews and monthly magazines, the last of which was his recent article on "Telpherage" in *Good Words*. His numerous scientific papers published since 1864 are to be found in the *Proceedings* of the British Association, the *Philosophical Magazine*, the *Proceedings* and *Transactions* of the Royal Societies of London and Edinburgh, the *Journal* of the Society of Arts, the *American Journal of Science*, and the *Journal* of the Society of Telegraph Engineers.

Technical education much interested him long before it acquired its present interest for the public, and he presided at meetings of the Society of Arts and other societies when papers on that subject were brought forward. As a director of the Watt Institute in Edinburgh for several years he helped to advance technical education in Scotland.

He was an enthusiastic admirer of ability in other men, and he was especially warm in his encouragement of beginners, whether they were his own pupils or not. To gain his help it was only necessary to let him see that it was anxiously wished for, and that the recipient was not likely to make a mean use of it. He had marked dramatic power, and the plays acted in his drawing-room will long be remembered by his friends; while to his conversation, his general reading and wide sympathies gave a charm which was as powerfully felt as it is now regretfully remembered by all who were fortunate enough to know him.

THE GEOLOGICAL SURVEY OF BELGIUM

ALL who are interested in the careful and methodical investigation of the geological structure of the European continent will be sorry to learn that the Belgian Chamber of Representatives has cut down the vote for the prosecution of the detailed Geological Survey of Belgium so seriously as practically to suspend the work. It is miserable to see personal dislikes, religious differences and political antagonism imported into the discussion of a scientific project. Every competent witness must bear testimony to the minute fidelity and conscientious labour with which M. Dupont and his staff have carried out their Survey. If any fault can be found with his maps it is that they are too complete. They give more information than any ordinary reader can assimilate. Each sheet, indeed, is a detailed treatise on the area which it depicts. There are certainly no such elaborately exhaustive maps published in any other country; and Belgium may justly boast that she has led the way in an important advance in the delineation of geological features. It is an open secret, however, that the official geologists have all along encountered the determined opposition of the "géologues libres" who were not so fortunate as to be entrusted with the control of the work. The Survey having been planned by the Liberal Ministry, and being stoutly supported by the authorities, has until now been able to hold on its course. Much time was, no doubt necessarily, spent by M. Dupont in perfecting his system of colour-printing, and the delay in the appearance of his maps, possibly also the difficulty found by the malcontents in understanding them, were used as arguments for a total reorganisation of the staff. The opposition has recently been renewed under the clerical Government now in power, and unfortunately with more success. From the published debate it is clear that the Minister in whose department the estimate for the Geological Map was prepared, and who was officially bound to support that estimate, sat still without speaking in its defence, and the House, taking this silence, no doubt, as an expression of the inclination of the new Government, cut down the vote. We are sure that this retrograde step will be regretted by all who wish well to the progress of science. Into the personal squabbles connected with the subject we have no wish to enter. But as a public act of unwisdom the vote of the House of Representatives will, we hope, be rescinded and the prosecution of the Survey will be again allowed to proceed. If any fault is found with the way in which the map has been prepared, surely the Commission contains talent and energy enough to inquire into this and set matters right without practically bringing the Survey to a stand.

THE CONGO[1]

THESE two welcome volumes from Mr. Stanley testify to the accelerated rate of events in these latter times. It is only twelve years since Livingstone died in the vain search for the sources of the Nile down by Lake Bangweolo, and under the belief that no river but the Nile could sweep past Nyangwe with such a breadth and volume as he found the Lualaba to have. He was not singular in cherishing such a belief; many geographers believed, like him, that the Congo could not fetch such a sweeping circuit, and that the Lualaba must make its way northwards in spite of differences of level and somehow add its waters to the Albert Nyanza. It is only eight years since Mr. Stanley dispersed the delusion, and solved the problem both of the Nile and the Congo; it is just about six years since he began operations as the agent of the International African Association. To judge from the narrative of his journey across the continent, there was no blacker part of the Black Continent than the river banks between Nyangwe and the Atlantic, and no more intractable people than many of the tribes through whom he and his men had to run the gauntlet. Yet already, almost solely by his exertions, this most unpromising region has become "A land of settled government," at least on paper. It has engaged the continued attention of diplomatists from all the great States of the world for months, and is the subject of as many treaties as if it had been founded a century ago.

In reality, however, it is something more than a paper State. No one can read Mr. Stanley's narrative without being convinced that all along the river from Vivi to Stanley Falls there already exists what may fairly be regarded as an organised Government, carried on from some twenty-four stations as centres. But with the merely political aspects of this successful undertaking we cannot deal here. It is certainly an interesting experiment, both from a political and social point of view, this attempt to raise into a State a region not yet redeemed from savagery. What the ultimate result will be it is hard to say; on the one side a great mass of savagery, and on the other the most advanced European influences in politics, in commerce, in industry, in religion. For already we find bands of missionaries everywhere, and as among them are many men of prudence, tact, and ability, Mr. Stanley acts wisely in encouraging their efforts; they will certainly be of service in helping him to accomplish the object he has in view.

Without the aid of the latest applications of science, Mr. Stanley could never have succeeded in accomplishing all he has done in the brief period of six years. Steam has been of infinite service to him, and engineer-

[1] "The Congo, and the Founding of its Free State." By Henry M. Stanley. Two Vols. (London: Sampson Low and Co., 1885.)

ing contrivances in many ways. His flotilla of steamers, some of them most ingeniously contrived for the special navigation of the Congo, may be said to have been everything to him in carrying out his work; and the Congo Free State may be fairly set down as another "triumph of steam." Mr. Stanley claims for the Congo Free State an area of over a million square miles and a population of 42,608,000. As to the area, that is probably not far out; but the population seems to us excessive. Mr. Stanley reaches this great figure by generalising the density which he finds on the banks of the river itself. Between Stanley Pool and Stanley Falls, a distance of about 1000 miles, and including part of the Biyerré and Kwa Rivers, he finds a population of 806,300, and takes for granted that a similar density will prevail throughout the whole of the Congo Basin. This is very unlikely. In uncivilised countries the population naturally crowds itself along the river banks, and it would be very unsafe to calculate on finding regions at a distance from rivers equally well populated. Throughout the whole of the million square miles claimed by the Congo State only a few lines of exploration have as yet been run, though we know that as a whole it is probably the best-watered region in Africa, and possibly therefore the most thickly peopled. But the tendency among African geographers recently has been to reduce previous estimates of the population of Africa, and instead of 200 millions it is thought that 170 millions is one more likely to be nearer the mark. But all estimates, except for districts that have been settled for some time, are necessarily conjectural; and even for Morocco the greatest difference exists between the estimates of different travellers.

On the Lower Congo the Free State has been able to secure only a comparatively narrow strip of territory on the north bank—enough, however, to give it the right of free navigation between the sea and Vivi, where the first series of cataracts begin. From Vivi upwards to Manyanga the State possesses territory on both sides, when France comes in and claims the whole of the right bank of the river to the Likona tributary in 1° S. lat. Thence the Free State expands into boundless and unknown regions, which we hope it will do its best to explore and open up to science as well as to commerce. The aim in the north has been evidently to draw the boundary of the

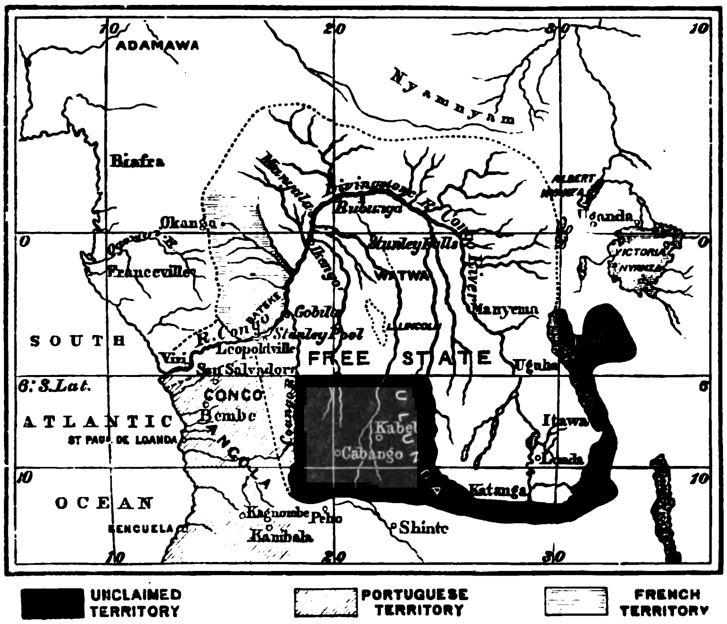

FIG. 1.—Political Divisions of the Congo Basin.

State between the basins of the Nile and the Congo. The western basin of the Upper Nile, no doubt, is fairly well known, but the region between that and the Upper Congo is just that part of Africa about which we know scarcely anything. The boundary on this side, therefore, has been drawn with the freedom of conjecture. All the rivers that are not known to send their waters to the Nile must, in Mr. Stanley's opinion, come down to the Congo, or, at least, ought to do so, and are made to conform with Mr. Stanley's idea of what is right and proper, in the large map which accompanies his work. In spite of Dr. Junker's discovery of the water-shed which separates the Nepoko from the Welle, they are both made to send their waters southward to swell the magnificent Aruwimi. This may be so; only actual exploration will decide the matter. It is mainly to settle this question that Dr. Lenz is preparing to proceed to the Upper Congo as leader of an expedition into the region that lies between that region and the Upper Nile tributaries. And here we have one very beneficial result of the work which Mr. Stanley has done on the Congo. His numerous stations form so many starting-points for further exploration. They can be easily and rapidly reached from the West Coast, and through the agencies at their command, all the men and goods obtained necessary for the conduct of an expedition into the interior. If every station on the river were made the basis of further exploring work, one of the greatest blanks in our knowledge of Africa would soon be filled up. In the interest of the enterprise itself this must be done. If the manifold products of the wonderful land over which Mr. Stanley is so enthusiastic are to be brought down to the river for shipment to the upper terminus of the future railway that is to convey them past the cataracts, it is evident that station after station must be pushed on into the interior. Among the white *employés* of the Association are many men of education and intelligence; and while their first duty is to look after the interests of the "Free State," these interests, instead of suffering, are likely to be advanced by a scientific knowledge of the country around the States. Already good meteorological work has been done at Vivi by Dr. Danckelmann, whose recently published

Fig. 2.—Yellala Falls from Left Bank.

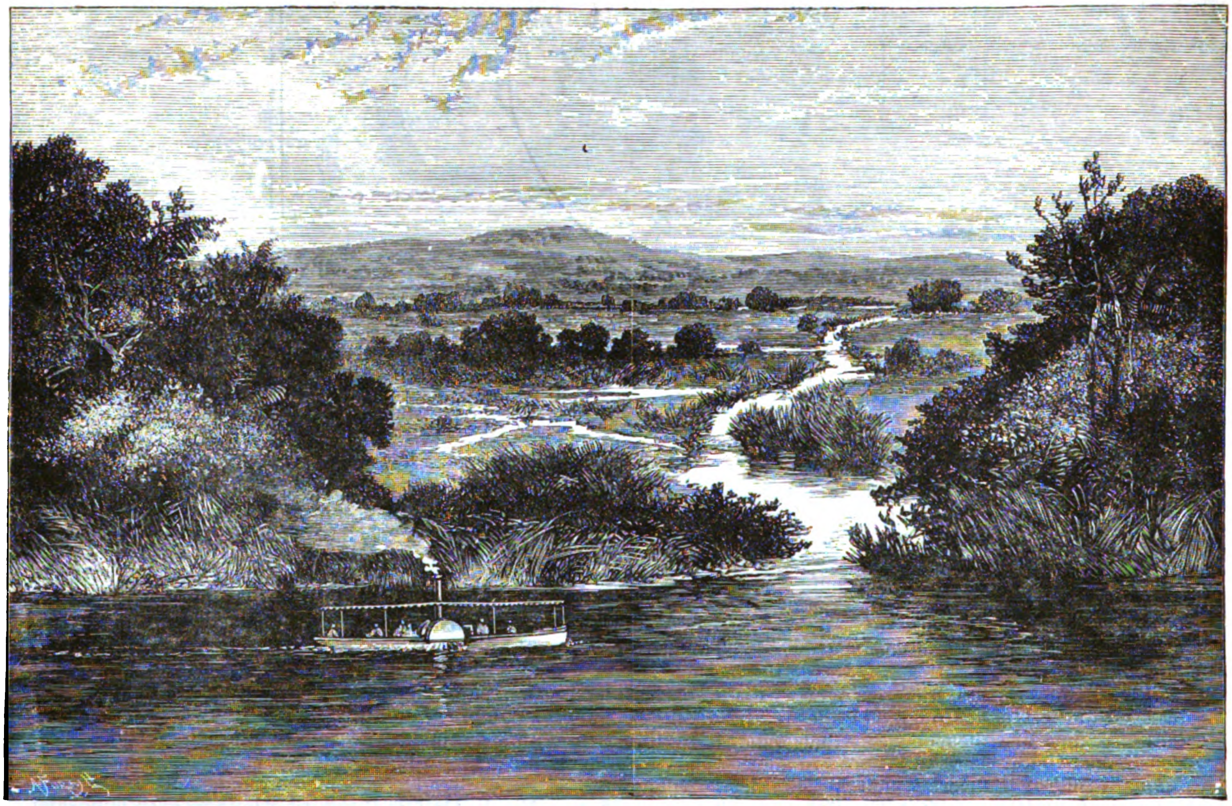

Fig. 3.—Head of Lake Leopold II.

observations we reviewed some time ago.[1] The utility of such observations is evident from the volumes before us. Mr. Stanley makes considerable use of them in his chapters on the Climate of the Congo. These chapters are of much interest; they are written mainly with a view to show that, with reasonable precautions, Central Africa ought to be perfectly tolerable to the European constitution. What these precautions are he describes in minute detail. At the same time he admits that a lengthened residence in such tropical regions must in the end tell on

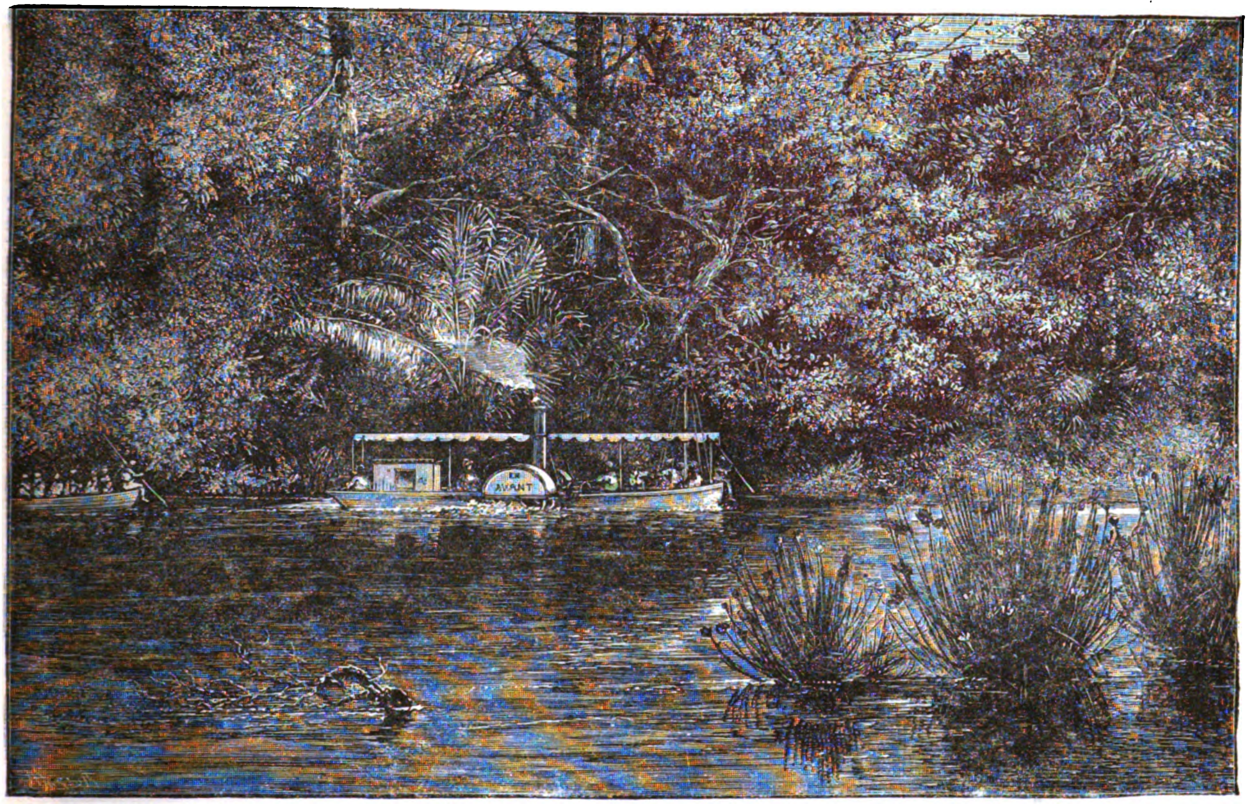

FIG. 4.—Banks of the Upper Congo.

the Europeans, and is only possible with a run home every eighteen months. Thus it is clear that if the resources of the Congo are to be developed, it must be by native labour, and there is therefore every inducement to treat the population humanely.

Of course, Mr. Stanley himself in his frequent journeys

Fig. 5.—A Type of the Basoko.

up and down the river has added considerably to our knowledge of it. His original sketch of its course, made in one rush downwards, seems, however, to have been wonderfully accurate; though the hundreds of observations as to direction, altitude, depth, and width has enabled him to lay it down with much greater precision. It is to be hoped that the geology of the basin will be well worked out, and even from a "utilitarian" standpoint it might be useful for the Association to engage one or two competent men to work out the geology. The numerous cataracts on the lower as well as on the upper river prove that there is much here to interest the geologist. On the lower river, just where the great central plateau begins to shelve down to the coast, they are to be expected; but what is the exact geological explanation of the numerous cataracts on the upper river and its tributaries, as far south as Bangweolo, let us hope, will ere very long be explained. The banks of the river itself are in many places remarkably picturesque; indeed Mr. Stanley would make us believe that he thinks no other river is equal to it in this respect. Magnificent bluffs, he tells us, are met with in many places, and gorges that are almost *cañons*. At Stanley Pool and elsewhere the river has broadened out into lake-like reaches studded with islands, and at one place a few miles south of the equator there is a complicated offshoot of lakes and streams which reminds one of what is observed in so many places on the Central and Lower Amazon. This stretch has not, however, been completely explored, though Mr. Stanley's account of his journey up the Kwa and Mfini to Lake Leopold is one of the most interesting chapters in the volume. The Kwa discharges at about 3° S. lat., and Lake Leopold, Mr. Stanley joins conjecturally to Lake Montumba, which is connected with the Congo at about fifty miles south of the equator.

With regard to the volume of discharge of the Congo, from careful observations made at Stanley Pool, Mr. Stanley calculated that it reached 1,436,850 cubic feet per second when the river at that point was at its lowest. During flood it rises, he believes, twelve feet higher, giving a volume of 2,529,600 feet per second. If these estimates are correct, then Mr. Stanley calculates that the river discharges into the sea three million cubic feet of water per second.

Mr. Stanley's new work is so fully occupied with the details of the founding of his numerous stations, his dealings with chiefs and people, his road-making and other engineering enterprises, and the general work of engineering the enterprise, that there is little space left for geographical details. He does give a list of the products of the Upper Congo region, but as this is entirely from a commercial standpoint, its value to science is not great. The various species of palms, as might be expected, abound on the banks of the river and its islands, the oil-palm being the most valuable from a commercial point of view. Then come the various species of india-rubber plants, besides other gum-producing trees. Ivory, Mr. Stanley reckons only fifth in rank among the natural products of the Congo. He presumes that there are

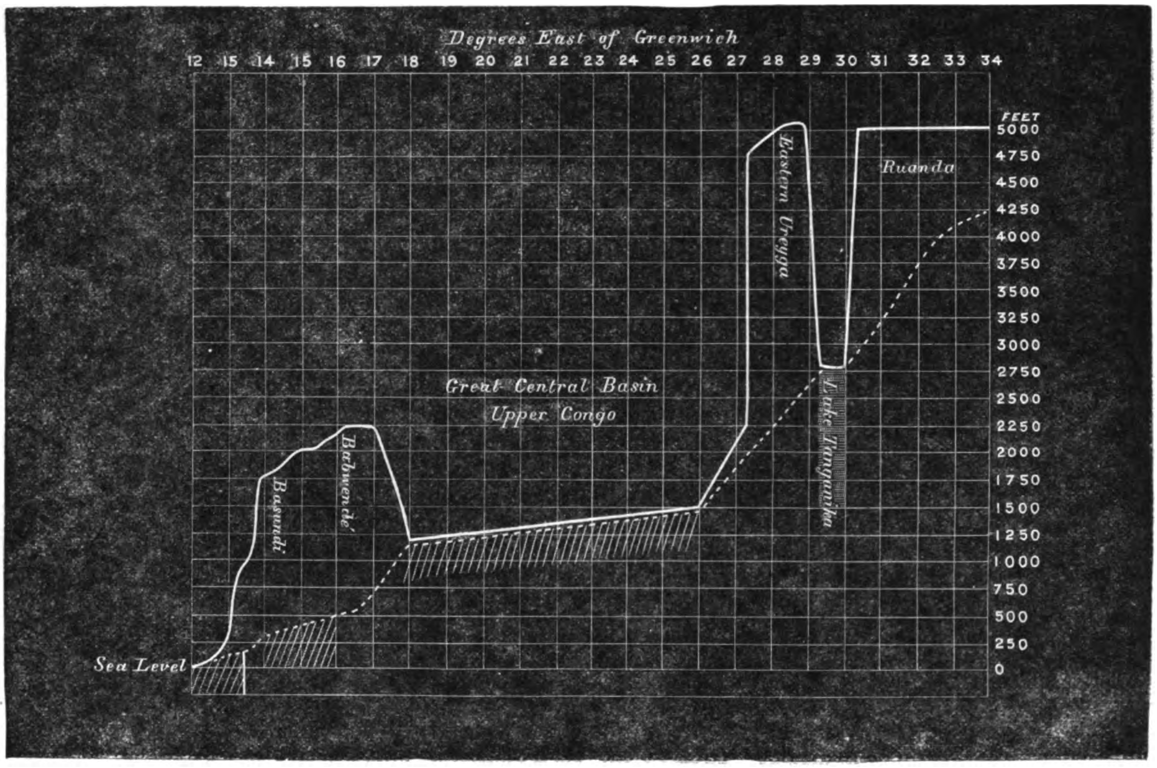

FIG. 6.—Profile of Country between the Sea and Ruanda, across the Congo Basin.

almost 200,000 elephants in about 15,000 herds in the Congo basin, each carrying an average of 50 lbs. weight of ivory in his head. Iron, he tells us, is abundant. The copper mines near Philippeville supply a large portion of Western Africa with their ingots. Plumbago is also abundant, and gold has been found in the beds of streams. Mr. Stanley gives a long list of tropical plants which abound in the Congo basin, while several European vegetables and fruits have been found to thrive. The Arabs, moreover, he tells us, are introducing the large-grained upland rice with extraordinary success. He adds many details concerning the trade, actual and possible, of the Congo region, his object, of course, being to show that here exists a magnificent field for the European trader, European capital, and European settlers.

Mr. Stanley's work is chiefly of value as telling the story of one of the most unique and interesting enterprises on record. This story he tells with abounding interest; there are many incidents throughout the volume told with the dramatic effect so well known to readers of "Through the Dark Continent." The work of founding the Free State has been well begun, but it is only the beginning; for the sake of its complete success it is to be hoped that nothing may occur to sever Mr. Stanley's connection with it until it has been firmly established.

NOTES

THE Royal Society's *conversazione*, held on the evening of June 10, was a very great success, and those who had the labour of bringing the various things together must have felt themselves amply rewarded by the great interest taken in them by the Fellows and guests, both ladies and gentlemen, who attended. Among the objects exhibited we may note the following:—Geological map (unpublished) of Palestine and Arabia Petræa, exhibited by Prof. Edward Hull, F.R.S.; original drawings of the skeletal, digestive, and vocal organs of birds, made in the years 1842-46, drawn and exhibited by Prof. W. K. Parker, F.R.S.; Sketches of the eclipse of the moon, October 4, 1884, and a very beautiful series of sketches of the wonderful sunsets and after-glows, painted and exhibited by Mr. W. Ascroft; star-charting by photography (enlarged prints rom negatives made in 1883 and 1884), exhibited by Mr. A. A.

Common, F.R.S.; electrical influence machine, exhibited by Mr. James Wimshurst; New microscope with novel fine adjustment and sub-stage arrangements, exhibited by Mr. Crouch; large Nicol prism polariscope, for projecting axes of crystals, &c., on the screen (improved form), exhibited by Messrs. Harvey and Peak; Tate's calculating machine, exhibited by the inventor. By means of this machine long operations in the fundamental rules of arithmetic can be performed with rapidity and unfailing accuracy. Eight figures can be multiplied by eight figures in about fifteen seconds. New forms of spectroscopes, exhibited by Mr. A. Hilger; photographs of fractures of railway carriage and waggon axles, tested to destruction by Mr. Thos. Andrews, Wortley Iron Works, near Sheffield, exhibited by Mr. Andrews; three cases of living animals: (1) Examples of the Tuatera (*Sphenodon punctatus*) from New Zealand. This reptile is remarkable as deviating from all the lizards in its osseous structure, and is considered by Dr. Günther (*Phil. Trans.*, 1867, p. 620) to constitute an order by itself—*Rhynchocephalia*. (2) Large bird-eating spider of the genus *Mygale* from Burmah—probably *M. fasciata*. (3) Butterflies and moths, showing the way in which living insects are exhibited in the Zoological Society's Insect House, exhibited by the Zoological Society of London. A series of microscopic sections of vegetable tissues, prepared and lent by Mr. J. E. Sunderland, of Hatherlow, near Stockport, showing remarkable effects of double and triple anilin staining; a series of botanical microscopic preparations, mounted by Charles Vance Smith, of Carmarthen, being part of a series prepared by him to illustrate the text-books of Julius Sachs and Otto Thomé, exhibited by Prof. Moseley, F.R.S. A series of slides with stained specimens of *Tænia echinococcus* of the dog, prepared and lent for the occasion by Dr. J. Davies Thomas, of Adelaide, Australia, in illustration of his paper on the artificial rearing of this parasite by feeding with human hydatids (to be read before the Royal Society, June 18); a slide showing the same species of tape-worm, reared by Mr. Edward Nettleship, F.R.C.S., by means of hydatids obtained from the lungs of a sheep (*Proc. Roy. Soc.*, 1866). To compare with the above:—Specimens, in bottles, of *Tænia serrata*, *T. marginata*, and *T. cœnurus*, &c., artificially reared by Dr. Cobbold, by feeding dogs with the scolices appropriate to each particular species. Also adult examples of *Tænia cucumerina* and of *T. canis lagopodis* (*T. littera a*), the latter from Iceland, prepared by Dr. Krabbe, *Bothriocephalus dubius*, and other species from the cat and dog, exhibited by Dr. Cobbold, F.R.S. Case of gems, including a great Indian diamond, the largest known opal, a series of cat's eyes, and allied mineralogical specimens, exhibited by Mr. Bryce Wright, F.R.G.S.; "Frith's Selenium Cells," showing the alteration of resistance and photo-electric currents due to the action of light on selenium, exhibited by Prof. W. Grylls Adams, F.R.S; a sulphur cell, the electrical resistance of which, like that of selenium, is reduced by light, exhibited by Mr. Shelford Bidwell. The sulphur has been heated while in contact with silver, and therefore contains some sulphide of silver. The electrodes are of silver. The original integrating machine, invented by Mr. C. V. Boys; engine-power meter which has been developed from the same, exhibited by Mr. Boys.

We give in another column, on the *audi alteram partem* principle, the first part of an address recently given by Dr. Janssen, putting before us the French view of the Prime Meridian question. It will be gathered from it that the feeling in France is strongly against the conclusion at which the Washington Congress arrived. Taking the world as it is, however, much as a strictly neutral prime meridian might be to be desired, the general opinion will probably be that the Congress arrived at the only *practical* solution.

We are glad to see that University College, Liverpool, is about to appoint a Professor of Engineering. An endowment of 375*l.* has been raised, and the advertisement of the Chair appears this week in our pages. We understand that a certain amount of professional work, such as is consistent with a due fulfilment of the duties of the Chair, will be permitted, and recognised as enabling the Professor to keep himself in touch with the life of the practical world. The College already has endowed Chairs of Mathematics, Physics, Chemistry, and Biology, in addition to the Literary and Medical Departments: it has lately become a part of the Victoria University, and in many ways it shows signs of health and vitality.

In the production of the first part of the Philological Society's new English Dictionary, the editor, Dr. Murray, was obliged to advance 150*l.* out of his own resources, and, further, to incur a debt of 500*l.* The delegates of the Clarendon Press, who are publishing the Dictionary, decline to contribute more than 100*l.* towards the payment of this debt, and the Council of the Philological Society deem it their duty, therefore, to appeal to the public to relieve Dr. Murray from a debt incurred on behalf of what is really a national undertaking. It is to be hoped that there will be no difficulty in obtaining the sum required; those of our readers who are inclined to help should send their subscriptions to Mr. Benjamin Dawson, the Mount, Hampstead, London, N.W.

The Spanish Commission of Medical Inspection has examined the composition of the liquids and virus employed by Dr. Ferran against cholera. The opinion of the majority of the members is that the presence of Koch's *Bacillus virgulus* cannot be questioned. After some opposition, the Spanish Government granted the necessary authorisations for inoculation, which has been practised on a number of doctors and four newspaper writers. It is said, moreover, that all the inoculated patients experienced during the first twenty-four hours after the operation all the symptoms of cholera with more or less intensity, but without any fatality having occurred. When twenty-four hours had elapsed, a favourable reaction took place. The question which remains to solve is the extent of the protection resulting from Dr. Ferran's system. The numbers given are in favour of the new theory, but all the documents coming from Spain on cholera must be received with caution, owing to the intense panic prevailing in that country since the last outbreak of the plague was noticed in Valencia. A fact curious to notice is the tendency of the rural populations of this province to congregate in the cities in spite of all the measures taken against this exodus. *El Imparcial* states that not less than 7000 people have located themselves in the chief city.

Prof. Pasteur, the *Standard* Paris correspondent states, has published an interesting letter from Dr. Ferran, concerning vaccination for cholera. In this letter Dr. Ferran asserts that the results obtained become every day more irresistibly eloquent. The experience of Alcira had been confirmed in numerous other towns. Anti-cholera vaccination had been practised upon all classes of society, but in many places the greater number of those operated upon belonged to the pauper class, and the results proved no less satisfactory. While of opinion that one inoculation is effective, Dr. Ferran recommends that it be repeated, in order to make assurance doubly sure. In reference to the official prohibition of vaccination for cholera (which has since been cancelled in deference to public opinion), Dr. Ferran intimates that the measure was taken in consequence of two persons belonging to an already cholera-visited family dying the day after vaccination. These casualties Dr. Ferran attributes to the use of impure lymph, and states that in 16,000 cases, for which he had personally inspected the lymph, no evil results had followed. It is not claimed that vaccination for cholera will give actual immunity, but that it will alleviate the attack whenever it may come. Anti-cholera vaccination, affirms Dr. Ferran, can never itself be the cause of an attack. If an attack comes within five days of vaccination it must have been previously contracted. Dr. Ferran attributes the discovery of anti-cholera vaccination to the theories of Prof. Pasteur.

DR. CORNISH, known for his investigations into the nature of cholera, has proposed (according to *Allen's Indian Mail*) that as between 300 and 400 persons are every year judicially sentenced to death in the Indian Empire and its dependencies, a number of these, say one-tenth, be made, with their own full knowledge and consent, subjects of experiments as to the spread of cholera, on condition that if they escape their lives be spared. An international commission of experts might, he suggests, be appointed to determine upon the experimental tests needed to ascertain if cholera is or is not a disease capable of being communicated from person to person. This would do more in the space of a few months to help forward the inquiry into the nature of cholera than has been accomplished by indirect observation during the last century. But if the principle underlying this proposal is admitted by the Indian Government, it might be extended to other most important experiments, such as the various causes and cure of cholera, the cure for snake-bites, hydrophobia, and the like.

THE following is an official statement of the number of visitors to the Whitechapel Fine Art Exhibition during the time it was open in March and April last:—Saturday, March 28, 1008; Sunday, March 29, 2494; Monday, March 30, 2622; Tuesday, March 31, 3332; Wednesday, April 1, 3292; Thursday, April 2, 1823; Good Friday, April 3, 3703; Saturday, April 4, 3269; Easter Sunday, April 5, 2717; Easter Monday, April 6, 4332; Easter Tuesday, April 7, 3720; Wednesday, April 8, 2944; Thursday, April 9, 2872; Friday, April 10, 1942; Saturday, April 11, 3348; Sunday, April 12, 3345; total for 16 days; 46,763. The Exhibition was opened in the afternoon of March 28, admission being by ticket only until 6 p m., 6 to 10 p.m. free; after that it was opened free from 10 to 10 daily (Sundays 2 to 10).

AT the meeting of the International Committee of Meteorology (instituted by the Congress held at Rome) in the beginning of September next, at Paris, the following topics will be considered:—Report of the Secretary on the work of the Committee since the Copenhagen meeting; report of MM. Brito Capello, Hildebrandson, and Ley on the observation of Cirrus; Should a third International Congress be convoked? the establishment of stations of the first order on the Congo; discussion of the meteorological *résumés* issued in different countries, and eventual preparation of a more uniform plan; the utility of American meteorological telegrams proposed by Gen. Hazen, and organisation of their distribution in Europe; best means of securing the timely reception of meteorological telegrams; ought barometric heights to be reduced to the pressure under 45° of latitude? Should meteorological hours be reckoned from 1 to 24 in conformity with the resolution of the Washington Conference? Designation of a completely covered sky as to the form of clouds; definition of days of rain and snow; should not a uniform height above the ground be recommended for pluviometers? recent progress in the more exact measurement of snow; international meteorological tables; modification of the rules for administration of the International Meteorological Committee. Communications should be addressed to Mr. R. H. Scott, F.R.S., Meteorological Office, 116, Victoria Street, London, S.W.

IN a communication to the Physical Society of Berlin, on April 24 Herr Kayser read a note concerning his experiments on the condensation of gases on surfaces, and Bunsen's criticisms thereon. In a paper published last year Bunsen had declared that the previous results under this head were erroneous, inasmuch as the observers had proceeded upon the false assumption that a maximum of condensation was attained in a few hours or days, Bunsen himself finding that the condensation might go on slowly for years. Herr Kayser, however, had, in reply, pointed out that Bunsen had not been sufficiently careful in cleaning the glass surfaces on which his experiments were made, and he now had the satisfaction to announce that Bunsen, after repeating his experiments with the necessary precautions, had arrived at the same conclusion as himself, namely, that there was no demonstrably slow condensation, but that the maximum of condensation was reached with extraordinary rapidity.

THE project to build a "Grassi-Museum" has now assumed a tangible shape at Leipzig, inasmuch as the site for the new museum has been chosen. The new museum is to contain the collections belonging to the Ethnographical Society, which are now crammed into premises entirely unsuitable for them.

DR. OTTO ZACHARIAS has recently made interesting researches concerning the freshwater fauna of the Silesian Riesengebirge and the county of Glatz. The Royal Prussian Academy of Sciences has just granted him a sum of money towards the continuance of his labours.

MR. HOWARD NEWTON, assistant municipal engineer, of Singapore, has published a series of notes and experiments on the different kinds of timber in ordinary use in the Straits Settlements. The pamphlet contains observations on the forests adjoining our colonies in the Malay Peninsula, and the need already of conservation. The trees are felled in large numbers for ordinary use, and the jungles are cleared and exhausted by the Chinese gambier and pepper planters. Twenty specimens of woods are then described in detail, and finally an account of the mode in which the experiments were conducted and elaborate tables of the results follow. The breaking weights of some of the timbers tested were as follow:—1850, 1836, 1656, 1374, 1286, and 1284 lbs. Notes on the toughness, fracture, deflection, &c., are also given. It is curious to notice that some of the finest trees near Singapore (in the Johore forests) have no botanical equivalents. Mr. Newton specially mentions a tree called by the Malays the *ballow*, which grows from 60 to 100 feet in height, with a diameter of 3 to 6 feet. It is a close-grained, tenacious, hard, heavy wood, very valuable for building. It is called popularly Johore teak, although it does not belong to the natural order *Verbenaceæ*.

THE Russian Geographical Society has awarded a gold medal to M. Klossowski for his work on thunderstorms in Russia. We take the following from M. Rykatcher's analysis of this remarkable work. The initiative of thunderstorm observations having been taken by the Geographical Society in 1871, no less than 1821 regular observations were made during the years 1873 to 1882 at 176 different stations. For 145 of them annual and monthly averages were calculated, and gave the following interesting results. The minimum of thunderstorms (5 to 7 per year) is found in the north; their number increases towards the Gulf of Finland (with a depression south of it) and on the middle Volga, where it reaches 12 to 15 per year, and remains nearly the same throughout middle and southern Russia, with a slight decrease in the Crimea. A rapid increase in the number of thunderstorms is found in Western Russia, especially in Bessarabia (33 at Kishineff), as also in the East, at Tamboff, Penza, and on the Lower Don. The maximum of thunderstorms, 41 per year, is found at Tiflis. As might be expected, the thunderstorms are more frequent where the summer rains and the relative humidity are the greatest. Their diurnal maximum is between

3 and 6 p.m., and the minimum between 3 and 6 a.m. Availing himself of the synoptical maps of Hofmeyer for 1874 to 1876, the author compares, day after day, the thunderstorms with the cyclones which reach Russia, and he arrives at the important conclusion that thunderstorms in Russia—without exception—accompany cyclones, their appearance being influenced at the same time by the local state of temperature and humidity. Marié-Davy, Mohn, and others subdivided thunderstorms into cyclonic and local ones, and the continental ones were reckoned to the second category; but M. Klossowski shows that even in so continental a climate as that of Russia, thunderstorms depend also directly on cyclones. They appear on the borders of the cyclones and mostly in their south-eastern quarters. By further researches, the author arrived at the conclusion that thunderstorms in Russia are secondary or tertiary cyclones appearing on the borders of a cyclone, and thus explains the oscillations of the barometer during thunderstorms, already noticed by Messrs. Scott, Mascart, and others. Hail is obviously closely connected with thunderstorms. It also accompanies cyclones and is always concentrated in its south-eastern quarter, in the zone of 750 to 760 millimetres' pressure. On the whole, the work of M. Klossowski is a valuable contribution to the study of electrical energy in the atmosphere.

IN a lecture delivered in the Institute of the Khedive at Cairo, Dr. G. Schweinfurth has given some account of the seats of manufacture of prehistoric stone implements in the desert of Eastern Egypt discovered by him in 1876 and 1877, and again visited and examined by him in his last journey. The two spots referred to are in the Wadī Sanur and Wadi Warag. The former lies due east of Beni Suef at a distance of thirty miles from that town; the latter is in the upper portion of the Wadi at the place where this water-course begins to be discernible as a longitudinal depression on the heights of the western part of northern Galala. Dr. Schweinfurth's belief that the two sites in question are really those of ancient manufactories of stone implements is grounded partly on the presence of accumulations of cores in the beds of the streams, partly on the fact that the raw material is found abundantly in the neighbourhood. The source of the raw material is a bed of flints belonging to the upper nummulitic limestone corresponding to that which exists behind Cairo. Implements and utensils indicating a stone period have now, Dr. Schweinfurth remarks, been found even in the very heart of Africa, and these show a surprising resemblance in form to those discovered in Europe. Those recently obtained by himself from Sanur and Warag, however, are of a special type, and Dr. Schweinfurth regards them as clearly distinguished from the forms already familiar by the fact that the facets are usually only upon one side and are very seldom seen surrounding the entire core.

IN connection with the trial of Pel for poisoning, which has just resulted in Paris in the condemnation of the accused, some interesting experiments were conducted at the Morgue with a view to testing whether it was possible, as alleged by the prosecution, that the murderer could have got rid of the body of one of his victims by burning it piece by piece in a common stove. The professional witnesses stated that they procured a body weighing sixty kilogrammes. They removed from it forty kilogrammes of organic matter, and lighted a fire of wooden logs. They thus ascertained that in an hour the complete reduction to ashes of one kilogramme of organic matter could be effected, and in forty hours the complete combustion of a body weighing sixty kilogrammes could be completed. The accompanying smell was not disagreeable. The bearing of this on the question of cremation is obvious. It is possible to consume the human body by fire at a comparatively small expense, as these experiments show. In Japan, where cremation has been practised for ages, the quantity of wood consumed in the cheapest cremation is so small that European doctors doubted the evidence of eye-witnesses. Cremation of the lowest class costs only two shillings, on account of the small quantity of wood used, and the operation generally lasts from six to nine hours. The smell for a considerable distance around the crematorium is, however, of a very offensive kind, and the accessories are, as a rule, far from agreeable. There is, however, no doubt that the body can be consumed at a far less expenditure of fuel than is generally considered possible.

THE following appears in the *Times*:—Last autumn, a bookseller named Meyer, of Ronneburg, tied a water-proof label under the wing of a swallow which had occupied a nest at his house, and had become comparatively familiar. On it he wrote a query in German to the effect that he wished to know where the swallow would pass the winter. The bird returned to its former nest bearing an exchange label similarly fastened, saying, in German also, "in Florence, at Castellari's house, and I bear many salutations."

THE Austrian Government has refused to authorise the establishment of private cremation societies, on the ground that they might encourage crime. The decree states that murders are often detected by the exhumation of bodies, and that, even if bodies were to be examined before cremation, there would be no time to apply in every case those delicate chemical tests which are used where poisoning is suspected.

A TELEGRAM from Tiflis states that a severe earthquake has occurred in the Eastern Caucasus. The town of Sikuch is said to have been completely swallowed up. The loss of property is estimated at several million roubles.

THE latest telegrams from India state that the Cashmere earthquakes continue to occur with increased severity. It is reported that 2280 persons have perished in the district of Muzufusabad.

INFORMATION has been received at the Hague from Java that the state of Krakatoa was causing some anxiety. Towards the end of April subterranean sounds were heard in the neighbourhood day after day, and flames arose from the crater. The rocks which emerged from the sea during the last eruption suddenly disappeared.

FROM a report of Mr. H. Walker, Commissioner of Lands of British North Borneo, it appears that gold exists in considerable quantities in that territory. Some natives had brought a little to Sandakan, and Mr. Walker set out to verify its existence in the Sagama district. He searched thirty or forty different places and found gold at almost every place, generally in small distinct specks, large enough to be gathered with the fingers, sometimes larger, and always in conjunction with a black metallic dust and iron or copper pyrites. The rocks met with were granite, gneiss, quartz, limestone, jasper, porphyries, red sandstone. Steps will probably be taken to have the whole region thoroughly examined by a competent geologist. The minerals already ascertained to exist in North Borneo are gold, silver, copper, chromium, tin, plumbago, lead, and coal. Antimony and cinnabar are reported. On the west coast chromium, copper, and arsenic have been found; in the neighbourhood of Kinabalu silver ore and pyrites; a sample of native copper has been sent to London; a rich sample of galena and silver, yielding on assay 115 ounces of silver to the ton, has been found. Hitherto the officials of the Company and the other Europeans on the coast have been dependent for local information respecting these and other minerals on the rough statements of natives. It appears certain, however, that, besides its great forest and agricultural wealth, British North Borneo is also rich in minerals—how rich cannot be said until a thorough examination by an expert has been made.

ACCORDING to the *San Francisco Courier* the great glacier of Alaska is moving at the rate of a quarter of a mile per annum. The front presents a wall of ice 500 feet in thickness; its breadth varies from three to ten miles, and its length is about 150 miles. Almost every quarter of an hour hundreds of tons of ice in large blocks fall into the sea, which they agitate in the most violent manner. The waves are said to be such that they toss about the largest vessels which approach the glacier as if they were small boats. The ice is extremely pure and dazzling to the eye; it has tints of the lightest blue as well as of the deepest indigo. The top is very rough and broken, forming small hills, and even chains of mountains in miniature. This immense mass of ice, said to be more than an average of a thousand feet thick, advances daily towards the sea.

IT is contemplated to use the electric light in Algiers for night work during harvest time, in order to escape the heat, which is almost murderous for Europeans, and is an obstacle to their carrying on agricultural work.

THE borings undertaken for scientific purposes in the shaft situated near the railway station of Koetzschau, about five miles from Lützen (Germany), have now reached the depth of 1500 metres. Observations of temperature are now being made in the shaft.

THE Norwegian Government has voted a sum of 50*l*. to Dr. O. J. Olsen for the prosecution of his studies of wild edible mushrooms.

THE education of girls in Russia does not appear to stand very high. According to the *Moskow Viedomoski* only 21 children out of 100 attending school were girls. The proportion varies with the religion. Thus, of Protestants the number was greatest, viz. 45·4 per cent.; of Jews, 34·1 per cent.; and of Roman Catholics, 14·4 per cent. The number is lowest amongst Greek Catholics, viz. 12·3 per cent.

THE additions to the Zoological Society's Gardens during the past week include a White-fronted Capuchin Monkey (*Cebus albifrons* ♂) from South America, presented by Mr. E. Luxmore Marshall; a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Mr. A. R. Brown; a Martinique Gallinule (*Ionornis martinicus*), captured at sea, presented by Mr. G. S. Webb; two Grey-breasted Parrakeets (*Bolborhynchus monachus*) from Montevideo, presented by Miss Buist; a Red and Blue Macaw (*Ara macao*) from Brazil, presented by Mr. J. W. Beswick Purchas; a Yellow Conure (*Conurus solstitialis*) from Venezuela, presented by Mr. Albert H. Nicholson; a Barn Owl (*Strix flammea*), British, presented by Mr. W. Ostle; an Æsculapian Snake (*Coluber æsculapii*) from Central Europe, presented by Miss Lenox Conyngham; a Domestic Sheep (*Ovis aries*, var. ♂) from Somali Land, deposited; two Larger Tree-Ducks (*Dendrocygna major*) from India, two Gould's Monitors (*Varanus gouldi*), two Great Cyclodus (*Cyclodus gigas*), two Carpet Snakes (*Morelia variegata*), three Diamond Snakes (*Morelia spilotes*) from New South Wales, received in exchange; a Japanese Deer (*Cervus sika*), three Pigmy Hogs (*Porcula salvania*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

COMETARY ORBITS.—Prof. J. G. Galle has formed a most useful and very complete catalogue of orbits of comets which have been calculated since the publication of the third edition of Olbers's "Methode zur Berechnung der Cometenbahnen" in 1864. This catalogue appears in Nos. 2665–66 of the *Astronomische Nachrichten*. In one table are collected orbits of comets before 1860, which have been more definitively determined during the past twenty years, with a few orbits of ancient comets computed for the first time or founded upon better data, including those observed by Toscanelli; in a second table are contained the most reliable orbits of all comets discovered since the year 1860. The elements are given in an approximate form only, but in the notes accompanying each table reference is made to the place of original publication. Prof. Galle's *résumé* will be of much service to the student in this branch of a tronomy. It appears to have been drawn up on the suggestion of Prof. Krüger, seeing that there was no immediate intention of publishing a fourth edition of Olbers's celebrated treatise. Five newly-detected comets of short period figure in the second table.

BINARY STARS.—The following calculated angles and distances of several of the more rapidly revolving double-stars will serve to indicate how nearly measures made about the present time are represented by the best available orbits:—

Star	Epoch	Pos. °	Dist. "	Authority for orbit
ζ Cancri	1885·0	62·0	0·93	Seeliger
	1886·0	57·6	0·95	
η Coronæ Bor.	1885·5	173·9	0·61	Doberck
	1886·5	182·2	0·65	
ζ Herculis	1885·5	90·3	1·49	Doberck
	1886·5	85·3	1·50	
μ^2 Herculis	1885·5	285·6	0·80	Doberck
	1886·5	296·5	0·76	

Dubjago's orbit of β Delphini (Burnham 151) gives for 1885·6, Pos. 238°·1, Dist. 0"·28.

TYCHO'S NOVA OF 1572.—Some years since it was shown by Prof. Wolf that this object was observed by Lindauer at Winterthur on November 7, 1572, and it is equally certain that it was seen by Maurolycus at Messina at its meridian transit on the following evening, though there appears to be some confusion between altitude and declination in his published description. It was not seen by Tycho until November 11.

In 1808 the Abbé Scina, in a work printed at Palermo, entitled "Elogio di Francesco Maurolico," referred to his observations of this star, apparently given in the first instance in a special treatise written by Maurolycus (*Judicium de nova stella*), to which Lalande alludes in his Bibliography, and subsequently in 1613 in a life of the astronomer written by his nephew. According to Clavius, Maurolycus thus records his first observation of the star: "Hanc ego stellam in hoc Messanæ horizonte observans in meridiano extantem circa tertiam noctis horam, reperi altitudinem ejus esse 62. Unde conjecturam feci eam locari quasi, in summitate circuli arctici, ut distet hic a meo vertice per gradus 28, ac proinde ab æquatore per gradus 66½ fere, quoniam Messanæ latitudo habet gradus 38½, et eam sitam in puncto, in quo colurus æquinoctiorum secat arcticum circulum, aut ipsi puncto vicinissimum."

According to Argelander the place of the star for 1573·0 was in right ascension 0h. 1m. 52s., declination 61° 46'·4; the sidereal time at mean noon at Messina on November 8 was 15h. 49m. 50s., and consequently the star was on the meridian at 8h. 10m. 41s. mean time, or at 8h. 24m. 46s. apparent time, 3h. 24m. after sunset, and, the latitude of Messina being 38° 11', the meridian altitude was 66° 25', which was the distance from the equator given by Maurolycus. Nevertheless the Abbé Scina did not agree with Piazzi's suggestion that there was a typographical error in Clavius, and that 61½° should be substituted for 66½°. The only alternative, however, would point to an error of 4° or 5° in the observation (or estimation), and Scina writes of Maurolycus at this time that he was "très-avancé en âge (il avait alors 78 ans) dépourvu d'instrumens, accablá d'infirmités." . . . Zach sought unsuccessfully for the special work by Maurolycus, as well as for his "Life" by his nephew; Lalande gives no particulars of the former, and hence recourse has to be had to Clavius, who, as stated above, made some extracts from the *Judicium*.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, JUNE 21–27

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on June 21

Sun rises, 3h. 45m.; souths, 12h. 1m. 30·5s.; sets, 20h. 18m.; decl. on meridian, 23° 27′ N.: Sidereal Time at Sunset, 14h. 19m.

Moon (Full on June 27, 11h.) rises, 14h. 14m.; souths, 19h. 44m.; sets, 1h. 5m.*; decl. on meridian, 8° 24′ S.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	3 12	11 29	19 46	23 33 N.
Venus	4 38	12 58	21 18	23 51 N.
Mars	2 4	10 0	17 56	20 26 N.
Jupiter	9 6	16 13	23 20	12 9 N.
Saturn	3 43	11 52	20 2	22 30 N.

* Indicates that the setting is that of the following day.

Phenomena of Jupiter's Satellites

June	h. m.		June	h. m.	
21	21 9	I. occ. disap.	25	22 30	III. ecl. reap.
22	20 47	I. tr. egr.	27	20 23	I. tr. ing.

The Phenomena of Jupiter's Satellites are such as are visible at Greenwich

June	h.	
21	—	Sun at greatest declination north; longest day in northern latitude.
24	8	Mercury at least distance from the Sun.
26	20	Venus at least distance from the Sun.
27	15	Mercury in superior conjunction with the Sun.

GEOGRAPHICAL NOTES

The last issue of the *Isvestia* of the Russian Geographical Society (xx., 6) contains an interesting paper, by M. Kosyakoff, topographer, who accompanied, in 1882, Dr. Regel during his journey through Karategin and Darvaz. The paper deals almost exclusively with the topography of the explored region, and thus gives a plain description of the explored routes, containing the necessary topographical data for forming an opinion on the much-debated questions as to the orography of that part of the Pamir region. A route-map, on the scale of ten miles to an inch, accompanies the paper. Starting from Penjkent, M. Kosyakoff soon reached the 9800 feet high lake, Kouli-kalam. Then he crossed the 12,000 feet high and snow-covered Badkhana Mountains which separate the Zarafshan from the upper Surkhab, tributary of the Fan, and continuing to make his way amidst deep and rocky mountain-gorges, he soon reached the lake, Iskander-kul, 7120 feet above the sea-level. Thence, crossing the Mura Pass, richly clothed with vegetation on its northern slope, the expedition descended to Karatag and Hissar, and, by a route quite suitable for carriages, they proceeded further to Kabadian. A good route along the Waksh River brought Dr. Regel and his travelling companions to Kurgantube; but, to reach Koulab, they had to cross the Tash-robat Pass, all covered from top to foot with pistach trees. From Kulab, which is more animated than Kabadian, the expedition went to the rich Mumin-abad Valley, peopled with Tadjiks agriculturists; thence to the twenty-five villages of the Dara district, and, continuing their journey north-east on the right bank of the Pendj, they soon reached Kala-i-khumb. The Pendj River being there but thirty-five miles distant from Tavil-dara on the Waksh, the expedition went there before proceeding further up the Pendj, and followed the upper Waksh in a north east direction for some fifty-five miles. From Kala-i-khumb, M. Kosyakoff made a further very interesting excursion up the Pendj and its tributary, the Vantch, up to its source, whence he was compelled by a fever to return to Kala-i-khumb and thence to Samarcand. The map published by the *Isvestia* contains, moreover, the very interesting route from Tavil-dara to Bal-juan, and thence to Hissar, and further west to Baisoun, Anar-bulak, and Yar-tube.

Among the works announced for this year by the Russian Geographical Society we see the last fascicule of the valuable "Geographical and Statistical Dictionary of Russia;" the atlas of maps to accompany Baron Kaulbars' work on the delta of the Amu-Daria; a geognostic map of the shores of Lake Baikal, by M. Chersky; the work of Dr. Sperck on the Amur region; and a work by M. de Vollan on the songs of Ugrian Russians. There is promised, also, the long-expected results of the great survey of Siberia, from the Ural Mountains to Lake Baikal, accomplished in 1874. The commander of the expedition having died since, the work had to be given for calculations to other persons; but now the name of M. Tillo, who has undertaken its publication, is a guarantee that this capital work will not be lost to science.

Dr. Fischer, of the University of Marburg, the author of a monograph on the climate of Mediterranean countries, read a paper before a recent meeting of the Verein für Erdkunde at Halle on the morphology of the coasts of the Mediterranean, which is reprinted in the *Hallische Zeitung*. "The Mediterranean," he said, "was specially important for some investigations into physical geography, for it has been the theatre of a long history, and we have therefore information about its coasts extending over many centuries. Although it washes the shores of three continents, this sea exhibits a striking similarity in its *fauna* and *flora* everywhere. It must, therefore, in its present form, belong to one of the most recent geological periods, even though particular basins may be much older. It owes its origin to great movements in the crust of the earth, and the form of its coasts is attributable to the same cause, modified by more recent influences. In the present coast formation in the north-western basin, two different types are perceptible, which may most conveniently be designated as the North Sicilian and the Languedoc types. If we follow the coast of Italy from Naples, then the Sicilian and North African coasts around to the Straits of Gibraltar, we meet with twenty-two smaller bays having the form of a semicircle. Their sizes do not vary greatly, the chord of the smallest being 15 km., that of the largest 65, and that of the great majority between 30 and 35 kms. Over this extent the coasts are almost everywhere precipitous, and a short distance from the shore the sea deepens rapidly. How has this formation arisen?" Quoting Suess's "Das Antlitz der Erde," Dr. Fischer said, "there appeared to be all along this coast a great fissure in the crust of the earth. The formation of the Appennines, the Atlas and the occurrence of volcanic phenomena along the whole line would point to this. But this would not account for the bays here mentioned; many of these are probably due to the sea washing away the softer from amongst the harder rocks. The projecting headlands are hard, old, crystalline rocks, while inside are the newer and softer kinds. These inlets, too, are not found everywhere along the coast, but only where the harder rocks are present. That the coasts here are greatly exposed to denudation by the action of the waves is shown by the numerous caves and cliffs, and the violent surge which beats against the vast harbour-works of the French on the coast of Algeria. The prevailing winds there are north and north-east, and thus assist the waves. Another factor is the current, which flows eastwards along the north coast of Africa from the Straits of Gibraltar. This meets the projecting capes and headlands, which deflect part of it into the bays, creating in the latter a counter-current which acts as a scour, keeping the bottom free from alluvium, and also exercising its influence on the semi-circular formation of the inlets. The Bay of Tunis is an exception. This is much deeper than the others, and the currents cannot therefore exercise the same influence over it. The alluvium is deposited, the River Medjerda brings down its contribution, and the result is a constant formation of land there. This bay belongs rather, on this account, to the second type, existing on the Mediterranean coasts of Northern Italy and Languedoc. The Tuscan coast was originally similar to that of Lower Italy, but it has now been altered beyond recognition. Here, to the west of the Appennines, there is a wide district with easily-denuded rocks. The rivers, especially since man has so disafforested the region, bring down vast quantities of alluvium. The current which flows into the Tyrrhenian Sea is deflected northward along the coast, and causes the deposit of the alluvium inshore, so that the ancient bays are gradually silting up. In ancient times the shores of this now harbourless sea had numerous bays, and Tyrrhenians were skilful navigators. At the mouth of the Arno the operation is best seen. Pisa, which was founded as the port on the sea at the mouth of the river, was no longer on the coast in Strabo's time, and is now some distance inland. The land-formation on the coasts of Languedoc is even more striking. In former times there were steep shores, protected by a row of islands, behind which lay a calm inland sea, on which the city of Narbonne was built. The sea silted up from inside and out—from inside by the rivers, from outside by the currents created by the frequent south-east winds which conveyed the alluvium of the eastern rivers, especially the Rhone, and deposited it there. The islands became joined to the land, and the inland sea disappeared. Thus arose on these coasts the flat plains, behind which are small lakes and marshes.

AT the meeting of the Paris Geographical Society of May 22 further information was read respecting the expedition of M. Teisserenc de Bort to explore the Sahara. Leaving Tuggurt, they marched south-south-west to Hassi Ouled Milond, the last point visited by the Flatters mission. Thence, passing through Bereçoff, they ultimately reached Gabes. Near Ghourd-Rouned M. de Bort found well-marked traces of an old lake of sweet water, about a kilometre long, and 700 or 800 m. wide. In the depression thus created there were evidences of a prehistoric station in numerous flint arrow-heads, and from this point to Gabes the presence of man at a very ancient epoch was attested by chipped flints.—M. de Quatrefages read a paper on the Red Indians, and on the half-breeds of the United States and Canada. The position which the writer maintains is that the Indians do not diminish so rapidly as is generally believed, as, for example, the Maoris. The half-castes are put in the census as whites; Indian women married to whites are similarly counted. "Placed in favourable conditions, the Redskins, far from diminishing in number, have increased, and are increasing. But they have not preserved their ethnic purity. Mixture with white blood has taken place even in the most remote tribes, and perhaps now the number of natives of pure blood is insignificant everywhere; but, on the other hand, the blood of the natives is mixing more and more with that of the whites, and the latter accept more easily day by day the half-breed as one of themselves." Although the Red Indians are disappearing as such, they will still live in the future true Anglo-American race. M. Henri Condreau gave a succinct account of six journeys which he made between 1881 and 1885 in Guiana. The writer is Professor at the Lycée at Cayenne, and performed two of these journeys during vacations; the others were undertaken at the request of the Governor of French Guiana. The most important one was from Manaos through the whole of Central Guiana, between the Rio Negro and Cayenne. He had already performed two-thirds of his task, and passed the sources of the Trombette, when he lost all his articles for barter amongst the Indians, and was deserted by his followers. During four months he was alone amongst savages, ultimately arriving at his destination by a forced march of thirty days through the virgin forest.

BEFORE the Society of Commercial Geography in Paris, M. Andreau described the prairies of Guiana which he traversed in his journey between the Rio Negro and Cayenne. Behind the enormous forests which extend inland from the coasts he found prairies wholly devoid of trees, where the air was dry and the climate mild. He strongly advocated the establishment of agricultural colonies there, describing the climate as in all respects the reverse of that found on the coast.

THE well-known African traveller, Major Serpa Pinto, is stated to have discovered large coal-fields south of the Rovuma River. The Rovuma is a coast river, and its estuary is situated about 11° S. lat. Along its banks runs the ancient caravan route from Cape Delgado to Lake Nyassa. The coal-fields were first claimed by the Sultan of Zanzibar, but have now been taken possession of by the Portuguese Government.

A SCIENTIFIC expedition under the charge of Lieut. Hovgaard, of the Danish Navy, is being prepared to investigate the eastern coasts of Greenland. M. Gamel, the owner of the vessel, has put it at M. Hovgaard's disposal, and the Danish Government will pay the cost of the expedition.

M. HANSEN-BLANGSTED has reported to the Geographical Society of Paris that the first steamer coming directly from the open sea arrived at Cologne on March 18. It is called the *Industry*, belongs to a company of Mannheim, and is of 513 tons burden. "This is an event important not only for Cologne, but also for every town on the Rhine."

PROF. KARL GOTTSCHE, of the University of Kiel, has just returned from his travels in Eastern Asia. After having lectured on Mineralogy and Geology for several years at Tokio, he undertook a scientific exploring expedition in Korea, at the request of the Korean Government, which lasted until December, 1884. His route extended over 3000 kilometres. Dr. Gottsche intends shortly to publish his geological, mineralogical, and ethnographical investigations of Korea. To our knowledge this is the first scientific investigation of the great East-Asiatic peninsula.

DR. H. Z. C. TEN KATE departed on May 18 from Southampton. He goes to the interior of Surinam, where he intends to devote himself to anthropological and ethnological studies. A grant has been given to him by Dr. Riebeck (Halle a/S) and Prince Roland Bonaparte.

A TELEGRAM dated "near Herat, June 9," states that, pending the settlement of the frontier question, the Frontier Commission is exploring and mapping out the country in all directions.

ON THE MESOZOIC FLORAS OF THE ROCKY MOUNTAIN REGION OF CANADA[1]

IN a previous memoir, published in the *Transactions* of the Royal Society of Canada, vol. i., the author had noticed a lower cretaceous flora consisting wholly of pines and cycads occurring in the Queen Charlotte Islands, and had described a dicotyledonous flora of Middle Cretaceous age from the country adjacent to the Peace River, and also the rich Upper Cretaceous flora of the coal formation of Vancouver's Island—comparing these with the flora of the Laramie series of the North-West Territory, which he believed to constitute a transition group connecting the Upper Cretaceous with the Eocene Tertiary.

The present paper referred more particularly to a remarkable Jurasso-Cretaceous flora recently discovered by Dr. G. M. Dawson in the Rocky Mountains, and to intermediate groups of plants between this and the Middle Cretaceous, serving to extend greatly our knowledge of the Lower Cretaceous flora and to render more complete the series of plants between this and the Laramie.

The oldest of these floras is found in beds which it is proposed to call the Kootanie group, from a tribe of Indians of that name who hunted over that part of the Rocky Mountains between the 49th and 52nd parallels. Plants of this age have been found on the branches of the Old Man River, on the Martin Creek, at Coal Creek, and at one locality far to the north-west on the Suskwa River. The containing rocks are sandstones, shales, and conglomerates, with seams of coal, in some places anthracitic. They may be traced for 140 miles in a north and south direction and form troughs included in the Palæozoic formations of the mountains. The plants found are conifers, cycads, and ferns, the cycads being especially abundant and belonging to the genera Dioonites, Zamites, Podozamites, and Anomozamites. Some of these cycadaceous plants, as well as of the conifers, are identical with species described by Heer from the Jurassic of Siberia, while others occur in the Lower Cretaceous of Greenland. The almost world-wide *Podozamites lanceolatus* is very characteristic, and there are leaves of *Salisburia sibirica*, a Siberian Mesozoic species, and branches of *Sequoia smittiana*, a species characteristic of the Lower Cretaceous of Greenland. No dicotyledonous leaves have been found in these beds, whose plants connect in a remarkable way the extinct floras of Asia and America and those of the Jurassic and Cretaceous periods.

Above these are beds which, with some of the previous species, contain a few dicotyledonous leaves, which may be provisionally referred to the genera *Stercula* and *Laurus;* and still higher the formation abounds in remains of dicotyledonous plants, of which additional collections have been made by Mr. T. C. Weston. The beds containing these, though probably divisible into two groups, may be named the Mill Creek series, and are approximately on the horizon of the Dakota group of the United States geologists, as illustrated by Lesquereux and others. The species are described in the paper, and differ for the most part from those of the Dunvegan group of the Peace River series, which is probably of the age of the Niobrara group, and, of course, still more from the overlying Laramie group. With regard to the latter, the author adduced some new facts confirmatory of his previously expressed view as to the position of the Laramie at the top of the Cretaceous and base of the Eocene, and also tending to show that some of the plants still held by certain palæo-botanists to be of Miocene age are really, in Canada at least, fossils of the Laramie group, and consequently considerably older than is currently supposed. The collections of plants studied by the author had for the most part been placed at his disposal by the Director of the Geological Survey.

HYDROMECHANICS

THE last of the series of lectures at the Institution of Civil Engineers during the session of 1884–85 on "The Theory and Practice of Hydromechanics," was delivered on Thursday

[1] Read before the Royal Society of Canada, May, 1885, by Sir William Dawson, C.M.G., LL.D., F.R.S.

evening, May 7, by Sir Edward Reed, K.C.B., M.P., on "The Forms of Ships." The President, Sir Frederick Bramwell, F.R.S., occupied the chair.

In the course of his address the Lecturer briefly explained the great development which the science of fluid resistance had undergone of late years, largely owing to the labours of Stokes, Rankine and others, but more largely still to those admirable investigations which had been carried out under the patronage of the Admiralty by the late Dr. William Froude, and subsequently by his son, Mr. R. E. Froude. He likewise explained the very great effect which those investigations had produced in the Royal Navy, owing to the judicious and prompt adoption of Froude's results by the Admiralty Constructors. Stress was laid throughout the lecture upon the importance of adjusting the form and proportions of ships not only to the loads which they have to carry, but likewise to the weight of the materials entering into their structure. It was a common error to judge of the merits of steamships by the relations which exist between their displacement, steam power, and speed, as expressed by formulæ of various kinds. Approximations to the theoretical form of least resistance were sought by some naval designers, and all considerable departures from that form were regarded as objectionable. The Lecturer, on the contrary, pointed out that no such theoretical form was any true or proper guide for a naval designer, since every change in the average weight of the hull necessitated a corresponding change in the form and proportions of the ship, and the great merit of a designer often was that he adopted forms differing widely from the abstract forms of the schools, and presenting a very inferior appearance when put into what are known as "Constants of Performance." This was illustrated by examples derived partly from actual ships and partly from calculations made for the purpose. Two actual warships were compared, one attaining the high figure of 213 marks when examined by the received formulæ, and the other gaining but 172 marks; yet in the Lecturer's view the latter was far and away the better ship, because she performed precisely the same service as the other, being inferior in no respect, and yet had cost less than the other by £114,000, and expended no more steam-power in attaining an equal speed. The Lecturer remarked that he should probably have regarded the abstract "form of least resistance" with more respect but for the circumstance that the designing of armoured vessels in which he was much engaged is "a branch of naval construction of much too concrete and ponderous a character to admit of any dalliance with abstract or fancy forms." He went on to express his regret that, owing largely to the restrictions which granite docks imposed upon naval constructors, and to the absence of iron floating docks capable of receiving ships of any form, and owing to other causes likewise, the construction of armoured ships—by which he meant ships which had a sufficient volume protected above the water to keep them afloat and upright while the armour remained intact—had been abandoned, and the first place upon the sea had been offered to any nation which had the courage and the will to assume it. In his opinion this was a purely voluntary abandonment, and was not the result of any scientific or economic necessity. He admitted that great changes in forms and proportions were very desirable in our great line-of-battle ships; for example, a great increase of breadth was necessary in order to economise the side armour, and to keep the ram and torpedo at ample distance from the boilers and magazines, which should be protected by an inner citadel, so to speak, well removed from the outer one. But so far was true science from presenting obstacles to these and other important changes, it actually invited these very changes, and increase of beam in particular had been shown by Froude to facilitate the attainment of practical invulnerability combined with very high speed. Size and cost were among the bugbears of our naval administration; by the true engineer they were always regarded as secondary to great and noble objects, among which objects he included the naval pre-eminence of our country. At any rate, there was no engineering obstacle whatever to England constructing and sending to sea, not merely those great and swift but delicate and fragile Atlantic hotels in which the British Navy is now to embark and fight, for the want of something better, but also war-ships—real war-ships—almost as invulnerable as these islands themselves, and capable of bearing the once-proud flag of England boldly into the waters of any enemy whatever.

On the motion of the President, a cordial vote of thanks was passed to Sir Edward Reed for his interesting and instructive lecture.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—In the second part of the Natural Science Tripos the examiners have placed the following in the first class in alphabetical order:—Men: Acton (Botany), St. John's; Eve, B.A. (Physics), Pembroke; Fitzpatrick (Physics), Christ's; Gordon (Physiology), Trinity; Shore (Physiology), St. John's; F. M. Young, B.A. (Physics), Trinity.

The Senior Wrangler, Mr. Berry, of King's College, was a student at University College School and College; the Second Wrangler, Mr. Love, of St. John's, was educated at Wolverhampton Grammar School. The Wranglers, thirty-four in number, are alone eligible to compete in the third part of the Mathematical Tripos a year hence.

In the Natural Sciences Tripos, Part I, the following were placed in the first class, in alphabetical order:—Men: Bury, Trinity; Couldridge, Emmanuel; Edgeworth, Caius; Evans, F. P., St. John's; Oliver, F. W., Trinity; Rolleston, St. John's; Seward, St. John's; Walters, H. G., Trinity. Women: Freund, J., Girton; Willoughby, C. A. J., Newnham.

The University Lectureship in Mathematics, lately held by Prof. J. J. Thomson, will be filled up by the General Board of Studies and the Special Board for Mathematics early in the Michaelmas Term.

It is proposed, in dealing with the increased income of the Craven Fund, to establish a new Studentship of 200*l.* a year for research in the Languages and History of Ancient Greece and Rome and the Comparative Philology of the Indo-European Languages; the Studentship to be tenable for one year, but a student might be re-elected on not more than two occasions.

It is proposed still further to systematise and improve the courses of local lectures in populous centres, and to give students University certificates and exemptions in all cases where satisfactory work has been done, instead of confining these special privileges to affiliated Colleges. The majority of the courses given in the past winter have been scientific, and the work continues to extend, under the energetic administration of Dr. R.D. Roberts. Much difficulty exists in some of the most promising centres, where the students (miners and artisans) are poor, in providing funds. There ought to be no difficulty in persuading colliery proprietors and manufacturers to find the money needed.

SCIENTIFIC SERIALS

Bulletins de la Société d'Anthropologie de Paris, 5me Fascicule, 1884.—On ancient superstitions still surviving among the Bretons, by M. Bonnemère. An interesting paper, showing among many other proofs of superstition that the peasantry believe in the possession by certain individuals, whom they characterise as "Ribotteurs," of the power of injuring others by causing their milch cows to lose their milk. The so-called "Ribotteurs" are believed to acquire this power by roaming naked through the fields on the night of April 30 to gather, at early dawn, the May dew, in which dwells the malevolent property of drying up the milk of cows.—On the uni-discoidal placenta of a mandril, by M. Chudzinski.—On the degree of atrophy of the olfactory nerves compatible with the persistence of the sense of smell, by M. Mathias Duval. The writer draws attention to the number of cases in which a post-mortem examination has proved the atrophy, or even total absence, of olfactory nerves, although there had been no apparent defect in the sense of smell during life. M. Dally is of opinion that in such cases an excess of the gray matter of the brain at any one point may serve to supplement a deficiency in some other cerebral region. —M. Topinard presented to the Society a copy of his great chart of the relative heights, registered among the conscripts and in the public schools of different parts of France.—Report of proceedings at the first meeting of the "Conférence Transformiste," organised last year in memory of Darwin. In accordance with the scheme of the Conference an address was to be annually delivered by a member of the Anthropological Society of Paris, who was to indicate the influence which Darwinian ("Transformist") views had had on the special branch of scientific inquiry which the lecturer prosecuted.—This year's address in the Physical Section of the Conference was delivered by M. Duval, who chose for his theme the evolution of the eye from the early development of the visual organs among the lower animals. His treatise is profusely illustrated by admirable diagrammatic woodcuts.—In the Psychical Section of the Conference M. Letourneau treated of the evolution of morality, tracing the rise and progress and various fluctuations of the moral sense among different races.—M. Pozzi, in announcing the decision of the Committee for awarding the Broca prize, explained that he and his colleagues had selected the works of three among the numerous competitors, viz. MM. Collignon, Chudzinski, and Testut, as of pre-eminent merit. The prize was, however, unanimously awarded to the last-named, M. Testut's great work, "Muscular Anomalies in Man explained by Comparative Anatomy," having secured him this distinction both on account of its able and exhaustive character and its great literary merits. The selected essays of MM. Collignon and Chudzinski, treated respectively of the "anthropometric differences of the leading races of France," and of the "Anatomy of the Negro." In his address M. Pozzi gave a summary of M. Testut's work, of which he spoke in terms of unqualified praise, both as regards the methods with which his observations had been conducted, and the manner in which the results were compared and tested.—Report of the eulogy on Paul Broca, delivered by M. Dally on the day the Broca prize was awarded for the first time. As an old friend and colleague, M. Dally, in his historical and literary notice of the life and works of Broca, was able to give many hitherto unknown particulars, which add largely to the interest of his address.

Bulletins de la Société d'Anthropologie de Paris, 1er Fascicule, 1885, containing *résumé* of the rules, organisation, and actual condition of the Society, with lists of members, affiliated societies, and recent obituary, &c., &c., &c. Among the works presented to the Society at its inaugural meeting, 1885, special notice is due to the "Elements of General Anthropology," by M. Topinard, who here gives a *résumé* of his lectures at the School of Anthropologie since 1876; the "Gitaños of Spain and Portugal," by M. Bataillard; "Ethnic Mutilations," by M. Magitot; and "Cannibalism among the Red-Skins," by M. Letourneau. In regard to each of these, the authors treated at great length of the objects aimed at in their respective works, the character and scope of which they fully explained.—M. Chudzinski presented the Society with the cast of the deltoid muscle of a negro, showing an anomalous separation of the bundles, which had a Simian character.—M. Delisle drew attention to an ox's head belonging to *Bos indicus* of Senegal, in which a perfectly developed horn protruded from between the nasal bones.—A paper by Dr. Hoffman, of Washington, on a curious relic found in South California, supposed to have been a case for keeping the colouring-matters and instruments employed in tattooing.—On the Quaternary deposits of Rosny (Nogent-sur-Marne), by M. Eck. Among these finds are fine teeth of *Elephas primigenius*, *Rhinoceros tichorhinus*, *Equus*, &c.—Report by M. Gouïn, of Cagliari, on the skulls and objects found by M. Issel in the recently-opened cave at Orreri, in the Island of Sardinia. M. Issel believes, from his study of the prehistoric remains of Western France, Spain, and the basin of the Mediterranean generally, that these and the finds at Orreri all point equally to the diffusion of a primitive race, which was extant in the Canary Isles within historic times.—On Laos, by M. P. Neis, who explored the Laotian territory bordering on Cambodia in 1882-84. The author, as a French official, enjoyed exceptional advantages for travelling in Cochin China and the neighbouring districts, and his careful study of the character and habits of the people has enabled him to collect much interesting information regarding the distinctive anthropological and social characteristics of the different races of Indo-China. M. Neis sees no ground for the opinion that these races exhibit traces of a Negrito element, but he draws attention to the fact that everywhere the Mongol is displacing the Thay and other ancient nationalities, although this is most evident in the territories between Mam-on and Tonkin, and he believes that, unless the King of Siam takes prompt measures to stop this invasion, Siamese supremacy and French authority will be alike endangered.—Ceylon and its inhabitants in ancient and modern times, by M. Beauregard. The author derives his materials from English sources.—On the caves of Saumoussay, by M. Bonnemère, who believes that these grottoes served in prehistoric ages as a tannery.—On the measurements of the long-bones as a basis for the reconstruction of the entire skeleton, by M. Topinard, with plates of the osteometric instrument used by Broca.—On will, considered from a physiological point of view, by M. Fauvelle.

SOCIETIES AND ACADEMIES

London

Royal Society, May 7, with a note added May 12.—"On the Electric Resistance of a New Alloy named Platinoid." By J. T. Bottomley, M.A., F.R.S.E.

In the course of a series of experiments on the electric resistance of various metals and alloys and in particular on the variation of the electric resistance of these metals and alloys with temperature, the author has examined a new alloy (called by the inventor "platinoid"), which has turned out to have important properties.

This alloy is the invention of Mr. F. W. Martino, of Sheffield, who kindly supplied specimens of the metal, and wires specially drawn down to the finer gauges for experiments.

Platinoid is practically German silver with the addition of a small percentage (1 or 2 per cent.) of metallic tungsten. The tungsten is added in the form of phosphide of tungsten, a considerable percentage of which is in the first place fused with a portion of the copper. The nickel is then added; and then the zinc and the remainder of the copper. The mixture requires to be re-fused more than once, and during the process the phosphorus and a considerable portion of the tungsten originally added is removed as scoriæ. In the end there is obtained a beautiful white alloy, which is platinoid. When polished the alloy is scarcely distinguishable in appearance from silver. To test the quality claimed for it as to being untarnishable, the author has been keeping ornamental specimens lying exposed to the ordinary town atmosphere; and has satisfied himself that the alloy has a very remarkable power of resisting the tarnishing influence of the air of a large town.

It is, however, the electric resistance of platinoid that has chiefly interested the author. German silver wire has proved of great use in the construction of galvanometer coils and resistance coils, on account of two important properties, viz., its very high resistance and the smallness of the variation of its resistance with change of temperature. Both those properties are possessed in a still higher degree by platinoid alloy.

The resistance of German silver differs considerably in different specimens. It is commonly stated to be $21{\cdot}17 \times 10^{-6}$ B.A. ohms between opposite faces of a centimetre cube at 0° C.;[1] or, reducing to legal ohms, $20{\cdot}935 \times 10^{-6}$ legal ohms between the opposite faces of a centimetre cube. The following table shows the resistance of a number of specimens of platinoid wire:

Specifying number	Diameter in decimals of a centimetre	Cross Section	Resistance legal ohms per metre	Resistance between opposite faces of a centimetre cube legal ohms.
16	·1610	·0204300	·181	$36{\cdot}98 \times 10^{-6}$
17	·1430	·0160200	·202	32·36
18	·1230	·0119400	·288	34·38
19	·1110	·0096770	·353	34·16
20	·0865	·0058760	·555	32·61
A	·0595	·0027180	1·250	$34{\cdot}76 \times 10^{-6}$
B	·0495	·0019240	1·707	32·85
28	·0402	·0012690	2·605	33·06
29	·0340	·0009070	3·412	30·94
32	·0290	·0006605	4·371	28·87
36	·0220	·0003801	8·219	31·24

It appears from these results that the specific resistance of platinoid is about *one and a half* times that of German silver.

The experiments on the variation of resistance of platinoid with temperature were carried on in the following way. The specimen of platinoid to be tested was wound on a wooden bobbin, on the surface of which a screw had been cut, and the spires of the helix were kept separate by lying between the threads of the screw. This coil was immersed in a bath of oil, and was connected in series with a known wire of German silver, the temperature of which was kept constant, and with a single Daniell's cell. The differences of potential between the two ends of the platinoid wire and the two ends of the German silver wire were determined by applying the electrodes of a a high-resistance galvanometer. The ratio of the differences of potential is the same as the ratio of the resistances of the two wires.

[1] Given by Prof. Fleeming Jenkin, F.R.S., as expressing the results of Matthiessen's experiments.

In the following table is shown the ratio of the resistances of a specimen of platinoid wire at different temperatures to its resistance at zero. The wire used was the same as that specified as No. 20 in the table of resistances. The length of the wire experimented on was about four-fifths of a metre. The only trouble in the experiment was the keeping the oil-bath, which was filled with linseed oil, thoroughly stirred, and of uniform temperature throughout.

Temperature.	Resistance. The Res. at 0° C. being = 1.
0°	1·0
10	1·0024
20	1·0044
30	1·0075
40	1·0066
50	1·0097
60	1·0126
70	1·0134
80	1·0166
90	1·0188
100	1·0209

This gives for the average percentage variation of resistance per 1° C., between the temperatures 0° C. and 100° C., the number 0·02087. A second wire tested very carefully in a similar way gave for this average percentage variation between 0° and 100°, 0·022 per degree, with a steadily increasing rate of variation from the beginning.

To compare this increase in resistance due to increase of temperature with that observed in other metals and alloys, we find that the percentage increase of resistance for 1° C. at 20° C. for copper is 0·388, platinum-silver alloy 0·031, gold silver alloy 0·065, and for German silver 0·044. These numbers were obtained by Matthiessen in the course of his experiments for finding a suitable metal or alloy for the purpose of constructing the British Association standards of electric resistance. It appears that the variation of resistance of platinoid with temperature is very much smaller than the smallest observed for any of the metals and alloys then examined.

The modulus of rigidity, the Young's modulus (or modulus for elastic longitudinal extension), and the breaking weight for platinoid wire were also determined. The wire used was a portion of that marked *A* in the foregoing table. This wire is a little larger than No. 24 of the Board of Trade standard wire gauge, and has a diameter of 0·0595 cm.

The rigidity modulus was found to be $4751·8 \times 10^6$ grammes weight per square centimetre. The Young's modulus is $1222·4 \times 10^6$ grammes weight per square centimetre.

The breaking weight is about $6·029 \times 10^6$ grammes weight per square centimetre.

The specific gravity of platinoid wire has also been found by the author to be 8·78 compared with water at 20° C. Platinoid when drawn hard is softened, like copper, by heating and sudden cooling.

Physical Society, May 23.—Prof. Guthrie, President, in the chair.—Dr. A. H. Fison was elected a Member of the Society.—The following communications were read:—Experiments showing the variations caused by magnetisation in the length of iron, steel, and nickel rods, by Mr. Shelford Bidwell. The subject of the extension and retraction of bars of iron and nickel under the action of magnetic force has been investigated by Drs. Joule and A. M. Mayer, and by Mr. Barrett. In the present experiments the magnetising force has been increased, with the result of bringing out some striking and novel characteristics. The apparatus employed consisted of a vertical magnetising helix considerably longer than the experimental rod, the latter forming the central portion of a compound rod, the two ends being of brass. The lower end of this rod is plane, and stands on a firm support; the upper end is a knife-edge, which bears against a brass lever 18 cm. in length, about 1 cm. from the fulcrum; the portion of the rod to be examined is in the central portion of the helix. The above lever is furnished with another knife-edge at the end, which acts in a similar manner on a second lever, at the extremity of which is a small mirror. A lamp and vertical scale being placed at a distance of 470 cm., the slightest motion of the mirror could be read with great accuracy, an elongation of the bar, amounting to 1-100,000th mm., being easily detected. A few of the more important results are as follow:—In the case of soft iron the bar continually increased in length till nearly saturated, up to which point Mr. Joule had traced it, but then it reached a maximum, decreased, and continued decreasing to the limit of the experiments, at which point the retraction was about double of what the extension had been. The effect depended upon the thickness of the bar, an increase of diameter diminishing the maximum extension, and increasing the critical magnetising force, or that force which produced the maximum extension; the results seemed to show that this extension varied inversely as the square root of the diameter of the bar. The general behaviour of steel was the same as that of soft iron, but the critical point varied with the hardness and temper of the metal, appearing to be a minimum for steel of yellow temper. The results of experiments upon nickel coincided with those obtained by Prof. Barrett, the effect of magnetisation being to cause a continuous retraction greater than that obtained with soft iron. In answer to Prof. Hughes, who believed that the effect of the coil was always to produce *retraction* of the bar, the *extension* at first being due to the molecular arrangement of the particles during magnetisation, Mr. Bidwell further described an experiment showing that the action of the coil was to produce the *extension* of a magnet. Two thin strips of soft iron fastened together at the ends, their central portions being about 2 cm. apart, were placed in the coil. On making the current the ends were drawn out, the sides coming together. Prof. Forbes suggested that the effect of thickness was really owing to the irregularity of magnetisation produced by the ends, and that in future experiments the middle of the bar only should be examined.—On the spectral image produced by a slowly rotating vacuum-tube, by Mr. Shelford Bidwell.—Note on the action of light in diminishing the resistance of selenium, by Mr. Shelford Bidwell. As the result of the investigation upon the behaviour of selenium, Messrs. Adams and Day arrived at the conclusion that it conducted electrolytically. Since this would necessitate the assumption that selenium is not an element according to accepted theories, caution must be exercised in accepting this. It seemed possible, however, that since the selenium in the cells had always undergone a prolonged cooking in contact with the metal terminals, selenides of these metals might exist in the selenium, forming a kind of network, and thus affording conduction through the mass, which, without the cooking, is non-conducting. It had not been possible to test this directly, but a somewhat analogous case had been tried. Some precipitated silver had been heated for some hours with sulphur, and the clear liquid poured off. A cell was then made by coiling two silver wires side by side upon a strip of mica, the spaces between the wires being filled with the prepared sulphur, which would contain a small quantity of sulphide of silver. It was found necessary to reduce the resistance of the cell by placing a small strip of silver leaf over the sulphur and cooking again. The cell thus prepared was very sensitive to light: by burning a piece of magnesium near, the resistance was reduced to one-third. Mr. Clark said that Mr. Bidwell's cells probably contained sulphides of copper or silver, substances which the researches of Faraday had shown conducted electrolytically in the solid condition. On the other hand, Cu_2Se and Ag_2Se conducted like metals and were probably often present in the ordinary selenium light cells. Mr. Clark thought that Mr. Bidwell's paper raised this question: What influence had light upon the electrolytic conduction of Cu_2S and Ag_2S and upon the metallic conduction of Cu_2Se and Ag_2Se?—On certain cases of electrolytic decomposition, by Mr. J. W. Clark.—The first part of this paper consisted of a critical examination of the behaviour of those substances which have been described as exceptions to Faraday's laws, with the object of generalising as to the condition of internal or molecular structure corresponding to their electrical properties. The second part described an experimental investigation into the nature of the conduction of fused mercuric iodide and mercuric chloride, both of which were stated to undergo electrolytic conduction. Decomposition and re-combination of the products of electrolytic action may, however, follow so closely as to simulate metallic conduction. The first product of electrolytic decomposition of mercuric iodide was stated to be iodine and mercuroso-mercuric-iodide (Hg_4I_6), which latter, under the continued action of the current, yields free mercury. Similarly it was found that fused mercuric chloride, when electrolysed between graphite terminals, split up into chlorine and mercurous chloride. Metallic conduction, *i.e.* conduction without decomposition, in fused compound solids, therefore appears to be unknown.—Note on electrical symbols, by Mr. J. Munro.

Mathematical Society, June 11.—J. W. L. Glaisher, F.R.S., President, in the chair.—Prof. J. Larmor was admitted into the Society.—Mr. Basset read a paper on the potential of an electrified spherical bowl, and on the motion of an infinite liquid about such a bowl, upon which Prof. Larmor made some remarks.—Mr. Elliott communicated a short paper by M. Z. J. Rogers, entitled, notes on the polism of the inscribed and circumscribing polygon.—Mr. Kempe, F.R.S., made a brief communication on pairs of collinear points; and a paper by Prof. Mannheim, liaison géométrique entre les sphères osculatrices de deux courbes qui ont les mêmes normales principales, was taken as read.

Chemical Society, June 4.—Dr. Hugo Müller, F.R.S., President, in the chair.—Mr. Harold Follows was admitted as a Fellow of the Society.—The following paper was read:—On the constitution of the haloid derivatives of naphthalene, by Prof. Meldola.

Anthropological Institute, June 9.—Francis Galton, F.R.S., President, in the chair.—Prince Roland Bonaparte exhibited a large collection of photographs of Lapps.—Mr. P. A. Holst exhibited three water-coloured photographs out of a collection of 240, representing all the tribes of the Russian empire.—Dr. J. G. Garson read a paper on the physical characteristics of the Lapps; and by the permission of the authorities of the Alexandra Palace, the family of Lapps now being exhibited there were present in the room with their sleigh, reindeer skins, and dog. The group consists of three men, two women, and two young children. The average height of the men is 5 feet 1½ inches, that of the women 4 feet 11½ inches. The chief characteristics of the Lapps may be said to be their low stature, round heads, and large cranial capacity.—Prof. Keane read a paper on the Lapps: after glancing at their origin, ethnical relations and nomenclature, explaining the perplexing terms Lapp, Finn, Same, &c., the Professor proceeded to describe their present habitat, their national and political divisions, and population; not more than about 30,000 Lapps remain, and their number appears to be diminishing. Their social usages were then described, and allusion made to their reindeer, dogs, sledges, snow-shoes, and tents, and the paper concluded with an account of their religion, education, present condition, and future prospects.—A paper by Dr. H. Rink on Eskimo dialects was taken as read.

EDINBURGH

Mathematical Society, June 12.—Dr. Thomas Muir in the chair.—Prof. Tait gave an address on the detection of amphicheiral knots, with special reference to the mathematical processes involved.

PARIS

Academy of Sciences, June 8.—M. Bouley, President, in the chair.—Action of chloroxicarbonic ether on the cyanate of potassium, by MM. Wurtz and Henninger. In an accompanying note it is stated that this important posthumous monograph was mostly prepared in 1875, but that its publication was delayed by the authors in order to complete their researches on various points. After the death of M. Wurtz the work was continued by M. Henniger, who was about to publish the results when he also fell a victim to his arduous labours. In its present form the paper has been prepared and edited by M. Edouard Grimaux.—Memoir on the temperature of the atmosphere and ground at the Paris Natural History Museum during the years 1883 and 1884, by MM. Edmond Becquerel and Henri Becquerel. This memoir forms a continuation of the researches begun twenty-two years ago at the Museum by M. A. C. Becquerel, by means of the thermo-electric apparatus invented by him.—On the geographical distribution of animal and vegetable species as affected by the climatic conditions, the character of the soil, the disposition of land and water, the progress of culture, and other outward influences of the environment, by M. Emile Blanchard.—Propagation of the earthquake shock felt in Andalusia on December 25, 1884, a rectification, by M. F. Fouqué.—On a new order of metallic spectra, by M. Lecoq de Boisbaudran.—Note on a new vegetable type from the lower coralline formations of Auxes, in the neighbourhood of Baune, Côte d'Or, by M. G. de Saporta. This type, by the author named Changarniera, from its first observer, appears to be of lacustrine origin, and to bear a certain relation to the Rhizocaulon from the freshwater chalk-formations of the South of France, still surviving in Provence. It may, perhaps, represent one of those proangiosperm types, the existence of which has only begun to be suspected by botanists.—Note on some recently-discovered documents connected with the infancy of Jean Le Rond d'Alembert, by M. L. Lallemand. These inedited records show that, contrary to Condorcet's statement, d'Alembert was sent to the Maison de la Couche, and placed with a nurse for six weeks in a Picardy village, after which he was consigned to the charge of Jacques Molin (Dumoulin), one of the most distinguished physicians of the time.—On a method of rapidly analysing all the nitrogen contained in substances in the organic, ammoniacal, and nitric state, by M. A. Houzeau.—On a method of employing the sextant in such a way as to obtain by a single observation the simultaneous altitudes or angles of two stars, of a star and the moon, or of a star and the sun, by M. Gruey.—On the convergence of a continuous algebraic fraction, by M. Halphen.—Remarks on the radiations emitted by incandescent carbons, such as those prepared for use in lighthouses for the production of voltaic arcs, by M. Félix Lucas.—Remarks on the apparatus usually employed for the measurement of continuous and other electric currents, by M. Mascart.—A thermo-chemical study of electric accumulators, by M. Tscheltzow.—Note on the action of silver, copper, iron, and some other metals on a mixture of acetylene and air, by M. F. Bellamy. The author's experiments show that in the burner these metals, and especially copper, act on acetylene in the same way that platinum does on hydrogen.—Note on the sulphurets of cerium and lanthane, by M. Debray.—On a new reaction for digitaline, by M. Ph. Lafon. This reaction, which is extremely sensitive, will enable the chemist to distinguish more sharply than has hitherto been possible between the numerous products employed in therapeutics under the general name of digitaline.—Note on aseptol (orthoxiphenyl-sulphurous acid), by M. E. Serrant. For this substance (so named by the author from the Greek negative particle ἀ and σηπτόν, corruption) it is claimed that it will be found three times superior to phenic acid as a practical antiseptic.—On electric alcoholic fermentation, by M. Em. Bourguelot.—Remarks on the tail of the human embryo, by M. H. Fol. From his researches the author is satisfied that during the fifth and sixth weeks of its development the human embryo is furnished with a tail in the strict anatomical sense of the term. Being destitute of all physiological use, this organ must be classed with all other rudimentary members.—On the natural evolution of the cantharides, by M. H. Beauregard. The results are here embodied of three years' research, during which the author has succeeded in clearing up many obscure points connected with the physiological life and functions of these insects.—Note on the extraction and composition of the gases contained in the leaves of plants, by MM. N. Gréhaut and Peyrou.

THE CHITTAGONG HILL TRIBES

The Chittagong Hill Tribes. Results of a Journey in the Year 1882. By Dr. Emil Riebeck. Translated by Prof. A. H. Keane. (Asher, 1885.)

THE visit paid by Dr. Riebeck to the frontier tribes between Chittagong and Independent Burmah in the spring of the year 1882 formed a mere episode in the great expedition to the Far East, from which he has recently returned, laden with ethnological treasures of all sorts. But this episode, carried out at the suggestion of Dr. Bastian, "prince of ethnologists," proved from a variety of causes so unexpectedly fruitful in results, that he has been well advised to publish a separate account of it, pending the appearance of a comprehensive work on his general travels in Somaliland, India, China, Japan, and other Eastern regions. In its arrangement, profusion of coloured and other illustrations, and especially in the treatment of the subject matter, this first instalment almost reaches the standard of ideal perfection—of such perfection as can be achieved only by patient and intelligent observation, and by the cooperation of specialists in their several faculties combined with a generous use of unlimited means. Certainly the principle of division of labour in literary and scientific work has never been more happily illustrated than in the present instance. Wisely limiting his own functions to those of a laborious collector and narrator of his personal experiences, Dr. Riebeck has placed all his rich materials at the disposal of the foremost naturalists in Germany, by whom the data thus supplied have been made a convenient text for so many separate monographs of great value on the various scientific aspects of the subject.

The work thus comprises, besides the journey itself graphically described by the traveller, four independent treatises—by Dr. A. Grünwedel, on the ethnology; by Dr. Rudolf Virchow, on the anthropology; by Prof. Julius Kühn, on the zoology; and by Herr von Danckelmann, on the meteorology of the hilly region traversed during the expedition.

The trip included altogether two separate excursions, the first from Chittagong up the Karnaphuli river to Pakhoma and Forts Sirtay No. 1 and 2, close to the Burmese frontier; the second, again from Chittagong southwards to the Sangu, up that river nearly to its source, thence across the border to Dalakmey on the Koladan in Arakan, and from that point down the Koladan to its mouth at Akyab. None of these river basins can be described as unknown regions, seeing that they all lie well within British territory, and have been frequently traversed in various directions by Lewin, Hunter, and other explorers, by Government surveyors, and even occasionally by military expeditions. Nevertheless, such is the intricate character of the land, consisting of nearly parallel mountain ranges running close together, mainly north and south, separated by deep intervening river gorges, often densely wooded, and inhabited by a multiplicity of semi-independent hill tribes in almost every stage of social culture, that the broad physical features both of the country and its inhabitants had hitherto been but imperfectly understood, while few of the details had been fully worked out. Hence a rich harvest still awaited our traveller, and the abundant materials collected by him and carefully sifted by his scientific fellow-workers could not fail to prove useful and help to solve some obscure problems in the natural history of the country.

Thus a comparative study of the two Gayal skulls from Chittagong and Arakan enables Dr. Kühn to clear up several questions touching the mutual relations of the gayal (*Bos gavæus*, Colebrooke), the arni or true wild buffalo (*Bubalus indicus*), the gaur (*Bos cavifrons*, Hodgson), and other members of the ox tribe in India and Indo-China. It now appears evident that the gayal or wild ox of Bengal, Assam and Further India does not differ specifically from the gaur of India proper, as George Vasey and others wrongly supposed. "While the wild gayals' skulls show all the features of the gaur, the forms of the tame gayal from the same locality correspond altogether to the normal gayal type as described by its best observer, Hodgson. Room is thus afforded for the surmise that both types characterise, not two distinct species, but forms only of the same species; that consequently gaur and gayal are specifically one, and that the deviations of the latter in its tame form have merely the value of a variation due to domestication."

Of more general interest are the admirable ethnological and anthropological papers of Dr. Grünwedel and Dr. Virchow, whose learned analysis of the data, and especially of the numerous measurements supplied by Dr. Riebeck, throws a flood of light on the many perplexing questions connected with this obscure ethnical domain. Accepting the already-established broad distinction between the Khyoung-thâ or River Tribes, and Toungh-thâ, or Hill Tribes (Lowlanders and Highlanders), a distinction which has more than a mere geographical significance, these anthropologists find that, on the whole, the hill tribes are of purer descent, that is, represent the aboriginal element more closely, than the riverain populations. The latter (Maghs, Chakmas, Toungjinyas, &c.), have become more intermingled with the Bengalese and other intruders from India, and are characterised by a yellower complexion suggestive of Mongol, or perhaps Malay, affinities. The former (Pankhos, Banjogis, Mros, Kumis, Kukis or Lushais, Shos, Shindus, &c.) are of a darker hue, and seem to approach nearer to the Kolarian aborigines of India. At the same time Dr. Virchow is careful to point out that none of these Hill Tribes lend any support to the theory of an aboriginal Negrito element formerly spread over the whole of India and Indo-China, advocated especially by De Quatrefages and other French ethnologists. "According to unanimous testimony they have all black, long, and smooth, but by no means straight, hair, and, although not athletic, their stature still at once separates them from the dwarfish Andamanese and Negritoes. On the other hand, in further inquiry the question cannot be waived whether the Hill Tribes of Chittagong, perhaps also of Nepal, may not, after all, be somewhat nearly related to the primitive 'black skins' of India. The name Dasyu, or

Dasa, recalls in a remarkable manner the word Dzo, applied both to the Lushais and their speech."

On the whole the Lowlanders appear to be closely related to the Arakanese, and consequently to the Burmese, and are characterised by distinctly Mongolic features. They may, in fact, be regarded as a Mongoloid people, intermediate between the true Mongols of Northern and Central Asia and the Malays of Malacca and the Eastern Archipelago.

This section of the subject is illustrated by very complete tables of measurements, and by as many as twenty-six photographs of Lushais, Pankhos, Maghs, Chakmas, Tipperahs, and other highland and lowland tribes.

Dr. Riebeck's account of his experiences amongst these children of nature is extremely graphic, and all the more entertaining that the arrangement with his collaborateurs enables him to eliminate all dry technicalities and strictly scientific matter. At the time of his visit a famine prevailed amongst the border tribes in the upper Karnaphuli basin, causing an irruption of Lushais and others into British territory. Thanks to this circumstance he was enabled to procure many valuable articles from the half-famished people in exchange for a little rice and spirits. The circumstances connected with these transactions are related with a frankness which almost savours of excessive candour. "The brandy I concocted myself," he tells us, "by diluting spirits of wine with water, and colouring it with burnt sugar, thereby producing a still more alluring drink for their uneducated palate. In return, they not only parted with a large quantity of their implements, but also allowed me to take bodily measurements and submitted to be photographed by my fellow-traveller Rosset. If for brandy I had substituted money, this would have soon found its way into the pockets of the Bengali dealers, who cozened and plundered the natives to the utmost. I may therefore be pardoned if I preferred to tickle the palate of the Lushais with fire-water rather than play into the hands of the blood-sucking usurers."

A tropical thunderstorm, by which he was overtaken in the Ruma district, is described in exceedingly vivid language. "The spectacle which now presented itself was one of the most stupendous imaginable. In a few seconds the firmament became completely overcast; then the welkin towered up, looking in the gleam of the electric flashes like mighty sheaves of flame. The weird effect was heightened by the neighbouring woodlands, which were now all ablaze. For the natives had fired the surrounding bamboo-clad hills in order to clear the land for paddy-fields, and sow their rice in the ashes. Thus was mingled the crackling of the burning and crashing bamboo canes with the roaring thunder aloft, the whole producing a din like that of a neighbouring battle-field."

These passages may also serve as specimens of Prof. Keane's very admirable, faithful, and idiomatic translation. It may be mentioned that the German and English editions, both in folio size and splendidly printed, were issued simultaneously by Messrs. Asher, of Berlin and London. The work forms a sumptuous volume which should find a place in every well-appointed library.

THE METEOROLOGY OF BOMBAY

Magnetical and Meteorological Observations made at the Government Observatory, Bombay, 1883, *under the Superintendence of Charles Chambers, F.R.S., Rev. Fr. Drechman, S.J., Ninayek Narayen Nene, and Frederick Chambers.* (Bombay, 1884.)

OF the series of volumes entitled "Bombay Magnetical and Meteorological Observations," the present one of forty pages folio is the twenty-fourth. The observations were begun in 1841, and whether we consider the high class character of the observations themselves, the fulness with which they were made from hour to hour, or the long period over which they extend. hey must be regarded as among the very best meteorological records we possess. In the discussion of many of the larger questions of Indian meteorology, such as are from time to time dealt with by the meteorologists of India with so much ability and success, the Bombay observations are simply invaluable; and they are at least of equal importance in the wider questions of the science, and particularly in those cosmical inquiries which have largely engaged the attention of physicists in recent years.

In this report a very satisfactory account is given by Mr. Chambers of the observatory, its position, and surroundings, the instruments in use, and the duties of the various members of the observing staff, all showing that a trustworthiness and an accuracy is secured for the observations which leaves nothing to be desired. Five eye-observations are made every day without exception, at 6 and 10 a.m., and 2, 4, and 10 p.m. In addition to these, continuous registrations are obtained by means of automatic recording instruments, consisting of the magnetographs, the barograph, thermograph, pluviograph, and anemograph, the first four registering photographically and the last mechanically.

From these observations and registrations hourly readings of the various instruments are obtained, and from them the daily means are deduced. These daily means, together with the monthly means, are published in a series of tables appended to the Report. The daily results of the wind observations are given with more than usual fulness,—these consisting of the mean velocity in miles per hour without regard to the direction from which it blew; the aggregate and mean velocities and relative frequency of different winds; and the mean daily velocities of the north or south and east or west components of the winds which blew each day, in miles per hour. At Bombay the greatest mean daily velocity in miles per hour was 31·8 on June 11, and the least 5·2 on October 4; whilst the mean hourly velocity from June to August was 16·2 miles, and from September to May it was only 10·9 miles.

Underground observations are made at depths of 1, 9, 20, 60, and 132 inches below the surface, the first two depths being observed five times daily and the last three once a day, inasmuch as at these depths no diurnal variation is shown. At depths of 1 and 9 inches the monthly maximum and minimum temperatures occurred in December and May, but at the depth of 132 inches these annual phases were delayed till March and July. The mean annual temperature of the air during 1883 was 78°·8, and of the ground, at a depth of 1 inch, 80°·9; 9 inches, 80°·7; 20 inches, 82°·6; 60 inches, 83°·8; and 132 inches, 83°·2. It is desirable that the errors of these underground thermometers were ascertained.

Down to the close of 1864 the hourly observations made at Bombay were published *in extenso*, and these twenty-four years' hourly observations furnish data for the prosecution of many inquiries, the value of which it would be difficult to over-estimate. From 1865 to 1872 the individual observations ceased to be published, but the hourly means for the different elements continued to be published. From these the hourly means of pressure, temperature, humidity, cloud, thunderstorms, &c., can be obtained for a period of more than thirty years. From the beginning of 1873, however, no hourly observations, or even hourly means, appear in the reports, want of funds presumably being the cause of the omission. Irrespective altogether of the length of time over which the observations have been made and the immense value this single consideration gives to the Bombay observations, the position of this observatory with respect to the monsoons and other vital elements of the meteorology of India render the maintenance of a first-class meteorological observatory in this part of the empire indispensable. It is in truth simply necessary in the interests of Indian meteorology and its satisfactory development that the Bombay Observatory be kept in a state of high efficiency, and that the individual observations made there be published and distributed among men of science at least as liberally as they were previous to 1865.

OUR BOOK SHELF

Supplement to "Euclid and His Modern Rivals," containing a Notice of Henrici's Geometry, together with Selections from the Reviews. (London: Macmillan and Co., 1885.)

We noticed the original work at such length in these columns (NATURE, vol. xx. p. 240), that it is not worth while on the present occasion to do more than draw attention to the issue of this "Supplement."

Prof. Henrici's "Congruent Figures" was published nearly contemporaneously with Mr. Dodgson's book, and so he was unable to discuss the methods employed by the Professor, who, in the words of the present preface, "fills the *rôle* of that popular functionary, dear to Parisian diners, *le quatorzième*."

The discussion forms scene vi. of Act ii., and is headed "Treatment of Parallels by Revolving Lines," and an extract, as usual, leads the way from Henrici's Art of Dining (so our humourist puts it), viz. "in order that an aggregate of elements may be called a spread, it is necessary that they follow continuously."

It will thus readily appear to the readers of the "Euclid and his Modern Rivals," or of our account referred to above—which by the way is honoured by a partial reproduction amongst the review-selections—that Mr. Dodgson is still himself, and that his hand has lost none of its former cunning. We should have liked him to have given his opinions on other parts of the Professor's book, but it has not seemed good to the author so to act, and he has confined himself mainly, if not entirely, to the Lobatschewky treatment of parallels. With two such combatants now fairly in the arena, we shall be content to act as a mere onlooker whilst the strife wages fiercely between them, eagerly noting the parry and the thrust, and ready, if need be, to use the sponge as this or that combatant is struck.

It might be a mighty pretty encounter—Modern Treatment versus the Euclidian.

Mr. Dodgson inserts remarks here and there in the text of the reprinted criticisms: he does not notice that a complaint he makes against us was in great part apologised for on p. 404 (vol. xx., see above).

Leitfaden bei zoologisch-zootomischen Präparirübungen. Von A. Mojsisovics Edlen von Mojsvár. 2nd ed. (Leipzig, 1885.)

We are glad to welcome a second edition of this work, which is a very useful manual for museum curators and for demonstrators in the rapidly increasing number of zootomical laboratories. Although it appears to be designed for use in high schools we cannot think that it is likely to displace the manuals already in use in this country: it wants the didactic character of Huxley and Martin's "Elementary Biology," the simplicity and directness of Prof. Milnes Marshall's admirable little book on the "Frog" (which is, we are glad to learn, to be soon followed by others), or the detailed directions of Prof. T. J. Parker's "Zootomy." We may note by the way that these works appear to be unknown to our author, whose knowledge, indeed, of English works on anatomy, or, as Messrs. Wilder and Gage call it, anatomical technology, is very incomplete.

So far as German authorities on "Museologie" are concerned, the second edition appears to have been brought up to date; some additions, not always, however, improvements, have been made in the illustrations; some of the English authors whose works are neglected would have provided the author with a better figure of *Astropecten* than the shocking "representation" which is copied from Bronn. When the third edition is called for we hope we shall find the grave, but perhaps the only important, defect which we have noted corrected and accounted for.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

On Watering the Coal-Dust in Mines

Referring to an explosion that happened at Lievin Colliery in the Pas de Calais on January 14 last, my friend M. Ed. Sauvage, Ingénieur des Mines, writes as follows:—"Some experiments have been lately made at Lievin Colliery (Pas de Calais), where a disastrous accident happened a few months ago. I do not think any report of these experiments has been published; but they found the coal-dust inflammable, and the watering of the ways in the mine has been resorted to as a precaution against future accidents."

Twenty-nine persons were killed by this accident, that is to say, all who were in the mine with the exception of one. The survivor, a miner named Cornet, and one of his comrades, had prepared a blasting-shot for dynamite, and called upon the shot-firer to ignite it. The latter examined the place, pronounced it to be free from fire-damp, and lighted the fuse.

At the inquest Cornet stated that he saw the shot go off, and had just time, by a quick movement, to throw himself under a heap of straw lying near when the explosion took place. He remembered nothing more, and attributed his escape to the partial protection afforded by the straw.

After investigating the case and hearing Cornet's evidence, the Government engineer and those of the Company who owned the mine came to the conclusion that the explosion was caused by the ignition of the coal-dust that had been lying upon the timbers which formed the supports of the gallery. In corroboration of this opinion they pointed out the fact that the current of air which swept through the gallery in which the explosion originated was too swift to admit of firedamp lodging there.

For some years past a system of more or less careful watering has been practised in some of the largest and driest of the steam coal collieries in South Wales as a precaution against explosions —and the recent occurrences at Usworth, Lievin, Camphausen, and Pendlebury seem to show that similar measures are greatly wanted elsewhere.

Should watering the dust (locally in the neighbourhood of blasting-shots, or generally in the workings) ultimately prove to be the panacea for great colliery explosions, then it is obvious that the responsibility for the holocausts that are now occurring lies almost as heavily upon those who, having the power, fail to hasten its adoption, as upon those who continue to offer it a selfish or factious opposition. W. GALLOWAY

The Colours of Arctic and Alpine Animals

I MUCH regret that I have been too busy to reply to my friend, Mr. A. R. Wallace (NATURE, April 16, p. 552), till the present moment, but this delay, unavoidable on my part, is the less to be regretted, since it has given an opportunity for the interesting facts recently adduced by Sig. Lorenzo Camerano (NATURE, May 28, p. 77) to be taken into consideration. As Mr. Wallace, with that keen penetration so familiar to all who know him and his writings, goes to the root of the matter under discussion and raises a distinct issue, I will now beg permission to offer a few words in reply to both these gentlemen.

First, with respect to the physical side of the question, Mr. Wallace is perfectly correct in supposing that colour *per se* has no influence upon the radiating or absorbing powers of bodies as far as regards obscure radiation. But I would point out that in the present case we are not concerned with colour alone; we have not merely to consider whether black or white is the best radiator, but we have for comparison two surfaces, hair or feathers, as the case may be, having, as far as we know at present, the same structure, and differing only in colour. The question before us is whether this colour-difference *in the same substance* is associated with any difference in radiating or absorbing power, and the final answer can only be given by carefully conducted experiments. I may add that I have long been waiting for an opportunity of conducting the necessary investigation, and with aid that has been kindly offered from several quarters I hope before long to be in a position to arrive at some satisfactory conclusion. The form of experiment suggested by Mr. Wallace, although decidedly worth the trial, does not appear to me to be very safe, inasmuch as the natural structure and arrangement of the fur would be lost in the process of weaving into cloth. Mr. Wallace's strictures as to the use of artificial dyes are, however, quite sound, and in these I fully concur. I may further state that when this question was raised some years ago, I searched literature (although by no means exhaustively) to see whether any experiments had been recorded, and although many hundreds of observations upon the radiative and absorptive powers of different bodies have been made by various physicists from the time of Franklin downwards, I have not been able to find any experiment bearing directly upon the question under consideration.

The point to be decided is, not only whether dark hair or feathers are better radiators than white hair or feathers, but whether the radiative power of these white coverings is less for that particular kind of radiation which is most greedily absorbed by the substance (snow) among which the animals have to pass their winter existence. Till this problem is solved physically we have, as it seems to me, only the purely biological considerations to fall back upon.

Before passing on to the more strictly zoological side of the subject I should like to disclaim the notion to which Sig. Camerano's letter may give rise, that the radiative (as distinguished from the protective) theory of Arctic colouring is original as far as concerns myself. With respect to the white covering of the warm-blooded animals, this theory was, as far as I knew at the time, original when first broached in 1880; but Lord Walsingham afterwards showed that the same conclusion had been arrived at in 1846 by Craven, with whose name it should be more fairly associated. The application of this theory (in a reversed sense) to explain the melanism of Arctic insects is entirely due to Lord Walsingham, and as my friend Mr. Wallace is disposed to give the weight of his authority to this extension of the theory, there is no occasion to discuss this point further on the present occasion.

It now remains to point out some of the considerations which have led me to the belief that the protective theory of white colouring is not wholly sufficient. Thus, among birds there seems to be a tendency among the falcons (*F. candicans*, *F. islandus*, &c.) to become white in high latitudes—a mode of coloration which does not appear to me to be of much use in such species. These birds, as far as I know, swoop down on their prey from above, under which circumstances the lighter colouring would be of no advantage in enabling them to approach their prey undetected; on the other hand, it can hardly be maintained that these birds are subject to any persecution which would cause their lighter plumage to be of protective value. When on the wing the back only would be seen by another bird hovering over the falcon, and it is noteworthy that this part of the falcons in question is *darker* than the under side. The same considerations apply to the snowy owl (*Nyctea scandiaca*). In many other birds, again, such as the plovers (*Charadrius pluvialis*, *Squatarola cinerea*, &c.) and various species of *Scolopacidæ* (*Tringa variabilis*, *T. subarquata*, &c.), the under side only changes to white in winter—a change which it is impossible to associate either with protection from foes or with predatory advantage. On the other hand, it seems not unreasonable to suppose (on the radiation theory) that the under side of the bird, being nearest to the snow-covered surface of the ground, would require the most protection. It is of interest also to bear in mind from the present point of view that many mammals are known to become white on the under side during winter. Thus, Surgeon-Major Leith Adams, F.R.S., states in his observations on the natural history of Eastern Canada[1] that "there is, moreover, a seemingly strong disposition for the lower parts of animals to become white in winter —*i.e.* the parts in closest contact with the snow; thus the under surfaces of the deer tribe are always whitest. And, as if from its habit of constantly digging among the snow with its snout in quest of food, we find the cariboo with a white patch on its lips and around the hoof, &c." Such facts as these cannot, as it appears to me, be explained on the protection theory; but if any connection exists between the mode of colouring of an animal and its external conditions of life, the theory of preventive radiation or even the direct action of low temperature on the formation of the pigment seems to be more applicable.

The objections raised by Signor Camerano, although supported by some interesting observations, are, I venture to think, somewhat wide of the mark. The writer, indeed, endeavours to bring within the scope of the radiation theory classes of facts which I for one should certainly never dream of attributing to this cause, even if it had been demonstrated on a sound experimental basis. There can be no question as to the truth of his concluding statement that the causes tending to modify the colours are of an extremely complex character. It is this very complexity, indeed, which renders it so highly important to thoroughly investigate any explanation which bears the stamp of truth, though perhaps applicable to but a very limited group of facts. In view of these difficulties, and bearing in mind the inexhaustible resources of nature in adapting organisms to their environment by apparently opposite means, it is not at all surprising that cases should exist which stand apparently opposed to the particular class of cases here dealt with. There are many conceivable ways of enabling an animal to struggle against a severe climate besides that of lightening the colour of its fur, and natural selection would take advantage of any and every means presented for securing this end. To say, therefore, that some animals become darker in winter (*Cervus mandarinus*), or that others do not change colour at all (*Rupicapra europea*, *Capra ibex*), is no real objection to the radiation theory, but simply an illustration of the principle that there are many ways of securing the same result. Thus, in the case of the two last-named species, Sig. Camerano himself states that there is a great difference in the thickness of the winter covering. Then, again, the statement that a more or less distinct seasonal change of colour is observable in many animals appears to me to have no precise bearing on the question—all that can be said from the point of view either of adaptation or climatic protection is that in such slight mutations we have given to us a hint as to the method by which the more striking seasonal changes have been brought about. We must regard such changes either as the incipient stages of a seasonal variation which could, if necessary, be worked up into a more perfect adaptation (*protective* or *climatic*), or as the vanishing remnants of a seasonal variation formerly important, but now useless. The facts that some animals which are not polar or alpine are *permanently* white, that the

[1] "Field and Forest Rambles," 1873, p. 124.

colours of some Alpine Coleoptera are brighter than those of the warmer plains, and that the species of small islands often show a tendency to melanism, are at present simply inexplicable, but, as far as I can see, do not tell for or against either theory. It would certainly be a strong case against the present view if any animal could be named which became white in winter and was not an inhabitant of a country subject to cold winters. As far as my knowledge extends no such species exists. The light colour of desert mammals is most probably due to predatory advantage—the melanism of desert insects mentioned by Sig. Camerano is, I must confess, a new fact to me, and not at all in accordance with my own limited experience. The strongest objection raised by Sig. Camerano is, perhaps, contained in the statement that in the birds of the Antarctic region black is much more prevalent than in those of the Arctic regions. It is unfortunate, however, that the writer adduces in illustration such countries as Australia and New Zealand, which certainly cannot be considered within the Antarctic region.

In conclusion I should like to emphasize that the theory of climatic protection is not, as Mr. Wallace appears to believe, *opposed* to the theory of adaptation. If my first letter gave rise to this impression, I will take the present opportunity of pointing out that the animal kingdom abounds with cases of what our German colleagues happily call "functional change" (*Functionswechsel*)—that is, the conversion of a character (or function) originally acquired for one purpose to a totally new use. It is thus not at all improbable that a mode of coloration originally acquired as a climatic protection, may afterwards be found to be of adaptive value, so that climatic and natural selection would in such cases work together. I fully concede that many of the Arctic and Alpine species now derive such advantages from their white covering; the question is whether this colouring was originally acquired solely for this purpose, or whether climatic adaptation may not have had an equal or even a greater influence in its production. R. MELDOLA

Clifford and Professor Tait

MAY a "(so-called) Metaphysician"—who has modestly waited to see if some one for whom Prof. Tait could have more respect would anticipate him—venture to remark upon a passage in the review of Clifford's "Exact Sciences" that appeared in NATURE of June 11?

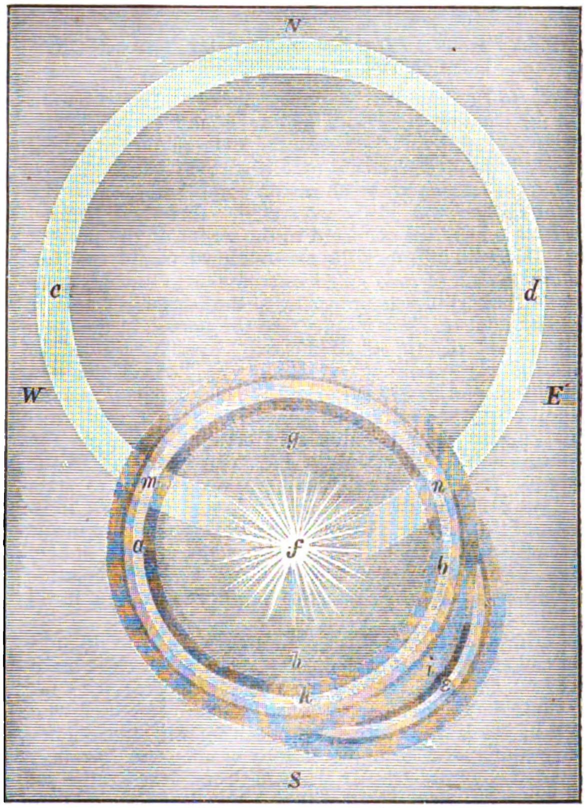
Prof. Tait first calls "awkward" and "unnecessarily puzzling' Clifford's statement that 'if we can fill a box with cubes whose height, length and breadth are all equal to one another, the shape of the box will be itself a cube'; and then, declaring with greater emphasis that it "at first sight seems to be nonsense," he adds:—"Read it, however, thus: 'If we can fill with cubes a box whose height, &c. . . . the shape of the box itself will be a cube,' and the absurdity, suggested by the collocation, disappears."

Now Clifford's statement is not sufficiently guarded, being, as it stands, not true of the cube only; but it surely conveys a real meaning, in a "collocation" of words as plain as possible. It is something (whether much or little) to be told that a cube can be made up of a number of equal cubes; especially in view of the context (p. 16). But does Prof. Tait, with *his* sentence, tell us anything at all, except that a cube is—a cube; or say even that plainly? R.

June 22

Unusual Atmospheric Phenomenon

THE accompanying drawing—a copy of a sketch taken at the time—represents an unusual atmospheric phenomenon witnessed by several friends and myself during a recent visit to Ireland. It occurred on the 6th inst., a bright warm day, with a light breeze blowing from the east. The sky was free from clouds, excepting a few cirrus and cirro-stratus collections on the northern horizon. Engaged at the time in fishing from a boat on one of the Irish loughs, I was conscious of a change in the character of the light reflected from the water and distant objects and looking towards the sun (*f*), noticed that it was surrounded by an exceedingly brilliant halo (*a b*) of about 48° diameter, the contained space (*g h*) being filled with vapour of a dull leaden blue colour, which, by obscuring some of the solar rays, apparently produced the peculiar light effects that first attracted my attention. The time was 1.30 in the afternoon. Calling the attention of my friend, Dr. Simpson, to the phenomenon, I recorded the accompanying details. The primary liula (*a b*) consisted of a brilliant, well-defined band of about 8 width, composed of the spectral colours in the usual sequence, the red ring being nearest the sun. The whole band was most vivid, but the northern half the brightest. At about two o'clock I noticed a bulging (*i*) of the leaden-coloured vapour of the primary halo (*a b*) to the extent of 6° or 7°, and in its south-eastern quadrant, and this protrusion, at first only faintly fringed with colour, soon was bounded by a spectral bow (*e*) at least as vivid as the brightest portion of the primary halo. The adjacent portion of *a b*, whether by comparison with *e* or whether because partially obscured by the protrusion of the vapour around which *e* was formed, I cannot be sure, seemed much paler than the rest of *a b*. Simultaneously with the formation of this secondary bow a large white ring, represented in the drawing by *c d*, slowly formed around a centre to the north of the sun, and rapidly assumed a well-defined contour. Its diameter was 72°. Had it been complete it would in its southern portion have passed through the sun, but after cutting the primary halo (*a b*) at the points (*m* and *n*),



which it rendered more faint, it gradually disappeared before reaching the sun. This latter ring (*c d*) began to disappear about a quarter of an hour after I first noticed it, its north-western portion fading first. I noticed no mock-suns at the points of contact of either of the excentric rings, and was, unfortunately, unprovided with my small pocket polariscope, and therefore unable to ascertain how much of the phenomenon was due to double refraction. The portion (*e*) may have been thus produced, but it certainly appeared, as drawn, to be a portion of a ring of *smaller* radius than (*a b*). The Rev. T. G. Beaumont, who also observed this spectacle, states that he saw the primary halo (*a b*) gradually start from a much smaller ring around the sun. The accompanying drawing, though rough, is as accurate as compatible with the absence of measuring instruments. ALEX. HODGKINSON

26, King Street, Manchester, June 16

Sky-Glows

Your correspondent of Clairvaux-sur-Aube says (NATURE, vol. xxxii. p. 147) the sky-glows are again visible in France. I can corroborate the fact as regards the valley of Lake Leman, in Switzerland. At Geneva, a newspaper has described the abnormal crepuscular glows of June 2, 3, 4, and 13. At Morges (46° 30′ N. lat.), Prof. C. H. Dufour and myself have observed them on the 12th and 13th.

On the 12th the sun disappeared beyond the Jura range about 7h. 30m. p.m.; at 8h. 10m. my attention was called by the brilliant illumination of a strange pale yellow, the same which in December, 1883, and January, 1884, always foretold the great crepuscular glows; at 9h. the western sky was coloured by brilliant purple red tints, which spread as high as the zenith; the red colour only vanished from the horizon at 9h. 30m.—*i.e.* two full hours after sunset. The successive phases of the phenomenon were the same as in the winter 1883-1884; the brilliancy of the colours was, however, fainter, but they were, perhaps, of greater duration.

On the 13th the same glows were observed, with decreasing intensity; on the following days nothing extraordinary has been noticed.

F. A. FOREL

Morges, Switzerland, June 21

THE INTERNATIONAL EXHIBITION—MUSIC LOAN COLLECTION[1]

THE story runs that a countryman, visiting London for the first time, and feeling bound to see Westminster Abbey, by a slight mistake overlooked the Royal Fane, and attended service in St. Margaret's Church hard by. He told his friends in the shires on coming home that the ancient edifice was sadly overrated. Exactly a parallel case to this has just occurred to the writer of the present lines. He was informed by an unknown friend that the small collection of unlabelled instruments in the basement of the Albert Hall was unworthy of the occasion; and he only made out on close inquiry that the person in question was speaking of one out of the two "overflow rooms" in which the superabundant stores of the Loan Collection are housed, and had never seen the Loan Collection itself at all. This was the more remarkable as the said individual carried the proof-sheets of his guide-book to the Inventories which he was in the act of sending to the printers. It is therefore clearly not superfluous to state that this, probably the grandest and most complete illustration of the history, progress, and development of music ever furnished, occupies the whole of the circular gallery which forms the top storey of Capt. Fowke's gigantic building, and runs over into two large rooms at a lower level.

It is impossible in a short preliminary notice to do more than call early attention to the vast mass of priceless materials here collected, and soon to be again dispersed; nor can sufficient credit be accorded to Mr. Alfred Maskell, who, aided by his learned father, has been mainly instrumental in arranging and bringing it into order. He has been seconded signally by Mr. Hipkins, representing the old and honoured firm of Broadwood and Sons, so that the collection of ancient spinetts, virginals, clavichords, harpsichords, and the like is the most remarkable ever brought together. There is at least one such instrument lent by its noble owner from his family seat in Ireland which is all but unknown even to connoisseurs.

The Belgian Government have most liberally lent the whole of the grand museum of the Brussels Conservatoire of Music, originally presented to that institution by M. Victor Mahillon. This in itself is a "*Syntagma Musicum*," like the scarce work of Prætorius, but presenting the very things themselves, not merely their graven images.

The realism of the exhibit is carried to the highest degree by three beautiful model rooms, designed with the taste and accuracy for which Mr. Davidson, himself an exhibitor of some grand fiddles, is so justly noted, each room showing furniture, decoration, and instruments of a great epoch in musical history. The visitor can, if he choose, yield to the pleasant illusion and revel in the madrigals of Orlando di Lasso, "*Il più dolce cigno d'Italia*," the motetts of the Elizabethan age, the Lulli-inspired melodies of Purcell; or sit at the clavichord with Handel and grand old John Sebastian Bach. Of its kind the thing is as nearly perfect as can be, and the undersigned takes the first possible opportunity of praying his brother and sister amateurs not to let slip the unique privilege of seeing it.

W. H. STONE

[1] We hope to supplement this preliminary note by a more detailed notice of the collection when it is complete and the Catalogue ready.—ED.

THE MEASURE OF FIDGET

LATTERLY—no matter where—I was present at a crowded and expectant meeting. The communication proved tedious, and I could not hear much of it, so from my position at the back of the platform I studied the expressions and gestures of the bored audience.

The feature that an instantaneous photograph, taken at any moment, would have most prominently displayed was the unequal horizontal interspace between head and head. When the audience is intent each person forgets his muscular weariness and skin discomfort, and he holds himself rigidly in the best position for seeing and hearing. As this is practically identical for persons who sit side by side, their bodies are parallel, and again, as they sit at much the same distances apart, their heads are correspondingly equidistant. But when the audience is bored the several individuals cease to forget themselves and they begin to pay much attention to the discomforts attendant on sitting long in the same position. They sway from side to side, each in his own way, and the intervals between their faces, which lie at the free end of the radius formed by their bodies, with their seat as the centre of rotation varies greatly. I endeavoured to give numerical expression for this variability of distance, but for the present have failed. I was, however, perfectly successful in respect to another sign of mutiny against constraint, inasmuch as I found myself able to estimate the frequency of fidget with much precision. It happened that the hall was semicircularly disposed and that small columns under the gallery were convenient as points of reference. From where I sat, 50 persons were included in each sector of which my eye formed the apex and any adjacent pair of columns the boundaries. I watched most of these sections in turn, some of them repeatedly, and counted the number of distinct movements among the persons they severally contained. It was curiously uniform, and about 45 per minute. As the sectors were rather too long for the eye to surely cover at a glance, I undoubtedly missed some movements on every occasion. Partly on this account and partly for the convenience of using round numbers I will accept 50 movements per minute among 50 persons, or an average of 1 movement per minute in each person, as nearly representing the true state of the case. The audience was mostly elderly; the young would have been more mobile. Circumstances now and then occurred that roused the audience to temporary attention, and the effect was twofold. First, the frequency of fidget diminished rather more than half; second, the amplitude and period of each movement were notably reduced. The swayings of head, trunk, and arms had before been wide and sluggish, and when rolling from side to side the individuals seemed to "yaw"; that is to say, they lingered in extreme positions. Whenever they became intent this peculiarity disappeared, and they performed their fidgets smartly. Let me suggest to observant philosophers when the meetings they attend may prove dull, to occupy themselves in estimating the frequency, amplitude, and duration of the fidgets of their fellow-sufferers. They must do so during periods both of intentness and of indifference, so as to eliminate what may be styled "natural fidget," and then I think they may acquire the new art of giving numerical expression to the amount of boredom expressed by the audience generally during the reading of any particular memoir. F. G.

RECENT EARTHQUAKES

THE shocks of earthquake in Cashmere continue with unabated violence and even appear to increase in frequency and force. Three severe shocks occurred during the night of the 13th and a smart convulsion on the morning of the 14th. It is now ascertained that 2281 lives were lost in the Muzzafferabad district, where at first it was thought there had been no casualties. The earthquake was also felt in Gilghit. Another very severe shock at Baramulla on the 17th demolished all the buildings which escaped former shocks. At Skardo on the 14th and at Srinugur on the 17th, 18th, and 19th, shocks were felt. In the Kamraj district the loss of life exceeds 2700. The Jheelum Valley, from Srinugur to Dopatta, appears to have suffered most. It is stated that both sides of the river from Sopur to Baramula have been seared with cracks, as also the low alluvial hills in the vicinity. The available data fix the centre of the disturbance in the vicinity of Gurais. It thus appears that in extent and amount of destruction the Cashmere earthquake must rank amongst the great seismic catastrophes of the century.

On Thursday morning last (June 18) a portion of Yorkshire was visited by an earthquake shock. The reports from outlying districts show that the shock extended from the east coast through the Wolds and westwards as far as Headingley, near Leeds. Signalmen on the North-Eastern Railway speak positively as to the vibration and noise. Crockery and glass rattled on the shelves of houses, and at Knottingley and Ferrybridge persons ran from their houses from fear. At Easingwold desks and tables were seen to move, and there was a rumbling noise as of thunder. In some cases there was a severe shaking of houses, and doors were moved. The various reports concur as to the time being 10.50, and it is said there were two shocks. It is a curious coincidence that about an hour previous to this on the same day and in the same region the frightful explosion at the Clifton Hall Colliery took place. Unhappily our knowledge will not permit us to connect seismic disturbances with disasters or mishaps in mines, but we have here a violent and unusual disturbance in the crust of the earth in Yorkshire and an almost simultaneous mining catastrophe in Lancashire.

We have received the following communications with reference to the Yorkshire earthquakes:—

A SLIGHT shock of earthquake was felt here yesterday morning in the favourable stillness of the "Friends'" meeting for worship. The time was observed to be about 10.47 a.m. I was seated with my back to the north, when a rumbling sound appeared to be swelling onwards for about two seconds from the south or south-west. I then noticed that the hanging leaf of a small table in front of me (its plane lying east and west) was rattling very distinctly, and immediately I became aware that the back of my seat was shaking me perceptibly. Others heard some of the windows rattling on both the east and west sides of the house, and were shaken by their seats moving slightly; these seats were some of them at right angles to mine. Some of these persons thought the rumbling came from the east; others from the west. One gentleman, sitting in a corner, thought that his right shoulder, against a north partition, was shaken more than his left, against the east wall. He also thought that the rumbling came from the south end of the house. The place of worship is about two-thirds of a mile to the north-east of our observatory, which is in lat. 53° 38′ 40″·8, and long. 1° 20′ 32″·75 W. Nothing was noticed at the time by a man and a boy working in our garden. It is reported in to-day's *Leeds Mercury* to have been felt at York, Leeds, and Driffield. WILLIAM SCARNELL LEAN

Flounders College, Ackworth, near Pontefract, June 19

CAPT. STAVELEY, at whose house the recent earthquake of June 18 was felt in a marked degree, gives me the following information respecting it. His house at North Dalton (seven miles south-west of Driffield) stands on a slight elevation surrounded with undulating hills common to the Cretaceous formation of the Wolds. The shock occurred between 10.30 and 10.45 a.m. (the exact time was not noted), and lasted about three seconds, travelling from west-south-west to east-north-east. Mrs. Staveley, who was in her bedroom at the time, felt a slight shock, then a rumbling sound as of thunder, and after that another stronger shock. The servants downstairs felt a distinct rocking, and the bricklayer's boy, on a ladder level with the roof, saw the whole roof heave up and down three times. In the dairy some dishes firmly placed on a high shelf were thrown down and broken, and at the inn on the other side of the road the walls trembled perceptibly, and the bottles and glasses were shaken and knocked against each other. The inhabitants of this and neighbouring villages felt the vibrations more or less distinctly, but the shock seems to have been greatest at, and in the direction of, Capt. Staveley's house. The colliery explosion near Manchester happened about an hour earlier; is it possible for there to be any connection between the two? J. LOVELL

Driffield

The following extracts are from the *Hull Express* of June 20:—

Information which reached us yesterday shows that the earthquake-shocks experienced on Thursday in York and Market Weighton were also felt in more or less degree in other parts of the great shire.

Mr. W. Botterill, of Parliament Street, Hull, writes:—"On returning home (Newland Park) from business last evening, my wife informed me that during the morning she had for some seconds very sensibly felt a vibratory motion in the house, which she fully believed to be caused by a slight shock of earthquake, and added that she should confidently expect to find in this morning's papers notices in confirmation thereof. It was, therefore, no surprise to learn from your current issue, and other papers of to-day, that similar effects had been experienced at York, Market Weighton, and elsewhere, about the same hour of the day."

A North Cave correspondent says that at about eleven o'clock in the morning nearly every house was subjected to a slight shaking.

A Driffield correspondent says that at the village of Hutton several residents felt a severe shaking of their houses, and at the same time the inner doors were suddenly moved, crockery upset, and other signs of disturbance were observed. People were so terrified that they cannot very accurately describe the shock, but state they felt a "reeling" sensation.

Another correspondent writing from Driffield says:—"Yesterday morning a somewhat severe shock of earthquake was felt at North Dalton, a village about eight miles from Driffield. The shock appears to have been the most distinctly felt at the residence of Capt. Staveley, which stands in an isolated and elevated position, and the house vibrated from basement to roof for several seconds. A bricklayer's apprentice who was repairing the roof had a narrow escape of being thrown down, and the greatest alarm was felt by the villagers, who 'ran out of their houses in fear for their lives.'"

The shock was also distinctly felt in Leeds. In Delph Lane, Wood-house Ridge, the occupants of three houses which adjoin each other noticed it. It resembled the effect which would be produced by the violent shutting of doors, the windows rattling, and there being a perceptible vibration of the buildings. The same tremulous motion was also felt in Victoria Road, Headingley, and no doubt in other parts of the town.

At Snaith and neighbourhood similar effects were produced. Mr. Barrett, the postmaster of that town, says the shock was so severe as to cause quite a noise with the goods on the shelves in his shop window vibrating, and he felt the floor under him shake distinctly. At 10·48 a.m. on Thursday morning an earthquake was distinctly felt at Thorne, Hatfield, Epworth, and Eastoft. At various parts of Thorne crockery and glass rattled upon the shelves in the houses, furniture was shifted, and many of the inhabitants were greatly alarmed by the floors slightly descending. At Hatfield Levels also some consternation was caused by the earthquake, which was felt very perceptibly. We have not heard of any damage being done by the shock.

About one o'clock on the morning of the 18th, north-western Argyleshire was visited by an earthquake. The shock was distinctly felt at Ballachulish, and in many of the houses in the slate quarry district of Glencoe. The shock was felt with distinctness in Clachaig Inn, at the top of Glencoe. It travelled in a south-eastern direction.

Dr. Forel, of Morges, writes that a pretty strong shock was felt on the morning of June 20, at 5.16, in the cantons of Neuchâtel, Vaud, Berne, Fribourg, and Geneva, the seismic centre being probably the neighbourhood of the Lake of Neuchâtel. The intensity was No. IV. of the scale of seismic intensity.

THE SCOTTISH MARINE STATION

THE equipment of the Research Station at Granton, Edinburgh, has now been increased by the construction of a system of large tanks provided with a constant circulation of sea-water. These tanks are arranged very nearly according to the plan described in the account of the station and its work which was published in April last. The aquarium itself occupies the ground-floor of the building, whose upper story forms the biological laboratory, and it consists of seven large tanks, five of which are shallow, and two deep, the latter being provided with glass fronts. The pump, which is driven by a steam-engine, the high-level reservoir, and the low-level reservoirs are situated at other parts of the premises. One of the deep tanks is being used for the study of the still mysterious life-history of *Myxine glutinosa*. Last week nearly 150 specimens of that animal were brought alive to the station from the neighbourhood of St. Abb's Head, where it is very abundant. These were successfully domiciled in the aquarium. As out of three specimens brought alive to the "Ark" (the floating laboratory belonging to the station) on May 1, and kept in a small glass aquarium about 15 inches long and 9 inches broad, two are still alive and healthy, there is good reason to hope that there will be no difficulty in keeping a large number alive for any length of time in a tank about 7 feet by 5 feet by 4 feet, which are the dimensions of the one now used for the purpose. It was found in the former experiment that the Myxine when left to themselves, burrowed into the layer of mud which had been placed at the bottom of the small aquarium, and lay for hours motionless, their bodies, with the exception of the extreme tip of the snout, being entirely buried. The snout is protruded for the purpose of respiration, a current of water passing constantly through the nostril into the œsophagus, and escaping at the two respiratory apertures. The normal condition of the animal when not actively engaged in the search for food is evidently to lie thus buried in mud. It is well known to fishermen, at least to those who are employed in line-fishing, that eellets, as Myxine are called by them, are met with almost exclusively on muddy ground. At the place where the creatures are more abundant than anywhere else in the neighbourhood of the Firth of Forth, namely, off St. Abb's Head, the sea-bottom throughout an extensive area consists of soft black mud. A quantity of this mud was brought to the station with the living specimens, and a layer of it 6 or 8 inches in depth placed at the bottom of the tank in which the Myxine were to be kept. The animals are now thickly scattered through the layer of mud, like earthworms in garden soil.

Some of the shallow tanks are being used for the study of the reproduction of the oyster. Supplies of oysters are being obtained from various sources, and before long a series of experiments as to the conditions necessary to the life of the oyster larvæ will be carried out. It is hoped, as the least result from this work, that new interest will be aroused in this country in the question of the scientific artificial cultivation of oysters.

The opportunities afforded for research by the laboratory and new aquarium cannot be fully utilised by those now working at the Station, and biologists who would come and carry out original work at the Station would be gladly welcomed.

A temporary branch of the station is now being organised at Millport, on the Firth of Clyde. It will be open during the months of July and August. The floating laboratory known as the "Ark" will be moored next week in still water off one of the small islands in the Bay of Millport, and the yacht *Medusa* will be stationed there for the purpose of dredging and providing material for study. Several naturalists have mad e arrangements to carry on work at Millport during part or whole of the time that the "Ark" will be there: amongst others the Rev. A. M. Norman, Prof. W. A. Herdman, of University College, Liverpool, Mr. David Robertson, of Glasgow; Mr. J. Harvey Gibson, Mr. J. R. Henderson. Mr. John Murray, convener of the Committee, entrusted with the management of the Scottish Marine Station, will be at Millport during the greater part of the time. It is hoped that one result of the work will be the preparation of an account of the fauna of the Firth of Clyde which will include, besides the results of the investigations to be carried on, the results of the previous work in the same field. As several of the experienced naturalists mentioned above are already familiar with the fauna of the Firth, a publication on the subject produced by their cooperation will be complete and authoritative. Any naturalists who may wish to carry on research at the Millport temporary station are invited to communicate with Mr. John Murray.

J. T. CUNNINGHAM

COMPOSITE PORTRAITS OF MEMBERS OF THE NATIONAL ACADEMY OF SCIENCES[1]

THOSE of the members who were present at the Washington meeting of the Academy last spring will remember that, at the request of Prof. Brewer and myself, they sat for their separate photographed portraits for the purpose of obtaining an experimental composite picture. Prof. Baird kindly offered the facilities of the photographic department; and the pictures taken by Mr. Smilie, the photographer in charge, bear the same stamp of excellence that characterises so generally the work of that department of the National Museum.

As only one or two previous attempts, I believe, have been made to produce composites in this country, I will state briefly what they are, and how they are made.

The idea in its broadest sense was conceived and applied by Francis Galton for the purpose of obtaining an average or type portrait—*i.e.* a picture that should show the features that are common to a group of individuals, and exclude those that are purely individual. It is clear that, in proportion as this result is attainable, the method will be of value in obtaining a clear conception of the external characteristics of any given type or class.

[1] From *Science*, to the editor of which we are also indebted for the use of the photographic plate accompanying the article.

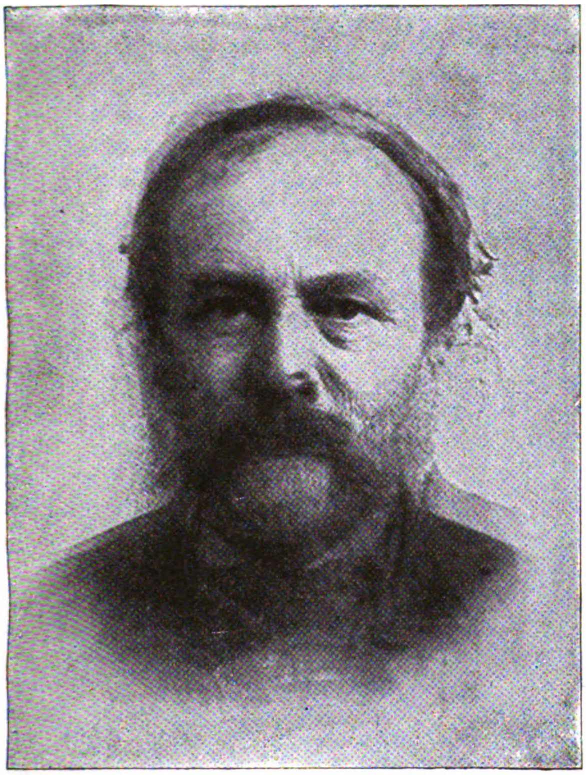


FIG. 1.—TWELVE MATHEMATICIANS.

FIG. 2.—SIXTEEN NATURALISTS.

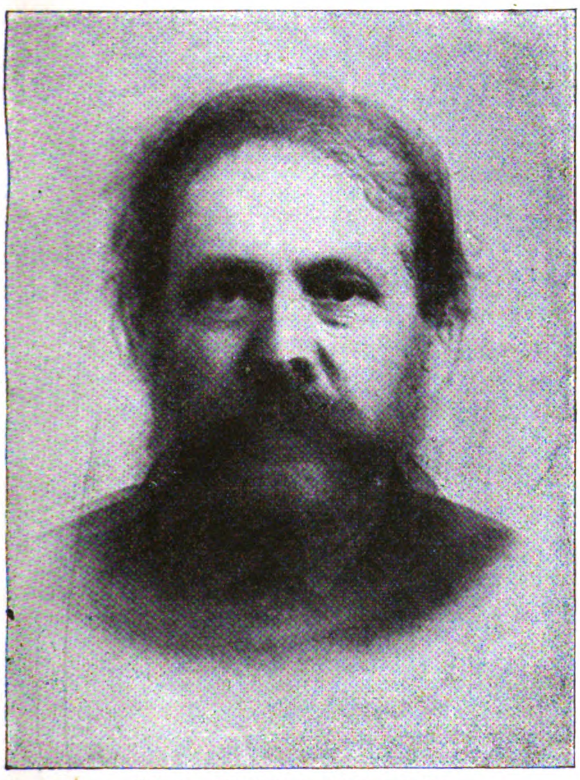

FIG. 3.—THIRTY-ONE ACADEMICIANS.

FIG. 4.—TWENTY-SIX FIELD-GEOLOGISTS, TOPOGRAPHERS, ETC.

COMPOSITE PORTRAITS OF AMERICAN SCIENTIFIC MEN.

Galton reminds us that, during the first days of a traveller's meeting with a very different race, he finds it impossible to distinguish one from another, without making a special effort to do so: to him the whole race looks alike, excepting distinctions of age and sex. The reason of this is that, by short contacts with many individuals, he receives upon his retina, and has recorded upon his memory, a composite picture emphasizing only what is common to the race, and omitting the individualities. This also explains the common fact that resemblances among members of a family are more patent to strangers than to the relatives.

The individuals entering into these composites were all photographed in the same position. Two points were marked on the ground glass of the camera; and the instrument was moved at each sitting to make the eyes of the sitter exactly coincident with these points. The composites were made by my assistant, Mr. B. T. Putnam, who introduced the negatives successively into an apparatus carefully constructed by himself, and essentially like that designed by Mr. Galton, where they were photographed by transmitted light. The arrangements of the conditions of light, &c., were such that an aggregate exposure of sixty-two seconds would be sufficient to take a good picture. What was wanted, however, was not an impression of one portrait on the plate, but of all the thirty-one; and to do this required that the aggregate exposure of all the thirty-one should be sixty-two seconds, or only two seconds for each. Now, an exposure of two seconds is, under the adopted conditions, too short to produce a perceptible effect. It results from this, that only those features or lines that are common to all are perfectly given, and that what is common to a small number is only faintly given, while individualities are imperceptible. The greater the physical resemblances among the individuals, the better will be the composites. A composite of a family or of near relatives, where there is an underlying sameness of features, gives a very sharp and individual-looking picture.

It would be difficult to find thirty-one intelligent men more diverse among themselves as regards facial likeness than the academicians entering into this composite. They are a group selected as a type of the higher American intelligence in the field of abstract science, all but one or two being of American birth, and nearly all being of American ancestry for several generations. The faces give to me an idea of perfect equilibrium, of marked intelligence, and, what must be inseparable from the latter in a scientific investigator, of imaginativeness. The expression of absolute repose is doubtless due to the complete neutrality of the portraits.

Fig. 3 contains eighteen naturalists and thirteen mathematicians, whose average age is about 52 years. Fig. 1 contains twelve mathematicians, including both astronomers and physicists, whose average age is about 51⅝ years. Fig. 2 is a composite of sixteen naturalists, including seven biologists, three chemists, and six geologists, with an average age of about 52½ years.

I may mention, as perhaps only a remarkable coincidence, that the positives of the mathematicians, and also of the thirty-one academicians, suggested to me at once forcibly the face of a member of the Academy who belongs to a family of mathematicians, but who happened not to be among the sitters for the composite. In the prints this resemblance is less strong, but in these it was observed quite independently by many members of the Academy. So, also, in the positive of the naturalists, the face suggested, also quite independently to myself and many others, was that of a very eminent naturalist, deceased several years before the sitting for this composite.

There is given also a composite (Fig. 4) of a differently selected group. It is of twenty-six members of the Corps of the Northern Transcontinental Survey—an organisation of which I had charge, and the object of which was an economic survey of the North-Western Territories. It was a corps of men carefully selected as thoroughly trained in their respective departments of applied geology, topography, and chemistry, and having the physique and energy, as well as intelligence, needed to execute such a task in face of many obstacles. The average age of this group was 30 years.

RAPHAEL PUMPELLY

HOW THE NORTH-NORWAY FJORDS WERE MADE

IN NATURE (vol. xxx. p. 202) there was published an article by me "On Northern Norway under the Glacial Age," in which, among other subjects, I referred to the course of the travelled granite blocks in the neighbourhood of Tromsö. The researches I had then made in this direction were, however, confined to a limited area, whilst last summer I was able to extend the same to the point whence the blocks started. Although one of my assumptions in the former article has not been confirmed by my last researches, the conclusions I then arrived at have in the main been corroborated. And as I believe that this subject is one of considerable importance to science, I venture to give an account of my last researches.

In order to understand the subject, it is necessary to explain the orographical conditions along the course of the travelled blocks from the Swedish frontier to the Arctic Ocean.

From the eastern end of the Alt Lake, near the Swedish frontier, and northwards to the Store Rosta Lake, the country on the Norwegian side assumes the form of an extensive alpine plateau, with broad depressions, the average height of which is about 2000 feet, running between low rounded ridges. In the south-eastern part of these plateaux, not far from the eastern end of the Alt Lake, the Divi River rises. Having for some 10 graphical English miles followed the plateau, this river flows gradually towards the Divi Valley, which it enters and follows throughout its whole course in a north-easterly direction, flowing eventually into the Maals River at a height of 260 feet (82 m.) above sea-level. Its length, from where it leaves the plateau, to the spot where it joins the Maals River, is about 30 geographical miles. In its upper course, where the Maals River receives the Divi River, the former flows through a wide plain or low plateau, the so-called Överbygd, which gradually slopes down to a distinct valley, the Maals Valley proper, which runs in a westerly direction along the southern slope of the high, island-shaped mountain ridge called Mauken. The latter begins about 5 miles west of the spot where the Divi River enters the Maals River, whence it runs in a direction east-west for a length of about 15 geographical miles, the highest tops being upwards of 4000 feet (1255 m.). On the north-western side, however, the Överbygd gradually rises towards the broad mountain depression filled by the Tag Lake, 7 miles in length, which runs in a direction east-west along the northern slope of Mauken, viz. between the latter and the more northerly-lying ridge Omasvarre, which, with tops upwards of 1900 feet (596 m.) in height, also runs in a direction east-west. The bottom of this depression is filled with the imposing Tag Lake, which lies on a height of about 600 to 700 feet (188 to 220 m.) above sea-level, and thus about 400 feet (120 m.) *higher* than the Divi River at the spot where it enters the Maals River. At the western end of the Tag Lake this depression takes the form of a broad mountain basin, the so-called Tag Valley, which in a north-easterly direction descends to Balsfjord. The distance between the Tag Lake and the Balsfjord is about 10 geographical miles. The Tag Valley is, on the western side, bordered by the lofty Maartin peaks, and further to the north-east by the Slet

Mountain, which, like an arm of the Maartin peaks, gradually slopes down to the Balsfjord.

The line of depression from the spot by the frontier where the Divi River rises, to the bottom of the Balsfjord which we have thus followed, is about 50 geographical miles in length. The course of the Balsfjord is north-westerly, but very crooked, between mountains upwards of 4000 feet (1255 m.) in height. The latter are, however, not continuous, but separated into island-like parts by deep depressions, which, in a recent geological period, when the level of the sea was 300 to 400 feet (91 to 126 m.) higher than at present, must have been submerged, thus making each part an island. In spite, therefore, of the typical fjord character of the Balsfjord, it was originally only a number of sounds, by which it was once connected with the Malangen Fjord on the western, and the Sörfjord, Ulfsfjord, and Lygenfjord on the eastern side. This is a circumstance of great orographical importance, and which deserves every attention, particularly because it does not apply to the Balsfjord alone, but is a characteristic of the formation of every fjord in the north of Norway from Salten (Bodö) in the south to Lyngen in the north—*i.e.* from 67° to 70° N. lat.

From the bottom to the mouth, in a sound between the mainland and the south-eastern side of the great island, Kvalö, the length of the Balsfjord is about 30 miles. At the Troms Island, which lies about five miles to the north of the mouth of the Balsfjord, this sound is divided into two narrow sounds, about five miles long, on each side of the Troms Island. From the northern point of this island these sounds reunite, and the sound becomes the broad Gröt Sound on one side, which, running in a northerly direction, joins the Ulfsfjord at its mouth by the Fugle Sound—a broad arm of the sea cutting into the land. On the other side, the sound is also connected with the open sea by the Kval Sound, 10 to 15 miles long, which runs in a westerly direction, between the two great islands Kvalö and Ringvadsö. The length from the mouth of the Balsfjord to the end of the Kval Sound by the ocean is about 30 miles, or about the same as the length to the end of the Gröt Sound. Thus, from the bottom of the Balsfjord to the sea the distance described is about 60 miles.

As regards the depth of the Balsfjord and the adjacent sounds, it may be mentioned that that of the former varies from 80 to 100 fathoms (480 to 600 feet = 151 to 188 metres), but from the mouth of the fjord towards the Troms Island the depth steadily decreases, being, in the sounds on both sides of it, not more than 20 to 30 fathoms (120 to 180 feet = 38 to 56 m.). To the north of this island, in the Gröt Sound, on the other hand, the depth increases to 100 or 120 fathoms. In the eastern half of the Kval Sound the depth is from 20 to 30 fathoms, while in the western half it reaches, at the mouth, 120 fathoms. It will therefore be seen that the depth of this channel in the main increases seawards, if we except the two places by the Troms Island and in the Kval Sound, the shallowness of which may be caused by narrowness of the sounds, and the consequent opportunity for the deposit of marine *débris*.

Thus, the entire length of the line of depression we have examined from the sources of the Divi River to the ocean is 96 geographical miles, while the bottom of the same falls from 2000 feet above the level of the sea to 720 feet below it—*i.e.* a total fall of 2720 feet.

The geological structure of the mountains here is very remarkable. A large mass of granite which appears at each end extends inland far into Sweden, and, on the Norwegian side, reaches the upper Divi Valley. The rock is composed of orthoclase, microlin, plagioclase, a great deal of quartz, but very little mica. The colour is reddish, the structure granulated. At the other end of the line we have followed, on the Kvalö and Ringvadsö Islands, there are several masses of a grayish, streaky gneiss-granite, rich in mica, closely allied to the gneiss-masses found here. Petrographically, the Divi Valley and the coast granites are so different, that it seems at first sight very easy to distinguish them, but this is not so easy with the variations of the two kinds.

The mountains which project into these granite-masses are built of layers of crystalline slate, and travelled blocks of this material may be found everywhere; but as it would be a matter of great difficulty to refer these to their original birthplace, I shall not take them into account here. We will, therefore, only follow the course of the granite blocks travelling from the Swedish frontier to the coast.

There are two roads by which they might have moved, viz., one from the southern part of the granite-mass along the Alt Lake to Bardö, and so on; the other more northerly, along the Divi Valley. It is the latter which I intend to discuss here.

The above-mentioned alpine plateaux are strewn with travelled granite blocks, and that the same have travelled westwards from the granite masses by the frontier cannot be doubted. The same applies to all the blocks strewn along the Divi Valley. At the spot where the Divi River joins the Maals River the travelled blocks have followed two courses—viz. one through the Maals Valley, along the mountain Mauken—which we shall not follow—and the other in a north-westerly direction across the Överbygd to the Tag Lake, the lower parts of the Överbygd being thickly strewn with granite blocks which, judging by their petrographical composition, I am sure belong to the Divi Valley granite. Hence the course of the blocks can be traced along the depression in the mountain by the Tag Lake, not only at the bottom, but high up on the mountain sides. Thus, the northern slope of the Mauken is everywhere, up to a height of 2500 feet (784 m.), strewn with travelled granite blocks; indeed the brink of every terrace looks—seen from below—as if it were faced with travelled blocks, which everywhere seem to belong to the Divi Valley granite. Travelled granite blocks were found, too, strewn up the slopes of the Omasvarre Mountain to a height of 1200 feet (376 m.)—viz. as far as I was able to carry my researches. I believe they would be found right up to the top.

From the western end of the Tag Lake the blocks have moved along the Sag Valley, and then to the bottom of the Balsfjord. The flat stretch of shore, 210 feet broad, high, and covered with loose *débris*, is strewn with blocks which without doubt belong to the Divi Valley granite.

From what I have thus explained we may safely assume that an enormous mass of inland ice has once moved from the frontier through the above-described channels, down to the Balsfjord, and that it must, along the Mauken, a distance of 10 miles from the fjord, still have maintained a height of at least 2500 feet (784 m.) above the then sea-level.

Before we follow the course of the blocks further, I will refer to certain circumstances connected with it thus far. About five miles to the westward of the mountain plateau near the frontier rises the isolated mountain Store Jerta to a height of 4500 feet (471 m.)—viz. about 1000 feet (314 m.) higher than any of the surrounding mountains. The Store Jerta is throughout built of hard crystalline slate. On the very summit of this peak I found a large block of granite which I feel confident is a travelled block from the granite mass to the east of it. Its birthplace must in that case have been at least 1000 feet (314 m.) *lower*, and, as the Store Jerta has been situated right in the track of the ice-stream from the east, I am of the opinion that the ice has been screwed up here to a very great height; but I confess it seems hardly possible to understand that it could be to such an enormous height.

I have stated above that the Tag Lake lies 42 feet *higher* than the spot where the Divi River enters the

Maals River, and supposing that this was also the case during the Glacial age the ice-stream must have moved up an incline before it could reach the depression leading down to the Balsfjord. This cannot, however, have been the case. As long as the ice-stream had perfect liberty to travel *down* an incline—here present in the shape of the broad Maals River, along the southern slope of the Mauken—it would hardly ever move in the opposite direction *up* an incline, leaving, however, local accumulations out of consideration. It might therefore be reasonable to suppose that the configuration of the land along the Divi Valley, and especially the Överbygd, was very different during the Glacial age. A continuous, though slightly inclining, surface must under these circumstances at that period have extended from the alpine plateaux above the Divi Valley to the depression along the Tag Lake, and the present configuration be caused by subsequent erosion. It should be stated that the outlet of this lake does not now follow the course of the ice-stream towards the Balsfjord—which might have been reasonably assumed—but is at the opposite, eastern, end towards the Maals River. This seems to indicate that the present declivity of the Överbygd in an easterly direction in any case cannot be older than the close of the Glacial age.

As stated, travelled granite blocks from the Divi Valley are found in great numbers along the northern slope of the Mauken, towards the Tag Lake, upwards of 2500 feet (784 m.); but that these should have been raised from lower levels to their present height seems improbable. The northern slope of this mountain does not lie transversely to the course of the ice-stream, but longitudinally to it. Of course the screwing-up of the ice may also take place in the latter case, but I should say only in isolated spots; this cannot have been the case along the Mauken. Neither is it possible that the bottom of the lake lay at that level in the Glacial age. It must then have lain lower than the alpine plateaux by the frontier, and even if we allow for enormous glacial erosions, it would be impossible to believe that the bottom then lay at such a height. As the blocks on the Mauken cannot thus have been deposited along the bottom of the ice-stream, nor brought thither through screwing-up of the ice, we must assume that they have been deposited from the surface of the ice-stream. The latter being strewn with blocks, which at the frontier was above 3000 feet (941 m.) high, has therefore, at 40 or 50 miles therefrom, had a height of 2500 feet. The surface can, therefore, under this long journey, only have had a very small declivity outwards.

From the western end of the Tag Lake the great ice-stream has moved forward to the Sag Valley, which, being then as it is at present, has been able to receive it and turn it in a north-westerly direction downwards to the Balsfjord. That the Sag Valley cannot be of glacial origin, produced by erosion, is clear from the very nearly acute angle it forms with the Tag Lake depression. It might also be assumed that the ice-stream here might have moved forward across the Slet Mountain and the long, narrow peninsula between the Malangen and Balsfjord, but that this was not the case is proved clearly by the circumstance that travelled granite blocks are found on this peninsula, or only at low levels, which I shall presently explain.

It may be probable that the ice-stream from the Tag Lake has met another descending from the Maartinder in the Sag Valley, but there is no middle *moraine* proving this. On the other hand, travelled granite blocks are but sparsely strewn along the north-western side of the Sag Valley, at the foot of the Slet Mountain. Should the Sag Valley, therefore, be of glacial origin, it might more naturally be attributed to the ice-stream from the Maartinder, but even then eroded before the great inland ce-stream entered it. If, however, this was the case, the former ice-stream must have been in motion long before the latter, of which there is no probability.

We therefore come to the conclusion *that the basin of the Balsfjord, viz., the Tag Lake depression and the Sag Valley, cannot be the result of the erosive action of the inland ice, but that it existed prior to the Glacial age, and that, in fact, the depression in question was the cause of the ice-stream taking this course.*

We will now follow the depression through the fjord and adjacent sounds.

As soon as we leave the true bottom of the fjord the travelled blocks are differently situated to those inland. There are plenty of granite blocks to be found, but *they are everywhere confined to lower levels, viz., from the shore-line up to 120 feet (38 m.). Above, there is none, and the line of disappearance is very marked.* My researches have extended, on the eastern side of the fjord, from the bottom to the sea; on the western side, though they do not extend so far, they go to show that the conditions there are identical with those on the eastern side. It is particularly significant that neither here are the blocks found above a height of 120 feet along the low, transverse ridge which runs from the Balsfjord on one side westwards to the Malangenfjord, and on the other, eastwards to the Lyngen and Ulfs fjords. Thus, the outer Malang isthmus, which, rising slowly to a height of 400 feet (125 m.), leads from the Bals to the Malang fjords, is along the former strewn with blocks, but only at lower levels. Above 120 feet they disappear. From this also it is clear that the inland ice cannot have moved forward across the Slet Mountain and the isthmus between the Bals and Malangen fjords, previously referred to. From the bottom of the Nordkjos, a short bye fjord of the Balsfjord, running eastwards, the Balsfjord isthmus, two miles long, with a height of 250 feet (78 m.), leads to the bottom of the Storfjord in Lyngen. Here, too, the blocks are confined solely to lower levels towards the Nord and Balfs fjords. The blocks have not reached as far as across the isthmus to the Storfjord.

The blocks may in the same manner be followed along the Ramfjord, which as a bye fjord runs from the mouth of the Balsfjord eastward to the Bredvik Isthmus. From the southern side of the mouth of the Ramfjord the Anders Valley runs in a southerly direction between lofty mountains and with a steady incline. Here, too, travelled granite blocks are found to a height of 120 feet, *but not a single one above.* The case is the same along the sounds around the town of Tromsö. Further, I have followed the blocks northwards, on the mainland to Tunnes, about five miles from the town, but whether they have travelled further along the Gröt Sound I have not yet been able to ascertain. The same applies to the Kval Sound. But researches made on the islands *outside* this sound prove beyond a doubt that the granite blocks from the Balsfjord cannot have reached these islands by way of the Kval Sound.

The greatest number of travelled blocks along the Balsfjord belong, judged petrographically, to the Divi Valley granite, blocks which might with certainty be referred to the coast granite not having been found. Along the sounds, too, the greatest number of blocks, if not all, may be referred to the Divi Valley granite; but blocks belonging to the gray, streaky gneiss-granite of the Kval Island are also met with here, some of which may even be referred to exact localities in the island. Among the rocks along the Troms Island and adjacent sounds blocks of a coarse-grained syenite are also often found. In the Divi Valley no varieties of syenite appear, but they are often encountered combined with gneiss and gneiss-granite on the coast. Although I have not yet succeeded in finding syenite in place which with certainty can be said to be petrographically identical with that of these travelled blocks, I have every reason to believe that they hail from the west.

We have now followed the course of the blocks along a continuous distance of 84 geographical miles—viz. 48 on the mainland and 36 on the shores of fjords and sounds.

From what I have advanced here as regards the blocks during their journey through the Balsfjord, it seems clear that their transport here cannot be ascribed to a moving stream of inland ice. The sharp line of demarcation, above which no blocks are found, seems in itself to demonstrate this. The line extending for miles along a long fjord and extensive sounds, and being so sharply defined, bespeaks that the transporting agency at work here must have been far more regular during a length of time than a stream of inland ice possibly could be. We have therefore every reason to conclude *that these blocks have been carried along the level of the sea on drift-ice*, i.e. *shore-ice*. As the block-transport appears from the first simultaneously along the long stretch of shore from the Balsfjord, and past the Troms Island, a strong in- and outflowing current during the diurnal tides has in all probability been at work at a period when the level of the sea was 120 feet higher than at present. And the strong drift of the ice outwards *must have been stronger than the one inwards up the fjord*. Travelled blocks of the Kval Island granite are, therefore, *not found in the interior of the fjord*, but the case is different along the broad sounds about the mouth of the fjord; here the in- and outflowing currents have had alternate sway, *and here are also found blocks of the Divi Valley, as well as of the coast granite*.

There is another important circumstance which beyond a doubt proves that the inland ice during the Glacial age cannot have moved along this fjord, scouring the bottom. Thus, if we consider the present depth, about 600 feet, and remember that the level of the sea during the Glacial age was about 600 feet higher than at present, and further that great quantities of *débris* must have been deposited at the bottom of the ice, it is evident that an ice-stream moving through the fjord, and a sixth part of whose volume rose above the then sea-level, must have reached several hundred feet above the former—that is, the outgliding stream must have reached several hundred feet above 120 feet, the line of demarcation for the blocks, as it then lay at least 200 feet below the sea. If, however, this had been the case, granite blocks should now be found at a far greater height than 120 feet. Neither can the Balsfjord during the Glacial age have formed a valley along which the inland ice might move, as, in this case, travelled blocks would have been found along the sides at even far greater heights.

I have, therefore, after the most careful researches here, yard by yard, and extending over many years, come to the conclusion *that the Balsfjord is not of glacial origin, but formed an incision or depression in the mountains of older origin than the Glacial age*. And this conclusion I believe *may, in the main, apply to the question of the formation of all fjords in the north of Norway*. But whether it is applicable to all fjords *in the whole of Norway* I shall not attempt to answer.

There may, however, be reason to assume that the explanation of the fjord-formation in parts which have lain under an earlier Glacial age as being of glacial origin, is rather based on speculation than such careful and minute researches as those I have referred to here, and which may, perhaps, contribute to prove the correct theory.

Tromsö Museum

VARIABLE STARS[1]

THIS catalogue may be regarded as complemental to the "Catalogue of Known Variable Stars," by the same author, which was read before the Royal Irish Academy, January 28, 1884. It contains a list, including lettered numbers, of 745 stars in which some change of magnitude is suspected. The stars are tabulated in order of Right Ascension for the epoch 1880·0, and in separate columns are to be found particulars of the supposed change of magnitude and the authority on which the supposed change rests. In the "Notes and Observations" by which the Catalogue is followed are given particulars of the history of each star, together with observations by the author of such stars as have received attention from him. The work is accompanied by a map showing the distribution of known and suspected variable stars.

A catalogue of this character forms a valuable working catalogue for the observer's use. By further observation suspected variation will in some cases be proved to be real, and the stars claim a place in a catalogue of known variables. A claim of this kind might indeed already be made in the case of Nos. 234, 455, and 635 of Mr. Gore's list. It may just be mentioned in passing that the place of No. 234, U Canis Minoris, is incompletely given in the Catalogue. Its more exact place for 1880 is R.A. 7h. 34m. 49s., Decl. + 8° 39'·5. There are other cases in which, though the period is as yet indeterminate, the fact of variation and its amount may be stated with some confidence. On the other hand further observation may tend to throw a doubt on the suspicion of change in the case of other stars, and (as our author observes) "these must of course be removed from future catalogues." In the notes to No. 287 of his Catalogue α Hydræ, Mr. Gore quotes remarks by Sir John Herschel, Dr. Schmidt, and Dr. Gould to the effect that the supposed variability of this star may possibly be due to the influence of its ruddy colour on the estimates of its brightness. Is it not possible that the effect of colour on estimates of magnitude as respects different observers, or the same observer at different times, has hardly received so much attention as it deserves?

Large as is the number of stars included in Mr. Gore's Catalogue, further additions might be made to it. Comparing it, for instance, with the Table of Suspected Variables extracted from Mr. Chandler's unpublished Catalogue by Prof. Pickering, and printed in his "Recent Observations of Variable Stars" in the *Proceedings* of the American Academy, we find some 30 stars which are not included in Mr. Gore's list, and it is probable that others might be found in other quarters also. Indeed the experience of most variable star observers would probably suggest the view that cases of slight but distinctly recognisable light variation are relatively numerous.

A word in regard to No. 445 in the Catalogue may possibly help to avert the chance of a little confusion in the future. This star was entered as U Bootis in Prof. Schönfeld's first Catalogue of Variable Stars, but was rejected by him in his "Zweiter Catalog." There is another star called U Bootis by Mr. Baxendell in a paper in the Manchester Lit. and Phil. Soc. *Proceedings*, vol. xxi. No. 11, the place of which, brought up to 1880, is R.A. 14h. 48m. 47s., Decl. + 18° 10'·9. This star has a period of 175·5 days, with a range of magnitude from about 13·5 at minimum to about 9·2 at maximum.

In conclusion we commend to the attention of all who are interested in the subject of variable stars a work the preparation of which must have entailed on the author a considerable amount of labour both as compiler and observer.

[1] A Catalogue of Suspected Variable Stars, with Notes and Observations, by J. E. Gore, M.R.I.A., F.R.A.S. A paper read before the Royal Irish Academy, May 12, 1884.

NOTES

A BERLIN telegram announces the sudden death of Dr. Emil Riebeck, at Feldkirch, where he was preparing for another five years' journey. Our first review in this week's NATURE refers to some of the last results of Dr. Riebeck's journeys. Either directly or indirectly he has done good work for science in various parts of the world. He was a liberal patron of explorers; the recent researches of Dr. Schweinfurth, in Socotra, for example, were carried out at Dr. Riebeck's expense. His death is a serious loss to science.

THE death is also announced, at the age of sixty-seven years, of Mr. W. S. W. Vaux, F.R.S., the well-known numismatist and Oriental scholar, and Secretary to the Royal Asiatic Society.

WE have still another death to record this week—that of M. Henri Tresca, an eminent French physicist and mechanical engineer. He was born at Dunkirk in 1814. He studied at the Polytechnic School, and on leaving it entered the corps of the Ponts et Chaussées, but soon afterwards quitted the service in order to devote himself to scientific study. In 1850 he was appointed principal inspector of the French Section of the Exhibition at London, and afterwards became sub-director of the Conservatoire des Arts et Métiers, and he there filled with great distinction the Chair of Industrial Mechanics. In 1872 he was elected a Member of the French Academy. Of his numerous works may be mentioned his "Cours de Mécanique Appliquée" and his "Écoulement des Liquides." The Academy of Sciences, on hearing of his death from the President, M. Boulay, closed the sitting as a mark of grief.

WE are informed that Dr. Barius, Surgeon-General to the French army in Tonquin, died on the 10th in Haiphong after a short illness caused by overwork and anxiety in that unhealthy climate. Dr. Barius is well known to the scientific world from his meteorological writings, especially his able and exhaustive "Recherches sur le Climat du Sénégal." While in Haiphong Dr. Barius took the trouble to make observations every day at 10 a.m. and 4 p.m., which he reduced and forwarded to Hong Kong, and his loss is severely felt; but some time before his death he mentioned in a letter that the meteorological observatory, of which he had urged the necessity, would be started in a few months.

AT the Oxford Commemoration, last week, the honorary degree of D.C.L. was conferred upon Prof. Huxley.

THE organising committee of Section A of the British Association have arranged for the following discussions at the Aberdeen meeting:—(1) On Kinetic Theories of Gases; (2) On Standards of White Light. It would be convenient if those wishing to take part in the discussion would send in their names before the meeting to the Recorder of Section A.

THE Council of the Society of Arts have awarded the Society's silver medals to the following readers of papers during the session 1884-85:—To Anton Jurgens, for his paper on "The Preparation of Butterine." To P. L. Simmonds, for his paper on "Present and Prospective Sources of the Timber Supplies of Great Britain" To A. J. Ellis, B.A., F.R.S., for his paper on "The Musical Scales of Various Nations." To Thomas Wardle, for his paper on "Researches on Silk Fibre." To H. H. Johnston, for his paper on "British Interests in East Africa, especially in the Kilimanjaro District." To E. C. Buck, for his paper on "The Agricultural Resources of India." To Mancherjee M. Bhownaggree, for his paper on "The Present Condition and Future Prospects of Female Education in India." To Dr. Frederick Siemens, for his paper on "Tempered Glass." To Frederick J. Lloyd, for his paper on "The Chemistry of Ensilage."

IF the few details that have reached us in the form of newspaper accounts are to be relied upon, Clifton Hall Colliery, near Manchester, in which the great explosion occurred on Thursday last, killing 140 men and boys, appears to have been dry and dusty and at the same time very free from firedamp. It remains to be seen whether those who investigate the causes of this accident will give due weight to the now undeniable influence of coal-dust, instead of contenting themselves with putting forward the usual set of traditional guesses and assumptions, which, it is to be feared, have too often supplied the place of those careful and exhaustive methods of inquiry and deductive reasoning that are alone capable of dealing with the apparent mystery in obscure cases of this kind. It is noteworthy also that this explosion has occurred in the inspection district in which shot-firing is supposed to be altogether prohibited except when the workmen are out of the mine; and it will be a curious commentary upon the late high-handed attempt of the Home Office to force a rule of the same kind upon the other mining districts of the country, should it turn out that the accident in question was not originated by a shot but was due to some other cause, such as the ignition of a local accumulation of fire damp. We await the result of the inquiry with very great interest.

MR. J. R. HENDERSON, M.B. (Edin.), F.L.S., zoologist of the Scottish Marine Station, Edinburgh, has been appointed Professor of Biology in the Christian College, Madras. This is, we understand, the first Professorship of Biology which has been founded in India. Mr. Henderson had a very distinguished career in the University, being awarded, among other honours in natural science, the Dobbie Smith Gold Medal. He is at present engaged in describing the Anomura collected during the *Challenger* Expedition.

PROF. T. C. MENDENHALL, of the University at Columbus, has received an appointment in connection with the United States Signal Service. This is an important accession to the scientific staff of the Meteorological Service of the United States, and is another instance of the enlightened policy carried out by General Hazen, the Chief Signal Officer. The high-class contributions to meteorology we receive from time to time from the office of the Signal Service are the outcome of these appointments.

To the *American Meteorological Journal* for June Mr. H. Allen Hazen sends a short but interesting communication on thunderstorms and air-pressure. Thunderstorms may be divided into (1) common storms with light winds, more or less rain, and generally not very heavy thunder; (2) those preceded or attended by a high and sudden wind; and (3) those that may be termed electric storms, mostly experienced in the west of the States, and of which little has been written or is known up to the present time. As to this third class, it is alleged that storms occur in the west with heavy electric discharges, and more or less wind *but no rain*. These storms the Signal Service proposes to investigate most carefully, particularly since, if it be conclusively shown that thunderstorms occur unaccompanied by any rain, a contribution of no ordinary importance will be made to the theory of the thunderstorm. It gives us the greatest pleasure to learn that the American observers are urged to take readings of their aneroid barometers every five minutes during thunderstorms, together with non-instrumental observations of rain and other accompaniments of the storm. In this department of meteorology, accurately observed facts continue still to be the great desideratum.

DETAILS of the recent violent volcanic eruptions in Java, of which brief telegraphic intelligence has already been published, have now reached Holland. The volcano of Smeru has been active for many years, casting out fire and smoke, but on April 17 and 18 an eruption of extraordinary violence occurred. The mountain is regarded as the highest volcano in Java, and takes the form of a handsome, regular cone. On the present occasion the side of the mountain for one-third of the way down from the summit is described as having been burst open, a tremendous cleft being formed, from which a torrent of lava and mud was ejected. A whole estate called Kalibening was overwhelmed, the manager and a large number of Javanese labourers being carried away by the torrent. From the reports it appears that the eruption of Smeru was accompanied by volcanic disturbance all over the western part of Java. A mud spring, or rather lake, bubbled up into the Preanger, in West Java; a volcano, Slamat, lying west of the Merapi (itself a quiescent volcano), has manifested signs of renewed activity, as has Klut, farther to the east. Lamongan, lying still farther eastward, throws out showers of ashes, and in Rotti, an island near Timor, mud has issued from the side of a mountain, and has overflowed a district described by the natives as twenty minutes' journey in breadth.

M. GASTON TISSANDIER made, on Friday, June 20, an ascent with a photographic apparatus to take instantaneous views. Not less than twenty-four were obtained on the trip, which began at 2 o'clock and lasted up to 6. The departure took place at Point du-Jour (Paris), and the descent in the vicinity of Rheims.

MR. R. ANDERSON, F.C.S., has in the press a new and enlarged edition of his work on "Lightning Conductors, their History, Nature, and Mode of Application." Messrs. Spon are the publishers.

MR. MORRIS, the Government botanist of Jamaica, delivered an address before the Jamaica Institute on the 7th ultimo on the scientific work done, and still to be done, by that establishment, more especially in the local museum. The latter is still in course of formation, but during the past four years there have been brought together collections of the fish, birds, insects, shells, and an illustrative collection of other island productions. The geological collection is described as being of a most complete and useful character. It shows not only the nature, age, and character of the rocks, their chemical constituents, fossil contents, and mineral wealth, but also deals with such topics as the nature and origin of soils, the character and quality of building stone, &c. The collection of Jamaica birds contains about 100 specimens, leaving 89 still to be added before it can be regarded as complete. The insects of Jamaica, Mr. Morris says, are comparatively little known to science, and this field is especially recommended to local collectors. Up to a few years ago the fish of Jamaica could best be studied in Boston and Washington Museums, but the local museum has lately commenced a collection of food fishes, and about 60 species are already carefully arranged and classified. Little, however, has been done of a practical and tangible character to develop the fisheries of the island. 630 species of land and freshwater shells have been found in Jamaica; these are being carefully arranged, and indicate that the island forms a rich province in the class Mollusca, and that "the classes of phenomena within her narrow limits afford room for the highest order of scientific studies." Jamaica is particularly rich in ferns; it contains about 500 species, which is one-sixth of the ferns of the whole world. The orchids and grasses are also being prepared for the museum, and it is hoped as opportunity offers to add a good collection of the medicinal and industrial plants. Here, as in his annual reports, which we have noticed on their appearance, Mr. Morris dwells on the immense economical value of a properly ordered and complete museum to an agricultural colony like Jamaica. There is no lack of materials; the difficulty has been to collect, preserve, and systematically arrange collections and place them in such a state and under such conditions as to conduce to their due and proper utilisation.

IN the first days of August next an International Botanical and Horticultural Congress will be held in Antwerp. Amongst the questions which will be suggested for special consideration is the flora of the new Congo Free State, the methods of culture already existing there, and the possibility of acclimatising new plants. The commission appointed to carry out the preliminary arrangements for the Congress has drawn up a series of questions, which, with the help of the Association Internationale Africaine, has been sent out to the Congo for replies. A special sitting will be devoted to this subject, and a herbarium of the principal flowers and plants of various neighbourhoods in the State and a collection of fruits and seeds will be accessible to members. The queries sent to the Congo refer to the nature of the soil; the maximum and minimum temperatures; the climatic conditions; the conditions favourable to cultivation, and those which are unfavourable; the food, medicinal, poisonous and industrial plants; the help which Central Africa offers to botanists for the study of tropical flora and physiology; the cultivation of vegetables on the Congo; the principal enemies of cultivation in the vegetable and animal kingdoms; and the best mode in which botanists and gardeners can utilise the labours of the Congo explorers. Like other recent Congresses the International Botanical and Horticultural Congress this year will apparently be mainly occupied with questions relating to Mr. Stanley's new State.

WE have received from Mr. F. W. Putnam, the Curator of the Peabody Museum of American Archæology and Ethnology, two papers by him: one, a first notice of the pine grove or forest river shell-heap, near Salem; the other, remarks on chipped stone implements, which we noticed on its appearance in the *Bulletin* of the Essex Institute.

MR. J. MACDONALD CAMERON has printed a report on the bituminous deposits of the Camamū basin of the province of Bahia in Brazil. In addition to the purely commercial portion of the report, there is much interesting information with regard to the various descriptions of these oleaginous deposits. Mr. Cameron has some interesting remarks on the influence of the mangrove on the muddy swamps on the coast. The dirty greyish black mud in which the mangrove vegetation is very luxuriant, resembles that noticeable in England in rivers and streams on the banks of which oil or soap works are situated. He inclines to the opinion that this mud is principally formed by the continuous decomposition of the roots and branches of the mangrove trees. The tidal currents ebb and flow slowly, and hence do not sweep away the mud. Thus abundant food for the tree is ensured, "as well as a store of oleaginous material for the use of distant generations of human beings."

WE have received the report of the Hackney Microscopical and Natural History Society for the past year. Mr. Greenhill's paper on Hackney Brook is of much interest, although the title is suggestive of the investigation in the Hampstead ponds undertaken by the immortal Pickwick Society. Mr. Greenhill has hitherto classified the stone implements which he has found in north and north-east London into (1) Hackney brook, (2) Lea valley, (3) Thames valley; and the purport of his paper is to arrive at a sound theory as to the comparative age of these three valleys and their implements. The principal conclusion of the paper is that the brook and its valley were not formed till long after the Stone age. Dr. Cooke's presidential address is a novelty; it is a Christmas vagary, describing the characteristics, the whims and oddities of the individual "chips" who attend one of the society's excursions.

THE Annual Report of the Bedfordshire Natural History Society refers to the work of preparing a new flora of the county. It is hoped that the first part of the work will shortly be ready for print. The *Transactions* of the past two years have contained a complete list of the phanerogams, mosses, and Characeæ of South Bedfordshire, by Mr. Saunders, and attempts are being made to form similar lists for other parts of the county. The papers read were few in number, but these do not represent the work of the Society. A scheme of village lectures on scientific subjects has been carried out with success.

In a paper read at the last meeting of the Librarians' Association, Mr. J. R. Boosé describes the progress of Colonial public libraries. Commencing with those in the Dominion of Canada, he stated that as far back as 1779 there was a public circulating library at Quebec. He then traced the progress of the public library system up to the present, giving a detailed account of the Parliamentary Library at Ottawa, and also referring to the recent establishment of free public libraries. He then traced the progress made in the Australasian colonies, dealing separately with the libraries of Victoria, and stated that the establishment of public libraries in those colonies only dated from the second decade of the present century. Their growth, however, had been of extraordinary rapidity; the statistics for Victoria showed that there were 143,073 volumes in the public library of Melbourne, 317,295 in the libraries of the colony, and that these institutions were visited in 1883 by 3,100,000 persons. Mr. Boosé, after describing the libraries of the other Australian colonies, referred to those of the Cape Colony, Natal, Singapore, Jamaica, British Guiana, Trinidad, the Bahamas, &c., and, in conclusion, observed that it was scarcely possible to overrate the advantages of these institutions, inasmuch as, in addition to their existing collections of books, every effort was made to enrich them by such valuable works of reference as were too costly to be purchased privately, and were only presented to libraries having a recognised status. He thought therefore that the Colonial Governments should provide means annually for their proper maintenance, and not throw the cost of them on the municipal authorities.

The additions to the Zoological Society's Gardens during the past week include two Barbary Apes (*Macacus inuus*) from North Africa, presented respectively by Mrs. Allison and Mrs. D. Fox Tarratt; two Common Marmosets (*Hapale jacchus*) from Brazil, presented by Col. Howell Davis; two Brown Bears (*Ursus arctos*) from Russia, presented by Mr. Walter Holdsworth; two Bandicoot Rats (*Mus bandicota*) from India, presented by Col. C. S. Sturt, C.M.Z.S.; an American Robin (*Turdus migratorius*) from North America, presented by Mr. H. Keilich; two Partridges (*Perdix cinerea*), British, presented by Mr. H. J. Snelgrove; an Azara's Fox (*Canis azaræ*) from South America, a Pleasant Antelope (*Tragelaphus gratus* ♀) from West Africa, six Common Chameleons (*Chamæleon vulgaris*) from North Africa, purchased; a Japanese Deer (*Cervus sika* ♂), three Canadian Beavers (*Castor canadensis*), a Chiloe Wigeon (*Mareca chiloensis*), seven Australian Wild Ducks (*Anas superciliosa*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN

The Periodical Comets of De Vico and Barnard.—As was first pointed out by Prof. Weiss, there is a certain degree of resemblance between the elements of the comet discovered by Barnard in July, 1884, and those of the comet of short period detected by De Vico in August, 1844, which Leverrier considered was probably identical with the comet observed by Lahire at Paris in 1678, though not known to have been seen in the long intervening period. It appears from Brünnow's minute investigation of the orbit of De Vico's comet that the mean motion at perihelion passage in 1844 is not determinable from the observations within very narrow limits, as might rather have been expected, considering the degree of precision with which that comet was observed from the beginning of September to the end of December, Mr. Otto Struve's observations in particular being of remarkable excellence. According to Brünnow's later calculations, the results of which were published in his "Ann Arbor Notices," the mean motion was close upon 650″ daily, but he considered that it might be as small as 640″ or as large as 660″, or, in other words, that the period of revolution at perihelion passage in September, 1844, might be as long as 2025 days, or it might not exceed 1964 days. Dr. Berberich finds the period of Barnard's comet 1959 days, and Mr. Egbert, of Albany, U.S., 1970 days, so that the periods of the two comets are pretty accordant; but the interval 1844–1884 does not correspond thereto, and the differences that exist in the other elements, notwithstanding the general similarity remarked by Weiss, point to considerable perturbation in this interval, supposing the identity of the comets. De Vico's comet in the orbit of 1844 could not have approached near to the planet Jupiter, to which body we are accustomed to look, as the great disturber of cometary orbits, but there is the possibility of a very close approach to the planet Mars, and this is also the case in a striking degree with Barnard's comet, which, in Dr. Berberich's last ellipse, is less than 0·008 of the earth's mean distance from the orbit of Mars in about 350° 50′ heliocentric longitude; as already pointed out in this column, there may have been a close approach of the two bodies at the end of 1873 or beginning of the following year. The nearest approximation of the orbits of 1844 and 1884 is 0·043 in heliocentric longitude 310°, and there is another approximation, 0·065, in 143°. At present, however, the identity of the comets of De Vico and Barnard is to be regarded as at least doubtful.

The Double-Star 19 (Hev.) Camelopardi.—The annual proper motion of the principal component of this double-star, which is Σ 634, resulting from a comparison of Groombridge's Catalogue (mean year of observation 1808·4) with the Greenwich Catalogue of 1872, appears to be $-0''·297$ in right ascension, and $+0''·164$ in declination, the accurate trigonometrical formula being employed. For the relative motion of the smaller component with respect to the principal one, we may compare Struve's epoch for 1834 with a mean of the measures of Dembowski, Flammarion, and Asaph Hall between the years 1875 and 1879, viz.—

1834·15 ...	Pos. 348°·57 ...	Dist. 34″·042
1877·29 ...	,, 1·11 ...	,, 20·303

Whence we find for the annual relative motion in right ascension $+0''·858$ and in declination $-0''·302$, and we have thus a confirmation of the opinion expressed by M. Flammarion in his "Catalogue des Étoiles Doubles et Multiples en Mouvement relatif certain," that the smaller component has a real motion, more rapid than that of the principal star, of contrary sign, and not far from parallel to it.

A Daylight Occultation of Aldebaran.—On July 9, civil reckoning, Aldebaran will be visibly occulted in this country about noon. If the distribution formulæ of Littröw and Woolhouse are applied, the following expressions result for finding the Greenwich mean times of disappearance and reappearance, and the angles from north point—

Disappearance ... July 8, 23h. 26·7m. $-$ [0·2369] L + [9·5144] M
Reappearance ... July 9, 0h. 15·3m. + [9·1126] L + [9·4189] M
Angle at Disappearance 49°·3 + [0·542] L $-$ [8·004] M
,, Reappearance 321°·6 $-$ [0·528] L $-$ [8·701] M

Here the latitude of the place is put $= 50° + L$, and M is the longitude in minutes of time, *positive* towards the *east*. If we apply the formulæ to Oxford, we have $L = +1°·76$, and $M = -5·043$ m., and hence

Disappearance, July 8, 23h. 22·0m. at 55°.
Reappearance July 9, 0h. 14·2m. at 316°.

It should be added that the above quantities within square brackets are logarithms.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, *JUNE* 28 *TO JULY* 4

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on June 28

Sun rises, 3h. 48m.; souths, 12h. 2m. 58·7s.; sets, 20h. 18m.; decl. on meridian, 23° 16′ N.: Sidereal Time at Sunset, 14h. 46m.

Moon (one day after Full) rises, 19h. 58m.*; souths, 0h. 27m.; sets, 4h. 58m.; decl. on meridian, 18° 1 S.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury ...	3 43 ...	12 8 ...	20 33 ...	24 33 N.
Venus ...	4 56 ...	13 8 ...	21 20 ...	22 55 N.
Mars ...	1 50 ...	9 53 ...	17 56 ...	21 25 N.
Jupiter ...	8 45 ...	15 50 ...	22 55 ...	11 45 N.
Saturn ...	3 19 ...	11 29 ...	19 39 ...	22 31 N.

* Indicates that the rising is that of the preceding day.

Occultations of Stars by the Moon

June	Star	Mag.	Disap.	Reap.	Corresponding angles from vertex to right for inverted image
			h. m.	h. m.	° °

Phenomena of Jupiter's Satellites

June	h. m.	
29	20 26	I. tr. ing.
	22 46	I. tr. egr.
30	20 56	I. ecl. reap.

July	h. m.	
2	22 35	III. occ. reap.
3	20 28	IV. ecl. reap.

The Occultations of Stars and Phenomena of Jupiter's Satellites are such as are visible at Greenwich.

July 3, 23h.—Sun at greatest distance from the Earth, the distance being one-sixtieth part greater than the mean distance.

GEOGRAPHICAL NOTES

THE Royal Geographical Society have decided to send out another African expedition. This time the region to be explored is one of more than usual interest, and the method of procedure will be considerably different from that which has been hitherto usually followed. We have had many lines run through Africa in all directions, and what is now needed is the leisurely study of the continent in detail. This is what will be done by the expedition which will leave England in August next, under Mr. J. T. Last, who, as a lay agent of the Church Missionary Society, has done admirable work in the Zanzibar interior. Mr. Last, after making up his caravan at Zanzibar, will proceed south to Lindi, to the north of the mouth of the Rovuma River. Thence he will proceed to the confluence of the Rovuma and Lutende Rivers, and fix the longitude of the junction—an important geographical point not yet settled. He will then go on in a generally south-westerly direction, and, before reaching the north end of Lake Shirwa, turn southwards and make for the Namulli Hills, which, with other new features in this region, were discovered by Consul O'Neill in the end of 1883. Here Mr. Last will establish himself and make a detailed study of the whole region in all its aspects. He will make a complete survey of the surrounding country, its topography, its people, its botany, economic products, climate, and languages. When this is completed Mr. Last will enter the valley of the Likugu River, which rises in the neighbourhood of these hills, and follow it down to the coast of Quizungu, whence he will travel south to Quilimane or north to Angoche, and thence to Mozambique. Mr. Last will make a special point of collecting all possible information concerning the country he passes through, its changes; its people, their customs, languages, &c.; the climate, its sanitary conditions, and its suitability for the introduction of European and other economic plants.

THE last number of Petermann's *Mittheilungen* contains the conclusion of Herr Schunke's account of Kaffraria and the eastern borderlands of Cape Colony; the Panama Canal, with a map, by the Editor; the German possessions on the Slave coast, also with a map, by Herr Langhans; the latest explorations in Costa Rica, by Dr. Polakowsky. This last is specially interesting. It is a continuation of a paper, published two years ago, and describes ten additional journeys to various parts of Costa Rica by Dr. Thiel the bishop. It is unfortunate for science that this ecclesiastic, whose energy in educating his flock and whose thirst for scientific investigation are alike remarkable, should have been expelled by the Costa Rican Government, and that in such haste that he was compelled to leave behind him all his journals, collections, scientific observations, &c. He travelled and lived much amongst the various tribes of Indians, and studied their dialects, the antiquities, and ethnology of the country. He is at present visiting the eastern coasts of Nicaragua and Honduras in order to collect Indian antiquities and the remnants of Indian languages. The same paper also contains a report of a journey in Costa Rica by Padre Fernandez.

A CORRESPONDENT writes to *Ausland* from Santiago to correct a mistake as to a reported discovery of a glacier in Chile. The glacier in question is called the Ada glacier, and occupies the upper end of the Cajon de los Cipreses, a branch of the valley of Cachapual. In a note which appeared in the fourth number of *Ausland* this year and was copied from the *Proceedings* of the Royal Geographical Society, the discovery of this glacier was attributed to Dr. Güssfeldt. Some years previously the same discovery had been ascribed to Mr. Charles Wiener. The fact is, the correspondent states, the glacier has been known to the visitors to the baths of Cauquenes for the last twenty years at least. MM. Wiener and Güssfeldt, like other visitors to the baths, had had their attention called to it, and each in turn was consequently credited with its discovery.

THE French Minister of Public Instruction has published a report which he has received from M. Chaffanjon, a professor in Guadeloupe, giving an account of his mission on the Orinoco. In order to investigate fully the hydrography of the river he has often found it necessary to travel far away from the banks on both sides, and he has thus been able to survey the former beds. He has also obtained the materials for a geological map of the region and for a description of the phenomena attending the formation of this part of the earth's crust. Hitherto we have had only vague ideas respecting the Indian races, because they were without history or ancient remains. Prof. Chaffanjon has discovered in five different places inscriptions and pictures in granite, which he has carefully copied. He has collected a crowd of ethnological objects amongst the Caribs, the Panaies, and the Mapoyes. He hopes also to be able to fill certain gaps in the zoological and botanical collections in the Paris Museum. The report is accompanied by a sketch on a scale of 1 to 660,000 of the course of the Orinoco between Caicara and Ciudad Bolivar, which gives a considerable number of names new to geography.

THE Berlin Geographical Society has decided to erect a monument at the burial place of the late Dr. Nachtigal, at Cape Palmas, and all Germans are invited to send contributions to the fund for this purpose.

ELECTRICAL DEFINITIONS, NOMENCLATURE, AND NOTATION[1]

WITH the rapid progress that has lately been made in electrical science and its applications, there has sprung up a new and fast-increasing class of practical electricians. These, partly from necessity and partly from well-meant respect, have adopted and applied the old terms and expressions which appeared suitable to their predecessors, as well as coined not a few new ones, until now their vocabulary is in considerable confusion, and, as all must admit, requires sifting and reform.

Nothing is more tantalising and perplexing than the different modes of expression and symbols used by different authors, and sometimes by the same author, to explain and interpret one and the same thing or result. All this might be avoided if an international system of definitions, nomenclature, and notation was agreed upon and legalised. The rapidity with which the new definitions of the ohm, ampere, and volt (issued and legalised last spring at Paris by the International Congress of Electricians) were universally adopted, shows this. These definitions should be still further extended to other electrical units. They should embrace a suitable system of notation, whereby electrician could represent in symbols and letters, terms, expressions, and formulæ of common occurrence, in a similar manner to that adopted by chemists in connection with chemical elements and their combinations. Last session the author promised a communication to the Society on this subject, and, being again reminded by the Secretary of his unfulfilled promise, he now submits a few of the more apparent instances where ambiguity or want of uniformity exists, with suggestions, in the hope that a discussion may follow, and that a Committee of this Society may be formed to consider and draw up a series of definitions, nomenclature, and notation that would be generally acceptable. The proposed Committee might then confer with the French Committee, also with a similar Committee appointed by the British Association, and, finally, this important question should be referred to the International Congress of Electricians, in order that they may legalise and issue their decisions in a similar manner to that adopted by them in the case of the ohm, the ampere, and the volt. Undoubtedly, if such a course were adopted, most beneficial results would accrue to all concerned.

[1] Paper read before the Society of Telegraph Engineers and Electricians on May 14, 1885, by Prof. Andrew Jamieson, C.E., F.R.S.E., Member. Principal, College of Science and Arts, Glasgow.

Only last November M. Hospitalier brought this subject prominently before the International Society of Electricians at Paris, and strongly advocated an investigation, so that you shall no doubt have their support and concurrence.[1]

Examples.—(1) At the very outset students are perplexed by such different terms as "Ordinary[2] or Static or Frictional or High-tension Electricity." One author will tell his readers or students: "For a long time the name Frictional Electricity was given to a group of phenomena produced by electrical charges. This is an improper expression, because friction is only one means for producing electrical charges."[3] Another says: "Static Electricity is, however, a misnomer: it has no existence: all the phenomena are due to static strains, but there is always a gradual loss called leakage, which is, however, the current due to the actual conductivity of all circuits, and every motion set up by so-called static electricity implies a transfer of energy and action occurring in a field of force set up in the form of strains in the particular inductive circuit in which the motions occur."[4] A third objects to the word "tension" in respect to electricity, and points out that "all the phenomena observable in connection with so-called High-tension Electricity may be produced by electricity drawn from batteries or dynamos if the electromotive force or difference of potential is sufficiently increased." Would not the term "Electro-statics" be more suitable and comprehensive?[5]

(2) The old nomenclature "vitreous" and "resinous," as applied to substances which, when rubbed by certain other substances, produce opposite electrical properties, and the scholastic one and two fluid theories based upon these effects, should be discarded for the more comprehensive modern theory of electric polarity of molecules or continuous particles, expressed by "positive" and "negative," or by the algebraical signs (+) and (−).

(3) "Electrics," "dielectrics," "non-conductors," "insulators," and "isolators" are terms used by different writers to express a condition or behaviour of certain materials with respect to electricity, in contradistinction to the terms "non-electrics" or "conductors" as applied to other materials. The words "electrics," "non-conductors," and "non-electrics" are, strictly speaking, meaningless, because all materials may be termed electrics and all conductors, only differing in degree. The words "isolators" and "isolation" (from the French verb *isoler*, to isolate or separate) should give way to "insulators" and "insulation" as applied to substances which offer a comparatively greater resistance to electricity than semi or good conductors used in connection with the apparatus being referred to at the time.

The term "dielectric"[6] was first used by Faraday on finding that conduction was effected by induction (of polarity from molecule to molecule), and is generally employed by practical electricians when speaking of the inductive capacity of the insulating material surrounding the conductor of leading wires or submarine cables, or that placed between the plates of a condenser. In this sense, viz., of a body transmitting electric induction, or capable of undergoing electric stress, and retaining the stressed condition, it is a very appropriate term to use.

[1] Communication faite à la Société Internationale des Électriciens, le 5 Novembre, 1884, par M. E. Hospitalier sur L'Unité de Définitions, Conventions, Notations, et Symboles Électriques (*vide L'Electricien*, 15 Décembre, 1884).

"Sur la proposition du Président, l'assemblée décide qu'une Commission spéciale sera nommée à l'effet de rechercher les meilleures méthodes à adopter pour les notations électriques et de codifier ces notations.

"M. le Président propose, au nom du Bureau, d'appeler à faire partie de la Commission des notations électriquez—

"MM. Ed. Becquerel	MM. H. Becquerel
E. E. Blavier	G. Cabanellas
Marié-Davy	J. Capentier
Tresca	Gauthier-Villars
Maurice Lévy	E. Hospitalier
G. Lippmann	D. Monnier
Félix Lucas	D. Napoli
Mercadier	Pollard
De Meritens	J. Raynaud

M. V. Williot.

"L'assemblée adopte cette liste à l'unanimité."

[2] The term used by Faraday. (See "Experimental Researches," by Michael Faraday, p. 82, Art. 264.

[3] "Electrician's Pocket-Book," by E. Hospitalier, p. 5.

[4] "Electricity," second edition, by Sprague, p. 6, Art. 20.

[5] "Electricity and Magnetism," by Clerk Maxwell, vol. i., part 1.

[6] Faraday's "Experimental Researches." p. 364. "I use the word *dielectric* to express that substance through or across which the electric forces are acting." (See also pp. 537, 538.)

(4) The term "accumulator" is the name given in several text-books to apparatus, such as the Leyden jar or condenser, for receiving and retaining quantities of electricity, but has been lately inappropriately applied to secondary batteries, which do not accumulate electricity.

(5) "Cascade," as applied to Leyden jars, should give way to "series."

(6) "Tension"[1] "potential," and "electro-motive force," are terms which, when variously and indiscriminately applied, have given rise to considerable confusion, and a great deal of writing in trying to define them. If we consider "tension" as simply the stress put upon the current by the electro-motive force, and not in the sense that it used to be employed (for example: "Join up a battery or set of condensers for tension"), it might do very well if kept in its place; but it can easily be dispensed with. "Potential" is a word that has also given great trouble.

We find in Sprague's "Electricity"[2] no less than three pages devoted to an explanation of the different ways in which the words "tension" and "potential" are employed. Clerk Maxwell said: "The theory of electro-statics is greatly simplified by the introduction of this new conception of potential." "As soon as we pass from electro-statics to other departments of electrical science, we find that the conception of potential is no longer available, except when used in a restricted sense and under carefully-defined conditions." "In other parts of electrical science we have to deal with electro-motive force in cases where 'potential' and consequential 'potential difference' are words without meaning." Prof. Fleeming Jenkin, in his well-known text-book on electricity and magnetism, devotes twenty-six pages to "potential," and defines "unit difference of potential or electro-motive force in electro-static measure to exist between two points when the unit quantity of electricity in passing from one to the other will do the unit amount of work." "The property of producing a difference of potential may be said to be due to a peculiar force, to which force the name *electro-motive force* is given." "The words *electro-motive force* and *difference of potential* are used frequently one for the other, but they are not, strictly speaking, identical." "Electro-motive force is the more general term of the two, and includes difference of potential as one of its forms." "Potential" might well be reserved for electro-statics, and "electro-motive force" for electro-kinematics, or current electricity, and thus prevent confusion. The word "electric-pressure" has come into vogue lately, and strongly appeals to those of a mechanical turn of mind, seeing that the hydraulic simile of "head" or "pressure" is often brought forward to assist in explaining the terms "potential" and "electro-motive force."

(7) In magnetism we find the same want of uniformity exists. Take the case of a freely-suspended magnetised needle. The pole which turns towards the geographical north is variously called the "austral pole," "north pole," "north-seeking pole," marked pole," and is painted red by Sir Wm. Thomson, while Sir Wm. George Airy, Prof. Guthrie, and others paint it blue. It is sometimes indicated by French makers by the letter *A*, and by British by the letter *N*. The pole which turns towards the geographical south is correspondingly called the "boreal pole," "south pole," "south-seeking pole," "non-marked;" painted blue by Thomson, and red by Airy, Guthrie, and others, and indicated by the letter *B*. or *S*. Such is the general doubt and diversity in regard to the nomenclature on this subject, that each author on magnetism considers it necessary to state at the outset which term and symbol he intends to apply. If once for all the pole which turns towards the north was termed the "*north* pole," painted blue, and indicated by the letter *N*, and the opposite pole was termed the "*south* pole," painted red, and indicated by the letter *S*, much vexation would be saved. The French terms "austral" and "boreal," with letters *A* and *B*, should be obliterated. In this way the earth would have a uniformly recognised polarity, which would of course be opposite to that of the magnetised needle—in other words, the true north pole of the earth would be that situated near the geographical south pole.[3]

(8) Sailors and some writers on the mariner's compass call the angle which the magnetic meridian makes with the geographical meridian the "variation" of the compass, while electricians

[1] For a good definition of these terms, see "Electricity and Magnetism," by Clerk Maxwell, vol. i. p. 49. [2] 1884 edition, pp. 58-62.

[3] Sir Wm. Thomson calls the magnetic pole of the earth, situated near the geographical north, the "north pole," and the end of the magnetised needle which points towards it the "*true south pole*" of the needle, and paints it red

call it the "declination." Variation is, properly speaking, the hourly, diurnal, annual or secular changes which occur in the value of the elements of terrestrial magnetism. This leads to great confusion and argument between the electricians and the officers of a telegraph steamer. The declination for each place is marked on the Admiralty charts. Sailors also speak of the "deviation" of a compass, meaning by that the local error due to the resultant of the quadrantal, semicircular, and heeling errors, &c. It would be far better if they simply spoke of the "compass error," or angle which the meridian of their compass-needle makes with the true north and south magnetic bearings. This deviation or compass error arises from local magnetic influences. Sir William Thomson's well-known compass, when properly adjusted on board a ship, has no compass error, and therefore the only thing to guard against and correct for in the steering of a ship is the declination of the place where the ship may be at the time of observation. Of course, if the magnetism of the ship changes in the slightest, due to a change of cargo or position thereof (if of iron or steel), or due to buffeting the waves for some time on one course, a slight error will creep in, but the compass can be soon adjusted to the new condition of affairs, and the officers have therefore seldom to think of or even speak of "deviation" or "compass error."

(9) When we come to electricity generated by batteries, we find the expressions "galvanism," "voltaic electricity," "dynamic electricity," "electro-kinetics," "current electricity,"[1] &c., according to the fancy of the writer or speaker. Surely one name might suffice; and certainly the older term "galvanism," and "voltaic electricity" might well be left to the past. The simple term "current electricity" seems to commend itself, as most of the effects in connection with this branch of the subject have reference to electricity as if it was in motion or distributing itself over a conductor.

(10) "Density of current" and "intensity of current" often cause great confusion. "Density of current" should only be used in the case of electrolysis or electro-deposition of metals. Here it means the amperes per unit of surface of the cathoder. In electro-statics "surface density" or "electric density" means the quantity per unit area of surface. "Intensity" was used at one time in the same sense as "electro-motive force" is now, and therefore not so much out of place there; but several writers, notably Prof. Silvanus Thompson, have thought fit to borrow the French term "*intensité de courant*" wholesale, instead of a translation thereof, and to symbolise it by the letter *I*. The literal translation of the French word *intensité* being strength or amount, therefore the expression "current strength," or simply "current," symbolised by *C*, is far preferable, for it conveys the correct meaning of the quantity in a given time. With a little pressure, French electricians would no doubt agree to the symbol *C* instead of *I*, to promote uniformity. Then *I* might be reserved for intensity of magnetism, where it suits very well.

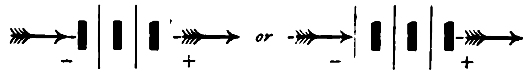
11. "Positive electrode," "(+) terminal," "zincode," "anode," "positive pole," and "negative plate," severally used by different writers to designate that end of a cell, battery, or pile where the current leaves, and "negative electrode," "(–) terminal," "platinode," "kathode" or "cathode," "negative pole," "chlorous pole," "positive plate," where the current returns to or enters the same, requires revising and simplifying, more especially when we consider that the end plates of a battery are of opposite sign to their electrodes or terminals, and that the nomenclature is still further complicated when we come to consider secondary batteries or electrolysis by the terms "anion," "kation" or "cation," and "ions." Take, for example, the definition given by Sprague[2] of "anode": "The positive electrode or pole of a battery; the wire or plate connected to the copper or other negative element of the battery; the plate which leads the + current into a solution to be decomposed, and at which are set free the oxygen, acid radicals and all —ions (anions).[3] In electro-metallurgy it is usually formed of the metal to be deposited, in which case it is called the soluble anode or pole"!!

[1] See Ferguson's "Electricity," second edition, by Prof. Blyth, p. 164. The term "electro-kinematics" has been used by Clerk Maxwell to cover a large part of this subject, such as "electric current," "conduction," "resistance," "electro-motive force," "electrolysis," &c. (See "Electricity and Magnetism," by Clerk Maxwell, vol. i. part 2.)

[2] Sprague's "Electricity," 1884 edition, p. 624.

[3] See Faraday's "Experimental Researches," articles 661 to 667, on *Definitions of New Terms*, where he very clearly points out the meaning he attaches to the words "electrode," "anode," "cathode," "ions," "anion," "cation," &c.

12. Again, we have the two different ways of graphically representing a battery



according to the whim or fancy of the writer. Practical submarine electricians were the first to use this very neat and handy way of representing a battery and its poles, and always adopted the former method, with the long thin vertical line for the plate where the current leaves, and the thick short line for the plate where the current returns to the battery. Why should this have been departed from? It is a mere arbitrary arrangement, but, being a most convenient symbol, it should be used in a uniform manner. Mr. John Munro proposes that the symbol for a secondary battery should be a modification of this, viz.,

the current outside the cell proceeding from the long line to the short one.

13. "Parallel circuit," "multiple arc," "loop circuit," "in loop," "derived circuit," "shunt circuit," are all expressions to signify pretty much the same thing, where one expression, "shunt circuit," would do.

14. "Polarisation" is a term used in many different senses—for example, the polarisation of battery plates, molecular polarisation due to electrification or magnetisation, polarisation of light due to magnetism, &c., as in Dr. Kerr's experiments. Some reform is required here.

15. Coming to telegraphy, telephony, and electric lighting, we find, as M. Hospitalier points out, "the words 'generator,' 'receiver,' 'transmitter,' and 'motor' are mixed up by different inventors, sometimes through ignorance, sometimes willingly." "A 'generator' is an apparatus which, receiving energy of a certain nature, produces an energy of another nature, and it borrows its name from the nature of the energy which it generates. A 'receiver' is an apparatus analogous to the generator, but it borrows its name from the energy which it receives." "A given apparatus is at once a generator and receiver—for example, an electric motor is a generator of mechanical energy and a receiver of electrical energy." "The name 'transmitter' ought to be reserved for an apparatus which, receiving an energy of a certain kind, produces or brings into play an energy of the same kind or of the same form." For example, a relay on a telegraph system, or induction coils as used on a trunk telephone line with several subscribers' lines at each end, or in electric lighting on the Gaulard and Gibbs' system, lately tried in London. Professor Silvanus Thompson uses the phrase "Dynamo-electric machinery" in the most general etymological sense of the term, as meaning machinery for converting the energy of mechanical motion into the energy of electric currents, or *vice versâ*, excepting such induction machines as Holtz, Voss, &c. He thinks this reduces the ambiguity to a minimum, and leaves the word "motor" to be applied, if desired, to the steam-engine, water wheel, &c., from which the mechanical motion is derived. The terms "magneto-electric machine," as applied to a dynamo fitted with permanent field-magnets, and "electro-magnetic machine" to a series, separately-excited, shunt, or compound-wound dynamo (generator or receiver) are very handy expressions, and should not be discarded.

16. We have dealt hitherto chiefly with definitions and nomenclature, and have given a few examples: others will occur to every member present. We now come to abbreviations and notation with symbols. The want of uniformity here, and the need for systematising, is still more obvious, but perhaps more difficult to accomplish. Every one admits the great advantage in being able to write down the symbols for chemical elements and their actions and reactions one with the other in the form of simple equations, which any one may comprehend who knows the subject, without a detailed description of what each letter or symbol stands for. Electricians should not rest satisfied until they are supplied with a similar universally-accepted notation, whereby electrical phenomena and actions may be similarly treated. The author submits a sample of what he considers would be useful in this respect. Many of them are taken from Munro and Jamieson's "Pocket-book of Electrical Formulæ," where an effort was made to use the same notation and abbre-

viations throughout, except in such cases as that of quoting direct from some other author.

It will be observed in this list that in most cases the first English or Greek letter of the word has been used. Those relating to the metric system have been copied from the French edition of Hospitalier's "Electrician's Pocket-book," which are no doubt copied from the list decided upon by the International Commission on the Metre, with a few omissions and additions by the author.

The Greek letters π, μ, ϵ are universally adopted—π for the ratio of the circumference of a circle to its diameter, μ for the coefficient of friction, and ϵ for the base of Napierian logarithms.

Metric Abbreviations

m. for metre.
cm. ,, centimetre.
mm. ,, millimetre.
m^2 ,, metre-square.
m^3 ,, metre-cube.
c^2 ,, centimetre-square.
c^3 ,, centimetre-cube.
gm. ,, gramme.
mg. ,, milligramme.
kg. ,, kilogramme.
kgm. ,, kilogrammetre.
&c. &c.
temp. ,, temperature.
res. ,, resistance.
g.d. ,, gramme-degré.
kg.d. ,, kilogramme-degré.

Electrical Abbreviations, Notation, and Symbols

When a capital letter is used for the symbol, then small capitals or italics with suffixes, 1, 2, 3, &c., may be used for parts making up a whole. For example—L for length, L_1, L_2, L_3, &c., or l_1, l_2, l_3, for different lengths, or parts of L.

Fundamental and Derived Mechanical Units

L for Length.
M ,, Mass.
T ,, Time.
V or v ,, Velocity.
A or a ,, Acceleration.
F ,, Force.
δ ,, dyne; *e.g.* 10δ = 10 dynes.
W ,, Work.
w ,, weight.
ft.lb. ,, foot pound.
H.P. or HP ,, Horse-power.
I.H.P. ,, Indicated horse-power.
B.H.P. ,, Brake horse-power.

Other Common Symbols allied to Mechanical Work

S for Speed or Stress.
D or d ,, Diameter.
r ,, radius.
ω ,, angular velocity = $2\pi n$ in radians per second.
g ,, acceleration due to gravity.
N or n_1 n_2, &c. ,, number of revolutions.
–^{s} ,, second; *e.g.* 3^{hr} 5^m 10^s = 3 hours 5 minutes 10 seconds.
τ_1 τ_2 τ_3, &c. ,, temperatures, absolute.
or $t_1°$ $t_2°$ $t_3°$, &c. ,, ,, common.

Practical Electric Units

The astronomical method of putting the small letters above the line of the figures, as in the case of the example 3^{hr} 5^m 10^s (3 hours 5 minutes 10 seconds), has not been followed in the following examples, as mathematicians object to the system, the letters appearing as if they were powers. Neither will they readily agree to suffixes, as suffixes have been already adopted by them to distinguish between things of the same kind. The author has therefore written the distinguishing letters on a level with the figures: for example, 10ω stands for 10 ohms (the methods 10^ω and 10_ω being both objectionable).

C.G.S. for centimetre, gramme, second.
R ,, Resistance.
ρ ,, specific resistance.
ω for ohm; *e.g.* 10ω = 10 ohms.
Ω ,, megohm; *e.g.* 10Ω = 10 megohms.
C ,, Current.

Important Electrical Definitions

A ,, Amperes; *e.g.* 10A = 10 amperes.
a ,, milliamperes; *e.g.* 10a = 10 milliamperes.
E ,, Electro-motive force, or E.M.F.
v ,, volts; *e.g.* 10v = 10 volts.
K ,, Capacity.
σ ,, specific inductive capacity.
Φ ,, farads; *e.g.* 10Φ = 10 farads.
ϕ ,, microfarads; *e.g.* 10ϕ = 10 microfarads.
Q ,, Quantity (coulombs).
P ,, Power.
W' ,, Watts, or Watt power.[1]
W ,, Work in Joules.
H ,, Heat in ,,
J ,, Joule's equivalent = 42×10^6 ergs, or work spent on ·2405 gm. of H_2O raised by 1° cent.

$$C = \frac{E}{R} \text{ (Ohm's law).}$$

$$E \times C = C^2 R = \frac{E^2}{R} = W' \text{ (Watt powers).}$$

$$E\,C\,T = C^2 R\,T = \frac{E^2 T}{R} = E\,Q = W \text{ (Joules).}$$

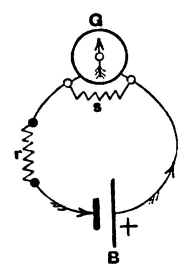
$$\frac{E\,C\,T}{J} = \frac{C\,R\,T}{J} = \frac{E^2 T}{J\,R} = \frac{E\,Q}{J} = \frac{W}{J}$$
$$= W \times {\cdot}2405 = \text{g.d. or gramme degrees.}$$

z = Electro-chemical equivalent.

Magnetism

N for North pole of a magnet, painted red.
S ,, South ,, ,, ,, blue.
m ,, magnet strength (of pole) or quantity of magnetism.
l ,, distance between the poles of a magnet.
M or ml ,, moment of a magnet.
ℑ or I ,, Intensity of magnetisation.
s ,, cross section of a magnet.
mp ,, magnetic potential.
μ ,, magnetic permeability.
κ ,, magnetic susceptibility.
H ,, Horizontal intensity of terrestrial magnetism.
θ ,, angle of deflection.
d_1 d_2 d_3 ,, divisions deflection, as in mirror galvanometer.
r ,, radius (mean) of a coil or solenoid.
n ,, number of anything; *e.g.* turns of wire in a coil or galvanometer.

Take Tangent Galvanometer Formulæ, as an example to illustrate the above:—



$$\text{Current, } C = H \frac{r}{2\pi n} . \tan \theta.$$

G for Galvanometer or galv. res.
s ,, shunt res. for galvanometer
r ,, resistance coils
B ,, Battery or battery res.

$$\therefore R = B + \frac{G\,S}{G + S} + r.\text{[2]}$$

[1] By adopting the term "Watt power," there can be no doubt what a Watt means.
[2] See Munro and Jamieson's "Electrical Pocket-book," p. 65.

Dynamo Circuits Contractions

Example:—

 or D for Dynamo.

T +	,,	Terminal positive.
T −	,,	Terminal negative.
E.M.	,,	Electro-magnet.
or F.M.	,,	Field Magnet.
c.p.	,,	candle-power of a lamp.
A.M.	,,	Ampere meter.
V.M.	,,	Volt-meter.
S.W.G.	,,	Standard wire gauge.

For use in Formulæ

R_a R_m R_e	,,	Resistance of armature, magnets, and external circuit respectively.
C_a C_m C_e	,,	Current in armature, magnets, and external circuit respectively.
L_s	,,	coefficient of self-induction.
L_m	,,	coefficient of mutual induction.

In the above notation the first letter of the most important words has been used wherever it was found practicable to do so, and the recurrence of the same letter under similar circumstances avoided as much as possible. In cases where no ambiguity can occur, such as H for the heat in Joules, and H for the horizontal intensity of the terrestrial magnetism; *m* for metre, and *m* for magnetic strength of pole; V for velocity, and v for volts, it will be observed that the same letters appear in each case.

M. Hospitalier, the Secretary for the French Committee on this subject, came over from Paris specially to take part in the discussion, and related what had already been done by him in Paris.

Prof. Forbes, Mr. John Munro, Prof. Ayrton, Dr. Fleming, Prof. Hughes, Prof. Silvanus Thompson, and others took part in the discussion, and generally agreed that a uniform system was much required. The paper, they said, had given a very fair start to this being accomplished.

The author replied that he was glad the Society had agreed so readily to form a thoroughly representative committee, and hoped that their work would be not only speedily accomplished but satisfactory to all concerned.

THE JUBILEE OF THE STATISTICAL SOCIETY

THE Statistical Society has been holding a series of meetings during the present week in celebration of the jubilee of its foundation. The meeting is really an International Congress of Statistics, some of the most eminent foreign statisticians being present as the guests of the Society; among others Sig. Bodio, of Rome; MM. Keleti, Körösi, and Prof. Neumann-Spollart, of Buda-Pesth; Prof. Levasseur and M. de Foville, of Paris; Gen. F. A. Walker, of the United States, Gen. Liagre, and others. The meetings have been held in the theatre of London University, and several subjects of much statistical importance have been introduced for discussion. One of them was the claim of statistics to be considered as a science, discussed at some length in the address of the President, Sir Rawson W. Rawson. Statistics, as usually treated in this country, little more than the mere calculating of numbers, is a mere mechanical operation; but which, treated as some of the most eminent statists have treated it, as dealing with the structure of human society, then it certainly becomes amenable to scientific methods. Sir Rawson Rawson referred further to the want of organisation in the collection and publication of official statistics in this country, and rightly advocated reform in this respect. Among the other papers read on Monday were—a sketch of the history of the Society, by Dr. F. J. Mouat; "Statistical Developments, with special reference to Statistics as a Science," by Dr. W. A. Guy, F.R.S.; and on "Statistics and their Enemies," by M. de Foville. One of the principal papers on Tuesday was by Mr. R. Giffen, on "Some General Uses of Statistical Knowledge," in which, among other things, he referred to the rapid increase of the population of Europe during the last century as compared with the increase in China and other Asiatic countries (except India) and in Africa. Should the present rate of European increase continue, the population of our continent in another century will be 1000 millions, whilst that of the United States would be 800 millions. Mr. Giffen maintained that the increase in Europe had been accompanied by a corresponding increase in the means of subsistence and improvement in the position of all classes.

Mr. J. S. Jeans read a paper "On Uniformity of Statistics." He held the chief *desiderata* required with a view to the improvement and co-ordination of the statistical work undertaken by different Government bureaux were: (1) an agreement as to the major facts necessary to be collected for each special department of statistics; (2) uniformity in the processes by which these facts were got together; (3) co-ordination of the methods whereby the materials thus collected were systematised and made use of; (4) the adoption, as far as possible, of the calendar year as the universal statistical period, so that when comparisons were made they should alway relate to the same dates; (5) the general adoption of the metrical system of weights, measures, and currency.

Herr Körösi spoke "On the Unification of Census Record Tables." The voluminous and polyglot census results of the world were, he found, practically non-comparable, and he proceeded to sketch a uniform scheme of record tables by which we should arrive at one bound at the highest aim of statistics—the possession of a uniform description of the different nations and of all mankind as regarded sex, age, civil state, illiteracy, occupations, &c.

Mr. F. Y. Edgeworth, in a paper entitled "The Methods of Statistics," confined himself to the treatment of numerical means. He showed that if we take several means of phenomena belonging to one and the same class (*e.g.* statures of men), each mean derived from numerous observations, the set of values thus presented would in general fulfil a certain simple mathematical law. The general formula involved a constant or coefficient peculiar to each class of phenomena, which must be discovered by experience. When this operation had been performed we had an apparatus for testing whether any given mean was or was not exceptional, indicative that the set of things of which the *datum* was the mean might (as compared with other phenomena of the same general class) be regarded as belonging to a distinct species. A pretty illustration of important principles was afforded by the statistics of a wasp's nest, "the image of trade which wasps entering and issuing from their nest present." It appeared that the exports and imports of this miniature commerce fluctuated with mathematical regularity. As further illustrations of the variety of interests amenable to the general law, he adduced the attendance of the members of a club at a *table d'hôte*, and the frequency of dactyls in the Latin hexameter. The conditions postulated by the Calculus of Probabilities were particularly well exemplified by the fluctuations of the Virgilian rhythm. In conclusion, he alluded to the simpler methods of statistics, and maintained that the mathematical, as compared with the more elementary, organon could produce the same effect with less trouble, or, with the same trouble, greater effect.

M. Emile Levasseur, Member of the Institute and Professor at the College of France, initiated a discussion on the graphic method applied to statistics, exhibiting diagrams and cartograms or statistical maps illustrating his views. Prof. Marshall, of Cambridge, who followed, advocated the use of a standard gauge for historical curves in order to simplify references to the graphic method of statistics, and pointed out dangers in the employment of curves arising from their deceptive appearance to the untrained eye. He suggested a ready means of testing the values of curves under comparison.

Yesterday was entirely occupied by a conference and discussion on the subject of an International Statistical Institute, the establishment of which was virtually agreed to.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—At the annual election at St. John's College on June 22, the following awards were made to students of Mathematics, Natural Science, and Medicine:—

Foundation Scholarships.—Mathematics: Love, Fletcher (each raised to 100*l*.), Bushe-Fox, Kirby, Mossop, Foster Hill. Natural Science and Medicine: Shore, Rolleston, Seward.

Exhibitions.—Mathematics: Holmes, Middlemast, Pressland, Roseveare, Bushe-Fox, Foster, Flux. Natural Science and Medicine: Rolleston, Olive, Jones. Natural Science: Evans, Rendle, Lake.

Proper Sizarships.—Mathematics: Norris, Varley.

Hughes Prizes.—Mathematics: Love. Natural Science: Shore.

Wright Prizes.—Mathematics: Fletcher, Bakre, and Flux (equal).

Herschel Prize (for Astronomy).—Bushe-Fox.

Hockin Prize (for Electricity).—Not awarded.

The Hutchinson Studentship (NATURE, May 28, p. 90) was awarded to Ds. Rapson (First Class, Classical Tripos 1883–85, and Indian Languages Tripos 1885) to assist him in the prosecution of his studies in Sanskrit literature.

The next Adams Prize will be adjudged in 1887. The subject is Ellipsoidal and Spheroidal Harmonic Analysis, attention being particularly drawn to the reduction of the formulæ in this calculus to practical forms adapted to numerical calculation. Since, with the exception of spherical harmonics, this method has remained almost barren in physical investigations, actual illustrations of its utility are invited. The essays must be sent in by December 16, 1886, and any Cambridge graduate may compete. The successful candidate will receive 170*l*.; he must print the essay at his own expense.

The Mathematical Board recommend that four separate examiners be appointed for the final portion of the Mathematical Tripos, in the hope of inducing more specially qualified professors and specialists to undertake this advanced work.

The Annual Report of the Observatory gives a very satisfactory record of progress. Among the 3253 observations with the transit circle were 2442 of zone stars on 100 nights, the greater number at five or seven wires, and all read off with four microscopes. The reductions of observations are in a forward state.

At the Botanical Gardens during the past year the collection of insectivorous plants has been greatly improved. A number of new or rare species have flowered—some for the first time in this country. A speciality has been made of Salvia, and four species from this garden have been figured in the *Botanical Magazine*.

A grant not exceeding 100*l*. is to be made to C. S. Sherrington, M.B., of Gonville and Caius College, from the Worts Travelling Scholars Fund, to enable him to proceed to Valentia to investigate the experiments now being made by Dr. Ferrand on inoculation as a preventive against cholera.

SCIENTIFIC SERIALS

IN the *Journal of Botany* for May and June Mr. W. B Grove continues his paper on "new or noteworthy fungi," which is well illustrated. Several new species are described, and one new genus, *Diplococcium*, near to *Cladotrichum*.—Mr. S. Le M. Moore identifies *Bacterium fœtidum*, Thin, found in association with profuse sweating of the soles of the feet, with the ordinary micrococcus of surface soil.—Mr. H. N. Dixon adds a new species to the British moss flora, *Catharinea dixoni*, from Northampton.—Mr. R. D. Fitzgerald and Mr. H. N. Ridley describe new Orchids; and Rev. B. Scortechini a new genus of Myrtaceæ, *Pseudoerigenia*, from the Malay Peninsula.—Dr. H. Trimen sends some notes on the flora of Ceylon, and Rev. W. H. Purchas contributes notes on Dovedale plants.

Rivista Scientifico Industriale, May 15.—A new explanation of the red after-glows (continued), by Prof. Carlo Marangoni.—On the diathermicity of fluids, by A. Volta.—Some electric phenomena associated with rarefied gases, by Emilio Piazzoli.—Variations in the electric resistance of solid and pure metal wires according to the temperature (concluded), by Prof. Angelo Emo.

Bulletin de l'Académie Royale de Belgique, April 4.—Crystallographic note on some specimens of calcite from the Carboniferous limestone of Blaton.—Note on the recent appearance of a school of whales (*Balæna biscayensis*) on the east coast of the United States, by M. P. J. Van Beneden.—Account of the discovery of a gigantic Mosasaurian (Hainosaurus) in the chalk formation of Mesvin-Ciply near Mons, Belgium, by M. E Dupont.—On Riccati's equation and its double generalisation, by M. J. de Tilly.—State of the vegetation during the month of March at Liége and Longchamps-sur-Geer, Belgium, by Baron de Selys Longchamps.—On the presence of Condroz graywacke in the neighbourhood of Beaumont, Entre-Sambre-et-Meuse, by M. SOCIETIES AND ACADEMIES

LONDON

Royal Society, June 18.—"The Action of Tidal Streams on Metals during Diffusion of Salt and Fresh Water. Experimental Research, Part II. (Gravimetric)." By Thomas Andrews, F.R.S.E. Communicated by Prof. G. G. Stokes, Sec.R.S.

In a paper last session on "The Electromotive Force during Diffusion in Tidal Streams" (see *Proc. Roy. Soc.*, No. 232), the author recorded the electrical part of this investigation. The present communication contains the concluding gravimetric experiments of the research. The effects attending the diffusion of the salt and fresh water in tidal estuaries, on parts of the same metal, of known composition and general properties, were estimated in each case for a period of *one year*, during which bright plates of the following metals—viz., wrought iron (combined carbon, none), "soft" Bessemer steel (c.c. 0·15), "soft" Siemens-Martin steel (c.c. 0·17), "soft" cast steel (c.c. 0·46), "hard" Bessemer steel (c.c. 0·51), best cast metal, "No. 1" (c.c. 0·39), common cast metal, "No. 2" (c.c. 0·67), were constantly exposed to conditions of galvanic action similar to those obtaining in some tidal streams. The results demonstrate that electric disintegration of the nature alluded to in this and the former paper (viz., the galvanic destructive action on parts of even the same metal, arising from difference of electrical potential during diffusion between the surface and lower waters in a tidal stream) is, on comparison with other investigations by the author, apparently of much greater extent than the loss either from simple corrosion in sea water alone, or than that which ensues from the action on each other of dissimilar metals of this group (such as wrought irons, cast metals, and steels) in galvanic connection in sea water. Compared with simple corrosion in sea water only, the increase in loss varied from about 15 up to 50 per cent., according to the nature of the metals. The results of the experiments in this and the former paper indicate, therefore, that the tidal action on any vessel or metallic structure, of sea and fresh water whilst diffusing is (in the case even of the same metal thus exposed to the simultaneous action of top and bottom waters) considerably more destructive in its nature and character than the action of sea water alone. Moreover, the author has found it (in other experiments) extending over long periods to considerably exceed (in some instances varying from about 55 to 120 per cent.) the loss caused by galvanic action between dissimilar metals of the iron and steel group in circuit in sea water.

Geological Society, May 27.—Prof. T. G. Bonney, F.R.S., President, in the chair.—George Ormond Kekewich was elected a Fellow of the Society.—The following communications were read:—On the so-called diorite of Little Knott (Cumberland), with further remarks on the occurrence of Picrites in Wales, by Prof. T. G. Bonney, F.R.S., Pres.G.S. The Little Knott rock and its microscopic structure were briefly described by the late Mr. Clifton Ward, who named it a diorite, but called attention to its abnormal character. The author gave some additional particulars, and showed that, although the rock varies in different parts of the same outcrop, and is not one of the most typical representatives of the picrite group, its relations on the whole are with this rather than with the true diorites. He also called attention to the extraordinary number of boulders which have been furnished by this comparatively small outcrop, and discussed the relation of their distribution to the former extension and effects of ice in the Lake District. He briefly noticed the occurrence of additional boulders of picrite in Anglesey, and described specimens from two localities (Caemawr and Pengorphwysfa) where a similar rock has been discovered *in situ* by Prof. Hughes. Hence it is probable that the Anglesey boulders are derived from localities in that island, and not from Cumberland. From a re-examination of specimens collected by the late Prof. Sedgwick and Mr. Tawney, preserved in the Woodwardian Museum at Cambridge, the author showed that the rock must occur *in situ* in two localities in the Lleyn peninsula—in the neighbourhood of Clynnog and of Aberdaron. Lastly, he described a very remarkable picrite boulder, discovered by Dr. Hicks, which rests on "Dimetian" rock at Porthlisky near St. David's.—Sketches of South-African Geology; No. 2, a sketch of the gold-fields of the Transvaal, South Africa, by W. H. Penning, F.G.S. The gold-fields of the Transvaal have been defined as covering nearly all the eastern and northern districts of the State, though but a small portion of the area is productive. In this paper the author described only the Lydenburg and De Kaap gold-fields, leaving those of Pretoria and Marabastadt for a future communication. The auriferous region is known to extend 350 miles to the northward beyond the Limpopo River, so that the gold-bearing rocks are found throughout at least 7½ degrees of latitude and 3 of longitude. The area of the two gold-fields mentioned, comprising together about 3000 square miles, was defined; and the author, after noticing some old gold-workings, proceeded to give an account of the physical features of the country. He especially called attention to the circumstance that most of the rivers rise to the west of the highest range, and flow eastward through it. The oldest gold-bearing rocks consist of unfossiliferous schists, shales, cherts, and quartzites, classed by the author as Silurian. Amongst these a great mass of coarse granitic rock is intruded, consisting of quartz and felspar, with but little, if any, mica. This granite, in the De Kaap valley, forms an ellipse seventeen miles long by ten broad, with a narrow northerly prolongation. Both the granite and the stratified rock are traversed by intrusive dykes, chiefly of diorite. These beds have been much disturbed and then cut down, probably by marine denudation, to a level plain 1700 or 1800 feet above the sea. Upon them rest unconformably a great sequence of conglomerates, sandstones, and shales, the "Megaliesberg beds" of a former paper, but now provisionally classed as Devonian. These rocks also are traversed by dykes of diorite and other kinds of trap. The "High Veldt beds" overlie the "Devonian" with some unconformity. Several sections and observations illustrative of these facts were described, and details were given of the different gold-mines in each of the great systems noticed, and also in alluvial deposits. It was shown that much gold was derived originally from veins in the older or Silurian rocks, and that some of that met with in the newer system occurred in conglomerates or other detrital beds. But there are also gold-bearing quartz-veins intersecting the latter.—On some erratics in the boulder-clay of Cheshire, &c., and the conditions of climate they denote, by Charles Ricketts, M.D., F.G.S.

Royal Meteorological Society, June 17.—Mr. R. H. Scott, F.R.S., President, in the chair.—Lieut. A. Leeper, R.N., was elected a Fellow of the Society.—The following papers were read:—A few meteorological observations made on a voyage up the Nile in February and March, 1885, by Dr. W. Marcet, F.R.S. The author, on a voyage up the Nile from Cairo to Assouan, made a series of meteorological observations, and in the present paper gives the results of those relating mainly to nocturnal radiation and the temperature of the water of the Nile.—The mean direction of cirrus clouds over Europe, by Dr. H. H. Hildebrandsson, Hon.Mem.R.Met.Soc. The author has collected a number of observations on the movements of cirrus clouds over various parts of Europe, and after discussing them has arrived at the following results: (1) the mean direction at all stations lies between south-west and north-west; (2) in winter the cirri come from a more northerly direction, and in summer from a more southerly; (3) in winter the northerly component is greater on the Baltic and the north coast of the Mediterranean; (4) the mean directions of the upper currents nearly coincide with the mean tracks of storm-centres; (5) the upper currents of the atmosphere tend in general to flow away from those areas in which a barometrical depression exists at the earth's surface towards those in which there is an elevation of pressure.—On the influence of accumulations of snow on climate, by Dr. A. Woeikoff, Hon.Mem.R.Met.Soc.—Note on the weather of January, 1881, by Mr. E. Harding, F.R.Met.Soc. It will be remembered that the weather of January, 1881, was remarkable for the prolonged and exceptionally severe frost, the heavy gale of the 18th and 19th, and the snowstorms. The author has prepared isobaric charts for the North Atlantic and adjacent continents for January, 1881, and compared it with similar charts for January in other years. He shows that the severe weather in 1881 was due to a reversal of the normal conditions, the atmospheric pressure being high in the north and low in the south.—Results of meteorological observations made in the Solomon Group, 1882-84, by Lieut. A. Leeper, R.N.—Graphic hygrometrical table, by Mr. D. Cunningham, M.Inst.C.E., F.R.Met.Soc.

Geologists' Association, June 5.—Wm. Topley, F.G.S., President, in the chair.—A paper was read by Mr. Herbert Goss, F.L.S., on some recently-discovered Insecta and Arachnida from Carboniferous and Silurian Rocks. The author stated that in 1879 only 103 fossil insects from the Carboniferous rocks of the whole world were known, but during the last five years a great number had been discovered, including about 1400 from Commentry, France, a few from Saarbrück, Klein Opitz, Lugau, and elsewhere on the Continent of Europe, and a considerable number from various parts of the North American Continent. The specimens were enumerated, some of the most remarkable forms were referred to in detail, and attention was drawn to their affinities with existing types. Many of the specimens were of gigantic size and in a fine state of preservation, and whilst the majority of them appeared referable to forms allied to existing genera of *Hemiptera*, *Neuroptera*, and *Orthoptera*, a considerable number consisted of synthetic types intermediate between these orders, uniting in themselves certain peculiarities of structure now characteristic of distinct orders. Attention was also called to the recent discovery of fossil scorpions in the Upper Silurian of the Isle of Gothland and Scotland, and the wing of a cockroach in the Middle Silurian of Jurques, Calvados, France. Prior to these discoveries no remains of terrestrial animals had been obtained from any strata older than the Devonian, and the result of their discovery in Silurian strata was to leave the *Insecta* the oldest known class of land animals, and the *Blattidæ* the oldest family of insects. The evidence afforded by Palæontology was therefore, as far as it went, in support of the views as to the origin of insects and the order of succession of the various groups previously arrived at from a study of the embryology of the class.

Edinburgh

Royal Society, June 1.—Robert Gray, Vice-President, in the chair.—The Astronomer-Royal for Scotland showed the solar spectrum, as observed last year by him, drawn to scale 80 feet long. He contrasted it with the spectrum as seen by Fievez, and with that as seen by himself some years ago, a special object being to determine the effect of the present cosmic dust.—Prof. Tait gave a number of perfectly general methods of enumerating the amphicheiral knots of any order, and pointed out the curious fact that amphicheirals may in many cases be transformed into other amphicheirals, sometimes in more than one way.—Mr. Hugh Robert Mill, B.Sc., communicated a paper on the chemistry of Japanese lacquer (*Urushi*), by Mr. Hikorokuro Yoshida, chemist to the Imperial Geological Survey of Japan. Lacquer juice was found to consist of a monobasic acid (Urushic acid), a small proportion of a nitrogenous diastatic matter, gum arabic, and water. The hardening of lacquer was shown to be due to the oxidation of the urushic acid to oxyurushic acid by the action of the nitrogenous substance in the presence of air and moisture, a number of experiments distinctly proving that it was not a case of hydration. Coloured lacquers are made by the addition of metals, their sulphides, or oxides, to the juice, which exerts no action upon them, except in the case of *roiro* or black lacquer, the colour of which is due to the presence of urushiate of iron produced by the addition of iron filings to the juice.—In a paper on atmospheric electricity at Dodabetta, Prof. C. Michie Smith pointed out that the forenoon observations show a mean curve of atmospheric potential rising to a maximum at about the period of maximum temperature. There is probably a much less marked night maximum, with, of course, a minimum between each maximum. From observations made on some exceptionally fine days, an afternoon curve was constructed. The afternoon observations, however, were usually much modified by mists, but the important fact was established that the potential was regularly less than the normal in a dissipating mist, and much above the normal in a condensing mist.—The Astronomer-Royal for Scotland exhibited a series of star-photographs.

Paris

Academy of Sciences, June 15.—Note on MM. Paul and Prosper Henry's apparatus for photographing the heavenly bodies, by M. Mouchez. The author presented to the Academy the already executed chart of a section of the Milky Way, including about 5000 stars from the sixth to the fifteenth magnitude comprised in the space between 2° 15′ right ascension and 3° declination. To complete the representation of the 41,000 superficial degrees of the firmament there will be needed 6000 similar sections forming 1500 of our ecliptical charts. Were the work undertaken by six or eight observatories well situated in the two hemispheres, the whole might be concluded in about five or six years. Such a work, containing the photographs of over 20 million stars down to the 14th or 15th magnitude, and bequeathing to future astronomers an exact picture of the starry regions at the close of the nineteenth century, would certainly be the greatest astronomic undertaking ever carried out.—Remarks on the study of the various floras and faunas in their relations to physical geography and the geology of the globe, by M. Emile Blanchard.—Remarks on M. Alfred Grandidier's "Avifauna of Madagascar," completing the third and last volume of that naturalist's great work on the "Physical and Political History of Madagascar," by M. Alph. Milne-Edwards.—Note on the fourth part of the Map of Algeria to the scale of 1 : 50,000, and on the second and third sheets of the Ordnance Map of France, presented to the Academy by M. Perrier.—Experimental researches on the diphtheric affections of animals, by M. G. Colin. —Observations of Palisa's new planet 248, made at the Paris Observatory (equatorial of the west tower), by M. G. Bigourdan. —Observations of the same planet made at the Observatory of Algiers (0·50 m. telescope), by M. Ch. Trépied.—Experiments on the propagation of waves along the course of rapid streams: confirmation of the formulas given by M. Boussinesq in his theory on the gradually varied movements of fluids, by M. Bazin. —Note on spectroscopic observations through the medium of radiant matter: mutual extinction of the spectra of yttrium and sanarium, by M. William Crookes. From the numerous anomalies presented during his present experiments, the author draws the important inference that the conclusions of spectrum analysis *per se* are liable to serious error unless at each step the spectroscopist is controlled by the chemist, who represents the last court of appeal.—On the action of cadmium on the nitrate of ammoniac, by M. H. Morin.—Note on the sulphur derived from the persulphuret of hydrogen, by M. Maguenne.—Note on the methylate of soda, by M. de Forcrand.—On the degree of volatility in the chloruretted nitrites, by M. L. Henry.—On the pretended elective fermentation, by M. Maumené.—On the geniculated ganglion of birds, by M. L. Magnien. From his researches the author finds that in birds there exists a facial ganglion, which must be assimilated to the geniculated ganglion of the higher vertebrate animals.—Note on the nervous system of the Buccinidæ and the Purpuridæ, by M. E. L. Bouvier.—Physiology of the composite Ascidians belonging to the family of the Diplosomidæ, by M. S. Jourdain.—Considerations on the Echinidæ of the Jurassic formations in France, by M. Cotteau. Of the fifty genera belonging to the Jurassic formations twenty-four are peculiar to this geological system; four only persist to the Tertiary epoch, and two alone (Cidaris and Stomechinus) survive to the present time.—An attempt to determine the variations in the length of time during which the human body rests on both feet while walking, by M. Demeny.—On the respiration of plants, by MM. G. Boneier and L. Mangin—Note on the artificial production of Strengite ($Fe_2(PO_4)_2 + 4H_2O$), by M. A. de Schulten.—Symmetrical disposition of the archaic formations on both sides of the Guadalquivir Valley, by M. J. Macpherson.

BERLIN

Physiological Society, May 15.—Dr. Höltzke spoke of the results of his investigations into intraocular pressure. It having been established that glaucoma was developed in the eye through pathologically increased pressure, the question of physiological pressure in the eye was of high practical importance. Yet was Herr Grünhagen the first, by means of a canula introduced into the anterior chamber of the eye, and a fine mercurial manometer connected with it, to measure the magnitude of this pressure in the eye of a cat and to determine its variations. He found the living cat's eye showing a pressure of 26 mm., which, on the death of the animal, sank to 10 mm. Everything increasing the blood-pressure was found to augment at the same time the intraocular pressure, while, on the other hand, everything lowering the pressure in the province of the carotid artery was found to lessen the pressure in the chamber of the eye. Stimulation of the trigemini raised the intraocular pressure considerably, as did likewise stimulation of the medulla oblongata, which pushed the pressure up to as high even as 200 mm. The effect of atropine was a diminution of pressure. A few later observers had, with somewhat modified manometers, attained like results for the influence of the blood-pressure and deviating results for that of the nerves and the alkaloids. Dr. Höltzke had in his investigations, which first of all referred to the effect of the alkaloids atropine, eserine, and pilocarpine, laid special weight on the improvement of the methods, and on one hand had, as a trustworthy measurer of pressure, made use of a double manometer, which he produced and explained to the Society, and on the other hand had confined the application of the alkaloids above mentioned to one eye, while the other eye was utilised in the way of control in the process of the measurements which were always carried out in both eyes. As the result of the measurements it was ascertained that eserine produced at first a considerable augmentation of the pressure, and then an abatement of it to a point below the normal value. Pilocarpine produced similar, but more reduced results; while atropine called forth quite the contrary effects. The speaker had further determined the pressure, still more directly concerned in the case of the production of glaucoma, in the vitreous humour, by means of a special canula, and with the same measurer of pressure. In this case he had found the pressure, both under normal conditions, as also under the operation of the alkaloids, and the changes of pressure in the blood, to be always similar to the pressure in the anterior chamber of the eye.—Dr. Virchow described the relation of the blood-vessels of the vitreous humour in cyprinoids. After having shown that the occurrence of blood-vessels in the vitreous body, and its absence from the retina was not a distinguishing character of the amphibia, seeing that blood-vessels in the vitreous humour were wanting in the case of many amphibia and reptiles, as also in the lowest fishes, while in other classes of amphibia such blood-vessels were to be found. The speaker commented minutely on the differences in the ramification and diffusion of these blood-vessels, as also the varying arrangement of their capillaries, and demonstrated them on preparations of carps, bleaks, and roaches, as well as by enlarged photographs.—Dr. Weyl reported on the negative results of experiments having for their object to ascertain the mode of nitrates in the animal body. It was a well-known fact that nitrates occurred in human urine, but were regularly wanting in the urine of dogs. By feeding dogs with ammoniacal citric acid a nitrate formation was not produced, not even when, along with the ammonia, a fixed alkali was administered by way of combining the acids arising under the flesh aliment. Only in a pathological case, in which a dog that had received ammonia died of a disease of the intestine and the kidneys, was nitrate found in the urine; consequently neither the mode of the formation of nitrates in the organism nor the cause of the difference between man and dog in this respect had been ascertained. For the demonstration of nitrates in the urine the speaker recommended distilling the urine with sulphuric acid, and treating the distillation with one of the many reagents of nitric oxide.—Dr. Friedländer demonstrated a case of carcinoma hitherto never observed in a pulmonary cavern. The carcinoma adhered firmly to the wall of the tubercular cavity, sent a stalk through the next branch, and at the stalk hung a somewhat large carcinomatous swelling in the bifurcation. The carcinoma was a horny carcinoma which was regularly observed at those places where stratified flattened epithelium occurred; on other membranes horny cancer had hitherto never been observed. So much the more striking, therefore, was it to find horny carcinoma in the lungs. This riddle perhaps found its explanation in two observations noted down in the literature of the subject, according to which defects in mucous membranes caused by abscesses, once in the lungs and once in the corpus uteri, became healed over by flattened epithelium instead of by cylindroid or ciliated cells. It was possible that the cavity occurring in this case also had covered itself with flattened epithelium which had become the starting-point for the horny carcinoma.

Physical Society, May 21.—Dr. Kayser demonstrated a new cathetometer constructed by Herr Bamberg, explained the arrangement of it, and set forth as its special advantages the facility of placing it vertically and the circumstance that after precise adjustment, by merely changing the eye-pieces, the instrument could be used both as a microscope and a telescope, without at all altering its position for the least as for the greatest distances.—Prof. Neesen sketched a very simple arrangement for demonstrating the effect of the lightning-conductor, which was particularly well qualified for class experiments.—Dr. König discussed the principle according to which he was getting a new spectro-photometer made, which he showed to the Society, provisionally put together. The instrument consisted in the main of an objective tube containing a lens and a diaphragm turned towards the source of light with two slits lying above each other, a prism for decomposing the two bundles of incident rays, and a second collimator tube, on the lid of which closing the end appeared two spectra showing an interval between them. Before the lens of the ocular collimator was placed a twin prism, the two prisms of which with their refracting edges of 1° to 2° were cemented together. By this twin prism each spectrum was decomposed into two spectra, and the dimensions of the twin prism were determined in such a manner that on the lid of the collimator one spectrum was situated above, the other below, while in the middle the second spectrum of the upper slit coincided with the second spectrum of the lower slit. In the lid of the ocular tube let a small opening be made cutting off a small piece of determinate wave-length from the double spectrum; on looking through it the field of vision would be seen divided by a line (the refracting edges of the twin prism) into two halves, both of the same colouring. Before each of the two slits of the objective tube through which the light entered was placed a Nicol prism in such a position that perpendicularly polarised light entered one slit and horizontally polarised light the other. The middle compound spectrum consisted, therefore, of a perpendicularly and a horizontally polarised spectrum, and in the field of vision the two like-coloured halves were also polarised perpendicularly to each other. If now the field of vision was viewed, not directly, but through a Nicol prism, then, according to the position of this prism would the one half at one time, the other half at another time, be withdrawn from sight; and if the two entering rays of light or their spectra possessed different degrees of intensity, by turning the ocular-Nicol the two halves of the field of vision could be made equal, and from the rotation the relative degrees of intensity of the two bundles of rays could be determined.

May 20.—Prof. Stefan was elected Vice-President of the Mathematical Class; Prof. E. Suess, Secretary; Prof. L. Boltzmann (Gratz), Prof. V. von Zepharovitsch (Prague), and Prof. C. Claus (Vienna) were elected Members; Prof. Escherich, Prof. A. Vogl, and Franz Exner (Vienna), Correspondents; Prof. A. Bayer (Munich), Prof. T. D. Dana (New Haven), Foreign Correspondents.

May 21.—Anniversary Meeting.—The opening address was held by the Curator's substitute, A. von Schmerling. Then the reports were read by the General Secretary, Prof. Siegel, and by the Secretary of the Mathematical Class, Prof. Stefan. Obituary notes were given by the latter on Hochstetter, Fitzinger, F. von Stein, and Siebold. A prize of 1000 florins was awarded to R. Maly (Gratz), for his paper, "Researches on the Oxidation of Albumens by Potassium Permanganate."

STOCKHOLM

Academy of Sciences, May 18.—For the *Transactions* of the Academy were accepted: Researches on the disjunctive electromotive power on the electrodes during the passage of electricity through air of greater or lesser density, by Prof. Edlund; and Ueber die Säugethiergattung Galeopithecus: eine morphologische Untersuchung, by Prof. W. Peche.—Prof. Edlund exhibited and described a specimen of meteorograph of Thorell's construction, made by Herr Sörensen for the Emperor of Brazil.—Prof. Warming gave an account of the botanical researches undertaken by Messrs. L. Y. Neumann and G. A. Tiselius in the Swedish provinces of Jemtland and Medelpad; and (2) contributions to the knowledge of the structure of the pericarp, by Miss Alida Olbers.—Prof. Toréel exhibited and described a geological map of Sweden, on the scale 1 : 600,000.—The Secretary, Prof. Lindhagen, presented for publication in the *Transactions* the following papers:—The transversal oscillations in a thin crystalline lamina with three plans of symmetry and elliptical limitation, by E. Sundberg.—Alpha-oxazonaphtalin alpha-sulphonacid and some of its salts, by Dr. J. E. Alèn.—On two isomeric beta-monochlor-naphthalin-sulphonacids, by Herr K. Arnell.—On mononitro-beta-naphtha-acids, by Dr. A. G. Ekstrand.—Some annotations on microscopic researches on plants, by Dr. A. Malm.—Contributions to the flora of fungi in the southernmost parts of Norway, by Dr. E. Henning.—On Sowerby's whale, by Dr. A. Malm.

CONTENTS

THURSDAY, JULY 2, 1885

TWO BOTANICAL TRANSLATIONS FROM THE GERMAN

I. *Text-Book of General Botany.* By Dr. W. J. Behrens. Translation from the Second German Edition. Revised by Patrick Geddes, F.R.S.E. (Edinburgh: Young J. Pentland, 1885.)

II. *A Guide for the Microscopical Investigation of Vegetable Substances.* From the German of Dr. Julius Wilhelm Behrens. Translated and Edited by Rev. A. B. Hervey; A.M., assisted by R. H. Ward, M.D., F.R.M.S. (Boston: S. E. Cassino and Co., 1885.)

I. A STUDENT of science in our Universities on running his eye along his bookshelves can hardly fail to be struck by the large proportion of translations which find their place there; in physics and in chemistry the proportion of them is large, but in biology and especially in botany the original productions of this country hardly hold their own against their foreign competitors. It must be freely admitted that there was a time, not long ago, when botanical laboratory work had fallen to a low ebb in England; the botanists of this country had failed to keep pace in this branch of their subject with their contemporaries on the Continent, and it was chiefly by the translation of the text-book of Sachs that laboratory work received a new stimulus on this side of the Channel. The translation of that work some twelve years ago has been followed by others of standard books, and we have reason to expect that their number will be further increased within a short period. Any reasonable person will welcome the translation of standard and classical works; their production is beneficial, and they may at times even bring about wholesome revolutions. But though the most important translations produced recently are from the German, it does not necessarily follow that all German text-books are good, and the first of the two books above named is an illustration of the truth of this.

Perhaps the greatest difficulty in the construction of an elementary text-book which aims at the general treatment of a science is suitably to balance the several parts of the subject, bringing out at length those parts of the science which are important to elementary students, and placing in the background those branches which are of less importance; it is on this rock that writers of text-books have most often split, and this text-book of Dr. Behrens is no exception. But it is also essential that a text-book shall be accurate in its facts; it will be seen from the quotations below that Dr. Behrens's book fails repeatedly in this respect.

The external morphology of the higher plants, including the structure of the flower and the principles of classification, occupies the first 160 pages; the treatment is neither better nor worse than that usual in text-books of the present day. Then follows, under the head of "Physiological Botany," an exposition of 70 pages in length on "flowers and insects," and transport of seeds. Anatomy and physiology judiciously welded together occupy 80 pages, while the whole series of "Lower Plants," including the Vascular Cryptogams, are dismissed in less than 40 pages, barely half of the space devoted to "flowers and insects, &c." If we take a rough estimate of the balance of the book by the number of pages devoted to the several branches it is clear the lower plants come off the worst, and a quotation will illustrate the result. On page 332 the following is the whole account given of the Florideæ:—"The Florideæ are sea-weeds containing red or brown colouring matter. They are distinguished from the sea-wracks by the circumstance that their spores are generated in capsules (cystocarps, *f*, Fig. 390), which arise in the axils of the leaf-like lobes of the thallus (*s.d*)." Then follows a short description of *Batrachospermum*. Not only is this description insufficient and useless to a student, but it is also obviously inaccurate. Of the other inaccuracies a few may be cited. In Fig. 371 the pit-membranes in the wood of *Pinus sylvestris* are altogether omitted; the flattened stems of *Phyllocladus* are described as leaves in the explanation of Fig. 408, notwithstanding the tall talk on morphology on pp. 237-8. On p. 350 we read: "In the highest Cryptogams only are the sporangia formed by leaves, or homologues of leaves; in the Phanerogams this is always the case;" and, on p. 101, "as *all* Phanerogams have either one or two seed-leaves, &c." The above quotations by no means exhaust the inaccuracies of the book.

In not a few cases statements are made which can only confuse the student. Thus on p. 352 we read: "In the Metasperms the two generations of the vascular Cryptogams are represented by one." And again, on p. 314, "Spores are entirely destitute of an embryo, having plumule, radicle and cotyledons." A man who can write such sentences shows that he is not in sympathy with the student.

Perhaps the most prominent error in the book is one of omission. In describing the stomata a special paragraph is devoted on p. 283 to their function, but not a word is said of transpiration; on turning to the description of transpiration on p. 305 the stomata are not mentioned! And this is a book which aims, as stated in the preface, at placing the student "at the newest standpoint of the science"!

Enough has now been said to show that the book is far from being a model text-book; but it must not be concluded that it is entirely without merit; many of the illustrations are good, and the exposition is for the most part clear, while historical notes interspersed here and there in the text lend additional interest. It is, however, obvious that neither in point of accuracy nor of balance is the book so near an approach to the ideal elementary text-book as to merit the honour, or deserve the trouble of translation.

The above notice has been extended to greater length than the importance of Dr. Behrens's text-book deserved, because the publication of this translation marks in a certain sense an epoch in the progress of botany in this country. For the last twelve years we have been dependent in great measure upon Germany for our larger text-books; we have in that respect been leading a parasitic existence, or rather passing through a period of *healthy symbiosis*, such as that of the embryo on the parent plant; the time is fast approaching when we may expect the young plant to assert its independence, when text-books designed to meet our own peculiar requirements shall be written by native authors. Meanwhile let the choice of books for translation be confined to those that are sound and good, let us guard jealously against any tendency to a *saprophytic* habit, with its attendant degeneration; the translation of an unsound text-book may be regarded in a sense as marking a saprophytic tendency, and the appearance of the translation of this book of Dr. Behrens is perhaps the first indication of such a saprophytic habit.

Lastly, would it not be possible, and much more advantageous, to transmute the energy now devoted to translation into original production? It is admitted that a teacher acquires both facility of exposition and clearness of view by writing down his ideas in the form of a text-book. It is for us to see that we do not continue our "healthy symbiosis" unduly, and thereby lose that power of original exposition for which so many English men of science have been properly celebrated.

II. The second work under review is a translation of a book by the same author, and it is one of those works now being produced in rapid succession which aim at assisting the student in his practical work in the laboratory. The keynote is struck by the following passage from the preface to the German original: "For a work to be useful in those microscopical inquiries which are most important in the botanical laboratory, it need teach neither optics nor histology." It may fairly be admitted that within the cover of this book the student will find clearly laid before him all that it is essential he should know of the theory and structure of the modern microscope, together with useful instructions as to the methods and reagents in use in the botanical laboratory. Dr. Behrens boldly challenges criticism in his preface, when he says "the chapter of this work which deals with the microscopical investigation of vegetable substances furnishes an *exhaustive* treatment of these matters." Whatever may be our opinion as to the correctness of this statement it must be allowed that the work now before us is the result of an earnest effort, and represents wide and laborious sifting of a scattered literature not easily accessible to most students. There is quite a pathetic ring in one sentence in the preface; referring to the literature of the subject in the University Library at Göttingen, the author says: "With hardly a noteworthy exception, I have seen and read it all." It is only those who know how voluminous and how scattered are the writings on this subject who can form an idea of the magnitude of this task.

The first two chapters, dealing with the microscope and microscopical accessories, have been subjected to considerable alteration and extension by the editors. Naturally German stands and objectives are not so accessible in America as those made on the spot; the editors have devoted considerable space to the description and illustration of the microscopes of American manufacture, so that this part of the book partakes, both in appearance and contents, of the character of an optician's catalogue. A few paragraphs have been added on the subject of "nose-pieces;" but there is no mention of that invaluable nose-piece of Zeiss which is calculated to save the time of workers in no small degree—viz. that which can accommodate four objectives, and on which the tubes carrying the objectives are cut of such length as to bring each in turn approximately into focus: the value of this arrangement is obvious.

Chapter III. contains useful directions for the preparation of microscopic objects, cutting sections, mounting, drawing, &c. The most important part of the book, and that which will assuredly be the most generally useful, is that comprised in the last 200 pages, and it is almost a matter of regret that this latter half has not been published separately from the first 260 pages, which have an interest chiefly for the beginner, while for the advanced student they will be little better than lumber. Pp. 267-311 are devoted to the enumeration and preparation of micro-chemical reagents, while Chapter V. deals with the microscopical investigation of vegetable substances. It is to be noted that no reference is made to the inventor of chlor-iodide of zinc beyond his name, which, according to the notice of the meeting at which his solution was first described ("Flora," 1850, p. 643), is spelt "Schulze" not "Schultz" as it stands in the text. There is no mention of the demonstration of protoplasmic continuity, even in sieve tubes, nor is the substance of the "callus" of sieve tubes or its reactions described. These omissions do not greatly affect the value of the book; they would not have been mentioned had not Dr. Behrens professed to give us an "exhaustive" treatment of the subject. One chief merit of the work is that copious references are given to the sources from which Dr. Behrens has drawn his information; this will greatly add to its usefulness, and the translation may be accepted as a valuable addition to the laboratory handbooks already before the English-speaking public.

F. O. B.

RUSSIAN CENTRAL ASIA

Russian Central Asia, including Kuldja, Bokhara, Khiva, and Merv. By Henry Lansdell, D.D. (London: Sampson Low and Co., 1885.)

DR. LANSDELL, already favourably known to the public by his interesting volumes "Through Siberia," gives in the present work a mass of information on a subject to which the attention of Englishmen has of late been perforce directed—the Russian dominions in Central Asia. In the two goodly volumes recently published he gives the narrative of a journey undertaken in the year 1882, in the course of which he traversed Kuldja, Bokhara, Khiva, and Merv. Turkistan has been rarely visited by Englishmen, and, as Dr. Lansdell believes, in certain parts he may claim to be the first. The principal object of his journey was a philanthropic one—the distribution of religious literature, especially in the prisons of the Russian empire; but in writing this book he has kept in view the requirements of students as well as of general readers, providing for the former by touching upon the "geography, geology, fauna and flora, the characteristics of the people, their government, language, and religion"—to which not only numerous notes but also whole chapters are devoted, as well as "appendices, derived from works only published in the Russian language, which treat on the fauna and flora of Turkistan."

It would be impossible in the space to which this notice must necessarily be restricted to give an adequate idea of the great amount of matter which Dr. Lansdell has collected in these two volumes, so that we must content ourselves with a brief glance at a few of the more salient features.

To geographers the account of the Thian Shan Mountains will be among the subjects of interest. These mountains, estimated by Réclus as forming a mass twenty-five times larger than the Swiss Alps, and a protuberance on the earth's surface larger than the united mountains of all Europe, begin in Mongolia, and develope by the addition of successive ridges until they occupy from north to south above eight degrees of latitude. The heights of the several ranges vary from about 10,000 to 14,000 feet above the sea, and in the Pamir range exceed 15,000. The number of glaciers exceeds 8000. The principal lakes are the Alakul, the Balkash, and the Issikul, the waters of which are brackish; the first and second are believed to have once been connected. Volcanoes have been stated to exist in the Thian Shan, but this appears to be incorrect. Much information of interest is given about the Ili Valley, a meeting ground of the Tatar and Mongol races. From this region Dr. Lansdell diverged eastwards from the course of his journey to reach Kuldja, a town within the Chinese frontier, for some time in Russian occupation. He then continued his journey in a westerly direction, passing through Semirechia, of which region he gives many particulars of interest, dwelling especially on the patriarchal life of its nomad inhabitants. From the Kirghi Steppe he passed into Turkistan. The climate of portions of the Aralo-Caspian region does not appear inviting: the summer temperature is from 68° to 77° F., the winter from 5° to 23°. In the lowlands rain falls rarely in summer, and in only a small amount at any season. Hence there is a general desiccation. The beds of tributary rivers are dry; the main streams lose themselves in sands or terminate in brackish marshes; the smaller lakes have evaporated, leaving behind them beds of salt; the larger are much reduced in size. The land is barren; trees are scarce; vegetation is stunted, and limited in its species. The geology, as might be supposed, has not been exhaustively worked, but from a small work of M. Mouchketoff the author has obtained an outline, from which it appears that in one part or another of the district almost every formation, from the oldest to the newest, is represented, and that the mountain-chains consist largely of igneous rocks.

Dr. Lansdell spent some days in Bokhara, which town no English traveller had visited since the time of Wolff's adventurous journey. The fear of the Russian is, however, now upon this people, and he appears to have met with little difficulty, though subjected to some surveillance. On his way to the city he visited the Emir, then at Kitab, and had a gracious reception. The description of the author's invention of a court costume for the ceremony of presentation is amusing: the chief components were a cassock, a D.D. hood, some masonic jewels, and a square college cap. From Bokhara Dr. Lansdell travelled through Khiva, and thence by a rarely-traversed route, which, after following the general direction of the Abu-Daria for some distance, runs in a west-south-westerly direction to Krasnovodsk, near the Karaboghaz Bay of the Caspian. Thence he returned to England, having accomplished in 179 days a journey of 12,000 miles—laborious, with considerable hardships, and not without some danger, though the Russian influence has rendered many places, formerly all but inaccessible, comparatively safe.

Dr. Lansdell does not profess to be a scientific traveller, but he is a careful observer, noting with an experienced eye the physical peculiarities of the regions through which he travelled; and he has been at immense pains to gather together a large mass of information concerning the flora, fauna, and ethnology of Central Asia,[1] which has been to a great extent accumulated by Russian men of science, and which, from being written in their language, is practically inaccessible to most Europeans. The appendices on the flora and fauna of Russian Turkistan occupy 148 pages of rather small print, and there is in addition a very full bibliography of the same district which extends to twenty-five pages. But much information, both from books and from personal observation, is also incorporated into the narrative of travel. Dr. Lansdell's picture of the desiccation of the western part of Bokhara, of the moving sands between the Oxus and the Karakul, of the "barren and dry land" of the Aralo-Caspian region, and of the Karaboghaz Gulf—a great area of evaporation which, should any physical change close its narrow and shallow communication with the Caspian, would soon become one vast salt-pan—cannot fail to interest the student of physiography. In a word, the ethnologist, geologist, and naturalist will find these volumes not only very pleasant reading, but also most valuable for reference.

OUR BOOK SHELF

Bulletin of the Bussey Institution. Vol. II., 1884. (John Allyn, 30, Franklyn Street, Boston, U.S.)

THE *Bulletin* of the Bussey Institution has many claims to be considered as original in its design and in the character of its reports. It contains a large amount of information upon out-of-the-way topics, mostly treated upon from the chemical side, and in all cases communicated by Prof. F. H. Storer, Dean of the Institution, and Professor of Chemistry.

The Bussey Institution is apparently a branch of Harvard University, having special endowments, and its objects comprise the teaching of young men intended to become practical farmers, land agents, gardeners, florists, or landscape gardeners.

The investigations conducted by Prof. Storer, reported in the *Bulletin* before us, are highly interesting to such students, and are characterised by a keen practical bias. The first paper is devoted to results of analysis of the leaves of *Rumex crispus* and the common milk-weed (*Asclipias cornuti*), with a special view to their economic value. The second paper is upon an ingenious plan of ascertaining the rate at which various fertilisers may be scattered by hand, or, in the Professor's own language, "about how much of a given fertiliser would a man naturally throw from his hand in sowing an acre of land?" Surely no learned professor ever set himself a more homely task! Next we find "Experiments on Feeding Mice with Painters' Putty and with other Pigments and Oil." This is almost revolting, and raises a feeling of pity for the mice, together with a certain sense of loss of appetite on the part of the reader if he is indulging in an ante-prandial study of scientific novelties. Mice, however, *do* eat putty, and, more curious still, red lead

[1] See an article by Dr. Lansdell, NATURE, May 21, p. 56.

mixed with putty, without injury. They thrive on the linseed oil used in the manufacture of this most unsavoury side-dish and the whitening which forms the other ingredient of "pâté de putty" seems to neutralise the evil effects of the lead. The bearings of these facts are important from a sanitary point of view, as Prof. Storer shows that the effects of mice eating away the packing of valves, of drains, and closets is an immediate frustration of the best efforts of plumbers and sanitary engineers to keep human habitations free from sewer gas. Not content with mice, the Professor tried similar experiments upon rats, when it was found that "rats when kept upon a rather short allowance of oats, ate putty freely. Finally "the surviving rat was fed with 'plain putty' for a day or two, after which he received and ate (poor wretch) each day for two days a ball of putty made with a mixture of equal parts of slaked lime and whiting. He was next given a ball of putty made from a mixture of one part of oxide of zinc and three parts of whiting, together with 2½ grammes of oats, and although he ate very little of the ball he died soon afterwards." The chief result of these experiments appears to be the injury rats and mice may do to houses and the curious protecting effect of whitening as an antidote to such active poisons as red and white lead and carbonate of baryta. Experiments upon the germination of weed seeds and a special instance of the resistance of clover seeds to water form two very interesting notes bearing directly upon well-known phenomena often ascribed by the ignorant to spontaneity of growth. The extraordinary irregularity of periods necessary for the germination of certain weed seeds is very clearly shown. "Of 400 seeds of shepherd's purse (*Capsella bursa pastoris*) three germinated on the fifth day and three on the seventh day, then none until the 145th day, when four germinated. Seven seeds germinated on the 1173rd day, or after an interval of about three years and two months—in all 18¾ per cent. to that date." Many similar cases are cited. Another article is upon "cherry stones eaten by domestic pigeons," which appears unpromising, but is rendered interesting by this versatile observer. Prof. Storer is evidently a man who is not likely to allow any natural phenomenon to pass unnoticed.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Clifford's Common Sense of the Exact Sciences

It does not seem to me necessary to reply to the charges made against Clifford by Prof. Tait in your issue of June 11—charges which, when freed from "mystery and insinuation," amount to accusations of plagiarism and inaccuracy—for Clifford's reputation is unlikely to be in any way affected by what Prof. Tait may write. But I do feel it necessary to make a remark on the last paragraph of his review. He therein accuses me of "mystery and insinuation," weapons which should not be employed in connection with Clifford's name. He does not do me the scant justice of publishing the footnote on which he passes these strictures. That footnote runs as follows:—

"A still more serious delay seems likely to attend the publication of the second part (*kinetic*) of Clifford's 'Elements of Dynamic,' the manuscript of which was left in a completed state. I venture to think the delay a calamity to the mathematical world."

When I wrote the footnote, I knew—

(1) That the manuscript was in existence, a fact with which any one who had examined the bibliography attached to the mathematical works must have been acquainted.

(2) That this manuscript, unlike that of the "exact sciences," had not at that time found a publisher, and therefore was more likely to be seriously delayed.

(3) That the mathematical world had been so far forgetful of its own interests as to raise no demand for its publication.

My note was written with the express purpose of recalling the attention of those who valued Clifford's work to the existence of this manuscript, in order that a general demand for its publication might produce a publisher. Those who find "mystery or insinuation" in this, or in whom this can "strike a jarring chord," must be singularly constituted individuals. The note had on the face of it an obvious purpose; that purpose, I am happy to know, it has to some extent helped to accomplish.

University College, June 12 K. P.

On "K. P.'s" note, which has been communicated to me by the courtesy of the editor, I desire to make one or two remarks.

In writing my notice of Clifford's book I endeavoured to state clearly the impression which its perusal had produced in my own mind, and to say a few fitting words as to the special qualifications of the author. I must have sadly failed in this endeavour if in what I have written there can be found either mystery or insinuation, still more so if there can be found "accusations of plagiarism and inaccuracy." But of course even an Act of Parliament has to be construed after the letter, the declared intention of its framers notwithstanding. On reperusing my notice, however, I still think that it expresses what I meant to say, and that it cannot bear the construction put on it by "K. P."

The remarks I made on the foot-note to the Preface accurately described the impression which it produced on me, and which I am sure it is likely to produce on the majority of thoughtful readers. So strongly did I feel this impression that, when I finally returned my notice for press, I specially requested the editor to try to obtain for me an elucidation of the mystery. This has been—in part at least—supplied by Mr. Tucker's note.

Whether "R.," who writes in NATURE of this week, be really a "(so-called) metaphysician" or no, he certainly expresses himself in the language of that school; for he mildly characterises as "not sufficiently guarded" the statement that a figure, obtained in a certain way, will be a cube:—whereas it obviously may be any rectangular parallelopiped whose edges are commensurable. But I did not blame Clifford for having made this statement; I merely said that it "ought not to have escaped correction." Perhaps even that expression is too strong. I have lately learned by experience that over-zeal on the part of a press-reader may sometimes render abortive the most sedulous care on the part of an author. Over and over again I have had proof-sheets, marked "*press*," returned to me with a learned query at the phrase "feet per second, per second"; and in one or two instances the supposed blunder has been *rectified* after all in spite of me. P. G. TAIT

June 26

Recurrence of Markings on Jupiter

In connection with my remarks on this subject (NATURE, xxxii., p. 31), and the suggestive coincidences which appear amongst certain drawings obtained in about the years 1857 and 1859, 1870 and 1872, and 1885, as to large elliptical markings in the southern hemisphere of Jupiter, I would further add that in about 1843 a remarkably large spot was visible, which may possibly be connected with the phenomena of more recent occurrence. Prof. Piazzi Smyth mentions in the *Observatory*, vol. iii., p. 450, that, in consulting some old observations preserved in the note-books of the Rev. H. C. Key, he found "a view of Jupiter, with not only the dark belts admirably drawn, but between them, in stronger black colour, a long oval spot. This spot, too, was so precisely the shape and size of the red spot which has of late been attracting the surprised attention of observers, that I could not but jump to the almost self-evident conclusion of their both referring to the same body, appearance, or phenomenon." The drawing alluded to was made on June 4, 1843, and Mr. Key described it as a "horizontal black spot in the light space between the two principal belts." In Chambers' "Descriptive Astronomy" (2nd ed., p. 107) it is stated, "In 1843 a very large black spot was observed by Mr. Dawes," and this object is doubtless identical with that figured by Mr. Key. It will be important to compare the observations and to learn whether these spots were situated in approximately the same latitude as the red spot of our own time.

The latter has been growing much darker and more conspicuous during the last few months, and it seems very probable that this object may resume a good deal of its former prominence during the opposition of 1886. With my 10-inch reflector, power 252, I recorded the spot as passing the central meridian of Jupiter on June 26, 1885, at 7h. 59m., and to-night, June 28, at 9h. 37m. A comparison of these times with the earliest I obtained during the present apparition (1884, September 21, 18h. 28m.) shows that in the interim of 279d. 15h. 9m. the spot has completed 676 rotations with a mean period of 9h. 55m. 39·0s., which is almost identical with the periods found during the two previous oppositions—viz. 9h. 55m. 39·1s. But I am hoping to obtain another observation of the spot before the planet leaves us for the season. W. F. DENNING

Bristol, June 28

Occurrence of "Torpedo Marmorata" off the Coast of Cornwall

AMONG the fishes included in the British fauna, but whose title to this designation has been considered but doubtfully proved, is the *Torpedo marmorata*, or a form having the spiracles fringed at their edges. It is true that Pennant figures this species, but he omits to mention whether his example was from the British seas or brought from the French coast by Walsh; and subsequent authors on ichthyology are not sufficiently precise in their descriptions to enable one to judge of which form they are adverting to. All the specimens which I have seen in the various British museums have been of the cramp fish, with smooth-edged spiracles, *T. nobiliana*. On June 26 an example of *T. marmorata* was trawled in Mevagissey Bay, and obtained by Mr. Matthias Dunn, who most kindly sent it at once to me, and it arrived at Cheltenham on the evening of the 27th. It was a female, quite fresh, and weighed 3 lb. 10 oz.; its length was 17½ inches, and its breadth across the disk 12 inches. It contained two ova in an early stage of development. FRANCIS DAY

Cheltenham, June 27

Composite Portraits

IT is always desirable to guard new discoveries and inventions by explicit investigation of the nature of the facts discovered and the mode of action of the invention.

The system of composite portraits ingeniously invented by Mr. Galton rightly attracts much attention, and those who have had their interest excited by Mr. Galton's curious portraits of thieves, ruffians, and consumptives, will be interested further by the portrait of American scientific men in NATURE, vol. xxxii. p. 176.

But in using this system as an instrument of discovery it must not be hastily assumed that by its means true averages are secured. At least, they cannot be averages in every respect Take, for example, the hair. The outer limit is determined by the greatest extent to which the hair has spread outwards on the plate in a number of sitters sufficient visibly to affect it—say three or four. But the inner limit is, in the same way, determined by the limit in the three or four in whom it stretched farthest in. Thus the result must be to give far more than the average amount of hair when the portrait is compounded from a great number of sitters.

As regards the nose, the eyes being the fixed starting-points, the root of the nose will be nearly a fixed point in the photograph; but the tip is limited by shading, and three or four short noses will be sufficient to determine where the tip is to be.

Again, the eyes being fixed points marked on the ground glass of the camera, and breadth between the eyes being different in different persons, it follows that those who have the eyes near together will be photographed on a larger scale than the rest. This enlargement will broaden the composite result. But the tip of the nose, like the tips of the really long noses, will be lost in the dark upper lips of others.

Proof that I am to an important extent correct in these remarks is to be found in your page of American portraits. They present a very remarkable non-American appearance about the nostrils, a vertical elongation accounted for by what I have pointed out. Also the ears are large and vague, the position of the ear relatively to the eye being variable; and there is a more than average breadth of face in three out of the four portraits.

I do not wish to detract from the value of these portraits, rightly understood, but assuredly they give prominence to certain types of face when these are mixed with others—namely, to broad faces with short noses, long lips, large ears, and a superabundance of hair—and it may be useful that attention be attracted to this.

It will be seen that composite portraiture is not suitable for anatomical objects whose generic characters are to be recorded in explicit statement. But for that and many other purposes, a trustworthy though more laborious and less elegant substitute may be found by determining the mean positions of a number of fixed points in figures accurately obtained.

JOHN CLELAND

Ocular Images and After-Images

MR. NEWALL'S experiment with the glowing match I have been in the habit of performing with my cigar or cigarette, and I have become familiar with the lurid ghost he describes, but the point that first interested me is one not mentioned in his letter, and has reference to the primary serpentine image. This I find to consist of a dark red head and a bright yellowish-red body—the light viewed at rest being of a mean tint, as if, owing to difference in rate of telegraphy, it underwent a process of analysis in its movement over the retina.

I have paid considerable attention to the dying phases of powerful retinal impressions, such as result from too bold a gaze at the sun or his vicar, the paraffin lamp, and am convinced that there is more to record than a mere fading away of a patch of colour. On careful scrutiny the patch is seen to be bordered with a series of coloured bands, which each in turn overspreads it; the order of succession being, unlike that of the primary image in the above experiment, towards the red.

I submit this for confirmation, being conscious that the region of these observations is so largely dominated by memory and imagination as to render it difficult at times to distinguish the psychical from the physiological. W. M. LAURIN

June 25

A Query as to Swallows

DURING a recent stay in Suffolk I found a belief prevalent there that swallows lay in necessary stores for their autumn migration by packing small flies under the feathers beneath the wings. My informant told me that he had shot a swallow once in order to ascertain whether this was actually the case; and that he had, as he expected, found many small flies beneath the down. Knowing how liable swallows are to parasitic invasions, I asked of what kind the flies were, and was told "Little gnats, and such like." Is this opinion to be found elsewhere, and is there any ground for it? E. H.

THE COMPOUND LOCOMOTIVE

VERY soon after the compound working of steam in marine and stationary engines became an accomplished fact, and the great saving of fuel thereby was apparent, the question of applying the compound principle to the locomotive attracted the attention of the locomotive engineers of this and other countries. At first it was received with very little favour, which is evident even at the present time, there being only two locomotive engineers in this country who are now either trying it experimentally or have it permanently in use on the lines under their control. This has been mostly caused by the idea that the additional gear necessary for the compound working with two or more cylinders would render the engines more liable to break down. Again it was thought, with very good reason, that such engines would have great difficulty at starting, for the reason that during the first revolution of the driving wheels all the power necessary to start the engine would have to be generated in the high-pressure cylinder. This difficulty was soon surmounted in engines fitted with only two cylinders working compound, by the addition of an arrangement by which the engine could be worked as an ordinary locomotive at the commencement, and when fairly started the compound arrangement could then be applied.

The usual arrangement adopted in the early trials of compound locomotives consisted of two outside cylinders of different sizes; the steam having passed through the smaller cylinder was conducted to the larger one, after going through a sort of intermediate receiver in the smoke-box. The arrangement to work the engine non-compound consisted of a sort of slide valve controlled by the driver, by which means the direction of the steam from the boiler was so regulated that in one position the engine worked compound, and in the other in the ordinary way ; this was called the compound valve, and was placed on the boiler with the necessary pipes leading to it, making the engine look very unsightly. In both positions the waste steam was exhausted in the usual way up the chimney.

Many combinations of the above arrangement have been tried both in this country and on the Continent. The earliest trials in England were made on the Eastern Counties Railway, now part of the Great Eastern system ; on the Continent trials have been made extensively. In all cases the economy of fuel was at once apparent, but there was something in the arrangement which stopped its progress ; this most probably being the general complication of the machinery, combined with a difficulty of management when at work.

In 1878 Mr. F. W. Webb, the able locomotive superintendent of the London and North-Western Railway, commenced to make experiments with an old locomotive converted to the compound principle ; this engine had two cylinders of different sizes. The results of the trials were of such a promising nature, that he went thoroughly into the subject, and eventually brought out an entirely new arrangement with three cylinders, which he patented. This arrangement is a really good practical solution of the question of compounding locomotive engines, and visitors to the International Inventions Exhibition will there see the sort of way it has been accomplished. The compound locomotive, the *Marchioness of Stafford*, built at Crewe Works, is a really fine engine and a credit to the builders.

In attacking this problem Mr. Webb had several objects in view besides the saving of fuel by working the steam compound. His arrangement has enabled him to do away with two of the chief sources of anxiety pertaining to the management of locomotives.

In most non-compound locomotives designed to take heavy loads at a high speed the arrangement of coupling the driving and trailing wheels together by means of outside connecting-rods is a necessity ; in order that all the available power of the engine may be exerted without slipping, the wheels are coupled, so that it may be transmitted by two pairs of wheels instead of one. These connecting-rods are a source of danger at high speeds, and when they break, which they sometimes do, the prospect of a serious accident is by no means distant. Again, in all engines having inside cylinders a two-throw cranked axle is required ; this axle has to transmit the whole power of the engine ; it has to withstand the constant vibration caused by points, crossings, and roughness of the road, besides the heavy straining caused by the powerful steam-brakes now in use. The breakage of this axle has been the cause of many serious accidents. In Mr. Webb's compound engine both of these sources of danger are done away with, and in place of the two-throw cranked axle we find a single-throw cranked axle, amply strong enough to be practically unbreakable, and giving a length of bearing otherwise impossible. The arrangement of the cylinders is as follows :—The engine has two outside high-pressure cylinders and one inside low-pressure cylinder. The high-pressure cylinders are attached to the frames about midway between the leading and central wheels, and are connected to two cranks at right angles on the trailing wheels. The low-pressure cylinder is placed between the frames at the leading end, and is connected to a single-throw crank on the axle of the middle pair of wheels. The valve motion is that designed by Mr. David Joy, which does away with all excentrics and rods, and considerably reducing the number of working parts per cylinder. This gear is singularly easy to adapt to the altered circumstances required in Mr. Webb's arrangement, and must have considerably helped him when designing the engine.

The working of the engine is as follows :—The steam is taken from the boiler through the regulator in the dome to the smoke-box, where it is divided, and taken by means of a pipe to each high-pressure cylinder ; here it does a certain amount of work, and afterwards is returned in a parallel pipe into the smoke-box ; each pipe is taken round the smoke-box and then enters the valve-chest of the low-pressure cylinder. Thus the steam is somewhat heated during its progress through the pipes in the smoke-box, the pipes themselves serving the purpose of an intermediate receiver. When the steam has completed its work in the low-pressure cylinder it is finally exhausted up the chimney.

The *Marchioness of Stafford* belongs to the class of most powerful compound locomotives yet built at Crewe, and is of course fitted with all Mr. Webb's latest improvements ; the reversing gear is of special design, and only fitted to this class of engine. It is desirable in any compound engine to be able to vary the cut-off of the steam in the high-pressure cylinders without affecting the cut-off in the low-pressure, or the reverse ; at the same time it is necessary to have the reversing gear of a locomotive all worked by one lever or wheel. Mr. Webb's arrangement will no doubt answer the purpose fully, the driver being able to vary the cut-off of the steam into the cylinders either individually or all at the same time according to circumstances.

These engines have now been at work some time, and are giving good results, both as regards fuel consumption and steadiness of running at high speeds. There are now thirty-four compound engines at work on the London and North-Western Railway, taking their turn in working some of the most important trains on the system, doing the work thoroughly well with a considerably less consumption of coal than that required by the ordinary locomotive.

Following Mr. Webb in solving the question of compounding locomotives we find Mr. T. W. Worsdell, the locomotive superintendent of the Great Eastern Railway, at work in the same direction, but evidently for a means of reducing the consumption of fuel, and not, as Mr. Webb has done, to try and make the locomotive at the same time less liable to break down at high speeds.

In Mr. Worsdell's design we have two inside cylinders of different sizes, with an arrangement to turn steam direct from the boiler into the low-pressure valve chest either when the high-pressure crank happens to be on one of the dead centres, or to augment the power of the engine in starting the train. This valve, compared with the old compound valve of the earlier experimental compound engines, is extremely simple, and is so arranged that when the driving wheels have made a complete revolution the engine will automatically commence to work compound. This engine is well designed and is a thoroughly good specimen of locomotive engineering, but we think Mr. Webb's engine is to be preferred, if only on the grounds that it does away with double-throw cranked axles and outside coupling rods. No doubt, as far as coal consumption goes, both engines will be very nearly equal, this being merely a question of proper proportions given to the cylinders and valves. Both gentlemen are to be congratulated on having broken through the bounds of locomotive practice and having succeeded in their different designs.

When we think of the millions of miles run each year by locomotives in this country alone, and that the compound working of the steam enables us to save three or four pounds of coal per mile run, the enormous saving is at once apparent, leading us to the conclusion that the compound locomotive has a great future.

THE GEOLOGICAL SURVEY OF BELGIUM

SINCE the publication of our note on this subject (NATURE, vol. xxxii. p. 154) letters have reached us representing both sides of the controversy; but into the controversy itself we do not propose to enter. The question whether this party or that is most orthodox and geologically accurate is not one that greatly concerns the world at large; but all who watch with interest the progress of national scientific undertakings cannot but feel regret that a geological survey which has already achieved such important results as that of Belgium should have been suspended. The Belgian Senate has followed in the wake of the Chamber of Representatives, and the Government is understood to be now engaged in the formation of a new Commission to deal with the reorganisation of the Survey. Meanwhile the field-work is suspended. Geologists everywhere will rejoice if by any means the Commission can succeed in producing better maps and memoirs; but those who are familiar with the publications of the Survey will not be very sanguine as to its success in this respect. They do not need better maps or memoirs, and can only regret that the further progress of the work should have been arrested for this year. The loss of a working season is itself a serious injury. The Belgian authorities would have acted more wisely had they kept the field-work going while they made any necessary investigations as to methods of procedure. We sincerely hope they may see their way to start the Survey again with as little delay as possible.

SYSTEM OF ORTHOGRAPHY FOR NATIVE NAMES OF PLACES

TAKING into consideration the present want of a system of geographical orthography, and the consequent confusion and variety that exist in the mode of spelling in English maps, the Council of the Royal Geographical Society have adopted the following rules for such geographical names as are not, in the countries to which they belong, written in the Roman character. These rules are identical with those adopted for the Admiralty charts, and will henceforth be used in all publications of the Society.

(1) No change will be made in the orthography of foreign names in countries which use Roman letters: thus Spanish, Portuguese, Dutch, &c., names will be spelt as by the respective nations.

(2) Neither will any change be made in the spelling of such names in languages which are not written in Roman character as have become by long usage familiar to English readers: thus Calcutta, Cutch, Celebes, Mecca, &c., will be retained in their present form.

(3) The true sound of the word as locally pronounced will be taken as the basis of the spelling.

(4) An approximation, however, to the sound is alone aimed at. A system which would attempt to represent the more delicate inflections of sound and accent would be so complicated as only to defeat itself. Those who desire a more accurate pronunciation of the written name must learn it on the spot by a study of local accent and peculiarities.

(5) The broad features of the system are that vowels are pronounced as in Italian and consonants as in English.

(6) One accent only is used—the acute—to denote the syllable on which stress is laid. This is very important, as the sounds of many names are entirely altered by the misplacement of this "stress."

(7) Every letter is pronounced. When two vowels come together each one is sounded, though the result, when spoken quickly, is sometimes scarcely to be distinguished from a single sound, as in *ai*, *au*, *ei*.

(8) Indian names are accepted as spelt in Hunter's Gazetteer.

The amplification of the rules is given below:—

Letters	Pronunciation and Remarks	Examples
a	*ah*, *a* as in *father*	Java, Banána
e	*eh*, *e* as in *benefit*	Tel-el-Kebír, Oléleh, Yezo, Medina, Levúka, Peru
i	English *e*; *i* as in *ravine*; the sound of *ee* in *beet*. Thus, not *Feejee*, but	Fiji, Hindi
o	*o* as in *mote*	Tokio
u	long *u* as in *flute*; the sound of *oo* in *boot*. Thus, not *Zooloo*, but	Zulu, Sumatra
	All vowels are shortened in sound by doubling the following consonant	Yarra, Tanna, Mecca, Jidda, Bonny
	Doubling of a vowel is only necessary where there is a distinct repetition of the single sound	Nuulúa, Oosima
ai	English *i* as in *ice*	Shanghai
au	*ow* as in *how*. Thus, not *Foochow*, but	Fuchau
ao	is slightly different from above	Macao
ei	is the sound of the two Italian vowels, but is frequently slurred over, when it is scarcely to be distinguished from *ey* in the English *they*	Beirút, Beilúl
b	English *b*	
c	is always soft, but is so nearly the sound of *s* that it should be seldom used	Celebes
	If *Celebes* were not already recognised it would be written *Selebes*	
ch	is always soft as in *church* ...	Chingchin
d	English *d*	
f	English *f*. *ph* should not be used for the sound of *f*. Thus, not *Haiphong*, but	Haifong, Nafa
g	is always hard. (Soft *g* is given by *j*)	Galápagos
h	is always pronounced when inserted	
j	English *j*. *Dj* should never be put for this sound	Japan, Jinchuen
k	English *k*. It should always be put for the hard *c*. Thus, not *Corea*, but	Korea
kh	The Oriental guttural	Khan
gh	is another guttural, as in the Turkish	Dagh, Ghazi
l, m, n	As in English	
ng	has two separate sounds, the one hard as in the English word *finger*, the other as in *singer*. As these two sounds are rarely employed in the same locality, no attempt is made to distinguish between them	
p	As in English	
q	should never be employed: *qu* is given as *kw*	Kwangtung
r, s, t, v, w, x	As in English	Sawákin
y	is always a consonant, as in *yard*, and therefore should never be used as a terminal, *i* or *e* being substituted. Thus, not *Mikindány*, but	Mikindáni
	not *Kwaly*, but	Kwale
z	English *z*	Zulu
	Accents should not generally be used, but where there is a very decided emphatic syllable or stress, which affects the sound of the word, it should be marked by an *acute* accent	Tongatábu, Galápagos, Paláwan, Sarawak

THE UNIVERSAL MERIDIAN[1]

II.

"IF, now, we examine the question of changes to be introduced into existing charts, these would, in accordance with our proposal, be imposed on the whole world; they might be greatly reduced, especially if people restricted themselves to what would be sufficient for a beginning, that is, by tracing on the existing plans only sufficient to allow us to make an immediate use of the international meridian. Later on, and in proportion as new plates were engraved, a more complete scale would be given; yet, in my opinion, it would always be of advantage to keep the two frameworks—the national and international—according to the example of what is done in several atlases.

"If, at the present time, it is necessary to facilitate external relations, it is also good for each people to maintain all the manifestations of its personal life and to respect the signs representing its traditions and its past.

"I do not insist on the details of the establishment of such a meridian. All we have to support before you is the principle of its acceptation.

"If this principle were admitted by the Congress, we are charged to inform you that you would there find a ground of agreement with France.

"Undoubtedly by reason of our long and glorious past, our great publications and our considerable hydrographic labours, a change of meridian would entail on us heavy and cruel sacrifices. Yet if one came to us, setting us an example of self-sacrifice, and thereby proving his sincere desire of the public weal, France has already given such proof of her love of progress that no doubt need be entertained of her concurrence in such an enterprise.

"But we should have to regret our inability to associate ourselves with a combination which, in order to safeguard the interests of one part of the contractors, sacrificed the higher scientific character of the institution, a character which in our opinion is indispensable if it would claim the right of imposing itself on all, and if it would secure to itself a definitive success."

Immediately after this discourse the general discussion was entered into, in which all the English and American delegates, and the Americans distinguished in science who had been invited, successively argued against the proposal of the French delegate. The latter had to reply successively to half a score of speeches embracing various phases of the question according to the various provinces of the speakers. It is, perhaps, allowable to say that notwithstanding the authority, talent and number of the distinguished speakers contending against the principle of the neutrality of the meridian, the principle withstood all those shocks without being shaken, and without suffering any scientific breach. The meridian proposed by France will remain always as representative of the impartial, scientific, and definitive solution of the question. We think it was a honour to our country to have defended this cause.

Before the vote, M. Cruls, the learned director of the Observatory of Rio de Janeiro, and delegate of Brazil, informed the French delegation that he had received instructions from the Emperor to vote with France. We were very glad at this concurrence of sentiment, and begged to be allowed to congratulate the august foreign associate of the Institute of France on his resolutions.

The following are the principal passages in the speech in which M. Cruls set forth the reasons of his vote:—

"Down to the present one point, and that of great importance, has been settled by the discussion—the necessity, namely, of fixing a single initial meridian. This point has, in fact, obtained the adhesion of all the delegates present at the Conference. This necessity recognised, it is proper to take a step farther, and to determine which shall be this meridian. An election of this kind forms at this moment the object of our debates, and a question on which we should have to pronounce our opinion.

"Our honourable colleague, Mr. Rutherfurd, delegate of the United States, has made a motion proposing the adoption of the meridian of Greenwich—a motion for the moment eliminated from our debates, its author having decided to withdraw it temporarily.

"The motion which was made at the last sitting, and formed the subject of numerous and interesting debates, is that formulated by our honourable colleague, M. Janssen, delegate of France, proposing that the meridian to be adopted should have a neutral character, and should not touch either of the great continents of Europe and America. This proposal has been strongly combated by the delegates of England and the United States, and valiantly defended by the delegate of France, and the debates thus arising on the question have furnished us with the opportunity of witnessing a scientific tournament of the highest interest. The speakers we have had the honour of hearing seem to me to have exhausted the whole series of arguments for and against; and at this stage I presume that the debates have enabled us, in full knowledge of the case in dispute, to form each his own opinion on the question on which we are called to vote.

"For my part I am anxious to have clearly defined the attitude which in my opinion Brazil is called upon to take in the midst of this assembly. This attitude is one of absolute neutrality so far, be it understood, as it is a question of choosing a national meridian—a question which may provoke among certain nations very legitimate personal rivalries.

"Now, till the day when the Conference assembled for the first time, I was in hopes that these debates, entered into under the influence of a generous aspiration, and with the single object of arriving at the establishment of a measure, the necessity of which is warmly proclaimed by manifold interests of diverse nature, might conduct us to a complete and definitive solution of the question. Unhappily, and to my great regret, I am compelled to add that the differences which have manifested themselves in the midst of the assembly do not allow this hope to be maintained.

"That which for my part I am not able to lose from view is the fact that it is indispensable that the solution of the question for which the Conference is assembled should be complete; or the end of this Conference would not be attained. Now, since the delegates of France have from the beginning of our debates manifested their opposition to the adoption of any meridian invested with a national character, an opposition which gave rise to the motion presented by M. Janssen, it follows that any measure voted by the Conference and tending to the adoption of a national meridian would, by the very fact of the abstention of France, be an incomplete measure, not corresponding with the object pursued by the Conference. I hasten to add, for fear of any erroneous interpretation being given to my words, that the same objection would apply, if, for example, the meridian of Paris were proposed, and any great maritime nation, such as England, the United States, or any other abstained from its adoption. In such a case, likewise, my line of conduct would be fully indicated.

"In short, I will say that the immense benefits which would accrue to the whole world from the adoption of a single prime meridian would be forthcoming in all their plenitude only in so far as the measure was unanimously accepted by the most important maritime nations. In every other case I am for my own part absolutely convinced that the measure would be in part inefficacious, its adoption not being general, and that everything would have to be done over again in a more or less distant future.

[1] Lecture by Dr. Janssen at the Paris Geographical Society. Continued from p. 151.

"Well, the debates at which we have assisted prove to me superabundantly that such will always be the unsatisfactory issue so long as the meridian of any great nation is proposed.

"In presence, then, of this difficulty, which on that supposition appears to me insuperable, the only solution which by its very nature will not excite burning questions of national jealousy is that of a meridian having a character of absolute neutrality. If the adoption of such a meridian were admitted in principle, I am certain that a discussion engaged in on the ground of pure science and directed according to the best conditions which such a ground is calculated to secure would soon lead to a practical solution.

"In such a discussion the arguments having any force should be, above all, drawn from science, the only source of truth alone able to enlighten us so as to guide us to a sound judgment and to a decision based solely on considerations of a purely scientific order.

"Such a practical solution seems to me, moreover, to be suggested by what our honourable colleague, M. Janssen, told us on this subject. The principle of the neutral meridian once adopted, the conditions it would require to fulfil and the determination of its site would remain to be discussed. Of two things—one, whether the meridian should be exclusively oceanic, and so by its very nature it would be neutral; or, second, whether it should cut some island, and in such a case there could be no obstacle, by means of an international diplomatic convention, in the way of rendering neutral the particle of ground on which it would be proper to establish an observatory, which in reality would be confined to a very small affair—of these two solutions both of which would satisfy the conditions requisite for the meridian, from the double point of view of its character of neutrality and the demands of science, I prefer for my part the second. I confine myself to intimating by these few words how it would be possible to arrive at a practical solution, since at this moment I have to occupy myself simply with the adoption of the principle of the neutral meridian.

"I conclude, then, by declaring that I shall vote in favour of the adoption of a meridian invested with the character of absolute neutrality; and in doing so I hope thus to contribute my part to the end that our resolutions may bear the impress of independence which they require in order to impose themselves spontaneously and naturally, generalise themselves in the future and rally from the beginning the adhesion of men of science, without distinction of nationality, who at this hour await our decisions."

I have to add that before the vote M. Galvan, the very distinguished representative of the Dominican Republic, who had studied at Paris under our most eminent masters, very cordially informed me that the attitude of France in this matter appeared to him to conform with that which the world was in the habit of seeing it take in all questions of general interest, and that it would give him such happiness once more to contribute in bringing a testimony of admiration to the nation—to the *puissante initiale de l'intellectuelle*, to use his own expression—by voting with France.

As to the vote, it was according to our expectations, seeing that, as I have said, almost all the delegates had received instructions to vote for the meridian of Greenwich.

The principle of the neutral meridian being rejected, we abstained from taking part in the discussion in the choice of the national meridian called to become international. As we already said, we did not come to Washington to sustain a candidature, but a principle.

Before the vote, M. Valera, delegate of Spain, announced that he was charged by his Government to say that, in voting for Greenwich, Spain expressed the hope that England and the United States would accept the French system of weights and measures. This declaration led Gen. Strachey to say that he was authorised to announce to the Conference that England had asked to join the Metric Convention.

We cannot pass over in silence the part taken in this discussion by the eminent Foreign Associate of the Institute of France, Sir William Thomson, who was then in America, and had very naturally been invited to our sittings. Sir William Thomson expressed his desire of an accord in regard to the meridian and the metrical system. The following are among the few words he spoke on this subject:—

"I cherish the sincerest and most ardent desire that the delegates of France and those of the other nations who by this vote supported the previous resolution, will be able to adopt the resolution now before the Conference. It appears to me that we have here to do with a sacrifice, and I am convinced that the honourable delegate of France who last spoke, M. Lefaivre, will clearly apprehend that there is no question of asking a sacrifice of France which she is not disposed to make.

"In the admirable speech delivered by M. Janssen before this Conference (a speech I had not the pleasure and satisfaction of listening to, but which I read with the greatest interest) he declared that France was willing to make a much greater sacrifice than that now in question. The amount of sacrifice involved in changing certain usages is always more or less considerable, in view of the fact that it is impossible to say that such an innovation can be effected without derangement. It may, however, be asserted that the sacrifice France is prepared to make would be much more considerable than that ensuing from the adoption of the resolution now before us.

"If the resolution relative to a neutral meridian had been adopted, all nations would have been called on to make the sacrifice involved in a change of meridian not yet determined, and the relations of which to the meridians now in use could not have been so easy as would be those of the meridian of Greenwich with the meridians at present employed.

"I am of opinion that if the delegates of France could see their way to the adoption of this resolution, they would have no cause to regret it.

"I highly approve of what has been said in regard to a common metrical system. My opinion on this subject is firmly established, and I shall by no means express it if the President thinks it would be inexpedient to enter on this subject; but it seems to me that England makes a sacrifice in abstaining from adopting the metrical system. The question cannot, however, be presented under this form. We have not to consider here whether England would gain or lose by adopting the metrical system.

"Such is not the way of looking at the question, considering that the adoption of the metrical system by England is a question restricted to her own convenience, to her own usages, and that whether she adopted it or not, her decision could not in any way affect other nations. It could result neither in advantage nor disadvantage of other countries."

When the meridian of Greenwich was adopted, the Assembly considered that it devolved on it to define the principle according to which the longitudes should be numbered. Should they be counted in one single direction in accordance with the almost unanimous opinion of the distinguished members of the Conference of Rome, or should they continue to be counted in the two opposite directions, as far as the anti-meridian? The latter method was adopted.

The method of counting longitudes east and west, starting from a central meridian—the method actually in general use—was evidently introduced and actuated by the use of national meridians. But when, instead of looking merely at one country in particular, the entire earth is contemplated, and it is desired to bring the general system of longitude into relation with a universal time, it is difficult to understand how in counting the longitudes, one should stop in the middle of the way, while in counting the time one goes the whole round of the day, reckoning the hours from 0 to 24, according to the decision of the Congress.

We are unwilling to believe that the advantage of not having to make any change in use and wont, not even to the extent of a few figures on English maps, was the ground of this decision on the part of the majority.

This majority, for the rest, consisted in a preponderance of but three votes, and among the opposite voters or abstentionists we observe all the great Powers, with the exception of Russia.

The question of a meridian being completely settled, the assembly had to address itself to the second part of its programme—that relating to universal time.

The commercial and maritime relations so developed at the present day by the progress of the marine and telegraphy render the inconveniences attending a diversity of origins in horary measures more sensible every day. It has, therefore, come to be desirable to establish a division of time having the same point of departure for the whole world. To attain this object the local time of a determined point is taken, and by a convention is made the universal time. In this system the influence of longitude is entirely eliminated. The same instant receives the same name all over the earth, and the acts of international life are dated in as close relation to each other in point of time as though they were acts transpiring all within the same town. As to the point to be chosen for giving the universal time, it is plain that it ought to be the same as that adopted for giving the departure of longitudes. The two systems cannot be separated.

As a matter of course, this universal time cannot claim to take the place of local time, nor of so-called national time. The local time, which is the expression for each place, at least very approximately, of the course of natural phenomena, the eternal regulators of the acts of life, can never be displaced. In the case of certain arrangements, such as that of railways, for example, is it found highly convenient to extend the use of the local time of the capital to the whole country, when this latter has not a too considerable range of longitude. Such is the case in France.

The Congress adopted in principle the establishment of a universal time defined in the manner I have just described. But, separating itself again on this point from the Congress of Rome, it assigned as the origin of the universal day the midnight of Greenwich, which, according to the proposals of the Washington Congress, should become the beginning of the day for international transactions all over the world.

The divergence of resolutions adopted at Rome and Washington in reference to the origin of the international day brings clearly into view the inconveniences of the vexatious disagreement still actually existing between the origin of the astronomical day placed at midday, and that of the civil day placed at the preceding midnight. This inconvenience grows greater and greater in proportion as the ephemerides and astronomical studies extend. We therefore eagerly associated ourselves to the resolution expressed by the Congress relative to the unification of the two systems, by making the astronomical day commence at midnight, like the civil day.

Astronomers will, we hope, understand that, being a far less numerous body, and much more conversant with these matters, it is on them that it devolves to make a slight sacrifice, so as to allow a progress very desirable at the present day to be effected.

After the discussion of these various questions, the labours of the Congress approached their term; it was then that the French delegation made the proposal it had been charged to present—a proposal having reference to an important extension of the decimal system.

The Congress of Washington, by its importance and by its object, which aimed definitively at the continuation of that great French work of unification and of progress inaugurated at the end of the last century, offered an altogether appropriate opportunity to ask for the world a new extension of those applications of the decimal system which constituted the whole merit and the whole success of our reform of weights and measures.

This extension had relation to the measurement of angles and of time.

At the date of the establishment of the metrical system the decimal division was, as is known, extended to the measure of angles and time. Numerous instruments were even constructed according to the new system. As far as time is concerned, the reform, introduced too drastically and without sufficient discretion, it may be said, clashed with too inveterate usages, and was rapidly abandoned; but in regard to the measure of angles, where the decimal division presents so many advantages, the reform held its ground much better, and has maintained itself in certain practices to this day. Thus, for example, the division of the circumference into 400 degrees was adopted from the beginning by Laplace, and it is currently employed in celestial mechanics. For the measurement of the arc of the meridian, whence the metre was derived, Delambre and Mechain availed themselves of repeating circles divided into 400°. Finally, in our days, Col. Perrier, Chief of the Geographical Service at our Ministry of War, makes use of instruments with decimal division, and at this moment calculates even logarithmic tables with eight decimals appropriated to this mode of division.

It is above all, however, when it is required to execute long calculations on angular measures that the decimal division presents immense advantages. On this point nothing but unanimity may now be said to reign among learned men.

The Conference of Rome, which assembled so many astronomers, geodesists, and eminent topographers—that is, just the men of most weight and having the greatest interest in the question—issued on this subject a resolution the high authority of which it is impossible to disregard.

It is now, then, evident that the decimal system, which has already rendered so many services in the measurements of length, of volumes, and of weights, is called upon to render analogous services in the domain of angular magnitudes and of time.

I am aware that this question of the decimal division has to contend with legitimate apprehensions, principally in reference to the measure of time. People are afraid of doing violence to secular customs and overturning consecrated usages. On this aspect of the business I think we ought to be fully assured. The lessons of the past will be put to profit. It will be understood how it was for having endeavoured to push a reform beyond the due domain of science, and for having done violence to the habits of daily life, that disaster was experienced during the epoch of the Revolution. It is proper to resume the question, but it is proper to resume it with an appreciation of the limits which good sense and experience will always indicate to wise and experienced men.

I think the character of the reform would be sufficiently indicated by saying that the question is principally to make a new effort towards the application of the decimal system in the scientific world.

We met at first with a sufficiently warm opposition. The President was of opinion that the proposal should not be offered for discussion, but I have to acknowledge that he finally yielded very courteously, "out of deference," he said, "to the delegates of France, and because we are happy to do them honour in all things."

The majority decided that the proposal should be discussed. The French delegate then spoke, and the meeting passed to the definitive vote. The success was then complete, for the proposal was adopted by twenty-one votes, without one dissentient voice.

Such is the work of the Congress.

This work is considerable. Its importance, however, is derived much more from the principles enunciated by the Congress than from the solutions it adopted.

The establishment of a single meridian and of a universal day, the unification of the astronomical and civil days, the extension of the decimal system,—these are reforms which the progress of science and of international relations rendered opportune and desirable.

In the application, however, of the principles, the Congress has been less successful.

In the choice of a primary meridian it allowed itself to be too much carried away by the practical and immediate advantages of a meridian already in very extended use, and disregarded the conditions which would have assured to its work a universal and definitive adoption.

In regard to ourselves we have in this question adhered to the part prescribed to us by our past, our traditions, and the very character of our national genius. Our proposal was precisely that which we should have adopted ourselves if we had had to take the initiation of this reform. The nation which created the metrical system could propose none other than it did. If our purely scientific and disinterested opinion did not unite the majority around it, the reverse was not for France, but for science. But science is the sovereign of modern times and one cannot now detach himself from it with impunity. It is vain to say that the meridian of Greenwich is *de facto* the universal meridian, that it reigns to-day over almost all the navies of the globe, and that its adoption only consecrates a fact which has already established itself and transforms into law the institutions of fact.

I reply that that is all true. I even add, if it is desired, that such is only what is merited by the great labours of the English marine—labours which we, the initiators of hydrography, more than any others appreciate at their true value. But however considerable may be these labours and however great the numbers of those availing themselves of them, yet with the experience of the past and in the name of history I say that these merits will not be able to prevent the inevitable consequences resulting from the personal character of this meridian. And in point of fact, has not France—she, too—had a great geographical career? The meridian of the Island of Ferro, which soon, in the hands of Gillaume Delisle and of our great geographers of the eighteenth century, became French—did it not bear sway in cartography for more than two centuries, and that with an authority not even equalled to-day by that on the other side of the Channel?

And yet the meridian of the Isle of Ferro, after that brilliant career, is to-day more and more abandoned, and the fair attempt of the seventeenth century finds itself entirely compromised!

What is the cause, then, which has led to this vexatious result? Apparently a mere trifle. It is because, as we have already said, instead of leaving the meridian of the Isle of Ferro in conformity with its first intention, instead of maintaining it in the purely scientific character which it received from the hands of Richelieu, that great spirit who so well understood that an institution of a universal order must bear no personal investiture, this character was imprudently changed by bringing the position of this meridian into relation with that of Paris, in place of bringing the position of this capital, like any other point, into relation with it.

That is the mistake which compromised the fortune of this reform so firmly and so judiciously established by its illustrious author. Now, this mistake, is it not committed to-day by once more taking a national meridian and making it the universal point of departure for longitudes? Is one not then justified in foreseeing that the same causes would produce the same effects, with this difference, nevertheless, that in the advanced state of civilisation prevailing to-day among the nations, a particular supremacy, of whatever nature, would be much more promptly abandoned than it was two centuries ago?

It is, accordingly, much to be feared that the establishment of the new meridian, if it even succeed in getting established, would again be but an attempt without a future.

France who finds in the history even of her own past the double lesson of the progressive abandonment of her national meridian and of the ever growing appreciation of the scientific and impersonal system of weights and measures, ought to make known to the Congress a counsel dictated by her own experience.

Does this attitude, however, sufficiently absolve us? Have we discharged towards the world and towards ourselves the debt due by a generous and enlightened nation which has always been delighted to take the initiative in tasks conducive to the general well-being? I do not think so; and, were it allowed me to express a wish, it would be that we should on this occasion again join example to precept. I should like that the France of the nineteenth century, considering herself the heir of the France of the seventeenth, would, with the benefit of the experience she has in that interval acquired, resume the fair attempt of Richelieu and herself establish the neutral meridian.

This institution, well conceived and planted on exclusively scientific bases, would gradually rally to it the adhesion of all. England herself, who, if possessing a lively national sentiment, has likewise an appreciation of what is just and great, would end by attaching herself to it. and then would this reform so long desired, always attempted in vain, and again quite recently compromised, be finally secured to the world and to science.

Be that as it may, and outside the question of the meridian, which is not yet settled, let us not forget that the accession of England to the Metrical Convention and the resolution for the extension of the decimal system are results demonstrating that our presence at Washington was not useless either to science or to progress.

THE VOYAGE OF THE "CHALLENGER" [1]

I.

NINE years have slipped away since the memorable expedition of the *Challenger* came to a close. During this interval from various published accounts of the voyage, the route around the world, the places called at, the life on board, the impressions, social or biological, left on the minds of the voyagers—are all now more or less familiar to us. There have likewise appeared numerous detailed quarto reports from different experts, into whose hands the great natural history collections amassed during the expedition were placed for description. We know precisely the additions made by the naturalists of the *Challenger* and their collaborateurs to our knowledge of the foraminifers, corals, medusæ, ostracods, brachiopods, echinoids, shore fishes, birds, and many other groups, and from the list of memoirs yet to come we can see how ample a store of detail is still to be produced. We know also how vast an amount of additional information has been gathered by the expedition regarding the physics and chemistry of the ocean. But as yet there has been no condensed official record of it all. The general public, and even the man of science, cannot be expected to master the series of special reports; life is too short for this, even if the power of comprehension were adequate. Admirable and exhaustive as the reports are, and indispensable for experts in the various branches of which they treat, each of these must necessarily appeal to a comparatively small

[1] "Report on the Scientific Results of the Voyage of H.M.S. *Challenger* during the years 1873-76." Prepared under the direction of the late Sir C. Wyville Thomson, and now of John Murray. "Narrative," vol. I., 1885

circle of readers. What has been needed is such an official summary of the whole work of the expedition as will convey to the general public a sufficiently clear and detailed account of the whole results of the voyage of the *Challenger*, and will enable the man of science to realise what has been done in other departments than his own special domain.

Such a summary has now been prepared and published as the "Narrative of the Cruise." It is called a volume, though in reality it consists of two stout quartos, comprising altogether upwards of 1100 pages. The first thought that will naturally occur to any intelligent person who takes an interest in these subjects, and who hears that at last the official narrative of the *Challenger* expedition is issued, will be that this at least is a part of the publications that he would like to possess, or at least would expect to find readily accessible as an authoritative and convenient record of what the expedition has done. His zeal

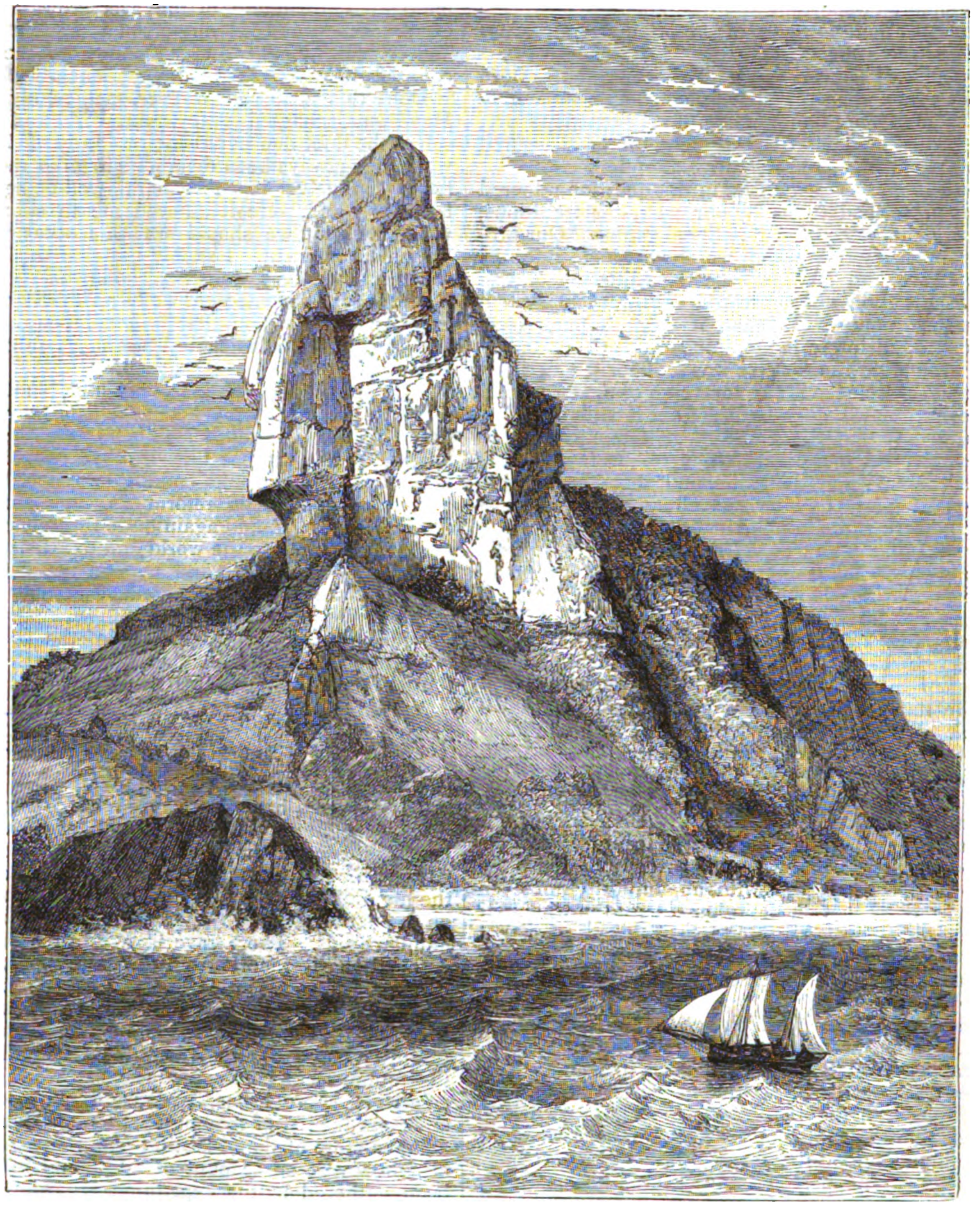

FIG. 1.—The Peak of Fernando Noronha, sketched from the Deck of H.M.S. *Challenger*, September 3, 1873.

for the acquisition of knowledge, however, may not improbably be damped when he learns that the book will cost him 6*l*. 16*s*. 6*d*. Why such a prohibitory price should have been affixed to this work is one of those mysteries of Government publication which it is hopeless to understand or explain. There can be no question that this Narrative volume is the one of the whole series most likely to sell. There are, no doubt, hundreds of institutions and private individuals that would gladly purchase it if the cost were within their means, but to whom the acquisition of the whole series of Reports, or even a small proportion of them, is impossible. The official rule has been, we believe, to print off only 750 copies of each Report, to charge the whole cost of production upon that number, and then to destroy the copper plates and lithographic stones, so that on the supposition that the whole edition is sold, no loss from its publication will be incurred by the national exchequer. This may or may not be a judicious rule for the reports of specialists for which no great sale can be expected; but surely it is not a wise one in the case of the Narrative volume, for which a much wider circulation may confidently be expected. It is understood that the type and plates of this volume are kept up, so that if the present edition is sold off another may be printed. But as the cost of production has been charged upon the first edition, every copy subsequently produced will cost nothing but the mere paper, printing, and binding. Government cannot, of course, wish to make profit out of the book as a commercial speculation. Would it not have been more in accordance with common sense and trade economy to have issued a much larger edition at first, and to have spread the cost of production over the whole of it? Had the book been sold at half its present price its sale would probably have been more than doubled. That,

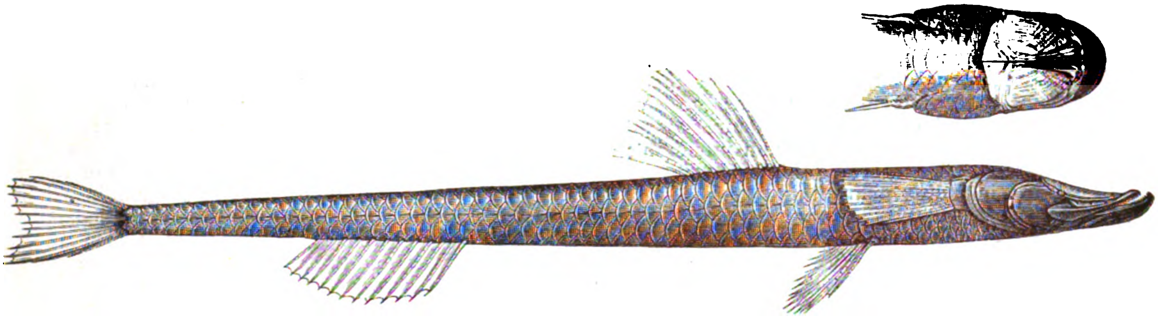

FIG. 2.—*Ipnops Murrayi*, Günth., 1600 to 1900 fathoms.

even as it is, the whole edition will be sold we confidently believe. But that will be no justification whatever for making the price so high. After so large a sum of money has been spent upon the expedition first and last, it seems perfectly childish to publish the results in such a form that even the most generally useful and intelligible part of them are out of the reach of most of those who really feel an interest in them.

There is another question which my Lords of the Treasury will have to face in regard to this Narrative volume. Many requests have been made to that pachydermatous body for gifts of different reports; many more would no doubt have been made but for the known determination on the part of the authorities to refuse them. Now, it is tolerably certain that public libraries all over the country will ask for at least copies of the "Narrative of the Cruise," and the whole of the first edition would probably barely suffice to supply their demand. That their requests will be again

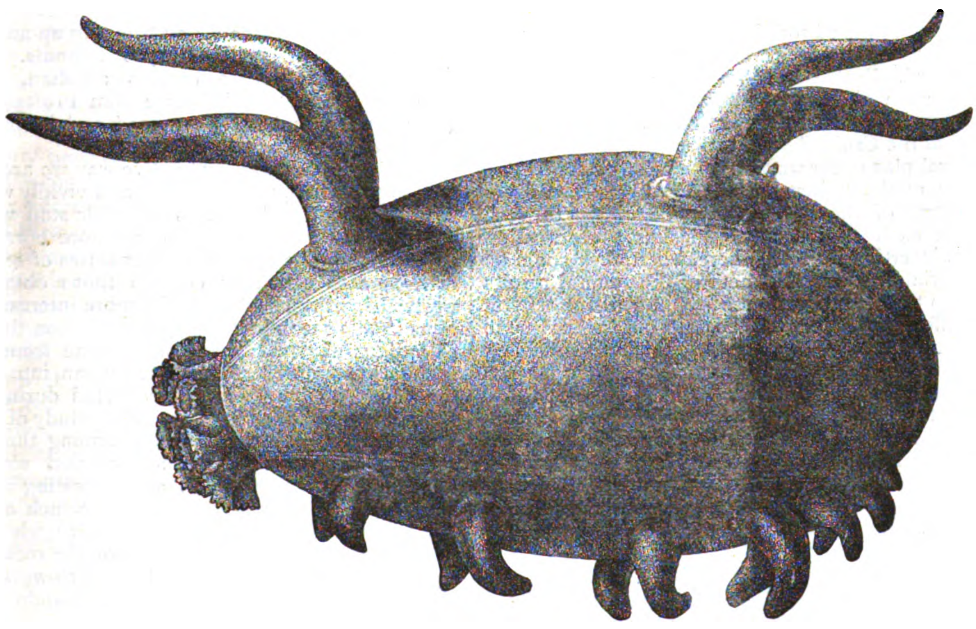

FIG. 3.—*Scotoplanes globosa*, Théel.

refused goes without saying. But it will be noteworthy if these public institutions are content with the refusal. The country has a right to insist that the results of an expedition on which so much public money has been spent shall be made as widely accessible as possible, and will no doubt brush roughly aside the stereotyped official objections. A more flagrant case of the stupidity into which a blind adhesion to red-tape rule may lead a Department that no doubt means well could hardly be found than this Narrative volume and its price of 6*l.* 16*s.* 6*d.*

With this preliminary protest we gladly pass on to notice the book itself. First of all, like the previously published Reports, the "Narrative" is admirably got up. The paper, print, illustrations, and binding are so vastly superior to ordinary Stationary Office productions that we wonder more than ever how the Treasury officials were ever prevailed upon to sanction such expenditure, even though with the prospect of charging a high price. The book is in two parts, each of which forms a thick, heavy quarto of more than 500 pages. It contains 14 chromo-lithographic plates, giving illustrations of deep-sea deposits, Antarctic icebergs, and various aborigines and their handiwork; 35 photographic plates, among which the glaciated pavement at Halifax, the lava-cascade at Kilauea, and some of the representations of growing vegetation are particularly good; 43 charts of the route of the voyage and of stations visited, including a large and valuable physical chart of the world on which all the newest information as to ocean depths is given, together with the track of the *Challenger* and the nature of the bottom observed in the different soundings; 22 diagrams showing the vertical distribution of temperature in the ocean, and embodying in a graphic and intelligible form a vast amount of detail regarding this fascinating subject; 340 woodcuts, including many illustrations of the more novel or interesting natural history "finds" of the voyage, and some of them remarkable for the exquisite beauty and fidelity with which they have been executed; and, lastly, which will surprise the reader accustomed only to the prosaic solidity of Government publications, there are tail-pieces to the several chapters—mermaids filling the tow-net for the naturalists above, scenes from the life of the cruise on deck and on shore, and little bits of fancy that remind one sometimes of Edward Forbes.

The general scope of this "narrative" was sketched out by Sir Wyville Thomson, and in his preface to the first volume of the "Zoological Reports" he referred to it as actually in progress. He died, however, before he had made any progress with it, the world losing in him the enthusiastic and kindly spirit that planned the whole expedition, saw it successfully completed, and organized the systematic working out of its collections. Since his lamented death the work has been vigorously prosecuted by his successor in the editorial supervision of the Reports, Mr. John Murray, who, in conjunction with Staff Commander Tizard, Professor Moseley, and Mr. J. Y. Buchanan, and with the co-operation of the various specialists employed, has compiled this voluminous "Narrative of the Cruise."

The general plan of the work may be briefly stated. The leading idea of the writers has been to give a chronological account of the voyage from beginning to end, recording at each station any remarkable observation there made, inserting here and there, where they could be most appropriately given, abstracts of the general results arrived at up to the present time by the various experts to whom different portions of the vast collections made during the cruise have been entrusted, and describing fully the various equipments of the *Challenger* for the scientific work for which the expedition was designed.

Some of these features of the book have, of course, already become more or less familiar from the publications of Sir Wyville Thomson himself, and of Professor Moseley, Lord George Campbell, Mr. Wild, and others. But they have never been presented so fully nor illustrated so amply. Unfortunately all the scientific work connected with the expedition is not yet completed, so that it was not possible to give in the "Narrative" a summary of the whole results achieved. But as far as the work had advanced up to the time of its publication, the volume now issued contains a digest of it, prepared by the various specialists by whom it has been accomplished. When the whole *Challenger* results have been published, we hope that in a future edition of the "Narrative," a conspectus of the entire work of the expedition may be completely given.

The introductory chapter presents an outline of the history of research in the ocean. This is followed by a detailed account of the fittings of H.M.S. *Challenger*, which will be useful as a record of the state of deep-sea investigation in 1872. The proper narrative then begins with the departure from Portsmouth, the various trials of the apparatus and training of the crew in the kind of work which was to be prosecuted during the cruise, and a full description of the instruments employed and the methods of observation with them. This, though to most readers rather a dry subject, is here treated with a fulness not elsewhere to be found. The account of the thermometrical observation and of Professor Tait's subsequent researches, with the actual instruments employed, is a valuable part of the book. Listening to these detailed descriptions of what they were trying to do and how they attempted to do it, we are hardly aware that we have been carried through more than a hundred closely printed pages, and from the shores of Old England to the Peak of Teneriffe. But the real work of the expedition was now to begin with the running of a section across the North Atlantic. A good deal of information from previous observation was already in existence regarding the depths and form of the bottom of this ocean. But no such series of soundings had ever been made across it as was now to be carried out by the *Challenger*. Twenty-four soundings, fifteen dredgings, two trawlings, and thirteen serial temperature soundings, were taken between Teneriffe and the West Indies. A brief description of the more interesting features of these researches is given, and then, as we are carried onward to Bermuda and as the various treasures of the deep are brought before us, some species of brachiopods hauled up from the bottom afford an opportunity of hearing Mr. Thomas Davidson discourse regarding his examination of the whole of the brachiopoda collected during the cruise. At Bermuda we hear again of the wonderful Æolian rocks, which from the early descriptions of Captain Nelson down to those of Sir Wyville Thomson have attracted the notice of geologists. Running up to Halifax, Nova Scotia, we catch a glimpse of the wonderfully glaciated rocks of that region, and on the return voyage to Bermuda we watch the officers of the Expedition gauging the temperature and depth of the Gulf Stream, and bringing up an Arctic fauna from depths of 1250 to 1700 fathoms. Among the novelties taken are a curious ascidian, which gives occasion for a short discourse from Professor Herdman regarding the tunicata discovered and brought home by the *Challenger*.

In this pleasant and instructive way we are led on from station to station, noting clearly and vividly what the ship passed through and what its scientific staff were engaged in. From Bermuda we are once more borne across the Atlantic and take part in another series of soundings and dredgings to check or confirm those obtained in the westward passage. Among the more interesting observations in this second traverse were those on the occurrence of various abysmal brittle stars, some from a depth of 2850 fathoms, and Mr. Theodore Lyman, into whose hands the whole of the ophiurans collected during the cruise were placed, gives us a *résumé* of his study of them. After some time spent in observations among the Azores and Cape Verde Islands, we are carried southwards to St. Paul's Rocks, of which an interesting account was, long ago, given by Darwin, and to which attention has recently been called by the Abbé Rénard, whose investigation of the microscopic structure of the rock has already appeared in the Reports of the *Challenger* expedition. We catch a tantalising glimpse of Fernando Noronha, regarding which little new information can be obtained, since the Governor refuses permission to make collections. So, casting a wistful look at its colossal peak (Fig. 1) we are transported to the coast of Brazil, and thence back again into the centre of the South Atlantic where the lonely rocks of Tristan da Cunha rise above the waves. This section of the voyage is full of interest. The naturalists are evidently getting more practised in their duties, the crew more expert in the labours of sounding, trawling, and dredging, and the hauls are more generally successful than in the earlier weeks of the cruise. The dredgings and trawlings along the American coast are specially important, bringing to light many new forms belonging to nearly all the invertebrate groups, and the first specimens of a new genus of nearly blind fish (*Bathypterois*). A *résumé* of all that has been added to our knowledge of the radiolaria is here inserted, with some excellent woodcuts which bring the structures of these beautiful organisms clearly before the eyes. On the way to Tristan da Cunha another new genus of fish (*Ipnops*, Fig. 2) is brought up having a quite unique structure of eye which appears to be designed for detecting the presence of very small quantities of light at great depths, at the expense of all apparatus for forming an image. From Tristan da Cunha, of which an interesting description is given with good illustrations, the section of the South Atlantic is continued to the Cape of Good Hope. The tow-nets did not yield such a rich assemblage of life as in the more tropical parts of the ocean, but the account of this section is enlivened by a summary from Dr. Hjalmar Théel of Upsala, giving the results of his examination of the holothurioidea collected during the whole cruise. One of the curious new forms described by him is shown in Fig. 3. From the Cape of Good Hope the *Challenger* strikes away south-eastward into the Antarctic regions, but a notice of the further progress of the cruise must be reserved till next week.

(*To be continued.*)

NOTES

THE death is announced at Lund, Sweden, of the distinguished physicist, Prof. A. W. Eklund, at the age of ninety years.

WE learn from *Science* that at the meeting of the American Association at Ann Arbor on August 26, the University will furnish electricity, either from a dynamo, from a storage-battery, or from primary batteries, as may be needed by members reading papers on electrical subjects. An evening reception on a day not specified will be given the association at the court-house, together with a lawn-party on the University grounds at the close of one of the regular sessions. The Excursions Committee has nearly completed arrangements for a trip, free of all expense, to the Saginaw Valley, including a steamboat run down the river, and view of the cities of Saginaw, East Saginaw, Bay City, and West Bay City, and the enormous industries in salt and lumber manufacture which have given the Saginaw Valley a world-wide celebrity. This valley produces annually a billion feet of lumber, and the excursionists will see half a billion piled on the docks. In conjunction with these vast lumber operations will be seen the production of salt on a scale unequalled in the world, and employing the various improved processes. The Committee has also arranged for excursions to Detroit and Mackinack Island, with side trips to Salt Marie, Pectoskey, and Marquette. Those wishing to make any special inquiries or arrangements should address Prof. J. W. Langley, local secretary, Ann Arbor.

A BARONETCY has been conferred upon Mr. Isaac Lowthian Bell.

THE Indian Government has sent a geological surveyor to report on the scientific aspects of the Cashmere earthquake of May 13. Further shocks are reported with renewed violence on June 24 and 25. A correspondent of a Calcutta journal, writing on the second day after the first great shock, says that the force of the earthquake appeared to have concentrated itself at certain spots, nd there to have spent itself. These spots look as though a large amount of gaseous matter under the earth had, with the strength of dynamite, been struggling for an outlet, and had torn and lacerated the ground at the point where it found an exit. Thus villages are seen with the huts all destroyed, the earth adjacent being cracked and split, and the air putrescent from the bodies of cattle buried under the houses, while not twenty yards distant a sloping, wooded hill seems untouched. In other places the side of a vertically-scarped hill has been sliced off as if by the guillotine, the earth so severed lying at the base. Some hill-sides are only partially disconnected, and a deep incision remains. Other hills present the appearance of an ordinary landslip. Near the village of Lalledourah three enormous chasms have been formed, one about three-quarters of a mile broad and 20 feet deep. Not far distant a tract of land 800 yards square has subsided, forming a trench 100 yards long, 50 feet deep, and 30 feet wide. The latest returns regarding the damage give the loss of life at 3081 persons, besides 25,000 sheep and goats and 8000 cattle. The number of dwellings destroyed is estimated at 75,000.

A VIOLENT shock of earthquake was felt at Douai, Dognies, and Flers-en-Escrebieux on Wednesday, June 22. The phenomenon was preceded by a rumbling sound, which is described as having resembled the distant report of a cannon. It occurred at ten minutes past four in the morning, when most of the inhabitants were still in bed. Many of them were awoke by the shock, and were so alarmed that they rushed in their night-clothes out of their houses into the streets and roads. The oscillation of the ground stopped a great many of the clocks. No very serious damage was done.

THE New York correspondent of the *Standard* telegraphs that the receipts from Prof. Tyndall's lectures in the States in the year 1872 now amount to a fund of 32,400 dollars. The Professor desired that the money should be devoted to the sustentation of science fellowships; but a difficulty arose in satisfying the conditions of the deed of gift, and meanwhile the money has accumulated. Acting, however, upon a suggestion from the trustees of the fund, Prof. Tyndall has now directed that the money shall be equally divided between the Universities of Columbia, Harvard, and Pennsylvania.

THE ninth anniversary meeting of the Sanitary Institute of Great Britain will be held, by the kind permission of the Board of Managers of the Royal Institution, in their Lecture Theatre, Albemarle Street, on Thursday, July 9, at 3 p.m. The chair will be taken by Sir John Lubbock, Bart., M.P., D.C.L., F.R.S. An address will be delivered by Prof. W. H. Corfield, M.A., M.D., entitled "The Water Supply of Ancient Roman Cities," and the medals and certificates awarded to the successful exhibitors at the Exhibition held at Dublin, in 1884, will be presented.

THE Organising Committee of the General Meeting of the Italian Meteorological Society, which meets in Florence from September 8 to 14, was held on May 15, under the Presidency of Prince Corsini, who was elected President of the General Meeting, the Vice-Presidents being Profs. Cecchi and Neucci, and the Secretary, Sig. Giovannetti; the Committee then divided into two Sections, one for scientific purposes, the other for practical and executive purposes.

THE Norwegian Government have contributed a sum of about 200*l.* for the prosecution of various researches during the summer, amongst which may be mentioned the zoological studies of Prof. R. Collett in East Finmarken; the entomological, malacological, and hydrographical studies of Dr. Schneider in the province of Tromsö; the researches of Dr. Johannsen on the appearance of struma in the vicinity of the lake Mjósen; and the algological studies of Herr Foslie on the south coast of Norway. A sum of 350*l.* has also been granted to the Society of Science at Christiania, as well as the usual annual grant to Dr. Sophus Tromholt for the prosecution of his studies of the aurora borealis.

ACCORDING to the Paris Correspondent of the *Times*, the Academy of Sciences, whose turn it is this year to award the Institute's biennial prize of 20,000f., has pronounced in favour of Dr. Brown Séquard.

ACCORDING to the Swedish papers, on the evening of June 19 a crane was shot at Orkened, in Scania, which had a parchment card tied to its neck with the following lines written in ink :—

I come from the burning sand
From Sudan, the murderers' land,
Where they told the lie,
That Gordon would die.

The bird had previously been wounded in the wing, and was very exhausted.

THE Japanese have at last, after much hesitation, promulgated a patent law. As in America, with respect to copyright, it was argued that with no patent protection the Japanese got the benefit of the inventions of the whole world. The new law appears, like many other recent Japanese laws, to be compiled from similar laws of other countries—a clause from England here, from France there, from Germany in another place, as seemed advisable in the circumstances. The term of protection is fifteen years; "articles that tend to disturb social tranquillity, or demoralise customs and fashions, or are injurious to health," and medicines cannot be patented; the inventions must have been publicly applied within two years, and patents will become void when the patented inventions have been imported from abroad and sold—an illiberal provision which prevents the patenting of foreign inventions in Japan unless the inventor also manufactures them in the country, and which therefore renders the new law practically useless to any but the Japanese inventor. The fees are low, amounting to about three pounds sterling for fifteen years' protection, the one payment down being sufficient, while there are no annuities or annual payments for keeping the protection in force, as in many European countries. The punishments for breaches of the regulations are sufficiently severe to act as a warning against infringement.

THE attention of all interested in the study of philology, comparative folk-lore, and cognate subjects, should be directed to a magazine which is now being published at Kandy in Ceylon. It has just completed its first year, and is called the *Orientalist*, the sub-title being "a monthly journal of Oriental literature, arts and sciences, folk-lore, &c." It is edited by a Singhalese gentleman, Mr. Goonetibleke, and its contributors are for the most part Singhalese. The last three numbers of the first volume are now before us, and among the contents we observe articles "on the terms of relationship in Singhalese and Tamil," the influence of the Portuguese and Dutch on these two languages, contributions to a descriptive catalogue of Sanskrit, Pali and Elu works extant in Ceylon, the progress of the Singhalese in literature, arts, and sciences. But folk-lore has, so far, been the strong point of the new magazine; it has published numerous articles on Singhalese proverbs and folk-lore; sometimes a popular tale amongst a particular Eastern people is started by a contributor, and is then pursued through other peoples having a parallel tale. These tales are translated in full, and are frequently accompanied by the originals. The address of the editor is Trincomalie Street, Kandy, Ceylon, and Messrs. Trübner are the agents for Europe.

WRITING to the *Times* on the subject of *Edelweiss*, Mr. Burbidge, of the Trinity College Botanical Gardens, Dublin, points out that the plant is easily grown in English gardens from seed. It is sown in common garden earth in a cold frame, and when large enough each little plant is placed in a small pot in a mixture of loamy earth and old lime rubbish, or the plants, he says, are equally well pleased by a niche in a sunny rock garden, provided a supply of their favourite lime rubbish or old mortar be afforded them. Contrary to the generally received opinion, the *Edelweiss* is really a plant of extremely easy culture from seeds as here directed, and, further, good fresh seeds of it are quite readily obtainable from the usual sources of seed supply.

WE have received the first number of the *Bulletin* of the Society of Natural History of Brookville, Indiana, an association organised in 1881, according to the report, with excellent results in an enlarged interest in the study of nature, the establishment of a valuable museum, and the founding of a large and excellent library. Amongst the contents we notice papers on the stone mounds on the Whitewater; on the flora, fossils, and land and fresh-water mollusca of Franklin County, and on the fauna changes of the same district. The last paper is especially interesting, as showing the effects on the fauna of civilisation and its accompaniments, such as draining, cutting down forests, &c.

WE have received the fifteenth annual report of the Wellington College Natural Science Society. The observations conducted by the society have been carried on as usual, and the more important of them are published in detail; beyond this the report offers no new features for special comment.

WE notice in the issue of the St. Petersburg *Izvestia* (xx. 6) two papers by MM. Popoff and Katatanoff on the customs of the Katchin Tartars of Minusinsk, with a notice, by M. Potanin, on wild plants used as food in Siberia. These last are numerous. The Katchin Tartars eat the grains of *Fagopyrum tataricum*; in the government of Irkutsk, during years of scarcity, the peasants add to their flour the *Polygonum convolvulus*. In Northern Mongolia the grains of *P. viviparum* (*oorgene* with the Mongols) are a common addition to food. The "ibseck," used by the Katchin Tartars, seems to be the *Cirsium acaule*, whose roots are eaten in Northern Mongolia. In Northern Siberia (Turukhansk, Yakutsk regions) the inhabitants eat the anti-scorbutic roots of the *Cochlearia sisymbroides*, Dec., var. *Czekanowskiana*, (Trautvetter). The exact determination of this plant is due to Czekanowski's expedition, for Middendorff had confounded it with the poisonous *Veratrum lobelianum*, Bernh., and he even saw in its eating a proof for the disparition of poisonous qualities of certain plants in a northern climate. When there is no pine-trees the Yakutes used to add to their sour milk a flour of dried roots of *Butomus umbellatus* instead of pine-bark. Great stores of these roots are usually made by Yakutes, who also use the grains of *Plantago media* and *P. canescens*, Adams. In the Khangai, M. Potanin was also shown a species of *Plantago* the fruits of which are eaten by the Khalkas Mongolians; but altogether, he observes, a confounding of *Polygonum* with *Plantago* has possibly been made by previous authors. We may add to this list that the *Lilium martagon* is eaten in large quantities in Transbaikalia, and that it is a common thing with the Buriates to pillage in the autumn the provisions of bulbs of this Lily made by the Arvicolæ, and to appropriate these provisions for themselves.

THE Stokes-Watson spark apparatus for showing the combustion of metals under the microscope, by the passage of the electric spark through them, made by Messrs. Watson and Sons, of High Holborn, from the design suggested by Prof. Stokes, was exhibited by Messrs. Watson at the *conversazione* of the Royal Society, Burlington House, on May 6, and again by them on Friday, June 5, at the Royal Institution. It is a most interesting apparatus, the different metals in combustion showing beautiful colours, and as the apparatus can be added to any ordinary microscope, no doubt it will become very popular.

THE Trilobites recently found in Eastern Siberia belong, according to Prof. Friedrich Schmidt, to very different ages. Those found in boulders on the Olenek (*Agnostus*, *Olenus*, *Anomocaxe*) belong to the Cambrian, and are closely akin to those collected by Richthofen in China. From the Lower Silurian, the *Chasmops* of the Podkamennaya Tunguska is especially worthy of notice. It belongs to the Trentock level, as far as we may judge from corals from the same locality described by Prof. Lindström. Finally, Mr. Schmidt has received from Krasnoyarsk several samples of a new genus, the *Proetus*, which is closely akin to species from the sub-divisions F and G of Barrande.

THE additions to the Zoological Society's Gardens during the past week include a Barbary Ape (*Macacus innus* ♂) from North Africa, presented by Capt. A. B. Hawes; two Common Badgers (*Meles taxus*) from Staffordshire, presented by Col. E. M. M. Buller; a Red Brocket (*Cariacus rufus* ♂) from Para, presented by Mr. H. E. Weaver; two —— Fruit Pigeons (*Carpophaga* ——) from the Samoan Islands, presented by Mr. T. H. Bowyer Bower, jun.; a Common Cuckoo (*Cuculus canorus*), British, presented by Mr. G. Lyon Leith; two Tuatera Lizards (*Sphenodon punctatus*) from New Zealand, presented by Mr. L. W. Buller; a Malbrouck Monkey (*Cercopithecus cynosurus* ♂) from West Africa, deposited; a Red-vented Parrot (*Pionus menstruus*) from South America, purchased; a Molucca Deer (*Cervus moluccensis*), a Thar (*Capra jemlaica*), born in the Gardens.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, *JULY* 5–11

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on July 5

Sun rises, 3h. 53m.; souths, 12h. 4m. 17·6s.; sets, 20h. 15m.; decl. on meridian, 22° 46′ N.: Sidereal Time at Sunset, 15h. 11m.

Moon (at Last Quarter) rises, 23h. 25m.*; souths, 5h. 45m.; sets, 12h. 16m.; decl. on meridian, 3° 2′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	4 30	12 45	21 0	23 19 N.
Venus	5 13	13 16	21 19	21 28 N.
Mars	1 39	9 47	17 55	22 15 N.
Jupiter	8 25	15 27	22 29	11 19 N.
Saturn	2 55	11 5	19 15	22 32 N.

* Indicates that the rising is that of the preceding day.

July	h.	
9	21	Mars in conjunction with and 5° 7′ north of the Moon.
10	23	Saturn in conjunction with and 4° 7′ north of the Moon.

GEOGRAPHICAL NOTES

IN concluding his notes on the Kurile islands, to the first instalment of which we have already referred, Prof. Milne has some interesting observations on the geology of this little known archipelago. The two islands, Iturup and Kunashiri, he says, form the two first of the series of stepping stones which connect Japan by means of Kamtschatka with Asia. They seem also to be the older members of the group. They contain a greater proportion of rounded hills and of deeply cut valleys than any of the islands farther north, and may therefore be regarded as older than those which are built up almost entirely of finely formed volcanic cones. The neighbouring island of Urup presents appearances similar to these two. He is inclined to think the formation of an island like Iturup commenced as a number of volcanic peaks forming islands, and that these have been subsequently united by elevation, indications of which there are in the stratified rocks and terrace formations. All the appearances, however, which he has ascribed to a raising of the land, might, he observes, be also explained by a raising and lowering of the sea, such, for instance, as that which Mr. Croll points out, might be produced by the accumulation of ice during a glacial period at the pole; and the fact that the height of the terraces increase as we go northwards appears to confirm this view. The steepest slope which he has observed in any portion of a volcanic cone was that of a small cone rising from the upper crater of Cha-cha-nobori, which had an inclination of 37°. This would indicate that it was formed of extremely fine materials, and that the last eruption by which these materials were formed had not been very violent.

IT is announced from Lisbon that the Portuguese explorers, Capello and Ivens, who left Loanda some time ago, have discovered the sources of the Lualaba, Luapula, and Chambeze, the upper waters of the Congo.

AMONG the recent scientific missions ordered by the French Minister of Public Instruction we find the following:—M. Bordas, to study the zoology of the Madagascar Islands, of the Seychelles, and Comoros; M. Clermont-Ganneau, to examine the epigraphy of the islands in the Red Sea, situated at the entrance to the Gulf of Akaba; M. Morgan, mining engineer, on a geological and mineralogical mission in the Orange Free State, the Transvaal, Zululand, and Natal; Lieut. Palat, to explore the route from Senegal to Algeria by Medina, Timbuctoo, Mabrouk, and the Touat.

THE island in the North Pacific which appears now to be definitely added to the British Empire is not, as was at first supposed, Quelpaert, but another Corean island, or rather group of islands, known as Port Hamilton, about forty-five miles to the north-east of the former, and about thirty miles off the Corean coast, in the Broughton Channel, separating the peninsula from Japan. The position of the group is 34° 1′ 23″ N. lat., and 124° 57′ 30″ east of Paris. The port is surrounded by three larger islands, and several smaller ones. The largest of all is on the west, and runs from north-west to south-east; it is hilly, but the height of the main eminence is not given by Sir Edward Belcher. Between the two main islands is Observatory Island, and the whole inclose an excellent harbour. The islets, except in one or two channels, which serve as entrances to the bay, are connected by barriers or reefs, above which the water is shallow. The islands are poor in wood, but water is good and abundant, and the sea abounds in fish. There are no cattle, but pigs, fowls, and some vegetables are found. The group was visited in 1846 by Capt. Belcher, and in 1855 by a French frigate.

AT the last meeting of the Geographical Society of Paris Baron Benoist-Méchin described a recent journey in the Merv oasis. This was a continuation of previous communications to the Society of the great journey made by the Baron and some companions from Peking through Manchuria, thence through Siberia, south to Samarkhand, Merv, and so into Persia. M. Simonin made a communication on the pictorial writing of the North American Indians; it appears that, of all the tribes, only the Cherokees and the Creeks possess a writing. The former have newspapers and books in their language, and write with seventy-seven phonetic characters in a syllabary invented by a Cherokee in 1830. The Creeks have nineteen characters. The notorious Sioux chief, Sitting-Bull, has written his autobiography in pictorial writing. His "Cæsar's Commentaries" are written on the back of a book which belonged to the Commissariat of the Third United States Infantry Regiment, and contain a recital of his adventures between 1864 and 1870. Each figure is roughly traced in ink, the men and horses being represented as a child might draw them; colours have in some cases been added to render the picture more vivid. The *Comptes Rendus* also contains the continuation of a paper by M. d'Aoust on the causes of earthquakes, and the itinerary of a journey in the basin of the Ruovouma by M. Angelvy, an engineer in the service of the Sultan of Zanzibar.

THE latest *Bulletin* (9me année, No. 2) of the Royal Geographical Society of Belgium is mainly occupied by a paper by M. Hennequin on the agricultural maps of Belgium, with reference to certain maps recently produced by the military cartographic institute for the Ministry of Agriculture. A brief account of Guatemala by M. Leclercq is compiled from the official publications of that republic, and a paper by M. Haron on the commune of Manage (Hainaut) is an interesting study in local geography. It deals, under successive divisions and subdivisions, with the commune on four main heads—physical, economical, and political geography.

THE last *Zeitschrift* of the Berlin Geographical Society contains the following papers:—The conclusion of "Achelis's" article on the methods and task of ethnology; rivers and lakes as the products of climate, by A. Woeikof, and a map of Paul Acherson's journey in the Libyan desert, with the accompanying descriptive account of the journey.

A LONG-DELAYED letter from the Bishop of Central Oceania gives, *Science* states, details of the honours rendered by the civil and religious authorities to the relics of the companions of La Pérouse. These last survivors of that unfortunate expedition were massacred by the Samoans on the Islet of Tutuila on December 11, 1787. Father Vidal, of the mission, had been searching twelve years for the remains, which were finally identified in October, 1882. The authorities in France, on being notified, caused a beautiful mortuary tablet to be prepared, and forwarded to the admiral on duty at that station. A monument was erected, upon which the tablet was fixed, and a small chapel built near it. The whole was dedicated by Bishop Lamaze and Commandant Fournier, of the French Navy, with solemn ceremonial and minute-guns on the ninety-seventh anniversary of the event.

LIQUID FILMS[1]

THE molecules in the interior of a liquid are surrounded on all sides by others which they attract, and by which they are themselves attracted, while those on the surface have neighbours on one side only. In consequence of this difference in their surroundings there is in all probability a difference in the grouping of the interior and exterior molecules which is attended by corresponding variations in the physical properties of the liquid of which they are constituent parts. Thus it was shown by M. Plateau that the viscosity of the surface of a liquid is in general different from that of its interior. The most striking example of this phenomenon is afforded by a solution of saponine. Two per cent. of this substance dissolved in water does not effect any marked change in the properties of the great mass of the liquid, but produces a most remarkable increase in the surface viscosity, so that forces which suffice to create rapid motion in bodies which are completely immersed, fail to produce any appreciable movement if they lie in the exterior surface. The first attempt to obtain a numerical estimate of the difference of the resistances experienced by a body oscillating in turn in the interior and in the surface of the liquid was made about two years ago by Messrs. Stables and Wilson, students in the Yorkshire College. In the case of a horizontal disc suspended in water, the logarithmic decrement diminishes to about one half as the surface is approached. In a saponine solution, on the other hand, it is 125 times greater in the surface than in the interior, and about 38 times greater in the surface than at a depth of 0·1 mm. below it. Even in the latter case the greater part of the resistance is due, not to the friction between the disc and the liquid, but to that experienced by the supporting rod in the surface, so that in all probability the surface viscosity is more than 600 times greater than that of the mass of the liquid.

The immense change in the resistance which takes place when the disc is immersed to a depth of 0·1 mm. only confirms the general opinion that any peculiarity of grouping or arrangement due to proximity to the surface extends to a very small depth. A liquid must thus be conceived as surrounded by a very thin layer or skin, the properties of which are different from that of the liquid in the interior, and to which rather than to any ideal geometrical boundary the term "surface" might be applied. It may, however, prevent confusion if it is called the *surface-layer*.

Many attempts have been made to measure the thickness of the surface-layer. In particular, M. Plateau studied a thinning soap film with a view of determining whether or no the pressure exerted on the enclosed air by the film when very thin is the same as when it is comparatively thick. Had any such difference been observed it might have been taken as *primâ facie* evidence that the tenuity was so great that all the interior portions of the film had drained away, and that the thickness did not exceed that of the two surface-layers.

This experiment has been criticised by Prof. Reinold and myself, but it is not intended in this lecture to enter upon the general question of the thickness of the surface-layer, or the interesting theoretical problems which are closely connected with it, as we are at present engaged in an investigation which we hope may throw further light upon the subject. There are, however, two preliminary questions on which we have arrived at definite conclusions.

[1] Lecture at the Royal Institution by Prof. A. W. Rücker, M.A., F.R.S.

In any experiments which have for their object the detection of small changes in the properties of a soap film as it becomes thinner, it is essential that we should be able to assert with certainty that no causes other than the increasing tenuity have been in play, by which the effect looked for might either be produced or masked. Changes in the temperature or composition of the film must especially be prevented.

The liquid ordinarily employed for such investigations is the "liquide glycérique" of M. Plateau. In dry air some of the water of which it is in part composed would evaporate, while in moist air, in consequence of the hygroscopic properties of the glycerine, additional water would be absorbed. Though these facts were well known, and though they are evidently possible sources of error, no attempt (as far as I am aware) had been made before our own to determine what precautions it was necessary to take to prevent the results of experiments such as M. Plateau's being affected by them. The first question then that we set ourselves to answer, was—to what extent is the composition of a soap film altered by changes in the temperature or hygroscopic state of the air which surrounds it?

The method adopted in answering this inquiry was to measure the electrical resistance of soap films formed in an inclosed space containing a thermometer and hair hygrometer. If the observations led to the conclusion that the resistance of film varied inversely as its thickness, they would prove that no change in composition had taken place, and that the film at the thinnest had afforded no evidence of an approach to a thickness equal to that of the surface layers. If the specific resistance was found to vary according to some regular law as the thickness altered, there would be a strong presumption that the thickness was not much greater than, and was possibly even less than that of the two surface-layers. If, lastly, the changes were irregular, they might safely be ascribed to alterations in temperature or constitution.

To obtain the desired facts it was necessary (1) to devise a method of forming the films in a closed chamber, (2) to measure their thickness, and (3) to determine their electrical resistance.

The films were formed in a glass box at the lower extremity of a platinum ring which communicated by means of a tube with the outside. In the earlier experiments a cup of the liquid was raised by rackwork to the ring and then withdrawn, leaving a film behind it. The latter was blown out by air which had been dried and passed through tubes containing "liquide glycérique." When large enough it adhered to a second platinum ring placed vertically below the first, and on some of the air being withdrawn it assumed the cylindrical form.

The thickness was measured by means of the colours displayed, two independent determinations being obtained by two beams of light incident at different angles. Newton's Table of Colours was revised, and it was found that the differences between the thicknesses given by him and those determined by new experiment were far greater than the error of experiment of a single observer. Hence, if accurate measurements are required by means of Newton's scale, every experimenter must reconstruct that scale for himself.

At first the electrical resistance was determined by means of Wheatstone's bridge. The edges of the film where it is close to its solid supports are often, however, the seat of phenomena which might affect the results. Thin rings of white or black appear which alter the resistance considerably, and which introduce errors for which it is almost impossible to make any accurate allowance. This fact, combined with the advantage of avoiding errors due to polarisation, and of being able to select any particular part of the film for examination instead of the whole, led us to adopt a different method. Gold wires attached to a movable support were thrust into the film, and the difference of potential between these when a current was passing through the film was compared with that between the extremities of a known resistance included in the same circuit.

The result of these observations was to prove that the specific resistance of the films altered in an irregular manner, varying between 200 and 137 ohms per cubic c.m. A closer inspection showed that abnormal results were always accompanied by abnormal variations in the thermometer or hygrometer. When those films were selected which had been observed when such variations were especially small, it was found that the range of variation of the specific resistances was only between 137 and 146, and that the mean value was 143, that of the liquid in mass being 140·5 (at the same temperature). It was also proved that between thicknesses varying from 1370 to 374 millionths of a millimetre, no regular change in specific resistance could be detected, the actual variations lying within 2·5 per cent.

The conclusion was thus arrived at that the specific resistance of the liquid of which a soap film is formed does not differ from that of the same liquid in mass, at all events when the thickness is greater than 374×10^{-6} mm., and that comparatively small changes in the temperature or hygroscopic state of the air in contact with the film are attended with great alterations in the specific resistance, which indicate a considerable change in composition.

The method of experiment made it possible to determine the amount of this change. Solutions were made up representing "liquide glycérique" which had lost or gained given percentages of water, their specific resistances were determined at various temperatures, and approximate formulæ obtained by which the percentage of water present could be calculated if the specific resistance and temperature were known.

The results of the application of this method of analysis to a film are shown in the accompanying figure. The abscissæ represent time, the ordinates of curve I. represent the average thickness of the film. It will be observed that the film continued to get thinner during the whole time that it was under observation. The electrical observations, however, proved that at first the product of the resistance and thickness steadily increased, indicating a continuous loss of water. Curve II. shows the number of parts of water in 100 of the solution lost

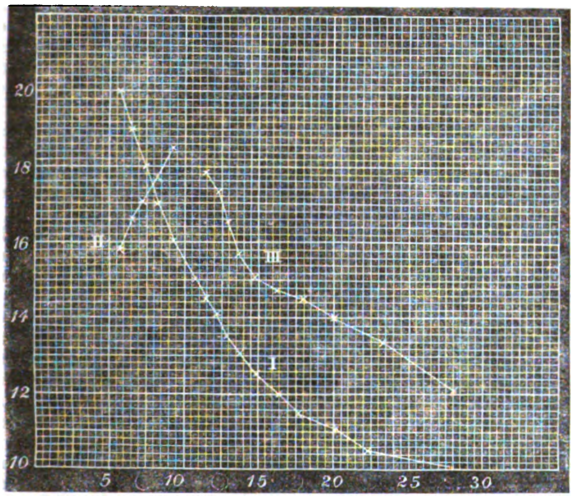

FIG. 1

at the times indicated by the abscissæ. After a while a piece of blotting paper which had been hung up inside the case was moistened with water. While this was being done the observations were interrupted. On their renewal it was found that although the film thinned as steadily as before, the product of the resistance and thickness diminished instead of increasing. Curve III. shows the steady absorption of water which followed the moistening of the air. These experiments proved that it is possible for a film to undergo great changes in composition without any indication of the fact being afforded by the colours it displays. They show that if the composition of the "liquide glycérique" is to be kept constant, all change in the temperature and hygrometric state of the air must be as far as possible prevented. In later experiments this condition has been secured by placing the film box in the centre of a water tank, and by keeping an endless band of linen hung up within the case, and which dips into the liquid, continually moistened. Observations made with this apparatus show that these precautions which are certainly necessary are also sufficient.

The second point to which special attention has hitherto been given by Prof. Reinold and myself is the measurement of the thickness of very thin films. If the thickness is less than a certain magnitude, the films appear black, and thus their colour gives only a limit to and not a measure of their thickness. Black films display many remarkable properties. In general there is a sudden change in thickness at the edge of the black indicated by the omission of several colours, or sometimes of one or two orders of colours. It is only under rare conditions that a gradual change in thickness can be observed from the white to the black of the first order.

To determine the thickness of the black its resistance was measured, and the thickness calculated *on the assumption that the specific resistance was the same as that of the liquid in mass.*

The observations were made in several different ways and proved that the thickness of the black portion remains constant in any given film, however much its area may alter. Thus, in the case of a group of films measured by Wheatstone's bridge, the average resistance of a black ring 1 mm. in breadth was 1·761 megohms when the total breadth was 2 mm., and 1,761 megohms when the total breadth lay between 10 and 12 mm.

Again, the resistance of the part of the film between the needles used in the electrometer method was practically the same when the black had extended over the whole film (40 mm. long) as it had been when only the upper 11 mm. were black. The final measurement differed from the mean by only 0·1 per cent. Again, in another film the resistance of the black per millimetre remained the same to within 2·5 per cent. for an hour and a half.

On the other hand the experiments also proved that the thickness of the black was different in different films. The values found varied between $7{\cdot}2 \times 10^{-6}$ and $14{\cdot}2 \times 10^{-6}$ mm. These differences are quite outside the possible error of experiment. If they were due to changes in the constitution of the liquid of which the films were formed, it is very improbable that the specific resistance of individual films would not have shown progressive changes. As has been stated, none such were observed. The mean thickness of the five films made of "liquide glycérique" which were observed was $11{\cdot}9 \times 10^{-6}$ mm., while that of thirteen films made of soap solution without any glycerine was $11{\cdot}74 \times 10^{-6}$ mm.

The assumption made in these calculations that the specific resistance of a film, the thickness of which is ten or twelve millionths of a millimetre, is the same as that of the liquid in mass, is not justified by the previous experiments, which had proved it to hold good only to the much greater thickness of 370×10^{-6} mm. It was therefore desirable to check the results by an independent method. For this purpose fifty or sixty plane films were formed side by side in a glass tube which was placed in the path of one of the interfering beams in a Jamin's Interferential Refractometer. The compensator was adjusted so that it had to be moved through a large angle to cause one interference band to occupy the position previously held by its neighbour, *i.e.* to alter the difference of the paths of the interfering rays by one wave-length. This angle was determined for the red light of known wave-length transmitted by glass coloured with copper oxide. When the films had thinned to the black they were broken by means of a needle which had been included in the tube along with them, and which was moved, without touching the tube, by a magnet. The rupture of the films produced a movement of the interference fringes which was measured by the compensator, and from which, in accordance with well-known principles, the thickness of the films could be deduced.

The mean thickness given by seven experiments on films made of "liquide glycérique" was $10{\cdot}7 \times 10^{-6}$ mm., that obtained from nine experiments on films made of soap solution was $12{\cdot}1 \times 10^{-6}$ mm. The mean of these, or $11{\cdot}4 \times 10^{-6}$ mm, differed only by $0{\cdot}4 \times 10^{-6}$ mm., from the mean thickness deduced from the electrical experiments.

The last point to which reference is necessary is one which lies outside the main line of the enquiries above described, but which is nevertheless not without interest. In the course of the observations it was noticed that the rate of thinning of a film seemed to be affected by the passage of the electric current through it. Some experiments made on this point last year proved the fact beyond the possibility of doubt. The current appears to carry the matter of the film with it, so that it thins more rapidly if the current runs down, and less rapidly if the current runs up than if no current is passing. This may be shown as a lecture experiment.

A vertical rod which can be moved up and down by rackwork is passed through the centre of the cover of a glass film-box. To the lower extremity is attached a horizontal platinum wire, from which another similar horizontal wire is suspended by two silk fibres. A film is formed by lowering the whole into the liquid with which the lower part of the vessel is flooded. The light reflected from the film is passed through a lens, and an image formed upon a screen. When the bands of colour are seen descending from the upper part of the film, a current from fifty Grove's cells is passed through it. If the current flows downwards the bands of colour move more quickly than before; if it flows upwards their motion is checked and they begin to ascend. The cause of this curious fact is still unknown. It may either be analogous to the phenomenon known as the "migration of the ions," or it may be a secondary effect due to a change in the surface tension.

The general relation of the results attained by these investigations as to the question of the size of molecules is interesting. Sir William Thomson has expressed the opinion that 2×10^{-6} mm. and $0 \cdot 01 \times 10^{-6}$ mm. are superior and inferior limits respectively to the diameter of a molecule. Van der Waals has been led, from considerations founded on the theory of gases, to give $0 \cdot 28 \times 10^{-6}$ mm. as an approximate value of the diameters of the molecules of the gases of which the atmosphere is composed. The number of molecules which could be placed side by side within the thickness of the thinnest soap film would, according to these various estimates, be 4, 26, and 720 respectively. The smallness of the first of these numbers, especially when it is remembered that the liquid used on some occasions was of a highly complex character, containing water, glycerine, and soap, points to the conclusion that the diameter of a molecule is considerably less than 2×10^{-6} mm.

THE FAUNA OF THE SEASHORE[1]

THE marine fauna of the globe may be divided into the littoral, the deep-sea, and the pelagic faunas. Of the three regions inhabited by these faunas, the littoral is the one in which the conditions are most favourable for the development of new forms through the working of the principle of natural selection. As Prof. Lovén writes, "The littoral region comprises the favoured zones of the sea where light and shade, a genial temperature, currents changeable in power and direction, a rich vegetation spread over extensive areas, abundance of food, of prey to allure, of enemies to withstand or evade, represent an infinitude of agents competent to call into play the tendencies to vary which are embodied in each species, and always ready by modifying its parts to respond to the influences of external conditions." It is consequently in this littoral zone where the water is more than elsewhere favourable for respiration, and where constant variation of conditions is produced by the tides, that all the main groups of the animal kingdom first came into existence; and here also, probably, where the first attached and branching plants were developed, thus establishing a supply of food for the colonisation of the region by animals.

The animals inhabiting the littoral zone are most variously modified, to enable them to withstand the peculiar physical conditions which they encounter there. Hence the origin of all hard shells and skeletons of marine invertebrata, various adaptations for boring in sand, the adoption of the stationary fixed condition, and similar arrangements. Almost all the shore forms of animals, however inert in the adult condition, pass through in embryological development free-swimming larval stages which are closely alike in form for very widely different groups of animals. Thus the oyster and most other mollusca of all varieties' and shapes when adult develop from a free-swimming pelagic trochosphere larva, and so do many annelids. Such larvæ cannot be of subsequent origin to the adults of which they are phases. If such were the case, they would not have become so closely alike in structure. In reality they represent the common ancestors from which all the forms in which they occur were derived, and as all these larvæ are pelagic in habits and structure, it follows that the inhabitants of the shores were derived from pelagic ancestors. The earliest plants were also probably free-swimming.

In the case of the cirripedia there can be no doubt, from the history of their development, that they were originally pelagic, and have become specially modified for coast life; and in the case of the echinoderms the only possible explanation of the remarkable similarity of the larval forms of the various groups of widely differing adults is that these pelagic larvæ represent a common ancestor of the group. The madreporarian corals all spring from a pelagic larvæ. The colonial forms probably owe their origin and that of their skeletons to the advantage gained by them in the formation of reefs, and the increase in facilities of respiration consequent on the production of surf. In the deep sea they are very scarce.

The vertebrata are sprung from a very simple free-swimming ancestor, as shown by the ciliated gastrula stage of Amphioxus. The ascidians afford another evident instance of the extreme modification of pelagic forms for littoral existence.

The peculiar mode of respiration of vertebrata by means of gill-slits occurs in no other animal group except in Balanoglossus, which will probably shortly be included amongst vertebrata. Possibly gill-slits as a respiratory apparatus first arose in a littoral form, such as Balanoglossus, and hence their presence at the anterior end of the body, that nearest to the surface in an animal buried in sand. The connection of Balanoglossus with the echinoderms through Tornaria is very remarkable. Possibly Amphioxus once had a Tornaria stage, and has lost it just as one species of Balanoglossus has lost it, as Mr. Bateson has lately discovered.

The littoral zone has given off colonists to the other three faunal regions. The entire terrestrial fauna has sprung from colonists contributed by the littoral zone. Every terrestrial vertebrate bears in its early stages the gill-slits of its aquatic ancestor. All organs of aërial respiration are mere modifications of apparatus previously connected with aquatic respiration, excepting, perhaps, in the case of Tracheata, tracheæ being most likely modifications of skin-glands, as appears probable from their condition in Peripatus. The oldest known air-breathing animals are insects and scorpions, which have lately been found in Silurian strata. Prof. Ray Lankester believes the lungs of scorpions to be homogeneous with the gill-plates of Limulus. Birds were possibly originally developed in connection with the seashore, and were fish-eaters like the tooth-bearing Hesperornis.

The fauna of the coast has not only given rise to the terrestrial and fresh-water fauna; it has from time to time given additions to the pelagic fauna in return for having thence derived its own starting-points. It has also received some of these pelagic forms back again, to assume a fresh littoral existence.

The deep-sea fauna has probably been formed almost entirely from the littoral, not in the remotest antiquity, but only after food derived from the *débris* of the littoral and terrestrial faunas and floras became abundant.

It is because all terrestrial and deep-sea animal forms have passed through a littoral phase of existence, and that the littoral animals retain far better than those of any other faunal region the recapitulative larval phases by means of which alone the true histories of their origins can be recovered, that marine zoological laboratories on the coast have made so many brilliant discoveries in zoology during late years.

The lecturer concluded by appealing for as istance, in the way of subscriptions, to the funds of the Marine Biological Association of Great Britain, the object of which is to construct a marine laboratory on the English coast for the purpose of researches such as those referred to. England is at present without any such laboratory, although nearly all Continental countries possess them.

[1] Abstract of lecture at the Royal Institution by Prof. H. N. Moseley, M.A., F.R.S.

THE PHILOSOPHICAL SOCIETY OF GLASGOW

THE *Proceedings* of this Society for 1884-85 have just been issued in a volume of 408 pages, with six plates and two maps. The following are the principal contributions:—On feeling and perception of relation, by Dr. H. Muirhead, President; on the proper motions of the stars, by Prof. Grant; on the first editions of the chemical writings of Democritus and Synesius, by Prof. Ferguson; on the composition of ocean water, by Prof. Dittmar; on the regulation of the supply of water to cities and towns, by Mr. W. Key; on a shadowless gas ventilator, by Mr. George A. Buchanan; on African colonies and colonisation, by J. E. Carlyle; a memoir of the late Mr. James Napier; on a new musical instrument, by Mr. Thomas Machell; on a description of a new Rotiferon, by Mr. W. Milne; on a theory of storm-travel, by Mr. P. Alexander; on national and local precautions against cholera, by Dr. James Christie; on an air or gas thermometer, by Mr. J. J. Coleman; on some experiments on the influence of cold on the putrefactive process, by Mr. J. J. Coleman and Prof. McKendrick; on the liquefaction of air and other effects of extreme cold, and on artificial light and other phenomena of high temperature, by Mr. J. J.

Coleman; on sanitary arrangements and house-building in towns, by Mr. James Sellars; on Egyptian obelisks, by Mr. T. L. Patterson; on producing cast iron or ingot iron from crude or pig iron, by Mr. W. Gorman; on the heat-restoring gas furnace and heating by radiation, by Mr. W. Gorman; on uncertified deaths, by Dr. Glaister; on the spread of disease by manure poisoning, by Dr. E. Duncan; and on the form of the human skull, by Prof. Cleland. The two maps, prepared by Mr. Ravenstein, and presented to the Society by Mr. James Stevenson, are specially valuable as showing the most recent results of African travel.

During the session M. Louis Pasteur, Prof. Asa Gray, and Rev. John Kerr, LL.D., were elected honorary members, and Mr. George Anderson, lately M.P. for Glasgow, and now Master of the Mint, Melbourne, was elected a corresponding member. The Graham medal was awarded to Mr. E. C. C. Stanford for his researches on algin. The Society at present has 18 honorary, 11 corresponding, and 691 ordinary members, and in addition to the ordinary meetings, there are sections for architecture, chemistry, biology, sanitation and social economy, and geography and ethnology.

AN EARTHQUAKE INVENTION

WE have been requested to publish the following correspondence:—

Royal Observatory, Edinburgh, June 5, 1885

MY DEAR MR. DAVID STEVENSON,—At p. 248 of the new British Association volume for 1884 there is a section on "Experiments on a Building to Resist Earthquake Motion," which reads amazingly like your paper of twenty years ago; but yet it is not that, for your name does not enter, and they have in a way got round the letter of your invention by employing, in place of your bronze balls in shallow bronze basins, cast iron balls and cast-iron plates, "with saucer-like edges" for the lower basins; and for the upper basins, "cast iron plates slightly concave, but otherwise similar to those below."

Against such men would any patent be safe? though you may not have taken out any patent for your philanthropic invention for saving life in earthquake-persecuted countries; but the whole section is the most indubitable approval of your methods and principles that could well have been proposed by any one. Certainly it transcends anything that could have ever entered the mind of Yours ever very sincerely,

C. PIAZZI SMYTH

Edinburgh, June 11, 1885

DEAR SIR,—Very many thanks for your letter to my father pointing out the report of the British Association on earthquakes for 1884, which I had not seen. My father, from the state of his health, is unfortunately unable to take the matter up himself, but if you will permit me to publish your very interesting and well-put letter in NATURE it will give the honour of the invention to whom the honour is due. My father, who read your letter with great interest, begged to be remembered to "his old friend." In order to save you the trouble of writing again I shall assume, if I do not hear from you in a few days, that you have no objection to your letter being published.

I may mention that the balls for the Japanese aseismatic arrangements for the towers were made of cast iron, and those for the tables in the light-rooms were of gun-metal.

Yours very truly,

D. A. STEVENSON

Professor Piazzi Smyth, &c., &c.

Westford House, Droitwich, June 13, 1885

DEAR MR. D. A. STEVENSON,—Yours of the 11th has reached me here; and, as I left Edinburgh on that day, it was a happy thought of yours to say that, if you did not hear from me soon you would assume my consent to your making some public use of my letter to your worthy father. For, in so far as I wrote it at all, I am ready to stand by it before many or few.

But it was only the beginning of what might have been said; and that I trust you will have perceived, and will supply some of the remaining *notanda*, such as the B.A. man praising up the system for so decidedly relieving the ball-supported building from all the *sharp*, destructive effects of an earthquake-shock, and leaving only a gentle to-and-fro motion on the balls;—because this was so admirably illustrated on your father's experimental model at Milton House—by the ease and safety with which the model lighthouse standing on balls in basins was knocked all about the yard by men with sledge-hammers, when they struck only the lower basins, or what they were fixed on as representing solid, yet earthquake-affected, ground; but the moment they struck the base of the lighthouse taken off the basins and balls and planted on the ground, down toppled lantern and lamps with such a fracture, that no more experiments could be made that day.

Then, again, your father had duly allowed that his system would not defend from vertical earthquake-shocks, but he hoped that they would be far more rare at any one place than horizontal shocks spreading all around and far from the places of vertical action; and exactly so says the B.A. man for himself and his imitation balls and basins.

And then he concludes with that he does hope for so much alleviation to human suffering in earthquake regions from the large amount of safety that balls and basin supports for dwellings must give in a general way that seismic science will be elevated in the eyes of the people, or something to that effect. To all which of course you can perfectly agree, both in your own and your father's name. I can mention that the turning-point with him as to the practicability of the scheme was when he ascertained by rigid and calm scientific measures that the amount of absolute motion which had done the most mischief in some of the worst Italian earthquakes was not more than three inches, so that it came legitimately within the compass of the means *he* first suggested, and R.S.S. Arts duly stamped with its approval ten years ago.

Hereabouts is a different earth effect—viz. the High Street, so called, of Droitwich—going down slowly but surely to fill up the vacancies occasioned below by the ceaseless bringing up of salt-rock dissolved in water pumped by numberless steam-engines, and furnishing, it is said, half the human family with that one necessary mineral condiment, salt; and so much vapour of it is in the air that mere residence here for a time is said to cure rheumatism and other complaints, even without taking the celebrated brine baths, of ten times the saltness of the ocean itself. Yours very truly,

C. PIAZZI SMYTH

P.S.—The spectroscopic salt line D is preternaturally strong in the air here; "D" might stand for Droitwich.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, June 18.—"Regional Metamorphism," by Joseph Prestwich, M.A., F.R.S., Professor of Geology in the University of Oxford.

Metamorphic rocks have been divided into two classes—(1) Those in which the change has been caused by contact with heated eruptive rocks; (2) Those extending over wider areas, in which the rocks are in no apparent relation to eruptive or igneous rocks. The first has been termed *Contact Metamorphism*, and the second *Normal* or *Regional Metamorphism*, the latter two terms having been used to express the same phenomena and treated as synonymous.

The author, however, for reasons to be assigned, proposes, while retaining the use of both the latter terms, to apply them differently. Normal metamorphism he would confine, as hitherto, to the changes caused by the heat due to depth, on the supposition of the existence of a heated central nucleus of the earth, while he would use the term *regional metamorphism* to denote changes effected by the agency of the physical causes to which Mr. Mallet referred the fusion of the volcanic rocks, namely, *the heat produced locally within the crust of the earth by transformation into heat of the mechanical work of compression, or of crushing of portions of that crust.*

The primary object of Mr. Mallet's experiments was to ascertain the force required to crush portions of various rocks of given size, and to determine the quantity of heat evolved by the process. For this purpose the work done was measured by the number of cubic feet of water at 32° F. that could be converted into steam of one atmosphere (or at 212° F.) by the estimated heat evolved by the crushing of 1 cubic foot of each class of rock.

With all the harder rocks the heat produced in the metal surroundings by the complete crushing was easily perceptible by the hand, and was so great with some of the granites and porphyries as to necessitate a delay for the apparatus to cool. Both Mr. Mallet and Prof. Rankine were of opinion that in the crushing of a rigid material such as rock *almost the entire* mechanical work (with the exception of a small residue of external work) reappears as heat. It was further shown that, even in the most rigid bodies, crushing begins by compression and yielding, and that at this stage heat begins to be evolved.

Consequently the work thus developed being transformed into heat, that heat will be greatest along those lines or planes at places where the movement and pressure, together constituting the work, is greatest; whence Mallet concluded that along or about such axial lines of concentrated compressive and crushing work the temperature may locally rise to a red heat, or even to that of fusing the rocky materials crushed and of the pressing-together-walls themselver adjacent to them. This was in his opinion the real nature and origin of the volcanic heat as now produced on the globe.

Although the hypothesis fails for various reasons in its application to vulcanicity, especially for the reason that the great lines of disturbances and compression of the Alps, Pyrenees, and other mountain chains are free from either active or extinct volcanoes, there is, nevertheless, reason to believe that this source of heat may have been adequate to produce great molecular changes in the rocks along the lines of disturbance and upheaval, though the extreme results obtained by entire crushing by mallet would rarely or ever occur in nature. It is, however, precisely along such lines that not only are older rocks metamorphosed, but rocks of Cretaceous and Tertiary age—which usually have not been affected by normal metamorphism—coming, in these mountain-chains, under the influence of the disturbing forces, have undergone a change analogous to that produced by normal metamorphism.

Objections have been raised to the explanation offered in some cases of alteration of sedimentary strata in mountain-chains by ordinary normal metamorphism, on the grounds that unaltered strata alternate with altered strata. Sometimes this may be explained by inversion of the strata, or, where that is not the case, it may be due to the circumstance that differences of mineral composition, or in the proportion of the water of imbibition, have caused the metamorphism to affect different beds in different degrees. On the theory of *regional metamorphism*, in the sense the author would use it, another explanation suggests itself by the way in which differences in the resistance of the rocks develop different quantities of heat. Mr. Mallet has shown by experiments on the compressibility of rocks at Holyhead that, although certain slate-rocks were compressed by precisely the same force before their elastic limits were passed, yet, owing to differences in their compressibility, the heat developed in the rocks when released would render the quartz-rock nearly three times as hot as the slate-rock. In this manner, therefore, it seems possible to account for a special and restricted metamorphism of the strata in mountain-chains, and for its frequently localised occurrence.

The remarkable changes which take place in the condition of the coal of Pennsylvania, as it ranges into the Appalachian Mountains, may also be owing more probably to *regional* than to normal metamorphism. This mountain-range consists of a series of great parallel folds increasing in acuteness as the central axis is approached. Eruptive rocks are absent, but, nevertheless, the strata as they approach the central chain become more crystalline, and the coal, which at a distance is ordinary bituminous coal, passes into anthracite and even graphite. The late Prof. H. D. Rogers divided this great coal-field into four basins. The coal in the less-disturbed district near the Ohio River, where the flexures are extremely gentle and wide apart, contains from 40 to 50 per cent. of volatile matter; in the wide basin further east it decreases to 30 or 35 per cent.; in the basins of the Alleghany range, in which, although there are no important dislocations or great flexures, there are some extensive and symmetrical anticlinal axes of the flatter form, the proportion of the volatile matter in the coal varies from 16 to 22 per cent.; while in the most easterly chain of basins which are associated with the boldest flexures and greatest dislocations, with close plications and inversions of strata, the quantity of volatile matter in the coal is reduced to 6 to 14 per cent.

A somewhat analogous instance is presented by the Carboniferous series of Belgium. The excessive squeezing, faulting, and inversion which the Coal-measures have undergone on the flanks of the axis of the Ardennes, is there accompanied by an alteration of the highly bituminous coals into dry coals and into anthracite; while the Carboniferous and Devonian limestones amidst the sharply convoluted and folded strata of the Ardennes are there, as they are also on the line of the same disturbance in the Boulonnais, transformed very generally into crystalline marbles. The few exposures of eruptive rocks are all on a small scale, and affect the adjacent rocks only by contact metamorphism. It is probable that the anthracite of South Wales is the result of similar *regional metamorphism.*

In the case of contact metamorphism the changes were produced by great heat, for the eruptive rocks must have had a temperature of 3000° to 4000° F. or more; while in the case of normal metamorphism it is evident that the changes produced did not depend so much on high temperature as on pressure or the presence of water, and there is reason to believe that a temperature of about 600° to 800° F. would suffice to produce all or almost all the observed hydrothermal effects. For although in many instances of normal metamorphism new minerals are formed, the rocks are not fused, nor are the fossils destroyed. In Brittany, black slates which pass into schists with large crystals of chiastolite still show impressions of *orthis*, *trilobites*, and other Silurian fossils. Devonian strata in the Vosges pass into a rock consisting of pyroxene, garnet, epidote, &c., and yet retain impressions of *corals*.

Of the enormous tangential pressure exercised in the elevation of these chains, some idea may be formed when we consider the amount of compression which those portions of the crust have undergone. Thus, for example, Heim estimates that in the Alps the compression has been to the extent of 72 miles; and in a recent paper by Prof. Claypole he arrives at the conclusion, after a careful investigation of the magnitude and width of each fold, that in the Appalachian Mounta ns "a tract of the earth's surface, measuring originally 153 miles from south-east to north-west, has been so crushed and compressed that its present breadth along the line of section is only 65 miles," and of this, in one part—the Cumberland Valley—"95 miles of country have been compressed into 16 miles."

These vast compressions could not have taken place without the transformation into heat of the equivalent amount of mechanical work, though the degree and centralisation of the heat would depend on the rapidity and completeness with which the crushing has been effected. It is not therefore surprising to find that, in some of the newer mountain-ranges, a small residual portion of the heat thus mechanically evolved may still exist and cause slight aberrations in the position of the underground isothermal lines, and the same cause may possibly account for other exceptional cases.

The only sufficiently complete set of observations on a mountain-chain of this character that have yet been made are those before alluded to by Dr. Stapff in the St. Gothard Tunnel. The author has before given, in his paper on "Underground Temperatures," particulars of these observations, and therefore here only mentions that at the north end of the tunnel in the part where an axis of elevation of late geological age (Pliocene) traverses the range, the thermic gradient, which normally equals about 57 feet for 1° F., is there not more than 38 feet; and for this Dr. Stapff states that there was no obvious explanation.

The author concludes by expressing a belief that there exists, in the compression and motion of the strata which has always accompanied the upheaval of mountain-chains, a *vera causa* for the production of an amount of heat sufficient to produce one form of metamorphic action—a form which can affect only particular regions—and he would, therefore, in order to show its distinctiveness from either *contact* or *normal* metamorphism, designate it by the term of "*Regional Metamorphism*."

Physical Society, June 13.—Prof. Guthrie, President, in the chair.—On the winding of voltmeters, by Profs. W. E. Ayrton and John Perry. As it is most important that voltmeters, ohmmeters, powermeters, and ergmeters should be so constructed that the percentage increase of resistance of their fine wire coils due to the heating effects of the currents passing through them should be as small as possible, the question arises as to whether such coils should be made of German silver wire, or of copper, or partly of German silver and partly of copper wire, and how the diameter of the wire should vary in different parts of the coil. The authors have therefore been led to investigate the conditions that make this heating error a minimum with cylindrical coils of internal and external radii r_0 and r_1. At a place whose distance from the axis is r, let the cross-section of the wire be x_1, ρ the specific resistance of the material; then, assuming that $x = x_0 r^a$, $\rho = \rho_0 r^b$, $\rho r = \rho_0 r_0 r^c$, and that a current, C, in one spire of radius r produces a magnetic effect, KCr^d, on the supended needle, they find that the heating error is proportional to

$$r_0 \rho_0 \frac{p^2}{(r_1^p - r_0^p)^2} \cdot \frac{n}{r_1^n - r_0^n} \cdot \frac{r_1^m - r_0^m}{m},$$

where $p = d - a + 1$, $n = 2 + b - 2a$, $m = 2 + 1·7144 b - 4a$. The conditions that make this expression a minimum are worked out in the paper, the result being that with one of their magnifying spring solenoid instruments, where $d = -1$, the values of a and b giving a minimum value are $a = 0·325$ and $b = -0·5$, and since in practice b cannot be negative, they conclude that $b = 0$ and $a = ·4$ give the best results—*i.e.*, that all the wire employed in the bobbin should be of copper, and the law of increase of cross-section proceeding from the centre should be $x = x_0 r^{0·4}$. The actual waste of energy in the instruments is next considered, and, lastly, the authors show how to pass from a voltmeter with known winding, and whose maximum reading is P_1 to another of the same volume and shape whose maximum reading is to be P_2, and they conclude that, as they have shown that the waste of energy is the same in both for their maximum readings, the resistances of the instruments must be proportional to the squares of P_1 and P_2, or, following the law already arrived at for a minimum error due to heating, the cross-sections of the wires of the two instruments at similar places must be inversely proportional to P_1 and P_2. The employment of outside coils for voltmeters is considered, and it is shown that if we desire the same error in the two instruments due to heating when the outside resistance coils are of the same size and shape, it is necessary to have the same ratio between the resistance of the resistance coil and that of the magnetising coil in the two cases. To have a less or a greater error in the second case it is only necessary to use the equation—

$$e\text{(the error)} = \frac{2 + F.V}{1 + F.V},$$

where F is a constant and V the volume of the German silver resistance coil. From this V may be determined and the ratio $\frac{R_1}{R}$ of the resistances of the resistance coil and the magnetising coil is given by $\frac{R_1}{R} = \frac{F}{D} V$, where D is a constant which, like F, is obtained from experiments on the first instrument. The diminution of the heating error by using much iron in the instrument so as to obtain the same magnetic action with a much smaller current is discussed, and experiments were shown to illustrate how such employment of iron introduced a permanent magnetism error and caused the indications of such an instrument on the lower part of the scale to be uncertain and to depend upon whether measurements were being made with an increasing or a diminishing current.—On the manner in which light affects the resistance of selenium and sulphur cells, by Mr. Shelford Bidwell. In a communication made to the Society at its last meeting, the author had described a sulphur cell which behaved in all respects like a selenium cell when exposed to light. The action of this cell was supposed to be electrolytic, the sulphur containing a small quantity of sulphide of silver. If this were the case the result of a current traversing the cell would be to deposit sulphur upon the anode, and, as sulphur has an enormous resistance, that of the cell would increase unless the sulphur thus deposited combined with the silver. It is this combination that is believed to be much facilitated by light, a supposition the author believed he had confirmed by direct experiment. Mr. Bidwell had also measured the resistance of a piece of selenium that was believed never to have been heated in contact with a metal. The specimen was crystallised by heating for some time in a glass mould, two opposite sides cleaned, and two pieces of tinfoil between which the resistance was measured pressed against them. In this way the specific resistance was found to be 2500 megohms, which is enormously higher than that of the selenium in the "cell," a fact tending to confirm the theory that the conduction in such cells is due to the electrolysis of the selenides of the metals forming the terminal produced in the "cooking," and similar to that of the sulphur cell described above.—On the error involved in Prof. Quinke's method of calculating surface tensions from the dimensions of flat drops and bubbles, by Mr. A. M. Worthington. In a series of well-known papers Prof. Quinke has recorded a large number of measures of flat drops and bubbles, from which he has deduced the values of tensions for the free surface of a liquid and for the common surface of two liquids in contact. The numerical results obtained in this way exceed those obtained from observations upon the rise in capillary tubes, which Prof. Quinke attributes chiefly to the fact that in the latter case the edge angle is not zero. Mr. Worthington, however, shows that the surface tensions obtained by Prof. Quinke with flat drops are too high, this arising from his having assumed that the drops were flat at the vertex. The error thus introduced is very considerable, amounting in most cases to as much as 10 per cent. of the whole value, and upon its being duly corrected, the values obtained do not appreciably exceed those obtained with capillary tubes.—On a comparison between the mercury standards of resistance issued by M. Mascart with those of the British Association, by Mr. R. T. Glazebrook.

Anthropological Institute, June 23.—Francis Galton, F.R.S., President, in the chair.—The election of the following new members was announced.—Prince Roland Bonaparte, Lady Brassey, Miss M. North, Dr. Robert Brown, M.A., Col. Cadell, V.C., C. Heape, H. H. Johnston, D. MacRitchie, Prof. H. N. Moseley, F.R.S., C. Seidler.—Lady Brassey exhibited a collection of objects of ethnological interest from Polynesia.—Several ethnological specimens from New Ireland were exhibited by Miss North.—Mr. Carl Lumholtz exhibited a series of Australian implements.—Mr. H. B. Guppy read a paper on the physical characteristics of the natives of the Solomon Islands. In this paper the author gave the results of observations made during the years 1881-84 on the natives of certain localities in the Solomon group. The typical Solomon Island native (male) is well proportioned, with a height of about 5 feet 3 inches, a weight of 125 to 130 lbs., and a chest-girth between 34 and 35 inches, whilst the colour of his skin is a deep brown, corresponding with colour-type 35 of M. Broca. Considerable variety. however, prevails in the physical characters of these natives, and it was shown, by comparing the inhabitants of the islands of Bougainville Strait with those of St. Christoval and its adjoining islands at the opposite end of the group, that in the former locality there exists a taller, darker, and more brachycephalic race, whilst in the latter mesocephaly prevails, and the average native is rather shorter and of a lighter hue. The colour of the skin varies considerably throughout the group from a very deep brown to a light copperish hue, the range being represented by colour-types 42 and 29 with their intermediate shades. After making 109 measurements of the heads and skulls of natives in order to obtain the ratio of the transverse to the longitudinal diameter, the author arrived at the conclusion that, although mesocephaly and brachycephaly most frequently characterise these people, the form of the skull varies between too wide limits to allow of one particular type being referred to this group. The range of the cephalic indices calculated from these measurements is 69 to 86, and the greater number are gathered in two groups—one around the indices 74 and 75, and the other around the indices 79 and 80.—The following papers were also read:—On the Sakais, by Mr. Abraham Hale.—Notes on the astronomical customs and religious ideas of the Chokitapia or Blackfeet Indians, by M. Jean L'Heureux.—Observations on the Mexican zodiac and astrology, by Mr. Hyde Clarke.—On the primary divisions and geographical distribution of mankind, by Mr. James Dallas.

Entomological Society, June 3.—R. McLachlan, F.R.S., President, in the chair.—Two new members were elected.—Exhibitions: Mr. F. P. Pascoe, aërial roots of an orchid which resemble caterpillars; and a new genus and species of *Colydiidæ* from North Borneo.—Mr. G. T. Porritt, larvæ of *Phycis betulæ* and of *Coleophora currucipennella*.—Mr. R. McLachlan, a specimen of *Deiopeia pulchella* captured on board ship in the Atlantic, many miles from land.—Mr. J. W. Douglas communicated notes on an apple-tree destroyed by *Schizoneura lanigera* and *Mytilaspis pomorum*, and Mr. F. Enock read the completion of his account of the life-history of *Atypus piceus*.

PARIS

Academy of Sciences, June 22.—M. Bouley, President, in the chair.—At the opening of the proceedings the President announced the death of M. Tresca, member of the Section for Mechanics, who died on June 21, and in whom the Academy loses one of its most distinguished and active associates.—Note on Dr. Raphael Dubois' apparatus for applying anæsthetics composed of titrate mixtures of chloroform and air, by M. Paul Bert. This apparatus has been tried with the greatest success in Brussels and Ghent, and especially by Dr. Péan of Paris, who has already tested its efficiency in 400 surgical operations. The anæsthesis in nearly all cases continues perfectly regular and complete, without any interruption, even under severe operations. The pulse remains normal, the respiration easy and undisturbed, the awakening calm and natural.—On the superiority of the new "tubes à ailerons" over the ordinary smooth cylinders at present employed in tubular boilers for generating steam, by M. J. Serve. The author and inventor claims by these cylinders to have solved the problem how to produce the greatest quantity of heat with the least expenditure of fuel.—On an arrangement by which the magnetic potential due to a system of bobbins may be determined without calculation, by M. G. Lippmann.—Note on the influence of thunderstorms on underground telegraphic wires, by M. Blavier. The occasional disturbances, to which even well-protected underground wires are subject, apparently in opposition to the theory of static electricity, the author thinks may be explained either as an effect of electrodynamic induction, or as an effect of electrostatic induction.—On the molecular lowerings which constitute the limits of congelation for bodies dissolved in water, by M. F. M. Raoult.—Description of two new types of hygrometers, by M. Bourbouze.—On the transformation of sulphur: MM. Reicher and Ruys' claims of priority of invention in connection with M. Gernez's recent communications, by M. J. H. Van't Hoff.—Alkaloids produced by the action of ammoniac on glucose, by M. C. Tauret.—Action of the seleniates and selenites, and the alkaloids. A new reaction of codeine, by M. Ph. Lafon.—Note on Aseptol (orthoxyphenylsulphurous acid), by M. E. Terrant.—Contribution to the study of antiseptics. Action of antiseptics on the higher organisms. Thymic acid, by MM. A. Mairet, Pilatte, and Combemale.—On the process of fructification of the genus Callipteris, by M. Ed. Bureau.—On the infusoria by Balbiani named *Anoplophyra circulans*, by M. A. Schneider.

CHRISTIANIA

Society of Science, May 15.—Herr Worw-Müller referred to the meritorious work of the recently-deceased Danish Prof. Panum. as regards physiology as well as pathology. He further presented a paper in which he demonstrated the utility of Robert's method for the determination of sugar in animal substances when above 0·4 per cent. Finally he explained the researches made by Herr J. Otto on the functions of the sugar in the liver. He stated that they proved that the blood contained far more sugar on entering than on leaving the liver, and more than the blood in general. The researches went to support M. Bernard's experiences, viz., that the quantity of sugar formed in the liver in the course of twenty-four hours was much larger than hitherto thought.—Prof. O. Sars presented a paper: "A contribution to the Norwegian invertebrate fauna," by Herr C. A. Hansson.

THURSDAY, JULY 9, 1885

THE INTERNATIONAL SANITARY CONFERENCE IN ROME

THE late Conference in Rome, which for some unknown reason stands adjourned for the present to reassemble again in November, has arrived at certain results, the details of which are not published yet, and until the full and authenticated report is at hand it would be unjustifiable to subject them to criticism. But as far as the gross results achieved and the methods followed by that Conference have already become known through the reports sent to the daily papers, there is no reason for viewing those results with any peculiar satisfaction. As far as we can follow the proceedings of the Conference, its achievements cannot be considered an advance on those of its predecessors held in Constantinople in 1866 and in Vienna in 1874.

During the present century Europe has been visited six times by cholera, and after the second visitation (1847-50) the first International Sanitary Conference was convened to Paris in 1851, in order to arrive at some common understanding as to quarantine, and to discuss various questions of hygiene, as well as the etiology of the disease.

Between 1852-56 Europe was again visited by cholera (England in 1853-4), and very important knowledge was then gained as to the intimate relations existing between general insanitary conditions and the spread and severity of the disease. After the next visitation of Europe by cholera (in 1865-6) the second International Sanitary Conference met at Constantinople (in 1866). The results of the deliberations of this Conference have been in many respects important. The Conference agreed, with few dissentients, that cholera has for its starting-point India; that its invasion into other countries is effected by human intercourse, including linen and wearing apparel; that its spread depends in a great measure on general insanitary conditions of habitation, air, water, and food. In order to avert and check the invasion of Europe by the disease, the Conference agreed to a certain complicated system of quarantine both by land and sea, which embodied and enlarged on the scheme laid down by the preceding Conference of 1851, but which had been found incapable to avert the introduction of the disease in 1865-6.

Next cholera appeared in Europe in various countries between 1869-73, and after the epidemic came to an end another International Conference assembled in Vienna in 1874. This Conference, while confirming the results of the deliberations of its predecessors, arrived at certain important conclusions as to the value of disinfection and quarantine. As regards the latter the Conference agreed that all measures of quarantine, as far as they are practicable, are fallacious and incapable of averting or checking the introduction and spread of the disease; that all measures of land quarantine are to be condemned; and that maritime quarantine is to be replaced by competent medical inspection. Cholera appeared next in Egypt in 1883, and from here was introduced into Marseilles, where it assumed, in July 1884, alarming proportions; thence it spread into Toulon, the south and north of France, into Italy and Spain, raging everywhere with great severity. If at any time land and maritime quarantine had a fair trial it was in 1884 in France, Italy, and Spain. Every one remembers the dictum of M. Fauvel, then at the head of medical affairs in France, that the disease that broke out in 1884 in Marseilles and spread thence into Toulon and other parts of France could not be Asiatic cholera, because quarantine, after the appearance of cholera in Egypt in 1883, had been very perfect and had been carried out in French maritime ports with great rigour. Every one remembers also that, in spite of all the measures of land quarantine practised in France, Italy, and Spain in 1884—and at the present moment practised in Spain—its lazarettos, fumigations, and military cordons with its attendant troubles, miseries, and cruelties, cholera spread and raged with great severity in France and Italy, and is at the present moment assuming alarming proportions in the eastern and south-eastern parts of Spain; while, on the other hand, this country, without any maritime or land quarantine, but with an efficient and competent medical inspection of all shipping in its maritime ports, has remained free from cholera in 1884 and hitherto, notwithstanding its vast communications with Egypt, Italy, and Spain. Maritime and land quarantine have had a repeated and fair trial, but have been found utterly wanting, and countries like France, Italy, and Spain placing the utmost faith in them have dearly paid for it. Now, what lesson is to be learned from all this, and let us ask at the same time what lesson has the late Conference in Rome learned from this?

The Conference of Constantinople (in 1866) had adopted ten days as the furthest limit of the period of incubation—that is to say, if any ship coming from an infected part had been at sea for ten days and no case of cholera has appeared on board, the ship is to be considered "clean" and is to receive free *pratique*. Now, steamers sailing from Bombay arrive under favourable conditions off Suez on the eleventh day, and therefore if no cholera has appeared during the whole of the voyage, the ship ought, according to the above, receive free *pratique*. But instead of this every ship is detained and kept under "inspection" for at least twenty-four hours at Suez, at the instance of the Egyptian authorities acting under the instructions of the General Board of Health. The majority of the medical members of the late Conference at Rome carried this still further in recommending that all ships coming from India should be detained and kept under inspection at Suez for five days, some delegates even for ten days. Another still more iniquitous recommendation, and one which, if carried into practice, is likely to have serious consequences for Egypt and Europe, is this: that if any "suspected" ship—the decision as to this "suspicion" resting with an Egyptian official of self-estimated competency—arrive off Suez, the passengers and crew are to be turned out into lazarettos, kept there under observation, disinfected, &c. Now, the Conference, in order to establish a permanent focus of cholera from which the disease might, and in all probability would, spread into Egypt and the adjoining countries, the Mediterranean Basin and Europe, could not have recommended any arrangement that is more likely to further such a hazardous and dangerous object. In vain did Dr. Thorne, one of the English delegates, urge at the Conference the iniquity and danger of this recommendation. The French delegates leading the majority turned a deaf ear to any reasonable suggestion; they seem to have learned no lesson from the misery that lazarettos, fumigations, and all other measures of land quarantine, without stopping the introduction and spread of cholera, have in the past inflicted on their country.

If we ask ourselves, What new facts, what new experiences have in the last cholera epidemic in 1884 been gained in order to justify these recommendations of the majority of the Conference? we have to answer—None; and those that have become known point in the opposite direction. The recommendation as to five to ten days' quarantine off Suez for ships coming direct from India seems to imply that the late outbreak of cholera in Egypt owed its origin to importation from India. This view has during 1883-84 been stated and re-stated by French writers with their usual self-confidence, but not a tittle of evidence has been brought forward to support it. Moreover there exists a good deal of evidence showing that that outbreak, which, as is well known, commenced in Damietta, owed its origin to importation from an altogether different direction—viz., overland by pilgrims from Mecca. As Prof. Lewis, another delegate from England, has urged at the Conference, no English ship coming from India has ever been known to have imported cholera into Egypt and Europe; and, considering the enormous number of vessels arriving from Indian ports in Egypt, the Mediterranean countries and Europe, it is certainly a very remarkable fact that importation, if it happened in this manner, should not be of common occurrence.

The real danger from cholera for Egypt, Turkey, and Europe does not lie at Suez and the Suez Canal, but at Mecca and the countries about the Caspian Sea, this being the route in which cholera has hitherto travelled—viz., from Mecca, Mesopotamia, and Persia, into the Red Sea coast, Egypt, Syria, the Levant, Turkey, and Russia—and therefore these are the portals, if any, which the European Powers ought to guard. As England has urged in the past, and as it has also urged on this occasion, every country may, and has a right to protect itself as it thinks best. France and Spain may make their own maritime quarantine as rigorous, their land quarantine as vexatious as they choose; but that these countries should dictate measures to others, which past experience has proved to be fallacious and futile to achieve the end they aim at, is as iniquitous as it is against common sense.

Cholera in Europe being dependent on importation from the East, it is quite clear that absolute prevention of such importation would theoretically be the best safeguard; but then the question arises, and it is one that has been repeatedly asked—viz., can this be practically achieved? To stop unconditionally every and all communication with an infected locality involves, apart from the great practical difficulties in carrying it out, such enormous hardships, material loss and misery, that the remedy would entail greater misfortunes than the evil it tries to cure, even granting, for the sake of argument, that it is capable of so doing.

Prof. von Pettenkofer in his various writings on the subject of quarantine has fully and clearly stated the case, and their perusal would have materially enlightened many of the members of the late Conference. They would also find in those writings what they might have found already in the protocols of the former conferences (in Constantinople and Vienna), viz. that one of the *chief* and *first duties* of the State in order to prevent and check the spread of cholera is a *proper attention to general sanitation*. Make your military cordons as strict as you please, stop and impede all traffic by sea and land as much as you like, fumigate your railway travellers and mails as carefully and rigorously as possible, you will not hereby succeed in stopping all communication with an infected country. On the other hand, give up all those silly and harassing limitations, but keep a good look-out for infected ships coming to any of your ports, detain the infected persons in a specially-fitted hospital, disinfect the ship and articles, but allow the rest of the passengers and crew to depart, keeping their names and addresses, and notify their arrival to the sanitary authorities of the place they are bound to. Further than this, see that your dwellings, your water and air are in sanitary respects looked after, and that filth is properly disposed of, and you will hereby have done what is compatible with all past and present experience in order to check the entrance and dissemination of cholera. It is admitted on all hands that general insanitary conditions of dwellings, water, and air are the most powerful allies of cholera; without them, cholera is as unable to spread as typhoid fever.

The principles just mentioned are practically those on which the sanitary authorities in this country have been acting in the past, and on which they are acting in the present. The danger to this country from importation of cholera from Spain is greater than perhaps to any other, seeing the vast maritime communications existing between this country and the east and south coast of Spain; but there can be little doubt that, if cholera should unfortunately be imported, it can never assume those gigantic proportions that it has assumed in France, Italy, and that it is now assuming in Spain.

If one reads of the unspeakably filthy conditions prevailing in Spain, and reads at the same time of the silly and arbitrary proceedings of the authorities in carrying out quarantine, one is reminded of the General who, in trying to keep out a powerful enemy is putting up on the frontier a few dummy soldiers and toy guns, but who has omitted to provide the interior of the country with a real army and guns. The result is, of course, clear: the enemy cannot be prevented from entering, and, having entered, cannot be kept from overrunning and devastating the country.

A NATURALIST'S WANDERINGS IN THE EASTERN ARCHIPELAGO

A Naturalist's Wanderings in the Eastern Archipelago, a Narrative of Travel and Exploration from 1878 *to* 1883. By Henry O. Forbes, F.R.G.S. With numerous Illustrations. (London: Sampson Low, Marston, Searle, and Rivington, 1885.)

MR. FORBES' Wanderings in the far East extended over about four and a half years, during which time he visited the Keeling Islands, Java, Sumatra, Amboyna, Timor Laut, Buru, and Timor. In Java, Sumatra, Buru, and Timor he made extensive inland journeys through districts rarely or never before visited by European naturalists; and as he everywhere collected assiduously and observed intelligently, the record of his travels is exceedingly interesting. His special studies were botanical and ethnological, and in these departments he has added much to our stores of knowledge. His observations on the manners and customs, the myths and superstitions of the various tribes among whom he resided or travelled will be of great value to anthropologists, owing to the wide range of his observations and the time and trouble he devoted to the inquiry. In zoology he did not collect largely, and indeed it was simply impossible for him to do so, since the continuous labour and attention needed to form a well-preserved herbarium in the damp equatorial climate and while almost constantly moving about, leave the traveller but little leisure to devote to other departments of natural history. To collect effectually in any wild tropical country, the naturalist should settle himself for at least six months at a time in a good central position from which short excursions in various directions can be made; and if these head-quarters are well chosen it is possible to obtain an almost perpetual "fine season," and thus greatly increase both his collecting power and his personal enjoyment.

Mr. Forbes appears to have had rather more than his fair share of accidents to his collections, and in every case what was lost was of especial interest. His insect collection from the Keeling Islands was destroyed on the way back to Java, and we thus lose the opportunity of comparing the list with that made by Mr. Darwin more than forty years before. In Timor Laut a large part of his herbarium was destroyed by fire, while a smaller collection made in the interior of Buru was actually left behind for want of porters to carry it. The Timor Laut collection is especially to be regretted, as it was obtained with great difficulty in perhaps the least known island of the whole archipelago, while it is probable that many years will elapse before any other naturalist will venture to explore so remote and inhospitable a country.

Mr. Forbes' residence for three weeks in the Keeling Islands enabled him to note what changes had occurred since Darwin's visit nearly half a century earlier. These are very slight, and seem incompatible with the theory that any subsidence has taken place, because the inner margin of some of the islands next the lagoon are sometimes half a mile distant from the outer edge, and the greatest cyclones do not carry the coral *débris* nearly so far. It is now generally admitted that the celebrated "subsidence theory" of the formation of atolls and barrier reefs is unsound as a general explanation of the facts; yet it so fully and plausibly explained all the details of coral structure known at the time, as to command universal acceptance and unbounded admiration. We have here a remarkable instance of the danger of founding a general explanation of widespread phenomena on an assumed basis, for the fact of long-continued subsidence, which was the very foundation of the whole theory, was in most cases quite incapable of proof. It is also now apparent that the theory was to some extent inconsistent with the views as to oceanic islands which Darwin himself originated and which are now generally admitted to be sound. His great argument, that no single oceanic island possessed ancient stratified rocks or contained a single indigenous mammal, was equally an argument against the view that the widespread coral archipelagoes of the Pacific and Indian Oceans were due to the subsidence of co-extensive tracts of land, since it is almost impossible that all the higher points of these submerged lands, spread over nearly half the surface of the globe, should be without exception of volcanic origin.

Crabs of two or three species were the most abundant terrestrial inhabitants of the Keeling Islands living in narrow corkscrew burrows, which are so numerous that one hundred and twenty of their holes were counted in an area only two feet aquare. Around these holes little mounds are formed, and the crabs carry into their burrows twigs of trees, pieces of seaweeds, seeds, &c., thus fulfilling in many ways the functions of earthworms in this newly-formed land. Their numbers are enormous, and Mr. Forbes thus describes the curious optical effect produced by them:—

"On placing the foot on the region occupied by them, one perceives an undulation of the surface followed, over a circular area, by a surprising change of the pure white ground into a warm pink colour, which for the moment the stranger puts down to some affection of his eyes from the reflection of the light. He soon perceives that this movement is caused by the simultaneous stampede of the dense crowd of the peopled shore into their dwellings, just within the door of which they halt, with the larger of their two pincer-claws, which is of a rich pink colour, effectually barring the entrance except where one watchful stalked eye is thrust out to take an inquiring look if the alarm is real. As one advances the pink areas again change into white, as the Crustaceans withdraw into their subterranean fastnesses. On traversing a broad field occupied by these crabs, the constant undulations and change of colours produce a curious dazzling effect upon the eyes."

During his long residence in the mountains of Java, Mr. Forbes made many interesting observations on the fertilisation of orchids. He was surprised at the large number of these plants which, though often possessing the combined attractions of showy flowers and fragrant odours, yet never or rarely produce seed-capsules. In one case, for example, out of 360 flowers examined till they withered or dropped off, only six produced capsules. Again, he finds a considerable number of species with showy flowers which are yet specially adapted for self-fertilisation and never seem to be visited by insects. The most extreme and marvellous example of this phenomenon is found in a plant related to *Chrysoglossum*, which fertilises itself without ever opening its flowers at all. Mr. Forbes observed these plants in the forest as well as in numerous specimens grown in a garden, and all were fertilised in the same way; and he adds:—"In opening the locked-up petals, I found the labellum beautifully marked with lines of purple, carmine, and orange, and the column also; but no insect eye could ever be fascinated or allured by its painted whorls."

These observations are of extreme interest, and they certainly prove, as Mr. Forbes remarks, that the rule "that the flowers of orchids are fertilised by the pollen of their flowers," is by no means so universal as has been supposed. Yet the phenomenon does not seem so extraordinary if we look upon it as one of the normal phases in the developmental life-history of species. The overwhelming amount of evidence which has now been obtained of adaptations for cross-fertilisation, not in orchids only, but throughout the whole series of flowering plants, and the almost constant association of conspicuous form, colour, and odour with adaptations for insect fertilisation, force us to the conclusion that in almost all the cases adduced by Mr. Forbes we have species which were once adapted for insect-fertilisation. But in the terrific struggle for existence ever going on in tropical regions, insects are subject perhaps more than any other group of organisms to excessive fluctuations of numbers, sometimes culminating in the complete extermination of species; because they are equally liable to severe injury by physical and organic causes—by adverse seasons which destroy them in some of their earlier stages, or by the excessive attacks of insectivorous animals in both their larval and perfect states. It must therefore often happen that certain species of insects almost disappear in districts where they are usually abundant, and if any particular plant has had its flowers so highly specialised as to be adapted for fertilisation by one of these insects only, it must become extinct unless it occasionally produces varieties which are capable of self-fertilisation. The species of orchids in which a very small percentage of flowers produce seed capsules are evidently those in which the special insects adapted to fertilise them have become either temporarily or permanently scarce, and if that scarcity goes on increasing one of three things must happen—either the flower must become modified so as to be fertilised by some more abundant insect, or it must become capable of self-fertilisation, or it must become extinct. No doubt all these three cases occur, but it is of the second alone that we can obtain any knowledge, because we there find, as in our own bee-orchis, the special attractions of conspicuous form and colour which have yet ceased to be of service to the species. But no naturalist can doubt that these attractions were once serviceable; and we are thus led to conclude that all such instances are forms of functional degeneration which under changed conditions of the environment have afforded the only means of preserving the species.

Mr. Forbes's record of his thirteen months of travel in Sumatra are perhaps the most interesting portions of his book. He here met with some of the most marvellous productions of the vegetable kingdom—strange parasitical Rafflesiaceæ, an eccentric fig which ran underground and there produced its fruit, just showing their tops above the surface, and the giant arum (*Amorphophallus titanum*), some of which were seventeen feet high and with tubers six feet six inches in circumference. In the same forest huge earth-worms raised tubes of mud four and a half inches in circumference and eight inches high; and were so numerous as to render the whole surface of the ground as rough and hummocky as that of a newly-ploughed field. Here too, as well as in Java, he found a wonderful case of mimicry in a spider which deceived him even a second time; and he here obtained the rare *Ornithoptera brookeana*, perhaps the most chastely beautiful of all butterflies. Grand mountains, active volcanoes, glorious forest scenery, strange antique monoliths, and many interesting races of men, combine to render Sumatra one of the finest hunting-grounds yet left for the naturalist, while over the greater part of it there are facilities for travel or for residence rarely to be found in so little known a country.

In his later and more adventurous explorations of Timor Laut and Timor, Mr. Forbes was accompanied by his wife, a lady who seems to have endured all the annoyances, privations, and dangers of such a journey with truly heroic fortitude. Although these islands are far less known to naturalists than almost any other part of the Archipelago, they seem comparatively poor in a natural-history point of view. A considerable proportion of the birds and butterflies of Timor Laut were new species, but the collections were scanty, and there is, no doubt, much still to be done there if a collector could freely explore the country and not be confined, as was Mr. Forbes, to a limited tract owing to tribal warfare. One of the interesting discoveries here was another example of mimicry among birds, in which a new species of oriole mimics a new honeysucker, just as do corresponding species in Ceram, Buru, Gilolo, and Timor. A most interesting case of protective colouration was also observed in the white-headed fruit-pigeon of Timor (*Ptilopus cinctus*). These birds sat motionless during the heat of the day in numbers on well-exposed branches, yet Mr. Forbes states that it was with the greatest difficulty that either he or his sharp-eyed native servant could detect them, even in trees where they knew they were sitting. The strongly-contrasted white and dark colours of this species are such that any person looking at a specimen in a museum might take it as an example of a defenceless bird with very conspicuous plumage, and might ask triumphantly how our theory of protective colouration can be applied here. Yet it turns out that these strongly-marked colours so exactly harmonise with the colours of the branches of the trees on which it sits, exposed to the glare of the tropical sun, as to be completely protective; and we thus have another illustration of the impossibility of forming any correct judgment on this question unless we are able to observe each species in its native country and among the exact surroundings to which it has become adapted.

The hasty journey through the interior of Timor, among strange scenery and strange people, is full of interest. Most of the mountain tops, where alone a rich and interesting vegetation was to be found, were strictly taboed, and it was often only by stratagem that specimens were collected; while the difficulties of travel in a country absolutely without roads and consisting almost wholly of an endless series of rugged mountains and deep valleys were exceptionally great.

The book is on the whole very well written, and will give the reader an excellent idea of some of the less known parts of the Malay Archipelago. The weakest part of it are the illustrations, which, though numerous, appear to be for the most part reproductions of rough sketches by some unsatisfactory process of photo-zincography. For this the author was probably not responsible, but his readers will regret that the strange and beautiful scenery he has so graphically described is not more effectively presented to the eye. The portraits of many of the natives are, however, very well done, while several good maps and a full index greatly add to the value of the book as a useful work of reference.

ALFRED R. WALLACE

FIVE ELEMENTARY TEXT-BOOKS OF HYGIENE

A Manual of Health Science. Adapted for Use in Schools and Colleges and suited to the Requirements of Students preparing for the Examinations in Hygiene of the Science and Art Department, &c. By Andrew Wilson, F.R.S.E., F.L.S. (London: Longmans, Green, and Co., 1885.)

The Laws of Health. By W. H. Corfield, M.A., M.D. (Oxon.). (London: Longmans, Green, and Co., 1880.)

Principles of Hygiene. Expressly Adapted to the Requirements of the Syllabus of the Science and Art Department, South Kensington. By Albert Carey, F.R.G.S. (London: Thomas Murby.)

Hygiene. Its Principles as Applied to Public Health. Adapted to the Requirements of the Elementary and Advanced Stages of the Science and Art Department, the Sanitary Examinations at the Universities, &c. By Edward F. Willoughby, M.B. Lond., San. Sci. Cert. Lond. & Camb. (London and Glasgow: W. Collins, Sons, and Co.)

Hygiene: a Manual of Personal and Public Health. By Arthur Newsholme, M.D. Lond. (London: Geo. Gill and Sons, 1884.)

THESE works are partly if not principally intended for the use of students of the Science and Art Department, South Kensington. It is very essential, therefore, that not only should the matter be put in a pleasant and readable form, but that there should be no serious errors, as students of elementary works cannot be expected to recognise errors as such, from any knowledge they may possess on allied subjects. In fact they, and many others besides, find a difficulty in conceiving that what is printed in a book need not necessarily be correct. It is also necessary that the chapters should be well arranged, with the matter well assorted under headings, and that nothing of importance should be omitted.

"A Manual of Health Science," by Andrew Wilson, F.R.S.E., F.L.S., cannot be said to be in agreement with the above principles. Many of the chapters are ill-arranged, and important points are omitted, especially in the chapter on Removal of Waste. It is not by any means free from errors, of which we may cite a few as specimens: thus on p. 20 it is stated that "the solids" of the gastric juice "amount to over 990 parts per 1000, the remainder being water;" if such were really the case, the juice instead of being a liquid like water, would be a solid of a very dense character. Again, on p. 80, "the cistern" for drinking water "becomes a necessary article of furniture in our houses on any system," whereas the chief advantage of a constant supply is that cisterns for drinking water are unnecessary. Again, at p. 91, it is stated that "each individual exhales about ·6 cubic foot CO_2 per 24 hours" instead of per hour. At p. 112 we find that "propulsion draws foul air out, and aspiration drives fresh air in." There are several other misstatements, but the above will suffice. An unnecessary amount of space is devoted to soaps and hair-washes. The notice of a soap of a particular manufacturer in a work of this class is, we think, undesirable as having somewhat the character of an advertisement. The illustrations, which are numerous, are very good.

"The Laws of Health," by Prof. Corfield, M.D., is a very valuable little work, and although not originally intended to form a class-book for the Science and Art Department, is admirably adapted for this purpose. It contains nearly all that it is necessary to know in a very small compass, and bears throughout the impress of the high scientific attainments and practical knowledge of the author. The chapter on Small-Pox and Vaccination is especially good, and its arguments very convincing.

"The Principles of Hygiene," by Albert Carey, F.R.G.S., is only of use for the first or elementary stage in Hygiene of the Department, although it is not so stated in the preface. The book is without illustrations, a great drawback to elementary students; and a good deal of space is devoted to matters of only secondary importance. It is therefore but moderately suited for the class of readers for whom it was written.

"The Principles of Hygiene," by E. F. Willoughby, M.B., S.Sc.C. Lond. & Camb., is intended for the use of students of all three stages of the Science and Art Department. It is also very well suited for the preparation of candidates for the University Examinations in Public Health. We can speak highly of this work, which contains sound and useful information on every subject necessary for the above courses, and is well up to the latest improvements and most generally received opinions in the science of which it treats. In our opinion it is perhaps better adapted for the advanced and honours students than for the elementary, as some parts intended for the latter are somewhat needlessly complex. The chapter on Vital Statistics is likely to be extremely useful to the University candidates, this somewhat difficult subject being here ably and intelligently treated.

"Hygiene, a Manual of Personal and Public Health," by A. Newsholme, M.D. Lond., is very well suited for students in the elementary and advanced stages. They will find here all that they require to know in an easily assimilable form. We do not, however, agree with Dr. Newsholme in thinking the "Banner" system of drainage one to be recommended, and our opinion coincides with that of several practical sanitarians. In every other respect the subject is ably treated by the author, and his work deserves a wide circulation amongst the science teachers of the country.

OUR BOOK SHELF

Euclid, Book I.; with Notes and Exercises for the Use of Preparatory Schools and Candidates preparing for Naval Cadetship and Sandhurst Preliminary Examinations. By Braithwaite Arnett, M.A. (Cambridge: Deighton, 1885.)

As the examinations for which this work is intended to prepare pupils rigidly require what are called Euclid's proofs we have here merely an edition mainly on the lines of Simson's text. This text is so presented that the pupil may see how to write out his "props" in such a way as shall please the examiner. Everything is done that can be done by another to secure success. That the pupil may not be physically incommoded more than is absolutely necessary the text is so printed as to involve the minimum of exertion.

On the sinister page of the open volume behold the text printed as the dreaded examiner desires to see it broken up, each new step in the reasoning claiming a fresh line, the figure correctly drawn (a really important matter), and to every page its own private "prop." These are merits which the editor can rightly appropriate to himself (which he does in his Preface).

On the dexter page, *in ordine longo*, come the "references," saving the pupil the horrid nuisance of turning back (as he lies prone on the ground) to see what "def. 15" is, and this kind (?) action is carried on to Prop. 48. So that if this one definition had obtruded itself into each proposition, it would have been printed forty-eight times and ever would it have greeted the student with a cheery "Here we are again!"

But this is a fault—unless all the first book could be printed on one side of a not too unwieldy page—which Mr. Arnett's book must be content to share with our "Revised Bible" references to such words as "slave" for the A.V. "servant."

Below the "references" come a very copious collection of riders. We have looked at the ludicrous side of matters, but it would be doing Mr. Arnett a very great injustice if we confined our attention to all the conveniences he has got together to ease the work of this class of students, of whom (*horres cimus referentes*) we have had experience in time past, in getting up this particular subject.

Throughout there is plenty of judicious explanation and illustration: the theorems are grouped in sections of subject-matter, as direct and converse theorems, so are the problems in sections, and there is a genealogical chart for the first twenty-six propositions. In fact nothing is scamped.

To return to the dexter page, the riders are exceedingly varied and well-grouped, and are calculated to draw out the intelligence of a thoughtful pupil if such an one uses the book.

If the first book of the glorious "Elements" must be edited at such length, we commend Mr. Arnett's edition to those who require such "props" as are here supplied, feeling convinced that if they cannot master the "props" with them, then the study of geometry is not their proper work.

Botany. A Specific Subject of Instruction in Public Elementary Schools. By Vincent T. Murché. (London: Blackie and Son, 1885.)

THE preface to this little volume states that "the three books which form this series are emphatically children's books, and not text-books for South Kensington students." As long as the author confines himself to that part of the science which is, in our opinion, best adapted to the mind of a child, his "chatty, experimental method" may very probably gain the attention of youthful readers. The first forty-eight pages, which he devotes to external morphology, are unpretentious and successful. We may well wish that the author had confined himself to external morphology; but he launches out into anatomy and physiology—branches of the science which are ill-adapted at best to the mind of a child: in this middle section of the book his success leaves him when he states that "the epidermis of the orange consists . . . of a thick peel;" that "there is in every plant . . . a peculiar vital fluid which is the source of all its solid parts;" this, we are told, is found in spring "in an active state between the bark and the wood. In this condition it is called *cambium!*" It is also stated (p. 58) that the cells of the pith "form the channel by which all the fluids absorbed by the roots are carried upwards towards the leaves and flowers," while the part played in the transfer of fluids by the lignified walls is systematically ignored, and it is expressly stated on p. 78 that "there can be no passage of fluids up or down, except by the process of osmosis." When the author leaves this part of the subject, on which he is, to say the least, not very sound, his success again returns: he describes simply and clearly the chief characters of the flower and fruit; but concludes with a condensed and not very satisfactory treatment of some of the lower forms of vegetable life.

It is unfortunate that a book, parts of which might prove so useful, should be disfigured by serious blunders; why should not the proof-sheets, in cases like the present, be submitted to some competent authority, who would easily sift out the grosser errors? F. O. B.

Journal of the Royal Agricultural Society of England. Second Series. Vol. 21, Part I. (London: John Murray, 1885.)

THIS journal fully maintains the high character it has acquired under the able editorship of Mr. H. M. Jenkins. The part under notice is a bulky volume of nearly five hundred pages, and includes some eight or ten original papers by well-known agricultural writers, besides the always valuable annual reports of the entomologist, chemist, and botanist to the Society. Prof. Wortley Axe reports on a recent outbreak of abortion in Lincolnshire ewe-flocks, and Prof. Robertson on anæmia in sheep. Mr. S. B. S. Druce, Barrister-at-Law, has a significant paper on the alteration in the distribution of the agricultural population of England and Wales between the returns of the census of 1871 and 1881. Dr. J. H. Gilbert, F.R.S., contributes a sympathetic memoir of the late Dr. Augustus Voelcker, the paper being accompanied by a graphic portrait. Sir J. B. Lawes, F.R.S., writing on sugar as a food for stock, concludes that even at its present low price, sugar does not appear to be an economical substance to use when brought into comparison with other foods which are available to the farmer. Mr. H. Ling Roth writes on Franco-Swiss dairy farming, and Mr. W. Little on the agriculture of Glamorganshire, while the longest contribution to the current part is the first instalment of a report on Canadian agriculture, by Prof. Fream. The author confines his remarks chiefly to the prairie region of British North America, and after discussing the physical and geological features of this vast region, the character of its soils, the composition and value of its native herbage, and the peculiarities of its climate, he proceeds to give an exhaustive description of the agriculture of Manitoba and the North-West Territories, and concludes with an expression of his opinions as to the probable future of prairie farming. The moderate and impartial spirit in which this paper is written will enhance its value to readers on both sides of the Atlantic, and lead them to look forward to the publication of the second part, in which it is proposed to deal with the agriculture of the Eastern Provinces of the Dominion. In the course of his inquiries, Prof. Fream appears to have discovered in "goose wheat" a novelty both of botanical and agricultural interest. This part of the *Journal* also contains a report on the field and feeding experiments at Woburn, by Dr. J. Augustus Voelcker, in which the author gives evidence of the same attention to accuracy and matters of detail as were so eminently characteristic of his late father, to whose vacant post as consulting chemist to the Society he was recently elected by the Council.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

"An Earthquake Invention"

WITH reference to the correspondence on this subject in this week's NATURE (vol. xxxii. p. 213), will you permit me to state that the gentleman to whose paper in the British Association Report for 1884 Prof. Piazzi Smyth refers has long been a resident of Japan, that he is now on a voyage from that country to Australia and New Zealand, and that it must, therefore, in the ordinary course of things, be some months before he can see and reply to the correspondence in question. In the mean time, it may not be amiss to point out that the capital of Japan is about 12,000 miles from the learned societies of Europe and their *Proceedings*, and that there, as described, a man must be content to work with what he finds at his hand; there are no great public libraries in which we can find out readily what has been done before in any particular field. Mr. Stevenson's paper appears to have been published twenty years ago, and the chances are that it never, from that time to the present, reached the East. That it never came to the knowledge of "the B.A. man" will be readily believed by the many readers of NATURE who know what a careful and conscientious worker that man is. Besides, unless it be presumptuous in an unscientific person to say so, the learned Professor's solitary premiss does not at all support his amiable conclusion. If he will again examine the letters, to the publication of which he appears to have given his consent without a clear notion of what he was doing, he will doubtless perceive that one man may carry out experiments in Japan in 1884 without knowing that similar experiments had been carried out by another man in England in 1864; and when Prof. Piazzi Smyth has reached this point, it may occur to him that the tone and expressions of his letters, so far as they refer to the gentleman in Japan, require more consideration than they received when they were penned.

It should also be added that these experiments with regard to buildings in earthquake countries form only one of a long series of investigations which the gentleman in question has for years past been pursuing over the whole domain of seismology. Most of his numerous papers on this subject have been noticed from time to time in NATURE. M.

Gray's Inn, July 3

On the Occurrence of Lumpenus lampetriformis and Gadiculus argenteus off Aberdeen

I RECORDED and figured in the *Proceedings* of the Zoological Society for 1884 the first species of *Lumpenus lampetriformis* obtained in Great Britain. It was a male 10.7 inches long, captured trawling by Prof. McIntosh, fifteen miles off St. Abb's Head. On June 20 I received a letter from Mr. Sim, of Aberdeen, inclosing a sketch of a fish which had become entangled in the net of a steam trawler, and which specimen he was good enough to forward for my inspection. It is a female of the same species 8·6 inches in length, in which the caudal fin differs from that of the male example in that its form is lanceolate. The second specimen, which I received at the same time from Mr. Sim, was that of a *Gadiculus argenteus*, Guichenot, which was cast up on the beach after a slight storm on April 13, 1885. To this latter fish a considerable amount of interest attaches itself. Pertaining to a genus whose habitat is considered intermediate between the littoral and deep-sea zones, I have been in doubt whether it has or has not been previously obtained off our shores. Couch labelled a fish of this species from the *Porcupine* Expedition as *Macrourus linearis*, and which is in the British Museum collection. Of it he wrote as follows:—"Much resembling a whiting, but shorter in proportion to its depth and with a much larger eye. Caught from a depth of 183 fathoms, muddy ground, 54° 10' N. and 10° 59' W. Length about 6 inches; no barb; the head short, eye large, mouth capacious, teeth small, dorsal fins three, anal two, tail a little concave, colour in spirit pale yellow. If we can suppose that a whiting can live at such a depth, we can suppose also that the eye might become larger and the body rather shorter, proportionally, but otherwise it is a distinct species and yet nearly alike; but from the latitude, and especially the longitude, it is scarcely a British fish."

I should have deemed a fish from such a spot undoubtedly British, but as I was not quite sure whether Mr. Laughrin, who had been in charge of the fish collection in the *Porcupine* Expedition, might not have inadvertently mixed up Mediterranean forms with those from higher latitudes, and as *Gadiculus argenteus* originally was obtained from the coast of Algiers, I wrote to him on the subject. However, he would only reply that "I do not think he [Mr. Couch] had any of the Mediterranean fish; I cannot remember, it is so long ago." It is very interesting being able, after so many years' interval, to adduce corroborative evidence as to this fish being entitled to a position in the British fish fauna, the *Porcupine* specimen having been obtained on the west coast of Ireland, Mr. Sim's on the east coast of Scotland. The specimen is 3·3 inches in length, D. 11/13/15, A. 16/16, L. l. 56. There is a dark spot at the base of the anterior rays of the first and second dorsal fins.

Cheltenham, July 4 FRANCIS DAY

Swallows

If "E. H." will take down a swallow's nest (*Hirundo urbica*) directly after the young brood has left it, he will find the lining swarming with two species of active insects altogether out of proportion as to size of the swallow on which they are parasitic. At the same time also the nest contains numerous ovate *pupæ* as black as jet, evidently the offsprings of the insects which, if kept during the winter following, will develop into wonderfully active wingless *imago*, which, when liberated, are difficult to capture and kill. These are the gnats, &c., to which "E. H.'s" informant alluded, but they approach in size nearer to sheep lice. Under the microscope they are interesting objects. Circulation can be watched, and in addition to a peculiarly-formed head, pointed rudimentary wings can be seen in shape much like the swallows. It appears to me that swallows do not hatch their parasites on their bodies, but incubate them in the lining of their nests; but a high degree of heat is not necessary to develop the pupa. In my opinion there is no design or intention on the part of the swallow to breed or cultivate parasites for consumption during migration. The life of the parasite depends on the existence of the swallow, and not the swallow upon the parasite. At the present time I have nests in the corners of my windows, and when the migratory season arrives I can safely rely upon a collection of insects and pupa from them which I would gladly send to any of your readers who care to write for them about the middle of autumn. WM. WATTS

Piethorn, Rochdale, July 4

SWALLOWS are infested by at least three genera of parasitic two-winged insects, *Ornithomyia*, *Stenopteryx*, and *Oxypterum*. Figures of these flies may be found in F. Walker's "Insecta Britannica Diptera," vol. ii. Tab. xx. O. S.

Heidelberg, Germany, July 4

"The Evolution of Vegetation"

As the science of botany is interesting to many people according as it throws light on biological questions, perhaps just now, while the Darwin Memorial is still fresh in your mind, you will allow one of the many to make known a want by inserting this letter in your paper.

Prof. Bower, in his article, NATURE, vol. xxxi. p. 460, seems to tell the young botanist to go to the other side of the globe in order to find fresh fields of labour. This sort of work, I should think, is very much needed; but if Prof. Bower or some other master in the science would publish his views relating to the evolution of vegetation, perhaps another motive would be added for the enterprise. I hope I am not asking too largely, though aware that men who have won good reputations may hesitate to print their theories. Yet a Parker has given us "Mammalian Descent," and, what he has done to teach us in one direction, surely some one else will in another.

On pp. 4 and 5, "Mammalian Descent," we are told that there are three groups of workers all labouring to build up the truth as it is in Darwin—the zoologists, the palæontologists, and the embryologists. Now there are some botanists who would gladly make a fourth group if a teacher would arise to direct them where and how to work, even if that work was with the zoologists in the land of the Monotremes or at home with the embryologists watching the development of plants, though the plants were of cellular tissue only.

I do hope that I have not written to you in vain.

Bradford, June 23 J. CLAYTON

Foul Water

ALLOW me to call attention to the fact every year—generally some time in May—the sea-water on this coast becomes in a condition that fishermen call "foul." It is due to the presence of enormous quantities of gelatinous masses of small size and spherical, cylindrical and irregular forms, in which nucleated granules are imbedded. After immersion, even for a few seconds, ropes, nets, &c., feel as if they had been dipped in thin glue.

The men allege that this "foul water" has an injurious effect upon their tackle, and also lessens their take of some kinds of fish. It continues for about a month and then disappears. This year I have had and still have some of the organisms under microscopic observation, and I am very anxious to know if they have already been the subject of scientific inquiry, or not; and also information as to the geographical extent of their diffusion.

Sheerness-on-Sea W. H. SHRUBSOLE

Composite Portraits

IT is most unfortunate, but an obvious fact, that in the sheet of composite portraits of American notabilities in NATURE of June 25, Figs. 2 and 3 are impressions from one and the same negative. Not only are they alike, but they present the same peculiarities, even the same defects. If it were not so, they would serve to blow to shivers the whole edifice founded upon such averages; for if 16 naturalists and 31 academicians present two composites which are indistinguishable, to what purpose is the average? IRIDESCENT CRYSTALS OF CHLORATE OF POTASH

THE appearance of Mr. Madan's paper in NATURE, vol. xxxii. p. 102, induces me to offer some additional remarks on this subject.

In the discussion that followed the reading of my paper Mr. Crookes referred to the closely analogous spectra exhibited by opals, as described in his paper (*Proc. Roy. Soc.*, vol. xvii.). This paper, though it came before me at the time when it was read, was not in my mind when I wrote my own. I called shortly afterwards at Mr. Crookes' house, and saw the spectra of his opals. Supposing that there were sufficient grounds for the commonly received idea that the colours of the opal are due to fine tubes in the mineral, we did not at the time conceive that the phenomena could be the same; were it not for this, I should certainly have added to my paper a reference to that of Mr. Crookes.

Mr. Crookes was so good as to lend me his opals for more leisurely study. The further examination has so impressed me with the similarity of character of the spectra, that I am strongly disposed to think that the colours of the opal and those of the chlorate crystals may be due to the same cause. This does not, however, lead me to attribute tubes or striæ to the chlorate crystals, the structure of which can comparatively easily be made out, but to doubt very greatly the theory which attributes the colours of opal to fine tubes.

Mr. Madan does not profess to have actually seen in the chlorate crystals such tubes as he supposes to exist, nor could I see anything of the kind on examining some of the crystals I have got after the appearance of his paper. On the other hand, I notice that Brewster did not state that he had actually seen the supposed tubes, but merely inferred their existence from a comparison of the appearance under the microscope of the precious opal with that of hydrophane. And Mr. Crookes tells me that an opal is not spoiled or affected by being immersed in water or even oil. The fact is that it is extremely difficult to make out what the actual structure is with which we have to deal in the case of the opal, whereas in the case of the chlorate crystals it is unmistakable. Moreover, in the case of the chlorate crystals there is a wonderful uniformity in the phenomena presented by the same crystal, extending, it may be, over nearly the whole of even a large crystal, whereas in the opal the colour extends over comparatively small patches; and even a single patch is seen under the microscope to present differences of structure in different parts. Hence if the colours in opal and those in the chlorate crystals are really due to a similar cause, it seems much more likely that a study of the phenomena of the chlorate crystals will throw light on those of the opal, than that the phenomena of the opal should furnish the key to the explanation of the colours of the chlorate crystals.

In truth, I do not see how the presence of tubes, if such there be in the opal, would account for the phenomena, and especially for the very peculiar spectrum exhibited. The supposition of the existence of rows of tubes leads one to look in the direction of diffraction. But I do not see how monochromatic light, or, at least, light almost monochromatic, can be obtained by diffraction. And even independently of this consideration there is one feature of the production of colour in the chlorate crystals which shows, at once and decisively, that at least in *their* case the colour cannot be due to diffraction. If an iridescent crystal be chosen with an even surface, and the flame of a candle in a dark room be viewed by reflection in it, it is found that the colour is seen in the direction of the regularly-reflected light. In fact, the coloured light forms a well-defined image of the flame of the candle, coinciding with, or overlapping, the colourless image due to reflection from the first surface. This differs altogether from what we get in the case of a grating, or in that of mother-of-pearl or Labrador spar. It agrees so far with the colours of thin plates, or the colours shown by reflection by certain quasi-metallic substances, such as several of the aniline dyes, though the production of colour in these three cases is due to three totally different causes.

It has been conclusively proved that the seat of the colour in the chlorate of potash crystals is in a very thin twin stratum; and I entertain myself little or no doubt that the colour depends in some way on the different orientation of the planes of polarisation in the two components of a twin, and on the difference of retardation of the two polarised pencils which traverse the thin stratum. But anything beyond this is at present only a matter of speculation. I see only two directions in one or other of which to look for a possible explanation; but as these could only be propounded at considerable length, and the matter has not at present advanced further, I refrained from saying anything about it in my former paper, nor will I further mention it here.

In conclusion, I would mention an interesting paper on "The Spectrum of the Noble Opal," by Prof. H. Behrens, a copy of which I have just received by the kindness of the author. In this paper, which is printed in the *Neues Jahrbuch für Mineralogie*, &c., 1873, the author, who was evidently unacquainted with Mr. Crookes's paper when he wrote his own, has described and figured the peculiar spectra of several opals. G. G. STOKES

EXPERIMENTAL FARMING

ENGLISH farmers are not readers. They do not know, apparently, that there is much to unlearn in the practice of their art, old as it may be. But although they will not allow themselves to be enlightened by books or newspapers, they are not incapable of imitation, and for that reason experimental farming, carried out in any particular district in a practical manner, has always proved useful. Up to the present time the history of experimental farms in England is, so far as their number is concerned, a meagre one. In the whole of Europe there are 160 experimental farm stations, of which number the United Kingdom can boast of about half a dozen, including Rothamsted; Woburn, which, by the Duke of Bedford's munificence, has become a field of experiments for the Royal Agricultural Society; the stations of the Highland and Agricultural Society, of the National Board of Education in Ireland, and of the Agricultural Association of Sussex. It is a characteristic feature of our English system that the State lends no assistance to either of these establishments, while that of Sir John B. Lawes, at Rothamsted, has been conducted for many years on a princely scale by the owner at his sole cost.

The Rothamsted station, founded in 1843, has become the most prominent teaching establishment in the world. There is not a single point of interest connected with the cropping and manuring of the land, the forming and treatment of pastures, and the feeding of animals, which has not been made the subject of exhaustive experiment at Rothamsted, while the silo experiments which have been lately undertaken for the purpose of testing the value of ensilage, will probably do more for the instruction of those land-proprietors and large farmers who are watching them than all else which has been said or done in regard to this much-praised cattle food. It would be strange indeed if agriculturists refused to listen to Sir John Lawes, but although certain facts of prime importance in the long catalogue of useful lessons from Rothamsted have been widely distributed, the voluminous writings of the great experimenter, trusted as he is, are not read by one per cent. of those on whose behalf they were undertaken. Some of the more important teachings of Rothamsted have become so familiar that they have passed into agricultural axioms, such as "phosphorus for turnips, nitrogen for corn." We have ourselves known farmers who have travelled a hundred miles—a long flight for such men—for the purpose of seeing for themselves at Rothamsted how corn might be grown continuously by means of small dressings of nitrogenous manures, and thus they have solved a problem of vital importance to themselves and their families. But comparatively few farmers will trust themselves so far from home, even on a matter of life and death, and it has become a business of grave importance to the rent-receiving portion of the landed interest to convey to the rank and file of tenant farmers the necessary knowledge which they are too inert and ignorant to acquire for themselves.

In the hope of teaching farmers, the Royal Agricultural Society, the Bath and West of England Society, some landlords in Sussex, and others, are endeavouring to increase the number of experimental farms. Minds that are entirely untrained or ignorant can only be taught orally or by imitation. Put an attractive story into the hands of an ill-instructed boy, and he will soon lay the book aside; but, read or relate the story to him, and he will probably be found a fascinated listener. It is the same with farmers and scientific farming. They cannot learn from books, but they will listen to the story by word of mouth. The leading agricultural societies are therefore making a timely move in considering the best methods of teaching farmers by example—that is, by the multiplication of experimental farms. Lectures delivered by professors, and listened to with stubborn incredulity, are of little use compared with experiments tried by the roadside and discussed at the market tables of the neighbourhood. It is gratifying to notice, therefore, that at a recent Council meeting of the Royal Agricultural Society a new departure was announced in the appointment of a committee to consider how the National Society could best co-operate with local societies in carrying out investigations into subjects of practical utility in agriculture. An additional reason for multiplying stations is that, in consequence of the variation of climate and other causes, farming is conducted under different conditions in the several districts. In one locality, for example, the special problem to be solved may concern the management of grasses, in another that of corn. In all alike the object of the teachers of agriculture must be to substitute, so far as may be possible, the rule of three for the rule of thumb at present in vogue.

At Rothamsted the experiments of the past forty years have related to the growth of continuous crops year after year on the same land, to the growth of crops under rotation, to the use of every kind of artificial manure, or of farm-yard dung, in varying quantities on every kind of crop, and, for the sake of comparison, to the omission of all manure on some of the land, to the manuring of permanent pasture, fallowing, the use of various feeding stuffs, town sewage, the question whether plants assimilate free nitrogen, ensilage, rainfall, and the waste of nitrogen in land-drainage water. It has been stated that some of the elaborate investigations which have been conducted at Rothamsted are too "scientific" for humbler establishments. If by science we mean a complete knowledge of facts the phrase is hardly accurate, but no doubt some of the Rothamsted experiments were accompanied by the analyses of animals, plants, and soils, and could not therefore be repeated at ordinary stations. On the other hand, the most useful experiments for the instruction of farmers are those which relate to the effects of the different foods employed for plants and animals, and in these cases farmers can themselves form estimates of the results which will prove sufficiently accurate for practical purposes and may lead to the saving of millions which are now annually wasted through the ignorant use of manures and improper feeding of animals. H. E.

ELECTRICITY AT THE INVENTIONS EXHIBITION

The Secondary Generators of Messrs. Gaulard and Gibbs

HITHERTO there have been two means employed for electric illumination and the electric transmission of energy—viz. supplying the electricity required for the lamps or other receivers (1) direct from the dynamo machines, and (2) from secondary batteries charged by means of dynamos. A third method has been recently introduced, by means of secondary generators, of which a small installation has been made at the Inventions Exhibition, to which we propose to refer in this article.

The object of this invention is to supply a current which may be varied at will both as regards electromotive force and quantity, and thus be made applicable to work at the same time arc lamps, incandescent lamps, and motors. The means by which this result has been effected is by interposing between the dynamo machine and the lamp or other receiver of electricity a supplementary apparatus, by the use of which an induced current is produced proper to the particular receiver which it is desired to work.

The National Company for the Distribution of Electricity by Secondary Generators, which works the patents of Messrs. Gaulard and Gibbs, originally used secondary generators of the following construction. They were composed of a thick insulated copper wire, surrounded by smaller coils formed of a number of thin insulated copper wires; the thick central wire receiving the current from the dynamo, which was distributed through the secondary wires. This method of construction has been replaced by one of exceeding simplicity, in which the difficulty of insulation and complication of manufacture of the original form are done away with.

The conductor for the primary current and the conductor in which the induced current is produced consist of a series of annular disks of sheet copper $\frac{1}{2}$ millimetre in thickness and $3\frac{1}{2}$ centimetres in width, slit across at one part and furnished with projecting pieces extending outwards on either side of the slit. The conductor for the primary circuit is made up of a series of these annular disks, and the conductor for the induced current is made up of a second similar series, the two series being so interlaced that the convolutions of the helix formed by the disks for the primary circuit alternate with the convolutions of the helix formed by the disks of the induced circuit. An annular disk of insulating material, such as paraffined cardboard, is placed between each convolution of the double helix thus formed, so as to prevent short circuiting between the helices and the several convolutions thereof, and the projecting pieces of all the disks for the primary current are soldered or electrically connected together, and the projecting pieces of all the disks for the induced current are similarly electrically connected. In constructing the secondary coils, they are fixed together between two insulating surfaces by bolts and nuts, the projections by which the several conducting disks are connected projecting helically or spirally around the coil (the projections of the primary alternating with those of the secondary coil), and form convenient means for connecting up any number of convolutions as required.

The end disks of one of the helices thus formed are connected to the leads of the primary circuit by binding-screws, and the end disks of the other helix are similarly connected to the leads for the induced or secondary current. In the centre of the disks is a hollow cylinder of paraffined cardboard or other suitable insulating material, around which the helices are arranged, and in this cylinder is a core of soft iron, or of soft iron wires, which is capable of being automatically raised and lowered in the cylinder, so as to regulate as required the current passing through the coil.

The main wire from the dynamo is connected up in series to the primary helices of a group of secondary generators, and, in passing through the primary helices, induces a current in the secondaries, the tension of which, according to the experimental investigations of the inventors, increases first with the intensity or quantity of the primary current, and, secondly, with the rapidity of the interruptions or alternations, or the variations of its potential. Each secondary generator forms a complete installation, and can be put in or out of circuit at pleasure. The secondaries may be connected up in series, in multiple arc, or in multiple series, as desired, the connections being readily altered by means of a switch-board; tension or quantity is thus obtained according to the nature of the current required. The lamps or other receivers fed from the secondary generator can be connected at will to their respective circuits, and are also independent of one another.

These generators are made to work in connection with alternate-current machines, because the latter can be constructed up to almost any power, as no two parts of the machine having great difference of potential need be in close proximity, and the alternation of current may be made as quickly as desired. The generating dynamo is so constructed and operated that the quantity of current is preserved constant, and the tension is varied to carry this current through the primary conductor against the varying counter electromotive force due to variations in the work done in the secondary circuits of a number of secondary generators. If W represents work, C current, E electromotive force, and R resistance, and if either of these factors be changed, the others must be altered in the same ratio, according to the formula—

$$W = CE = C^2R = \frac{E^2}{R},$$

if uniform effects in the secondary circuits are to be desired.

One of the chief characteristics of this system is that if the primary current be kept constant the loss due to resistance remains fixed, no matter what energy is transmitted—so that if an increase of energy is desired, the only factor that has to be increased is the electromotive force, which bears no ratio to the loss in the conductor. This circumstance is of importance in any house-to-house lighting scheme, where a conductor may be laid down to supply a certain area, and if the lights are not taken up at once, the necessary current can be supplied later within the limits of the dynamo, by increasing the electromotive force, without increasing the size of the conductor, the strength of the current, or the loss in the line.

As regards the very high potential required upon the secondary generator system, the danger is limited to the supply station, as between the two poles of the main dynamo there is an unbroken metallic circuit, which maintains the continuity of the flow of current; and as regards each secondary circuit the work done is represented by a secondary generator, and the only danger would be in grasping both primary terminals at once, which may be made impossible of performance. It will be necessary as regards the dynamo that it shall be insulated from the earth, and also that such parts of the circuit as carry high tension electricity shall be so protected that it shall be impossible to make contact between them and the earth.

In comparing this system, in which there is a loss in the transformation of the energy by the secondary generator, with the direct system, this loss will have to be balanced against that caused by resistance due to distance, whilst as regards the regulation of the supply of energy, this is effected by means of a regulator working the exciting machine of the dynamo at the station; by its means, when a secondary generator is cut out of circuit, a proportionate amount of power is saved. The secondary generators also regulate the energy absorbed, so that a perfect control of power is obtained, which is especially important for domestic supplies of electricity, as, when a suitable current measurer has been designed, consumers will be able to pay simply according to the amount consumed.

At present the extreme northern end only of the East Arcade at the Exhibition is being lighted on this system; it is proposed, however, to extend it to the full length of the East Arcade and to the concert-room.

THE AFGHAN DELIMITATION COMMISSION

WE are indebted to the courtesy of the Kew authorities for the opportunity of publishing the accompanying letter from Surgeon-Major Aitchison, C.I.E., F.R.S., which gives the most recent account of his work as naturalist to the Expedition:—

Camp Tir-Phul, Northern Afghanistan,
6 miles from Khusan

DEAR SIR JOSEPH HOOKER,—

I am now able to write to you with some pleasure, as I have been able to put together this year some 300 species in all. The last 100 I obtained on a ten days' trip that I made from this camp. I left this on April 25 under very bad auspices, as it had blown all night and was blowing a terrible gale with every chance of a heavy fall of rain from the north. But I started and got as far as Khusan, in the vicinity of which, beside the ruins of an old "serai," I halted. I picked up a few odds and ends, the chief attraction was the *Rosa margerita* (if a new sp.) *mihi*. It covers the whole country in localised patches, and being very dwarf in habit, not above 2 feet, the flowers are seen to perfection; they open out expanding almost flat, when the brilliant eyes, formed by the claret colour of the bases of the petals, gives it quite a character. Amongst my rose hips sent to you last year this was one of the species. I hope to be able to supply you with a lot more, it would make a lovely flower border.

I marched next to a place on the right bank of the Hari-rúd River opposite Tomăn-ághá, fifteen miles. Our route lay over a plain that had once been the bed of the river where the river had made a great bend; the river, after silting up this bend, had left it. The most characteristic plant here was a Rhubarb, usually with 3-root leaves of immense proportion for the size of the flowering stem; these leaves are so pressed flat to the ground that it reminds one more of the *Victoria regia* leaves (without the margin), and this is the habit of the plant; the plant was fruiting, having large winged fruit of a most brilliant scarlet; it will make a grand thing in gardens. The beautiful colour of the fruit is much helped out by the splendid green of the leaf background. There are, one may almost say, no leaves on the flowering stem—one or two most minute. I measured one of the largest on the ground: it was 4 feet from the base to apex and 5 feet across; the other two with this one were a little smaller; the three together gave it a very curious look. I hope soon to get the seeds home. I have collected a good deal of the root; it is called "Fool's Rhubarb" owing to its purgative qualities, and curiously enough the fruit is employed in preference to the root as a purgative, given as a decoction. With the exception of an occasional woody shrub that may rise to five feet, the place was covered with a species of Artemisia (probably several) about 2 feet high, and occasional Umbelliferæ. There were no trees of any sort: these are only to be found in the river bed —viz. *Populus euphratica*, and two species of Tamarisk and a Lycium. At Tomăn-ághá, in the bed of the river, was a woody salsolaceous shrub which I do not know. I got good specimens of the wood and flowering branches.

I left Tomăn-ághá on the 28th, passing the remains of some old ruins two miles from my encampment, and turned east by north towards "Galicha" (a carpet). As we marched along, fancy crossing the markings of two pairs of carriage wheels! These had been made some months ago by the carriage of a Persian Prince who had come to our camp at Gulran to be doctored. The route lay now across towards the base of the Paropamissus range over a most extensive plain on which the attraction was a miniature forest of a species of Umbelliferæ, excessively like, but not the, Assafœtida. This was in full bloom, the stem and flowers being at first all of a light orange yellow; as the fruit ripens, the whole colour changes to a russet brown. Each flowering stem is from 3 to 5 feet high, and there are usually 50 plants to 100 yards square, the interspaces being altogether filled up by a grass of a foot in height. On the 29th, left Galicha for the Kambao Pass to enable me to cross through the range. Our march lay over a plain the continuation of that of yesterday, and which from its extent is lost to the sight. This is celebrated as the plain of the wild donkey, and here I counted sixteen herds of at least 10,000 in each. The nearest was a mile off, and their presence was recognised by a cloud of dust rising in a swirl on their galloping—like the smoke from the chimney of a steamer. It was a most extraordinary sight, watching these clumps moving from place to place. They are occasionally shot and eaten. I forgot to tell you that, except my own party, there was probably not a human being within thirty miles of us. The country has *no* inhabitants, and until the nomads turn up with their flocks from the lower regions it is a desolation. The last part of our march was for six miles within the ridges of the base of the hills, and here in the stream beds Tamarisk was the only (woody) shrub. I halted some five miles to the west of the pass, hoping to make a great haul on the 30th. From the moment of entering these valleys they seem a mass of colour—one from buttercups (one species only), another from a poppy; the bed of the stream purple with a tall onion, and the interstices green with one grass. I had previously got most of the things so promising here, but saw signs of getting into a very fine new lot. On the morning of the 30th a regular hurricane of wind blew from the north, so that I thought the best plan would be to move my camp across the pass, and get a better and more sheltered locality. I just managed to get to the north-east side, when it *did* come down—such a torrent! but as all preparations had been made we were comfortable; had I remained on we must have been swept out of our old camp.

May 1 proved a most superb morning, so I was up and out at 6 a.m., went straight back to my old encampment on the west side, and from there collected back. I got some thirty-five species—a second Arum; a Prunus; an Elæagnus, of which I sent you the fruit last year; one Pistachia bush, a large number of Astragali, which I feel sure will stump Baker; a curious Rubiaceous shrub, a fine Orobanche, only five grasses, and a most lovely everlasting pea, like the ordinary English cultivated one, only dwarf. I believe everything here is dwarfed by exposure to the winds. You cannot understand the difficulty I have with it in collecting. To save my plants at all, I have to put them *at once* into paper. It takes three of us to do this, and not allow paper or plants to blow away. I must say it does not improve one's temper.

I got one or two species of a very nice Gentian like *Gentiana Kurroo* of Royle, the altitude of Hari-rúd River, 2000 feet; Kambao Pass, west side, 2900 feet; pass itself, 3550 feet; Kambao on north-east, 3250 feet. Not a fern of any sort, not even Ophioglossum, which I looked upon as a certain find. I spent my second day—viz. May 2—at the camp on the north-east side of pass; here there is a fine hawthorn, from which I collected flowers in bud on the 1st. Along the whole of this range, well within it, where the water is sweet and the air cool, the hawthorn, a common plum, and *Amygdalus eburnea*, are more or less plentiful. I picked up an Oxygraphis, and a very pretty geranium with a most curious potato-like root, only the tubers are heaped up on each other when there is more than one to a plant. You know they made me naturalist, so, in addition to collecting plants, I have to shoot poor little birds, and I hate it. I got two bee-eaters, the one more lovely than the other, and a nightingale.

On the 3rd I marched to a place 8 miles nearer our first Gulran encampment. I had picked up most of the cream, and there was not much, except additions in the way of fruiting species, to be made. This I did, and got a venomous snake which may be a cobra—all but walked on to him—5 feet long and 6 inches at his thickest, fangs three-quarters of an inch; a most unpleasant fellow to meet. I shot him, and after fancying I had killed him, cut off his head and neck to keep (I could not keep his whole body), when lo! his body, minus his head, walked off searching for escape, the head trying to fang its own neck.

On the 4th I moved still east-by-north some 12 miles to our first encampment at Gulran. I got some nice things *en route*, and had just ticketed and arranged them preparatory to great work for the morrow, when in came a letter from Sir Peter Lumsden telling me to return at once. Alas for my great expectations! I packed up, and we moved camp at 2 a.m. on the 5th, marched up the valley, passing our second Gulran encampment, and on south to the east-by-north side of the Chashma-sabz Pass. I had no time to halt and collect. I passed a Gladiolus and an immense number of things. On the pass I collected the "Siah-chot," which is to me, in all probability, *Cotoneaster nummularia*. I had collected its fruit and sent it to you from these very bushes. I got it in this pass last year. It is from this shrub that "Shir-Khist," the manna of these parts, is collected. I have sent you a bottle of it packed amongst some other things. They have two other kinds—one from a Tamarisk and the other from Alhagi. I myself collected it from a Salsola. I got across the pass by 2 p.m.; halted until 8 p.m. and got into Tir-Phul at 8 a.m., the camels at 10 a.m. of the 6th; did 60 miles in 34 hours—good going for camels, and men more or less on foot.

I am glad I am in, because my plants had to be looked to. I got, as I said before, 100 species in this tour, not less than 1200 specimens. It is much harder work than Kurram; the fact is, I am not younger, and my back wants a good deal of oiling.

Yours very truly,

J. E. T. AITCHISON

AN OLD DRAWING OF A MAMMOTH[1]

As an addendum to the historical review of the mammoth discoveries in Siberia and the traditions to which they have given rise, which I have rendered in the "Voyage of the *Vega*," I have the pleasure of presenting a curious drawing of the animal, discovered among the Benzelian MSS. in the Linköping library. My attention was directed to the original by the president, Herr Hans Forssell, who, in his memoir of Erik Benzelius the younger, has given an account of the proceedings which it occasioned in the Upsala Scientific Society.[2]

The drawing bears the following inscription:—

"The length of this animal, called Behemot, is 50 Russian ells; the height is not known, but a rib being 5 arsin long, it may be estimated. The greatest diameter of the horn is half of an arsin, the length slightly above four; the tusks like a square brick; the foreleg from the shoulder to the knee 1¾ arsin long, and at the narrowest part a quarter in diameter. The hole in which the marrow lies is so big that a fist may be inserted, otherwise the legs bear no proportion to the body, being rather short. The heathens living by the River Obi state that they have seen them floating in this river as big as a 'struus,' *i.e.* a vessel which the Russians use. This animal lives in the earth, and dies as soon as it comes into the air."

On the reverse of the drawing we read:—

"This drawing and description is given by Baron Kagg, who has just returned from captivity in Russia and Siberia,[1] 1722, in Decembri."

This drawing was exhibited by Benzelius at the meeting of the Upsala Scientific Society, December 14, 1722. The statement referring thereto in the *Journal* of the Society is as follows:—

"Herr Benzelius exhibited a good drawing of an animal, transmitted by Baron Kagg, who has just returned from captivity in Russia and Siberia, which the

Siberiaks call Mehemoth or Mammont, which has caused many to believe that it was identical with Behemoth of Job. Herr Prof. Rudbeck and Dr. Martin maintained that it was a sea animal, moreover as Herr Kagg stated that it was found at the River Obi. To this was added that Capt. Lundius had said that its bones were mostly found in the earth by the river. With regard to the animal being drawn with claws, Prof. Rudbeck pointed out that as yet no animal *cornigerum* had been found also to be *unguiculatum*, without being *palmipes* or having skin between the toes like geese, &c. It was decided to write to Herr Kagg, requesting some information about the figure, and asking how he had obtained it, so that it might be ascertained whether it was reliable. There is a description about this Mehemot in Capt. Müller's account of the Ostiaks."[2]

At a later meeting, January 11, 1723, Dr. Martin stated that he had carefully examined works of zoology, whether there existed any sea animal like that shown at the last conference, but had found nothing like it, although the head—excepting the horns—and probably also the feet and the tail, were like those of the hippopotamus of the River Nile. At the same meeting Benzelius announced that Lieut.-Col. Schönström had promised to forward a whole tusk of this remarkable animal.

On later occasions too the animal was discussed by the Society. Thus on January 18, 1723, a letter was read from the learned linguist, Sparfvenfelt, wherein he explains the derivation of the words Behemoth and

[1] Published in *Ymer* (Journal of the Swedish Anthropological and Geographical Society), 1884, Parts 7 and 8. (Translation communicated by the Author.)

[2] "Svenska Akademiens handlingar" (*Proceedings* of the Swedish Academy), Part 58. Stockholm, 1883, p. 315.

[1] Major L. Kagg was taken prisoner at the River Dnieper in 1709, and brought to Tobolsk, whence he returned in 1722.

[2] J. B. Müller's "Leben und Gewonheiten der Ostiaken unter dem Polo Arctico wohnende," &c. Berlin, 1720.

Mammont; on February 15 a letter was read from Benzelius, stating that Kagg had received the drawing from a Capt. Tabbert, and that he could give no information as to its correctness. Again, on October 3, Benzelius exhibited a large bone, almost petrified, which was the jaw of a Mammont, or as it was called Behemoth, received from Tobolsk in Siberia, through Capt. Clodt von Jürgensburg, and, on November 22, Benzelius exhibited "part of the tusk of a Behemoth, which was exactly like ivory." Finally, Benzelius communicated with the Russian Chief of Mines, Tatischew, who, in a letter dated May 12, 1725, had given long and important information of the history of the mammoth. This letter is printed in "Acta Literaria Sueciæ" (vol. ii. p. 36, 1725).

A. E. NORDENSKIÖLD

NIAGARA FALLS: THE RATE AT WHICH THEY RECEDE SOUTHWARDS

THE diagrams are from the map issued by the New York Commission for the establishing a State reservation at the Falls, based on surveys made in August and September, 1883, by Thomas Evershed, under direction of Silas Seymour, State Engineer and Surveyor. The scale of the diagrams is one half that of

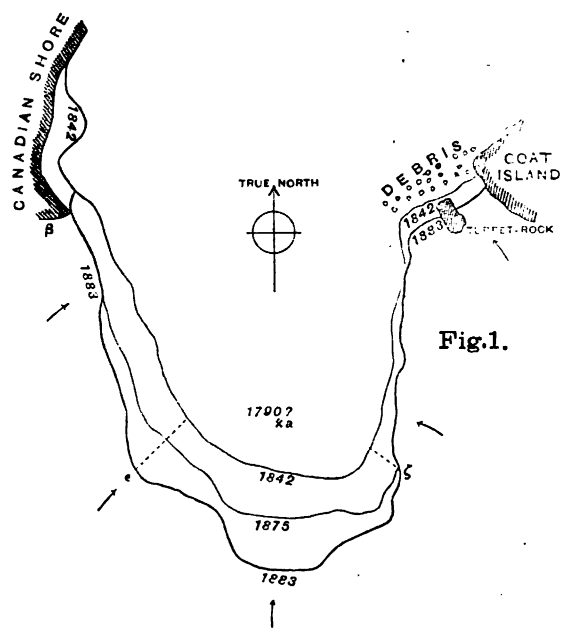

Fig. 1.

the map, which is on a scale of four chains to the inch. To have given all on one diagram with the intervening Goat Island would take up nearly an entire page of NATURE, and if the scale were smaller it would fail to show clearly the distinctive features of the changes in progress. Fig. 1 shows the Canadian or Horse-Shoe Fall, Fig. 2 the Eastern or so-called "American" Fall—a misnomer too deeply rooted in usage to be now supplanted by some more fitting name.

The rate at which the Falls are receding has been a matter of interest to geologists for over fifty years, but the results so far reached have been conflicting and inconclusive. The manner in which the Falls work backward, undermining their brink, is so well known from Lyell's clear description, that I shall not repeat it.

In 1830, Bakewell, on the basis of such information as he could gather from old inhabitants and from his own observations, concluded that during the previous forty years the Falls had receded at the rate of three feet per annum.

Lyell, from such materials as he could obtain during his own visit in 1841 and 1842, estimated the annual retrograde motion at only a foot. It is sufficient to recite such discordant results arrived at by two careful investigators to show how imperfect were the materials at their disposal, nor will any one who has been on the spot wonder at their differing so greatly. It would be possible to roughly compute the southward movement of the innermost recess of the Canadian Fall by referring its position from time to time to some fixed points on the adjoining shore, but any conclusive determination of the movement of the entire Fall could not be obtained in this way. The map referred to gives the outline of the Falls as determined by three surveys: the New York Geological Survey of 1842, the U.S. Lake Survey of 1875, and Evershed's Survey of 1883. The contours of the brink as established by these enable us to measure the total movement.

I divide the contour from β to Goat Island into thirty-three sections, disregarding for obvious reasons the overflow north of β, on the Canadian shore. From β to ϵ are eleven sections, from ϵ to ζ are twelve sections, from ζ to Goat Island are ten sections. It is obvious that much the greater work has been done between β and ζ, and that the innermost recess has kept in the same relative position.

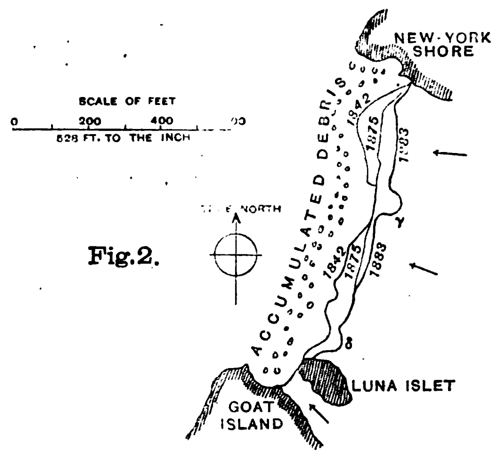

Fig. 2.

The means of the measurements on the sections, along perpendiculars from the contour at the date of each survey, measured on a tracing of the published map, give the following results for the Canadian Fall:—

	33 years ending in 1875 ft.	8 years ending in 1883 ft.	41 years ending in 1883 ft.
Mean aggregate recession along contour of 2000 feet, from β to Goat Island =	80	—	114
Mean aggregate recession along contour of 1200 feet, β to ζ =	—	60	—
Mean annual rate of regression along the whole contour where a visible change was effected =	$2\frac{1}{2}$	$7\frac{1}{2}$	$2\frac{3}{4}$
Total maximum regression at the innermost recess =	118	135	253
Annual rate of maximum regression =	$3\frac{3}{5}$	$16\frac{1}{4}$	$6\frac{1}{8}$

The "American" Fall, measured in ten sections, gave a total mean recession of $37\frac{1}{2}$ feet in the 41 years ending in 1883, which is at the rate of about 10 inches per annum.

I do not know that I have seen any estimate attempted of the relative volumes of water passing over the two falls. From such imperfect data as I have, referring to depth and swiftness, I should think that the rate of erosion for each fall gave some approximation to the volume of water discharged over each; that is to say, $2\frac{3}{4}$ feet per annum for the Canadian Fall, $\frac{5}{8}$ foot per annum for the "American" Fall, would signify that the former pours over its brink three times as much water as the latter.

At the rates of recession above shown it is evident that at no very remote age the two falls were united in one when abreast of the point in Fig. 2 marked "New York Shore," and the entire width was about the same as that of the present Canadian Fall alone. Moreover, the mean width of the fall, from the time it commenced its work at the "heights," seven miles below its present position, according to Lyell's statement as to the gorge of Niagara River, was not greater than the present Canadian Fall. Adding together the present work done by both falls, we should have about $3\frac{1}{2}$ feet per annum as the backward work performed when the entire volume poured over a single fall of the width of the present Canadian Fall.

At this rate 10,000 years would seem sufficient time for the cutting out of the present gorge terminating at the "heights" towards Lake Ontario, instead of Lyell's estimate of 35,000 years. All attempts to calculate the rate of movement proceed on the assumption that the hardness of the lime-rock and shale, the volume of water, and the height of the fall, were, for the whole distance, much the same that they now are; I merely use these same assumptions. It in no wise reflects on Lyell's judgment that he should have erred so greatly in attempting to estimate the rate of regression, while yet the contour of the fall at different periods had not been fixed by triangulation. He was ever the first to lay aside a conjecture when he could lay hold of something more solid in its stead, and it was by his candour and sound judgment in discussing natural phenomena that my interest in such matters was chiefly awakened.

The statement made by him that Hooker, his guide in 1841, reported that an indentation of 40 feet had been made in the "American" Fall since 1815 seems to contain the basis on which he estimated the rate of regression for both falls, as this amounts to a little over one foot per annum. A reference to the results given by me show this to have been approximately correct for the mean rate at the "American" Fall, but wholly inapplicable when applied to the much more important Canadian Fall.

A consideration of his section of the Niagara River leads me to suppose that the falls in the earlier part of their history worked even more rapidly than now in undermining the brink, but I will not venture further upon your space at present.

EDWARD WESSON

Providence, R.I., U.S.A., June 1

NOTES

THE Hon. William Macleay, one of the members of the Senate of Sydney University, has undertaken to give four fellowships, of 400*l.* a year each, for natural science, and to bequeath a sum sufficient to endow them permanently. In order to prevent any sleepy Fellows, we are told, from being quartered on this foundation, he stipulates that they must all have taken the degree of B.A. in the University, must be actively engaged in original study and research, and must not hold any other lucrative appointment, and the appointments are to be renewed every year, so as to give an opportunity for correcting any abuse.

THE Darwin Medal—founded by the Midland Union of Scientific Societies in honour of the great naturalist, and for the encouragement of original research—has been awarded for the current year to Mr. W. J. Harrison, F.G.S., of Birmingham.

THE long excursion of the Geologists' Association this year will be to Belgium (the Meuse and the Ardennes, Brussels, Dinant, Namur, Liége, Maestricht), under the direction of M. Ed. Dupont (Director of the Museum, Brussels, and of the Belgian Geological Survey), Prof. A. Renard, Dr. E. Purves, and Prof. J. Gosselet. The party will meet in Brussels on Monday, August 10, and will proceed the same evening to Charleroi. Further particulars as to fares, routes, &c., will be given in a special circular, which will also contain full particulars of the geology, with illustrations and references. The total expense during the five days of the excursion (Tuesday to Saturday) will vary from 15*s.* to 20*s.* per day for each person. This will include conveyances; also a special steamer on the Meuse, stopping at the various points of interest. By this arrangement much can be seen in a short time. The papers on the geology of Belgium read at the July meeting will be printed, with map and illustrations, for the use of the members during the excursion. Those proposing to join this excursion are requested to give early notice to the Secretary, who will supply further information if required.

A MONUMENT was unveiled last week at the École Normale, Paris, to Dr. Thuillier, the member of the French scientific mission to Egypt who died of cholera at Alexandria in 1883.

THE anniversary meeting of the Sanitary Institute is held today at the Royal Institution at 3 p.m. The chair will be taken by Sir John Lubbock, Bart., D.C.L., F.R.S. An address will be delivered by Prof. W. H. Corfield, M.A., M.D., entitled "The Water Supply of Ancient Roman Cities."

THE new buildings which have been erected in Chancery Lane and Fetter Lane for the purposes of the Birkbeck Literary and Scientific Institution were opened on Saturday afternoon by the Prince of Wales. The building, of which the foundation-stone was laid by the late Duke of Albany, contains accommodation for 6000 students. On the first floor are the library, reading and coffee rooms, and on the three floors above are the class rooms. A sum of over 20,000*l.* has been expended on the premises, which appear to be admirably adapted to the purposes for which they are intended.

THE Swedish Government have despatched Capt. R. Nissen to Kiel and Hamburg for the study of the chronometer observatories there and matters relating thereto. A sum of 250*l.* has been further awarded to Capt. Nissen for his valuable meteorological, astronomical, and magnetic observations during the recent cruise of the *Vanadis* around the world. A sum of money has also been granted to Dr. G. Tiselius, for the study during the summer of the attempts in progress in certain parts of Sweden of forest-cultivation from seeds; and a similar sum to Herr L. Baltzer for the drawing of the Runic inscriptions in the province of Bohus. It has further been decided to appoint an agent in London for one year to study and report on the fresh fish trade between Sweden and England, and the means to be adopted for its advancement.

THE Swedish Government have granted Dr. A. W. Liungman a sum of 350*l.*, in addition to his yearly salary, for the study of the herring and herring-fisheries of the west and south coast of Sweden, and the publication of the material collected.

AN unusually bright meteor was observed at Södertelje, near Stockholm, on the night of June 5, at 11.5 p.m. It came from the south, and went in a straight line west-east at about the height of Orion above the horizon. It could be followed with the eye in its course between Sirius and Algol, where it disappeared. The apparent size was one-fifth of that of the moon, and the colour brilliant white.

ADVICES received from Iceland by the last mail are ot a very disquieting character. Of the bodies of those killed by the avalanche in February last, twenty-four have been recovered, and the authorities have prohibited rebuilding in the valley. The weather during the spring has been exceedingly bad, snow falling incessantly from May 18 till June 5, and although the sea is open the fishing has in consequence been very bad. Agriculture and cattle-grazing are also very backward in consequence of cold winds and night-frost. In many places cattle have died from starvation, and if things do not soon mend there will probably be famine in the island next winter. In some valleys the snow was 30 feet in depth in the middle of June.

WE have received the report of the Liverpool Naturalists' Field Club for the year 1884-85. Steady, quiet prosperity appears to be the order of the day in this and similar associations in this country and in America. An elaborate system of prizes has been carefully organised, and the society appears exceptional in this respect. The report of the committee draws attention to the fact that in botany alone has much work been done; in the wide fields of zoology, geology, and microscopy little has been done. The presidential address is very interesting; it is called "Ornithopolis; bird-life under the shrubs, and what may be seen from my study chair." For the rest, there are the usual reports of excursions and of the evening meetings, and a list of books and scientific apparatus useful in the pursuit of natural history.

A SHARP shock of earthquake, accompanied by a loud rumbling noise, was felt at Kopreinitz in Styria on the night of June 28, which was followed by two others the following morning. Several houses were thrown down, and other damage done.

A NEW theory as to the origin and cause of earthquakes has been propounded by the Viceroy of the Chinese provinces of Shensi and Kansu. In a recent memorial to the throne, published in the *Peking Gazette*, this high official describes an earthquake which occurred on January 15 in various parts of Kansu, and summarises briefly the various reports which he has received on the subject relating to the motion, the damage done (which in some places was extensive), and the measures taken for the relief of the sufferers. He then proceeds to say that for years past earthquake shocks have been so frequent in these regions that people have grown quite accustomed to them; indeed, one officer informs him that in certain villages there were indications of a movement of the earth every night during the fourth watch, but these always ceased after a heavy fall of snow. The memorialist concludes by attributing the earthquake to the mildness of the winter, which caused an excess of the *yang*, or male element of Nature; "but it was due in a measure also to the perfunctory performance of their public duties by the local officials, who thereby failed to call down the harmonising influence of Heaven, and the memorialist can only endeavour to remedy this fault by encouraging his subordinates to cultivate habits of introspection and examination of their own shortcomings, himself setting the example."

ON the morning of June 15 a lovely mirage was seen at sea from Oxelösund, in Sweden, representing two islands, covered with trees, on one of which there was a building. Two monitors were seen steaming off the islands. It may be of interest to add that two Swedish monitors are at present cruising in the Baltic, and were about that time several degrees further north.

THE second annual issue of the "Year-Book of the Scientific and Learned Societies of Great Britain and Ireland" (Griffith and Co.) has appeared. We must still express surprise at finding the Royal Institution placed alongside of the Royal Society as a scientific society, while the London Institution is omitted entirely. A list of the papers read at the various societies is given this year; but it is difficult to see what purpose the publication serves in its present form.

HERR J. MENGES describes, in a recent number of *Globus*, the language of signs employed in trade in Arabia and Eastern Africa. This appears to have been invented to enable sellers and buyers to arrange their business undisturbed by the host of loafers who interfere in transactions carried on in open markets in Eastern towns, and it enables people to conclude their business without the bystanders knowing the prices wanted or offered. It is especially in use in the Red Sea, and its characteristic is that beneath a cloth, or more generally part of the unfolded turban, the hands of the parties meet, and by an arrangement of the fingers the price is understood. If one seizes the outstretched forefinger of the other it means 1, 10, or 100; the two first fingers together mean 2, 20, or 200; the three first, 3, 30, or 300; the four, 4, 40, or 400; the whole hand, 5, 50, or 500; the little finger alone, 6, 60, 600; the third finger alone, 7, 70, 700; the middle finger alone, 8, 80, 800; the first finger alone and bent, 9, 90, 900, while the thumb signifies 1000. If the forefinger of one of the parties be touched in the middle joint with the thumb of the other, it signifies ½, and if the same finger is rubbed with the thumb from the joint to the knuckle it is ¼ more, but if the movement of the thumb be upward to the top instead of downward to the knuckle it means ¼ less. An eighth more is marked by catching the whole nail of the forefinger with the thumb and finger, while the symbol for an eighth less is catching the flesh above the nail—*i.e.* the extreme tip of the finger in the same way. It will thus be seen that, by combinations of the fingers of the seller and buyer, a large range of figures can be represented. It is, of course, understood that average market value of the article is roughly known and that there can be no confusion between, for example, 1, 10, 100, and 1000. This language of symbols is in universal use amongst European, Indian, Arab, and Persian traders on the Red Sea coasts, as well as among tribes coming from the interior, such as Abyssinians, Gallas, Somalis, Bedouins, &c. It is acquired very rapidly, and is more speedy than verbal bargaining; but its main advantages are secrecy and that it protects the parties from the interruption of meddlesome bystanders, who in the East are always ready to give their advice.

THE additions to the Zoological Society's Gardens during the past week include a Collared Peccary (*Dicotyles tajaçu* ♂) from South America, presented by Mr. R. Forrester Daly; a Common Peafowl (*Pavo cristatus* ♂) from India, presented by Mrs. Courage; two Black-bellied Sand-Grouse (*Pterocles arenarius* ♀ ♀), two Bonham's Partridges (*Ammoperdix bonhami* ♂ ♂) from Asia, presented by Mr. W. E. R. Dickson; a Siamese Blue Pie (*Urocissa magnirostris*) from Siam, a Hunting Crow (*Cissa venatoria*) from India, presented by Mr. C. Clifton, F.Z.S.; two Rooks (*Corvus frugilegus*), British, presented by Mr. C. A. Marriott; a Lion (*Felis leo* ♀) from Africa, a Great Kangaroo (*Macropus giganteus*) from Australia, a Grand Eclectus (*Eclectus roratus*) from Moluccas, a Red and Yellow Macaw (*Ara chloroptera*) from South America, deposited; a Striated Coly (*Colius striatus*) from South Africa, purchased; a Mule Deer (*Cariacus macrotis* ♂), a Mesopotamian Fallow Deer (*Dama mesopotamica*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

THE COMET OF 1472.—M. Celoria of Milan has discussed the elements of the last comet observed by Toscanelli, which is the celebrated one of 1472, also observed by Regiomontanus, whose description of its path in the heavens enabled Halley to make a rough approximation to its orbit, as he states in his "Synopsis of Cometary Astronomy." The Chinese account of the Comet's track contained in the supplement to the great collection of Ma Twan Lin, of which Edouard Biot published a translation in the appendix to the "Connaissance des Temps" for 1846, enabled Langier to make a further calculation of the orbit, though the somewhat full description of the comet's course amongst the stars is unfortunately very deficient in dates.

M. Celoria remarks that possibly from the advanced age which Toscanelli had attained, and the inclement season at which the comet was visible, the Florentine astronomer has not left for the comet of 1472 a representation of its track relatively to the stars as he has done for those of 1433, 1449, and 1457, nor an ephemeris of positions as in the case of the comet of Halley at its appearance in 1456; but two pretty definite places are assigned in Toscanelli's manuscript for January 9 and 17, and with the help of provisional elements a third position for January 22 is deducible. Still, in determining the most probable orbit, M. Celoria has found it desirable to utilise the one definite observation on January 20 which has been left by Regiomontanus. The principal available data are:—

Paris Mean Time	Comet's Longitude	Comet's Latitude
	° ′	° ′
January 9·6326	193 0	+13 0
17·6007	190 20	26 30
20·4021	185 12	46 3
22·2347	110 30	+80 32

Two orbits result from the discussion of these positions, and M. Celoria concludes that it is difficult to decide which is preferable. These orbits are as follows:—

	Orbit II.	Orbit III.
Perihelion passage Paris mean time	1472, Feb. 29·89097	Feb. 29.94555
	° ′ ″	° ′ ″
Longitude of perihelion	39 14 56	39 46 27
,, ascending node	296 7 49	285 53 25
Inclination	14 11 46	9 9 54
Log. perihelion distance	9·68072	9·68654

Motion—Retrograde.

Both sets of elements have the degree of precision compatible with the nature and number of the observations, and beyond doubt afford a closer approximation to the true orbit than either of the previous computations. Perhaps we may attach a slightly greater weight to M. Celoria's orbit II., from which it appears that the nearest approach to the earth took place at midnight on January 22, when the comet in right ascension 293°·5 and declination +76°·6 was distant 0·0652, with an apparent motion of 40° of a great circle daily. On this day Toscanelli refers to the interference of moonlight, and it appears certain that the presence of the moon must have greatly diminished the imposing aspect of such a comet while in the earth's vicinity. In fact we find that the moon was at the first quarter on January 18, and consequently at full soon after the nearest approach of the comet, when the theoretical intensity of light was one hundred times greater than at the end of the first week in January.

One of the European chronicles dates the first appearance of the comet on December 25, 1471, when it will be found from elements (II.) that it was in right ascension 194°·4, declination + 5°·5 at 6 a.m. in London; intensity of light, 0·38. In a quaint description of the comet's track by John Warkworth, Master of St. Peter's College, Cambridge, and a contemporary, which was published in the *Philos. Mag. and Journal of Science*, vol. xiv. (1839), we read: "And some men saide that this sterre was seen ii or iii oures afore the Sunne rysynge in Decembre iijj days before Chrystynmasse in the Southwest . . .;" calculating for 6 a.m. on December 21 we find the comet was in right ascension 193°·8, declination + 5°·2: it would consequently be near the meridian two hours or so before sun-rise, instead of the western quarter of the sky. It is clear that as regards position it might have been found three weeks earlier than Toscanelli's first observation. Warkworth says the comet disappeared on February 22. The Chinese saw it on February 17 approaching one of their constellations composed of α, δ, &c., in Pisces, and it is added in Biot's translation "elle fut longtemps à s'effacer;" calculation gives the place in right ascension 11°·9, declination +0°·7, intensity of light 3·3, in the early evening at Pekin on that date.

M. Celoria's notice contains the geocentric track of the comet, according to both sets of elements, from January 9 to February 27. There is some reference in Pingré to a comet at the beginning of May, 1472, when the comet of Regiomontanus and Toscanelli would rise in Central Europe before 2 a.m., with an intensity of light about equal to that it possessed at the previous Christmas.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, *JULY* 12–18

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on July 12

Sun rises, 3h. 59m.; souths, 12h. 5m. 20·7s.; sets, 20h. 11m.; decl. on meridian, 21° 56′ N.: Sidereal Time at Sunset, 15h. 35m.

Moon (New on July 12) rises, 4h. 31m.; souths, 12h. 20m.; sets, 20h. 2m.; decl. on meridian, 16° 47′ N.

Planet	Rises	Souths	Sets	Decl. on meridian
	h. m.	h. m.	h. m.	° ′

GEOGRAPHICAL NOTES

Dr. Gottsche, formerly a professor in the University of Tokio, has, as we have already intimated, returned to Europe after a long journey in Korea, during which he acquired much information with regard to that country. The length of his journey was over two thousand miles, and he visited all the eight provinces of Korea, as well as 84 out of the 350 districts. The main object of Dr. Gottsche's explorations was to ascertain whether coal and other useful minerals existed in the country; but, on account of influential support which he received he was able to obtain from the native authorities information with regard to the population, taxation, harvests, trade, &c. He has also collected much statistical information which is wholly new and which it is expected will show that the recent English consular reports are quite incorrect. Amongst others the population of the peninsula has been greatly underrated. It has generally been put down at nine millions, whereas it really is over twelve millions, for the official census from which the former estimate is taken only takes into account adults. Dr. Gottsche's principal stations on the journey were Söul, Ichhön, Kwisan, Mangyöng, Kyöngyn, Pusan, Changwön, Cwangyn, Chinsan, &c. He was 138 days *en route*, and, although this was not rapid, he was compelled to neglect some branches of investigation, such as botany and zoology, for his main business was with geology. In this respect Korea appears to belong to the bordering Manchuria. He found but few traces of the high development which the art and science of the country reached in early ages, and which made it the instructress of Japan. Dr. Gottsche, it is said, intends publishing an account of his journey.

Prof. Blumentritt, in an article in *Globus* on the Negritos of the Philippines, points out that the notion which was general at one time that these aborigines of the Archipelago were almost extinct, or absorbed into the Malay population, is an error. It may be said with certainty that they no longer exist in the Babiuyanes, Batanes, and other groups lying to the north of Luzon: but we know too little of the interior of Sámar and

Leyte, as well as of the great island of Mindoro, to say this. We know from Montano's explorations that they live in great numbers in Mindanao and elsewhere; but nevertheless, the *Negrito puro* sooner or later adopts the dress and customs of his Malay conqueror. All the efforts of the Spanish Government and of the Catholic missionaries tend to efface the peculiarities of the Negrito; and the Professor therefore states that, before it is too late, some scientific traveller should visit Mindanao to study the Atás and Mamanuas thoroughly; likewise an investigation of the Negritos of Panay and Negros is much to be desired.

M. LE MONNIER contributes to the last number of the *Deutsche Rundschau für Geographie*, &c., an article on the Island of Hainan, off the coast of China, to which some attention was recently directed on account of the rumoured occupation of it by the French. It has been known to the Chinese since 110 B.C., but it was not till the 13th century that it received its present name. From the earliest times to the present the aborigines, the Li, who inhabit the mountains in the centre, have maintained a struggle against the Chinese. It is even less known than Formosa, for no Europeans have travelled in it. One port, Kiungchow, has recently been opened to foreign trade, the north and south coasts have been surveyed, but there is no survey of the east coast. As to size, it is a little smaller than Formosa, and is larger than either Sicily or Sardinia. The centre is exceedingly mountainous, and from it rivers radiate in all directions to the sea. It is so near the mainland that its flora and fauna are in all respects continental. The direction of the mountain system is from south-west to north-east. Volcanoes have been examined there, but they appear to be now extinct. Earthquakes are frequent. As in Formosa, the population consists of three elements—the Chinese, the subjugated and the independent natives. Amongst the former are the Miaotsze, who have crossed over the narrow strait from time to time from Kwangsi and We tern Kwangtung, and have taken possession of some of the smaller hills. Their language is said to be similar to that of the Li; they are good husbandmen, and are on friendly terms with both the Li and the Chinese. The independent Li appear to be an aboriginal race which has been driven back to the hills by the Chinese immigrants. Information with regard to them is very scanty, but they appear to have a reddish skin and to be of small stature; their language resembles that of the Miaotsze of the mainland. The women are tattooed after their marriage, and they paint their faces with indigo. The Li are expert hunters and shots; the weapons are bamboo bows and arrows and a short sword in a sheath. The main sources of information with regard to Hainan are a paper by the late Mr. Mayers in the *Journal* of the North China Asiatic Society (No. vii., 1873); one by Mr. Swinhoe, entitled "Narrative of an Exploring Visit to Hainan," in the same periodical (No. vii., 1871-2); and a map of the Kwangtung Province, and other publications by Dr. F. Hirth.

HERR GLASER, the Arabian traveller, has returned to Arabia to resume his explorations. This second journey is to be mainly geographical, but archæology will also receive attention. Besides visits to Marib and Nejdran, Herr Glaser contemplates a long journey through the interior from Hadramant to Omaun, and a second across South Arabia.

M. BAUX, member of the Geographical Society of Paris, has been despatched on an ethnographical mission to China; and M. Guerné proceeds to Kiel to take part in the labours of the commission for the scientific examination of the German coasts. These missions are undertaken by direction of the Minister of Public Instruction of France.

PROF. SEELSTRANG, of the University of Cordoba, has been appointed by the Argentine Government to superintend the publication of an atlas of the Republic, and a considerable sum has been appropriated for the work. It is to consist of twenty-seven parts, and four of these are already in hand.

AT the last meeting of the Geographical Society of Paris, M. Alphonse Milne-Edwards in the chair, M. de Saint-Pol-Lias, who is now in Cochin China, presented a map of the upper course of the Red River, prepared by the Annamites. Another map of importance is that of the navigable water-ways of southern Indo-China, prepared by M. Rueff, who has established a company for navigating these waters. A letter was read from Jeddah stating that the collections of the unfortunate M. Huber, including his remarkable examples of Semitic epigraphy, were safe in the hands of the French Consul, and that the explorer's remains were buried in Jeddah on May 27.

THE last number (Band viii. Heft 2) of the *Geographische Blätter*, published by the Bremen Geographical Society, contains a study on the Congo region by Dr. Oppel, dealing with the scientific and economieal importance of this district. The paper is divided into two main sections: (1) The discovery and investigation of the Congo (*a*) between 1484 and 1872, (*b*) the systematic exploration since 1872; (2) The extent and boundaries, geology, &c., of the Congo region. Prof. Seelstrang writes on the Argentine province of Buenos Ayres, its geography, fauna, flora, climate, inhabitants, trade, industry, &c., in short, a kind of encyclopædic article on the province. Another paper on South American geography, or rather geology, is that by Dr. von Thering on the Lagoa dos Patos, in the province of Rio Grande do Sul, the largest lake in Brazil This is accompanied by a map of the extent of the sea in the province at the beginning of the alluvial epoch. Herr Zöller writes on the Batanga River; the number also contains a report of the late *Geographen-tag* at Hamburg.

ON A RADIANT ENERGY RECORDER

SUNSHINE-RECORDERS may be divided into two classes, viz., those which roughly measure solar energy by the burning of card and wood, and those which, by means of some photographic process, yield a record of the relative intensity of some more or less definite ray. The principle of the instrument which I am about to describe differs from those referred to in this respect—that it depends upon the evaporation of water *in vacuo*, and its indications are therefore readily expressible in heat-units.

The form of instrument with which I have sought to test the applicability of the method consists of a Wollaston's cryophorus (of the form pictured in Ganot's "Physics," p. 272, edition 1872), in which the vertical tube and lower bulb are replaced by a simple glass tube graduated in cubic centimetres. The bulb containing the water to be evaporated is blackened by holding it in the smoke of burning camphor, and is then exposed to the sun, the rest of the apparatus being silvered or properly protected by bright sheets of tin. At sunset the quantity of water which has distilled over can be read off on the graduated tube.

An experiment on June 6 showed 1·8 cc. to have passed over from a bulb of about 2 inches in diameter, and to have condensed in a narrow measuring tube between the hours of 10.40 and 3.20. The instrument seems very sensitive, and may well find many applications. In a suitable form of instrument the total nett solar energy gained by the blackened absorbing surface will be almost exactly represented in heat-units by multiplying the number of cubic centimetres of water distilled by the latent heat of steam. To measure the loss of the earth's radiation at night a similar instrument containing alcohol or some other liquid of low freezing-point might be employed. In either case, when a continuous time record is required, the graduated tube might be used as a cylindrical lens to condense light on photographic paper.

The following are the more important conditions which the apparatus in a future form should probably fulfil:—

(1) To present a constant and known absorbing surface to the sun.

(2) To preserve a constant surface for evaporation which should be the same in the condenser, so that a reversal of the direction of distillation can take place under the same conditions when the black bulb is losing energy.

(3) To give rise to the minimum of reflection and convection currents on the absorbing surface.

(4) The apparatus should be so screened as to be at the temperature of the air apart from the gain of energy at the blackened surface.

Some of these conditions seem likely to be more or less fulfilled in an apparatus consisting of two glass bulbs of equal diameter connected together by a tube bent through an angle of about 150°, to bring the bulbs near together, and thus keep them in air of the same temperature. In the bulb containing the water to be evaporated, a black bulb might be fixed to absorb the solar radiation, whilst to the upper part of the second bulb should be sealed a graduated tube in which the distilled water might be measured by inclining the instrument. If metal globes were employed the connecting tube might be made to form the beam of a balance.

The completion of other work will prevent my return to this subject at present—perhaps altogether—but I have ventured to publish this incomplete account of an apparently promising method for the measurement of solar radiation, in the hope that it may be of use and interest to others.

University College, Liverpool. J. W. CLARK

P.S.—It may perhaps be found advantageous to use an apparatus like an inverted cryophorus, in which the absorbed radiant energy generates a vapour-pressure, and is made to lift a column of water in the tube—the height of the column and the time being registered photographically.

THE GROWTH OF CEREALS

PERHAPS nowhere is the influence of the different climatic factors on the rapidity of growth so well illustrated as on the plains of Russia. Therefore W. Kowalewski's careful researches into this subject, summarised in the *Memoirs* of the St. Petersburgh Society of Naturalists (xv. 1), are especially worthy of attention. The author has gathered all necessary information for showing the periods of growth of various cereals on the soil of Russia, from the far north of Arkhangelsk, to the southern province of Kherson, and he has arrived at most interesting results, of which the following is a summary. If the periods of growth of the same cereal be taken throughout Russia, it appears that, altogether, it is in the higher latitudes that it ripens fastest. Oats and spring wheat take 123 days and barley 110 days to ripen about Kherson, and only 98, 88, and 98 days at Arkhangelsk, the difference in favour of the north being respectively thus: 25, 35, and 12 days. The intermediate regions show also intermediate differences, while for each latitude the growth of cereals proceeds faster in the eastern parts of Russia than in the western. It is obvious that if the rapidity of growth were due to temperature, the phenomena would be the reverse of what they are. Moreover, the want of moisture in the southern steppes is also a condition in favour of the rapidity of growth: so that it is in the insolation that we must seek for the cause of the above-stated difference. In fact, oats being usually sown about May 17 at Arkhangelsk, and the harvest usually occurring about Sept. 1, the insolation continues there for 2000 hours in 98 days, not to speak of the 240 hours of bright nights; while at Kherson, during 123 days (from April 1 to Aug. 1) the insolation lasts only for 1850 hours. The difference in favour of Arkhangelsk is thus equal to 150 hours (to 400 hours, if the bright nights be added), and it compensates for the influence of temperature. It is useless to add, moreover, that the cereals cultivated in the north have already undergone a certain accommodation to their conditions. As to the intensity of light, Prof. Famintzin's work on the subject, corroborated by ulterior researches, shows that the great intensity of light in Southern Russia, combined with the great transparency of the atmosphere, is rather a condition against the rapidity of growth, the intensity of light exceeding the limits of the maximum of decomposition of carbonic acid. Winter rye shows the same differences as the spring cereals. It appears from M. Kowalewski's tables that in the Arkhangelsk district winter rye takes 375 days to arrive at ripeness, of which there are 202 days of winter rest, 68 days of autumn growth, and 105 days of spring and summer growth, making thus a total of 173 days of growth. At Kherson the total growth lasts for 290 days, of which only 101 days of winter rest and 189 days of productive growth (63 during the autumn and 126 during the summer). The difference reaches thus 16 days in favour of the north, and it would rise to 20 or 25 days if only spring and summer be taken into account. The graphical representation of all these data is most interesting. Thus the lines of simultaneous sowing of winter rye from north-west to south-east correspond to the isochimenes, while the lines of simultaneous ripening of the spring cereals—oats, barley, sarrazin, wheat—run from south-west to north-east, corresponding to the lines of equal summer temperatures. The retarding influence of rain comes out also pretty well.

THE ROYAL SOCIETY OF NEW SOUTH WALES

THE annual general meeting of the members of the Royal Society of New South Wales was held on May 7. The president, Mr. H. C. Russell, B.A., F.R.A.S., occupied the chair, and delivered an address, from which we give the following extracts:—

"There is a very general impression, borne out by the evidence which geology has furnished, that at least the east coast, if not all Australia, is rising in relation to the mean level of the sea. The late Rev. W. B. Clarke, in a report to the Port Jackson Harbour Commission, said 'that the coast has risen in former geological epochs, and that it has risen during the present epoch is capable of distinct proof.' 'Raised beaches of shells, which are not kitchen middens, may be seen about twenty-five feet above the sea, near Ryde, on the Paramatta estuary, and at Mossman's Bay, in Port Jackson, at a height of 132 feet above high-water.' Again, 'regarding the whole coast from Broken Bay to Botany Bay as mere peninsulatic fragments, united only by low isthmuses, bare or covered with sand, as they actually are, one may still see that there must have been oscillations of level, and finally elevation.' Speaking of other portions of the coast, Mr. Clarke says:—'At Adelaide in 1855 the railway between the city and the port was being constructed, and Mr. Babbage has since shown that in four years a difference of four inches of rise between the levels of those places has taken place.' And again, 'according to Mr. Ellery, the accomplished and accurate Williamstown observer, the self-registering tide-gauge at that place indicated a rise of the bottom of Hobson's Bay of four inches in twelve months, and a deposit of recent shells and imbedded bones of sheep and bullocks which had been thrown into the bay is now seen at a level above the reach of the sides.' Again, quoting from a letter by the late Mr. John Kent, of Brisbane:—'A survey was made of a shelf of rocks in Brisbane River in 1842 by Captain Gilmore, Mr. Petrie, and myself, and in making a re-survey in 1858 Mr. Roberts found the relative depths were singularly correct, but that the general depth of water over the shelf of rock had decreased eighteen inches in sixteen years since the first survey was made.' Sir Roderick Murchison, in the *Proceedings* of the Royal Geographical Society of London (vol. vii. p. 42) quotes from a letter he had received from the late Mr. Kent, of Brisbane:—'I have lately drawn the attention of the Rev. W. B. Clarke to the fact that the eastern coast of New Holland is rising at the rate of (say) one inch per annum, as ascertained by the height of rocks in the river Brisbane above tide levels, through a period of twenty years, and he assures me that to the south the same result has been inferred, though the observations have not extended over so long a period. At what rate the rise is now going on there are no data to establish. Till a series of mean tidal levels are marked on the rocks of the harbour, and the alteration made as distinct as that in Hobson's Bay, any deduction as to the rate of rise must be conjectural and unreliable.' I have but taken a few extracts from a great mass of evidence which Mr. Clarke brought forward in proof of the rapid elevation of the coast of Australia. I was deeply interested in this report when it was published in 1866, and as soon as I had opportunity determined to make such observations with a self-registering tide-gauge as would determine the rate of rise, if any, and in collecting information bearing upon this subject during the past thirteen years. I wrote to Mr. Ellery and asked him for further particulars of the rise going on in Victoria, and in reply he said that Mr. Clarke had in some way misunderstood his remarks, which had reference to the silting up of the harbour, not the elevation of the land; and he at the same time sent me a copy of his paper on 'The Tidal datum of Hobson's Bay,' read before the Royal Society of Victoria, August 14, 1879. After giving the history of the tide-gauge, which was started in 1858 under the Harbour Department, and was not under his control till 1874, Mr. Ellery says:—'It is to be regretted that no precise references to mean tide level in the earlier days can be found. Where measurements do exist in Hobson's Bay they are lacking in accurate information as to the state of the tides, and I find nothing trustworthy upon which to base any statements as to change of sea level since surveys have been made. I think it desirable that permanent bench marks on the natural faces of the rock *in situ* should be established around our bay, carefully connected by accurate levelling with one another and with the tide-gauge, for it is very doubtful if bench marks on buildings can be assumed to afford a permanent datum.' The first self-registering tide-gauge in Sydney was erected on Fort Denison by the late Mr. Smalley in 1867. Unfortunately the design was so faulty that all the records of the heights of tides made by it are of no value, although the times of high and low water are correct. The reason for this fault in its records was that an ordinary hempen cord was used to connect the float and the pencil, and this gradually got longer by use, and also varied with the weather. Finding it impossible to remedy this fault satisfactorily in view of the necessity for exact records of the heights of the tides, in 1872 I had a new gauge made, which, without losing the accuracy of the time record, which the old one possessed, insured the correct record of the height of the tides. This instrument is figured and described in the 'Sydney Meteorological volume for 1878,' and to that work I must refer you for particulars. The record by the new gauge was begun on June 27, 1872, and at that time the precaution was taken of measuring the length of the chain connecting the float and the wheel, so that should any change take place its exact amount could be ascertained. The wisdom of this has been evident on several occasions when the chain was broken by accident, and the exact length restored. The well made for the tide gauge is in part cut in the solid rock, and from the rock to the surface of the ground the sides of the well are built up (round) with solid masonry, so that the top ring of the well is practically part of the solid rock, and cannot move unless the rock does so. On this ring the frame of the tide gauge stands, and the instrument, therefore, has a permanent relation to the rock, and there can be no change in its parts which might be mistaken for a change in sea level. I have been particular in detailing the conditions under which the tide measurements have been made, to show you that sufficient precautions to ensure accuracy have been taken. In each year the mean of all the tides is taken as the mean sea level for that year, and when these results for the past twelve years are placed side by side, it is at first sight rather puzzling, for although the greatest departure from the mean of all is only one inch, yet within this small range the land seems to rise and fall in an erratic way. The cause of these variations, however, was found in the varying relative positions of sun, moon, and earth, and perhaps, to some extent, in the effects of heavy gales. Taken as a whole, these results seem to prove conclusively that no change whatever has taken place in the relation of land and sea during the past twelve years. Of course the question is not settled—a slow change that would be visible in centuries might be altogether hidden in the results before us; but so far as they go these results will be interesting to scientific men, for they are the first that have been taken with such accuracy as the investigation demands. Mean Sea Levels: 1873, 2 feet 5·9 inches; 1874, 2 feet 7 inches; 1875, 2 feet 6·3 inches; 1876, 2 feet 5·5 inches; 1877, 2 feet 6·7 inches; 1878, 2 feet 6 inches; 1879, 2 feet 5·5 inches; 1880, 2 feet 6·2 inches; 1881, 2 feet 5·2 inches; 1882, 2 feet 6·1 inches; 1883, 2 feet 6·8 inches; 1884, 2 feet 6·95 inches—2 feet 6·11 inches. In examining this question I looked for some mark of old surveys which might show what the evidence of a longer period would be, but I have failed to find any mark put in with such care as the investigation demands. There is, however, one mark on the north-east face of the round tower on Fort Denison which was put in by H.M.S. *Herald* during her survey of Sydney harbour. It is cut in the stone three feet above mean sea level, and is marked with the broad arrow under it. I have been at some trouble to find out on what observations this mark was based; but although I have learned that the survey was made in 1857, and that the *Herald* was in port from February 26 to December 21, 1857, I cannot learn how long the tide observations were continued, but I hope still to do so. The time and method of taking mean sea level might account for a difference from the true mean of four or five inches, as is shown by the different monthly means from the recording tide gauge, and until I can learn on what observations the *Herald's* mark depends, it cannot be used as evidence of change of level of the land. I have, however, connected it carefully with the zero of the tide gauge, and if it exactly represents mean sea level in 1857, it proved that the land has risen five inches in twenty-seven years; but, since the tide gauge shows no change whatever during twelve of these years, I think the evidence of the mark cannot be taken without full particulars of the observations on which it depends. In the course of conversation with the late Rev. W. B. Clarke on the question of the elevation of the coast, he pointed out to me evidence not only of the elevation of this coast, but also of its subsidence, and expressed his conviction that Port Jackson, Hawkesbury River, and other places on the coast had been cut out by the action of fresh water, when the coast was much higher than it is at present—in fact, that these inlets had been at one time gullies exactly similar in character to those which now exist in the Blue Mountains, and which have been so obviously cut out by fresh water. Since that time many bridges have been made along the coast, and the borings made for foundations for these bridges have special significance in connection with Mr. Clarke's opinion; and by the kindness of the Engineer-in-chief for Railways and the Engineer-in-chief for Roads and Bridges I am able to quote here some of these measures, which prove conclusively that the sea was at one time much lower than it is at present. The soundings taken for the Parramatta Railway bridge show 26 feet water, 32 feet mud and silt, 8 feet loose sand, 12 feet hard sand, 10 feet loose sand: total, 88 feet. George's River bridge—8 feet water, 87 feet mud and sand, 9 feet black clay, 16 feet sand, 4 feet hard sand: total, 121 feet. Hawkesbury River bridge—44 feet water, 31 feet light mud, 87 feet black mud, 8 feet very hard sand: total, 170 feet. In the road-bridge over the Parramatta River—41 feet water, 16 feet shells and mud, 15 feet sand, 9 feet blue clay, 6 feet clays and shells: total, 87 feet. Ironstone Cove road-bridge—26 feet water, 7 feet stiff blue clay, 36 feet very stiff blue clay, 15 feet yellow clay, 5 feet stiff black clay, 11 feet sand and clay, 2 feet clean sand, 3 feet gravel and wood: total, 105 feet. Shoalhaven River road-bridge—14 feet water, 103 feet mud and silt: total, 117 feet. The bottom of the Hawkesbury, therefore, where the railway-bridge is to be, is 170 feet below the level of the sea to-day; and when the rocks were washed away to form the river-bed to that depth, the sea must have been at least 170 feet below its present level, and the bearings in Sydney Harbour and George's River indicate a similar fact, if not to the same extent. Without going further into this question, which is foreign to my present purpose, I think I have said enough to show that the evidence for elevation and subsidence of the land are about equal, the question before us being, In which direction is the change going on now? In estimating the value of the evidence quoted as to the rate of rise in Queensland and South Australia, we must not forget that when engineers adopt the usual rule as to mean sea level—that is, as to the mean of high and low water at any time of the year—they assume that all such means are equal or represent a constant level, when in point of fact two such determinations of sea level may differ by 8 inches or even more, and in the absence of a self-registering tide-gauge, or constant observations extending over a year, no levelling referred to the sea in the usual way is of any value whatever in such an investigation as that required to determine whether the relative level of land and water varies. I have already shown that Mr. Ellery thinks there is no evidence of present rising in Hobson's Bay, and the fact that at the time the engineering levels referred to were taken in South Australia and Queensland there were no self-registering tide-gauges to determine accurately mean sea level, is sufficient to warrant us in hesitating before we receive the evidence as to the rate of elevation furnished from these colonies, which I quoted from Mr. Clarke's report. Some few months since it occurred to me that it would be desirable to put a self-recording gauge on Lake George, with a view of keeping a continuous record of evaporation and other changes of level in it; and as soon as the instrument could be got ready I put it up on the west side of the lake, in front of Douglas House, which is about a mile from the present southern end. The work of erecting the instrument was completed on the afternoon of February 18, and the pencil was put down on the paper to begin its curious record at 7 p.m. on that day. At the time the lake seemed calm as a millpond, and, looking at its smooth surface, no one would have dreamed that such changes were going on in it as began to reveal themselves so soon as the pencil touched the paper, and in two hours the pencil had recorded a rise and fall of about 2 inches. This is not a motion like the ordinary wind-made waves, which pass by in two or three seconds, but a slow and gradual rise, occupying an hour, and then a corresponding fall in about the same time, to do which a current must first have set from north to south for an hour, and then reversed; and if we consider for a moment the force necessary to put a body of water 18 miles long, 5 wide, and 15 or 20 feet deep, in such motion, we shall get some idea of the magnitude of the forces at work. The record had not been going 24 hours when it became obvious that these periodic motions in the level of the water had a period of about two hours, and on the afternoon of the second day a heavy thunderstorm passed over the south end of the lake, and threw a little light on the cause of the pulsations. The storm rain was very heavy and much of it must have run into the lake, tending to raise the waters there. With the storm there came a violent squall of wind from the south, on to the south end of the lake; in a few minutes great foam-crested waves could be seen in the middle, and the recording gauge at once showed what was the matter; the wind had blown the water away from the south end and reduced the general level 3 inches. In 10 minutes the squall was over, and the water began to recover its level, in doing which the current set towards the south end of the lake, and could be seen running past the jetty at the rate of about two miles per hour. But it did not stop when the old level was reached, the momentum carried it beyond that point, and raised the water up at the south end of the lake. Then it turned and ran back again, repeating this process time after time at intervals of about two hours, the rise and fall getting gradually less until in about eight hours the water was almost still, when suddenly, at 11.30 p.m., the water began to rise faster than ever, and in 30 minutes had risen 4 inches; it then turned and fell nearly as fast as it had risen, and reached its lowest point in 1 hour 41 minutes, having fallen exactly 6 inches. At Douglas House the night was fine and calm, without the sign of a storm. Yet it seems probable that a storm passed over the north end of the lake, and started the motion, which kept on at intervals of about two hours for 14 hours, the rise and fall gradually getting less. I was fortunate enough to be present and see so much of the record and the corresponding weather. You have no doubt noticed that one set of pulsations was started by a sudden fall, and the other by a sudden rise, in the lake, and that the impulse which caused the water to rise was greater than the other. Similar impulses have kept the lake in almost constant motion ever since, and when once under way, they will go on throughout a gale of wind with just as much regularity as in a calm. Ordinarily such a set of motions lasts 10 or 12 hours, decreasing gradually as if the friction of the water stopped it; but on several occasions they have kept on for days together. The most remarkable impulse yet recorded was on the 14th of April, when the water was remarkably still, and had been so during the 11th, 12th, and 13th. At 11 a.m. on that day Mr. Glover, who has charge of the gauge, saw a thunderstorm coming down from the north, and went into the recording-house to see its effect. The lake was rising fast, and in 30 minutes rose 4 inches; as the storm passed overhead the rising ceased, and the lake at once began to fall, getting back to its previous level in 15 minutes; passing this point it fell 2 inches more– in all 6 inches—and then began to rise again, so starting a series of pulsations that lasted five days. Rain came with this storm, and on the 14th and 15th measured by gauges at each end of the lake 1·10 inch rain fell, and this caused a rise of 1½ inches in the lake, which can be distinctly seen in the record as something independent of the pulsations. With the rain there was a strong breeze of wind, and by the third day after the water had returned to its old level, all the rain having evaporated in three days. In each of the cases I have mentioned so far the impulses seem to have been given by a sudden storm breaking over the lake, but there are other instances in which the impulse was of a totally different character, and it seems as if a small force properly managed was made to do duty for a large one, just as we should set a heavy weight suspended by a string in motion by giving it first a little push, and then adding impulse at each swing. So the force, whatever it be, which in these cases acts on the water in the lake, gives it a little start and gradually gets it in motion. The best instance of this occurred on the afternoon of April 5, at the time the lake was very quiet, and suddenly the water rose an inch, and fell again within 30 minutes; next time it rose an inch and a half, and fell 2 inches in three-quarters of an hour; the next time it rose 2 inches, and fell 3½ inches in an hour; it then rose 3¾ inches in 40 minutes, and so started a series of pulsations which settled down to two-hour intervals, and lasted twenty hours. Usually, the rise and fall take about equal times, but now and then the whole fall will take place in 14 or 15 minutes, and the corresponding rise takes 116 minutes, and it is not very unusual to find one in a set of twice the period of the others, as if one had been left out. In fact the variations in the conditions of vibration are very puzzling. With a view of finding out the most common period I have measured 54 of the best defined amongst those already recorded. Of these 33 have a period of 2 hours 11 minutes, five a period of 2 hours 5 minutes, six a period of 2 hours 17 minutes, and ten a period of 1 hour 12 minutes. The periods of those on the Lake of Geneva are 72 minutes and 35 minutes. Of those in Lake George which have a period of 2 hours 11 minutes, some are the largest yet recorded, and others only a half or a quarter of an inch rise and fall; so that there must be something which makes or tends to make the period 2 hours 11 minutes. It is noteworthy that at Lake George as well as the Lake of Geneva, the short seich is not half the long one; but they bear about the same proportion one to the other in each case. As to the cause of these motions in the lake I am not prepared to say much at present. Further investigation is needed, and I hope, by the aid of a recording aneroid already there, and a recording anemometer to be erected shortly, to be able to compare the changes of wind and pressure with the changes in the lake; but I do not expect to find everything. Changes of level, &c., are going on in the earth surface, which, from an astronomical point of view, are intensely interesting, because they affect the instruments, and therefore the measures. They are very minute, and we have no means of keeping a continuous record of them; but it is possible that if such changes affect the lake they will be so magnified by its comparatively enormous extent as to show themselves on the recording instruments there. The baragraph at Sydney has shown long since that thunderstorms come on with a sudden rise of the barometer, which at times amounts to a tenth of an inch. If such a change could affect one end of the lake for a few minutes it would be equivalent to putting suddenly on to it an inch of water, which would make itself known at once by a rush to the other end; but although such changes must have some effect, I do not think it can be considerable, because, as I have elsewhere shown, these storms move at the rate of about 60 miles per hour, and are often 70 miles wide, so that such a storm coming on to the lake would spread all over it too rapidly to cause much motion in the water. I am here assuming that the storms there are of the same character as those which pass over Sydney, but they may be smaller when passing the lake, and travel more slowly. Certainly the storm which I saw coming down the lake did not traval with anything like such velocity. M. Vaucher, who studied for years the motions of the same kind which take place in the Lake of Geneva, considered himself justified in saying: "The lake is disturbed when the barometer is unsteady, and because of the varying pressure." From what I have seen so far, the first part of this is true of Lake George, but it is not because the barometer is unsteady, but because at such times the wind is puffy and variable, and imparts to the water its own peculiarity. Of the power of the wind to set the water in motion I have mentioned several instances to-night, which I need not repeat, but I may add that the large impulses come from the north, because, as it seems to me, the wind from that direction acting on the water, the whole length of the lake has greater power than when blowing from the south over a short stretch of water, the gauge is fixed about a mile from the south end. But, although the wind is such an obvious cause of the phenomena under discussion, I think the barometric changes have some share in it, and there are some changes recorded which, so far, I am unable to refer to any cause. Mr. Russell then entered into details of the surroundings of Lake George, which, he stated, are of very great interest, viewed in the light of discussions as to the possible change in the amount of rainfall in the colony during long periods. The persistence of level in Lake George, he pointed out, is very strong evidence in favour of the view that there has been no great change in the rainfall there for thousands of years, and probably the same may be said of Australia. The rainfall on the lake in 1870, Mr. Russell said, was 50 inches, double the average rainfall, which is 25 inches, and it is not to be wondered at that the lake rose at an unusual rate. Still this rain, heavy as it was, only served to cut little gutters in the older deposits which had been brought down the gullies. The primary object in placing the recording gauge on Lake George was to ascertain the rate of evaporation from such a large body of water, the conditions at the lake being very favourable for such an investigation. The record began on February 18, and the time since is too short to justify any assumption of the rate of evaporation there; but I may mention some of the facts that have been recorded bearing upon this question. In 68 days the level of the lake has fallen 7 inches by evaporation; in this interval, according to the records of rain-gauges at each end of the lake, 3·55 inches of rain has fallen, so that, ignoring the water which may have run from the hills during these rains, the lake has lost all the rain falling into it and 7 inches more, that is, 10½ inches. During the past 14 years the lake has lost by evaporation 12 feet; and in May, 1878, the railway survey carried down the western side showed that the lake was then

6 feet below its 1871 level, or 2225 feet above the sea. It appears, therefore, that in 7 years, 1871 to 1878, the lake lost 6 feet; and again, from May, 1878, to February, 1885, say seven years, the lake again lost 6 feet by evaporation, and this of course in addition to all the rain which fell during that period. Taking the records at Goulburn and Gungahleen, near the lake, the average rainfall for the first 7 years was 27·95 inches, and during the next 7 years 23·68 inches. One would expect to find more evaporation during the drier years, but this is not borne out by observations. From the rainfall and recorded evaporation the lake, therefore, lost by evaporation at least 3 feet per annum. I say at least, because some rain water must have run into the lake in addition to that which fell into it directly, but its amount cannot be determined. In future the recording gauge will determine this, and perhaps then we may apply the experience gained to estimating how much ran in during the past fourteen years. Lake George is called a fresh-water lake, and some have even gone so far as to propose to use it as a reservoir for the supply of towns. When there I ascertained that no one could use the water on account of its purgative properties, one glass full being quite enough to satisfy those who made use of it; and it is there said that the water running into the lake from the Currawang copper mine had poisoned all the fish. This is not literally true, for there are still fish in the lake; but very many were killed some years [since, presumably by the cause mentioned. I obtained some of the water, and am indebted to Mr. Dixon, of the Technical College Laboratory, for the following interesting information as to what the water contains:—It is quite evident that with 187·5 grains of mineral matter per gallon the water cannot be used for domestic purposes, and from the fact that this matter is constantly being added to, it cannot improve, unless it were possible to withdraw large quantities of the water, and supply its place with rain-water; but during by far the greater number of years during which the lake has been known, viz., 64 years, the supply of rain-water going into it annually has not been equal to the evaporation, and there is no other outlet. After the great flood of 1870 the lake, during the last 14 years, has gradually decreased by nearly a foot per annum, and similar conditions existed before; and it is therefore obvious that it would not be possible to wash out the salts with rain-water and artificial drainage except in wet years—perhape once in 20 years. Extract Mining Department's report, 1880:—'Three samples of water from the Currawang Copper mines were sent for analysis, with special reference to their poisonous action on the fish in Lake George, and were therefore only examined with regard to the metals in solution. The metals were present as sulphates, and are stated below:—Water from the creek contains: Sulphate of copper, 1·12 grains per gallon; sulphate of zinc, 16·78 grains per gallon; sulphate of iron, 0·43 grains per gallon. Water from the working shaft: Sulphate of copper, 17·67 grains per gallon; sulphate of zinc, 53·54 grains per gallon; sulphate of iron, 1·42 grains per gallon. Water from the old shaft: Sulphate of copper, 6·42 grains per gallon; sulphate of zinc, 7·20 grains per gallon; sulphate of iron, 0·98 grains per gallon.' This water would necessarily be poisonous to fish, and flowing into a lake without outlet, would ultimately render the whole water poisonous. 'Technical College Laboratory, Sydney, 2nd May, 1885. My dear Mr. Russell,—The water from Lake George contains 187·5 grains per gallon of solid matter dried at 212° F. The residue has a strongly alkaline reaction, effervesces with acid, blackens much on ignition, but does not show the presence of nitrates in doing so. The metals present are aluminium, calcium, and magnesium; the acids chlorine, carbonic acid, sulphuric acid, and phosphoric acid, the last two in small quantity. The salts are probably arranged as chloride of sodium, sulphate of sodium, phosphate of sodium, carbonate of sodium, and carbonates of calcium and magnesium. The purgative properties of the water are probably due to the salts as a whole, and especially the carbonate of magnesia. It should be borne in mind, however, that waters containing much organic matter frequently have a purgative effect.—Signed, W. A. DIXON. P.S.—Zinc and copper are entirely absent.'"

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

SCIENCE AND ART DEPARTMENT.—The following Prizes, Scholarships, Associateships, &c., have been awarded in connection with the Normal School of Science and Royal School of Mines, South Kensington.

First Year's Scholarships: — James Rodger, Andrew McWilliam, Tom. H. Denning, John Richards.

Second Year's Scholarships:—Arthur E. Sutton, Thomas Rose.

The following Prizes were also awarded:—Alfred V. Jennings, the "Edward Forbes" Medal and Prize of Books for Biology; Arthur E. Sutton, the "Murchison Medal" and Prize of Books for Geology; and the "Tyndall Prize" of Books for Physics, Course I.; Henry G. Graves, the "De la Beche" Medal for Mining; John C. Little and James Allen, "Bessemer" Medals with Prizes of Books from Prof. W. Chandler Roberts for Metallurgy; Arthur W. Bishop and Peter S. Buik, the "Hodgkinson" Prizes for Chemistry.

Associateships, Normal School of Science:—Isaac T. Walls (Chemistry, 2nd Class); Alfred Fowler (Mechanics, 1st Class); George H. Wyatt (Physics, 2nd Class); Martin F. Woodward (Biology, 1st Class).

Associateships, Royal School of Mines:—John C. Little (Metallurgy, 1st Class); Thomas A. Rickard (Metallurgy, 1st Class); Percy E. O. Carr (Metallurgy, 1st Class); Walter A. A. Dowden (Metallurgy, 2nd Class); Henry G. Graves (Mining, 1st Class); Ernest Woakes (Mining, 1st Class).

DR. REDWOOD has retired as Emeritus Professor from the Chair of Chemistry at the Pharmaceutical Society. The vacancy has been filled by the appointment of Mr. Wyndham Dunstan, Demonstrator of Chemistry in the University Museum of Oxford.

SCIENTIFIC SERIALS

Rendiconti del Reale Istituto Lombardo, May 21.—A science of criminal legislation in connection with the projected Italian Penal Code, by E. A. Buccellati.—Note on the inscribed Etruscan arms and mirrors in the Fol Museum, Geneva, by Prof. E. Lattes.—The system of projected homogeneous co-ordinates for the elements of ordinary space, by Prof. F. Aschieri.—On the separation of cream from milk, and the conditions tending to accelerate the process, by Prof. G. Morosini.—Further researches on the functions that satisfy the differential equation $\Delta^2 u = 0$, by Prof. Giulio Ascoli.—Remarks on the Mexican skulls deposited in the Civic Museum, Milan, by E. A. Verga.—Meteorological observations made at the Brera Observatory, Milan, during the month of May.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, June 18.—"A Memoir introductory to a General Theory of Mathematical Form." By A. B. Kempe, M.A., F.R.S.

The object of the memoir is the treatment of the "necessary matter" of exact or mathematical thought as a connected whole; the separation of its essential elements from the accidental clothing—algebraical, geometrical, logical, &c.—in which they are usually presented for consideration; and the indication of that to which the infinite variety which those elements exhibit is due.

The memoir opens with the statement of certain fundamental principles, viz.:—Whatever may be the true nature of things and of the conceptions which we have of them (as to which points we are not concerned in the memoir to inquire) in the operations of reasoning they are dealt with as a number of distinct entities or *units*.

These units come under consideration in a variety of guises—as points, lines, statements, relationships, arrangements, intervals or periods of time, algebraical expressions, &c., &c.—occupy various positions, and are otherwise variously circumstanced. Thus, while some units are undistinguished from each other, others are by these] peculiarities rendered distinguishable. For example, the angular points of a square are distinguishable from the sides, but are not distinguishable from each other. In some instances where distinctions exist they are ignored as not material. Both cases are included in the general statement that some units are distinguished from each other and some are not.

In like manner some *pairs* of units are distinguished from each other while others are not. Pairs may be distinguished even though the units composing them are not. Thus the angular points of a square are undistinguishable from each other, and a pair of such points lying at the extremities of a side are undistinguishable from the three other like pairs, but are distinguishable from the two pairs formed by taking angular points at the extremities of a diagonal, which pairs again are undistinguishable from each other. Further, a pair, *ab*, may sometimes be distinguished from a pair, *ba*, though the units *a* and *b* are undistinguished. Thus if *a*, *b*, *c* be the angular points of an equilateral triangle, and barbs be drawn on the sides pointing from *a* to *b*, from *b* to *c*, and from *c* to *a* respectively, the angular points *a*, *b*, *c* will be undistinguished from each other; each has an arrow proceeding from it and to it, but the pair *ab* is distinguished from the pair *ba*, for an arrow proceeds from *a* to *b*, but none from *b* to *a*.

In the same way we have distinguished and undistinguished triads, tetrads, &c.

Every collection of units has a definite *form*, due—(1) to the number of its component units, and (2) to the way in which the distinguished and undistinguished units, pairs, triads, &c., are distributed through the collection. Two collections of the same number of units, but having different *distributions*, will be of different forms. The angular points of a cube and of a regular plane octagon furnish examples of two systems of eight units, having different distributions. In the former case there are three sorts of pairs, in the latter four.

Each of the forms which a system of *n* units can assume owing to varieties of distribution is one of a definite number of possible forms, and the peculiarities and properties of the collection depend, as far as the processes of reasoning are concerned, upon the particular form it assumes, and are independent of the dress—geometrical, logical, algebraical, &c.—in which it is presented; so that two systems which are of the same form have precisely the same properties, although the garbs in which they are severally clothed may by their dissimilarity lead us to place the systems under very different categories, and even to regard them as belonging to "different branches of science."

It may seem in some cases that other considerations are involved besides "form," but it will be found on investigation that the introduction of such considerations involves also the introduction of fresh units, and then we have merely to consider the form of the enlarged collection.

Taking these principles as a basis, the memoir, which is a lengthy one of 426 sections arranged under 42 heads, discusses the various forms which systems can assume, and gives some general modes, graphical and literal, of representing them. The genesis of algebras is considered, and the nature of the particular forms dealt with in geometry, ordinary algebra, formal logic, and other cases, is specified.

Zoological Society, June 16.—Prof. W. H. Flower, President, in the chair.—The Secretary read some extracts from a letter addressed to him by Mr. J. Buttikofer, of the Leyden Museum, calling attention to a paper published in 1857 by the late Dr. Bernstein, concerning the material of which the edible birds' nests of *Collocalia esculenta* are composed.—A letter was read from Major-General Sir Peter Lumsden, K.C.B., giving details of the place and time of capture of two young Snow-Leopards sent down from the Afghan frontier to Quettah, and intended for the Society's collection.—Mr. Oldfield Thomas exhibited and remarked on a specimen of a rare burrowing Rodent (*Heterocephalus glaber*) procured by Mr. E. Lort Phillips during his recent expedition in Somaliland, remarkable for having an almost completely naked skin, and for its extraordinary habits.—Dr. Guillemard exhibited a series of eight skulls of the Kamtschatkan Wild Sheep (*Ovis nivicola*), pointing out the difference existing between it and *O. canadensis*.—Mr. W. T. Blanford exhibited the skull and an imperfect skin of a supposed new species of *Paradoxurus* from the Pulnai Hills, Southern India.—A communication was read from Dr. G. Hartlaub, F.M.Z.S., giving an account of a new species of Parrot of the genus *Psittacula* recently received from Barranquilla, U.S. of Colombia, which he proposed to describe as *Psittacula spengeli*.—Dr. Guillemard, F.Z.S., read the sixth part of his report on the collection of birds formed during the voyage of the yacht *Marchesa*. The present communication treated of the birds collected in New Guinea and the Papuan Islands.—Dr. Guillemard also exhibited a very fine series of Paradiseidæ obtained during the yacht's voyage.—Mr. G. A. Boulenger read a paper containing a description of the German River-Frog (*Rana esculenta*, var. *ridibunda*, Pallas).—Mr. P. L. Sclater read the description of a new species of *Icterus*, obtained by Mr. Hauxwell on the Upper Amazons, which he proposed to name *I. hauxwelli*.—A second paper by Mr. Sclater contained notes on the way in which *Lemur macaco* carries its young, as observed in a specimen living in the Society's Gardens.—Mr. A. D. Bartlett read some notes on the female Chimpanzee now living in the Society's Gardens, which he showed to be different from the ordinary Chimpanzee, and to be probably the *Troglodytes calvus* of Du Chaillu.—Dr. Gadow, C.M.Z.S., communicated a memoir by Miss Beatrice Lindsay, of Girton College, Cambridge, upon the Avian Sternum. The different theories held as to the origin of the sternum having been reviewed, the author proceeded, after an explanation of the various types of structure examined, to give an account of her own views. Miss Lindsay came to the conclusion that the keel is an apophysis of the two halves of the sternum, and is not produced by the clavicles or any other parts belonging to the shoulder-girdle; also that the part of the sternum whereof the keel is an outgrowth is itself of secondary origin, and that the various processes of the sternum are produced by addition and not by resorption of bony matter.—Col. J. Biddulph read a paper on the Rocky Mountain Sheep, in reference to the new geographical race lately named by Mr. Nelson *Ovis montana dalli*, and confirming the view that there are two distinct types or races of this sheep in North America.

Geological Society, June 10.—Prof. T. G. Bonney, F.R.S., President, in the chair.—Dr. A. G. Nathorst, of Stockholm, was proposed as a Foreign Correspondent of this Society.—The following communications were read:—Note on the sternal apparatus in *Iguanodon*, by J. W. Hulke, F.R.S., V.P.G.S.—The Lower Palæozoic rocks of the neighbourhood of Haverfordwest, by J. E. Marr, F.G.S., and T. Roberts, F.G.S.—On certain fossiliferous nodules and fragments of hæmatite (sometimes magnetite) from the (so-called) Permian breccias of Leicestershire and South Derbyshire, by W. S. Gresley, F.G.S.

SYDNEY

Linnean Society of New South Wales, April 29.—Dr. James C. Cox, F.L.S., Vice-President, in the chair.—The following papers were read:—Revision of the genus *Lamprima*, with descriptions of new species, by William Macleay, F.L.S.—Notes on the zoology of the Maclay Coast, New Guinea, by N. de Miklouho-Maclay. This paper consists of a carefully detailed account and description of a rare species of *Macropus*, to which the Baron gives the specific name of *Tibol*, the native name for the animal. A plate accompanies the paper.—On two new species of *Dorcopsis* from the south coast of New Guinea, by N. de Miklouho-Maclay. This contains descriptions and illustrations of *Dorcopsis macleayi* and *D beccari*, two new species in the Macleay Museum. This brings the number of known species of the genus up to five.—The Australian sponges recently described by Carter, by R. von Lendenfeld, Ph.D.—On the fertilisation of *Goodenia hederacea*, by Alex. G. Hamilton.—Notes on the habits of *Falco subniger* and *Glareola grallaria*, by K. H. Bennett.—The geology of Dubbo, by the Rev. J. Milne Curran.—Dr. J. C. Cox exhibited a sandstone nodule, the outer crust of which to a considerable depth was stained with iron, the original colour, as shown by the central portion, having been white. Also a large *Cephalopod*, belonging to the family *Sepiidæ* and genus *Sepia*, which had been recently presented to the Australian Museum by the Hon. William Macleay. This unique specimen is about three feet long from the hinder part to the apex of the arms; the body is about eighteen inches long, and eighteen inches broad, deeply notched at the lower margin, and peaked in the centre at the neck, and arched on each side; the head is about eighteen inches from the body to the apex of the arms. It is of a dark brown olive colour, quite smooth, the tentacles are about two feet long, the cups on the arms do not correspond with any known species, nor do the cups on the tentacles; it is very like *Sepia tuberculata* of Lamarck, but no tubercles exist on the surface, and it is much longer. *Sepia vermiculata* of Quoy and Gaim. is very like it, but is only fifteen inches long; most of the species, however, of the genus have been described from the shell.

PARIS

Academy of Sciences, June 29.—M. Bouley, President, in the chair—Remarks on Poinsot's theory, and on two movements corresponding to the same polhodie, by M. G. Darboux.—On Palmieri's experiments relative to atmospheric electricity, by M. Faye.—Remarks on the same subject by M. Mascart.—Researches on isomery in the aromatic series. Heat of neutralisation of the oxybenzoic acids, by MM. Berthelot and Werner.

—Note on the monument to be erected to the memory of Nicolas Leblanc, inventor of artificial soda, by M. Eug. Peligot. For various reasons it has been decided to place in the Conservatoire des Arts et Métiers the statue raised by international subscription to Leblanc. In the report of the Committee it is stated that the illustrious savant was born, not at Issoudun, as is generally supposed, but at Yvry-le-Pré, Department of the Cher, on December 6, 1742.—Note on the peculiar properties of Poinsot's "herpolhodie" curve, by M. J. N. Franke.—Remarks on the same subject, by M. Darboux.—On the reduction of the problem of the brachistochrones to canonical equations, by M. Andoyer. —On the secular variation of the magnetic declination at Rio de Janeiro, by M. Cruls.—On the crepuscular light, by M. P. J. Denza. These after-glows, which seem to have become nearly extinct during the past winter, have again begun to appear about the beginning of this summer. At Moncalieri, and in other parts of Italy and Sicily, they became very intense towards the end of May, and their brilliancy was even increased during the first days of the month of June. On the 13th especially the effects were most surprising, rivalling those witnessed during the winter of 1883. The phases of the phenomenon have also closely resembled those so often described during the periods of its greatest intensity. The author considers that all this tends more and more to confirm his own theory, that the crepuscular lights are due, not to the Krakatoa eruption, but mainly to the vapour of water disseminated throughout the higher regions of the atmosphere.—On the reappearance of the crepuscular glows, by M. A. Boillot. The author describes the effects seen at Paris on June 12 and subsequently, and also considers that their reappearance can scarcely be brought into connection with the Krakatoa eruption of August, 1883.—On the nacreous crystals of sulphur, by M. D. Gernez.—On the properties of the persulphuret of hydrogen, by M. P. Sabatier.—On the nitrate of anhydrous ammoniacal ammonia on iron, zinc, and some other metals, by M. G. Arth.—Note on the reduction of the hexatomic alcohols, by MM. J. A. Le Bel and M. Wassermann. —On a new method of preparing pyrocatechine, by M. J. Meunier.—On the action of chlorine and iodine on pilocarpine, by M. Chastaing.—Note on the quantitative analysis of the phosphoric acid present in the natural and mineral phosphates employed for manuring the soil, by M. E. Aubin.—On the development of the vascular glands in the embryo, by M. Retterer.—On a new type of Sarcosporidies, by M. R. Blanchard.—Calorimetric observations on children, by M. Ch. Richet.—New researches on the regeneration of the nerves in the periphery of animal organisms, by M. C. Vanlair.—A note on the influence of the attraction of the moon on the creation of the Gulf Stream was submitted, by M. Ch. Dufour.

Berlin

Meteorological Society, June 2.—Dr. Neuhauss communicated meteorological observations instituted by him during a voyage around the world from April to December last year. During the whole passage through the Mediterranean Sea, the Suez Canal, the Red Sea, the Indian and Pacific Ocean, he had regularly every day made observations with a compared thermometer, aneroid barometer, and psychrometer, of the temperature and the atmospheric pressure every two hours from 6 a.m. till 8 p.m., and three times a day determinations of the humidity. His attention was specially directed to determine these meteorological conditions within the tropics and more particularly in the neighbourhood of the equator. Among the more noteworthy results of these observations he showed that the daily range of temperature over the Suez Canal amounted to 29°·2 F., from a maximum of about 86°·0 to a minimum of 56°·8, while the range of temperature on the Red Sea was only about 6°·8 to 9°·0, and that on the Indian Ocean in the neighbourhood of the equator was still less. The maximum temperature under the equator amounted nearly to 99°·5, and always coincided with the culminating point of the sun. The opinion that the maximum temperature in the tropics occurred at 10 a.m. was not confirmed by the observations. What was observed on this point was simply that the maximum temperature frequently began in the region of the tropics at 10 a.m., and lasted two hours, when, from some secondary cause or other, a small abatement of only a few tenths of a degree might be observed just at 12 noon. Squalls and rain-showers were always accompanied by a sinking of temperature which occasionally showed a range of 4°·5. On his voyage from New Zealand to Hawaii in June and July Dr. Neuhauss daily observed within the tropics a constant rising of the temperature till evening, reaching the maximum between 6 and 8 p.m. On the open sea he nowhere found higher temperatures than those he had observed on first crossing the equator. The registrations of the barometer within the tropics exhibited the well-known daily oscillation of the atmospheric pressure with two maxima and two minima. The first maximum showed itself at 10 a.m., the second at 6 p.m. It was remarkable that the squalls and rain-showers did not affect the regular march of the barometer. The hygrometric observations in the tropics on the Indian Ocean yielded considerably less daily amplitudes than on the Mediterranean Sea and on the Suez Canal. The phenomena of the twilight on the Indian Ocean, whose magnificence of colour was described, were particularly beautiful. Very noteworthy were the observations on the duration of the twilight, but a regular difference between the evening and the morning twilight was not established. Their respective durations on particular days were, on the other hand, very unequal. The astronomical twilight—*i.e.* the time from sunset till the last evanescence of light in the western sky—usually lasted from an hour to an hour and a quarter. The end of the twilight at sea could be precisely determined to a second. A great charm was afforded in the observations of the zodiacal light, which Dr. Neuhauss was able to watch every morning before sunrise on the Indian Ocean. In the evening with fatigued eyes the observation of the zodiacal light was not successful. In the morning, on the other hand, the bluish-white light pyramid could be followed by the eye to the zenith. Its brightness excelled that of the brightest parts of the Milky Way; its light was quite steady without any quiverings, and thus showed no polarisation. This phenomenon, still so little understood, was recommended as an object of observation to marine officers.—Prof. Spörer described a whirlwind observed at Potsdam on April 15 at 12 noon. The air was quite still, the sky perfectly clear, when, from a grassy sward begirt by bush, an eye-witness observed the whirlwind arise. He first heard a rustling in the leaves of the shrubs, and then observed a column of dust, of about the height of the surrounding inclosures, which, on its continued movement, split into two vortices. One of these, or perhaps only a branch of one, moving onward, without leaving any traces on its way, arrived at a neighbouring garden, where, at a particular spot, it tore up and carried aloft in a whirling manner to a considerable height the windows of several hot-beds, rending them in pieces. The weight of each of these windows was about 30 lbs. Thence the whirlwind advanced towards a neighbouring garden and tore off the windows, which were open in the direction from which the whirlwind was coming. On its further course, which was marked out by a powerful rushing noise and by a very high dust-column, the whirlwind inflicted no more destruction. Prof. Spörer was of opinion that the whirlwind originated and grew in intensity over ground which was greatly heated, just as happens in volcanic outbursts and high protuberances of the sun, when in the one case ashes and in the other hydrogen are swept aloft over highly heated surfaces.

Physiological Society, June 5.—Prof. Brieger, following up his communications of a year ago, reported on his further investigations into the ptomaïnes. In his former communications the speaker had described five well-characterised bases —neurine, muscarine, neuridine, and two other diamines—extracted from the ptomaïnes, which were developed in putrefying nitrogenous substances, and in the form of beautiful crystallised salts, and had subjected them to precise chemical and physiological analysis. As the result of this analysis, neurine, muscarine, and a base similar to, but not identical with, trimethyldiamine had were found to be very violent poisons, while the two others showed themselves to be less poisonous. Seeing that the ptomaïnes must here be regarded as products o the putrefactive bacteria, Prof. Brieger set himself the task o studying the products of pathogenic bacteria. He proceeded, however, beforehand to investigate the ptomaïnes which developed under natural putrefaction in the case of human corpses, and found that here quite different bases came to light than those which appeared under artificial putrefaction. Immediately after death lecithin decomposed itself, and large quantities of choline became developed, and, along with this base, neuridine appeared on the third day of putrefaction, increasing in quantity with the progress of putrefaction. From the seventh day after death there came to view an entirely new base, which, with hydrochlorate of platinum, yielded very beautiful crystals, and, both in this connection as also in the form of hydrochlorate of gold and in its conjunction with hydrochloric acid, had been searchingly examined. This base, altogether different both in its quantities and in its composition from the bases hitherto known, was named "cadaverine." It increased in quantity with time while choline and neuridine diminished. Later on there appeared another new base which was also characterised by its hydrochlorates of platinum and gold, as likewise by its chemical composition, which the speaker called "putrescine" and was able to show in the form of beautiful crystals, both in a pure state and in the hydrochlorates of platinum and gold. Both these new bases, cadaverine as well as putrescine, acted but weakly on the animal organism. The first possessed the well-known smell of coniine, which former observers had already noticed in putrefying bodies. Besides these weakly acting nitrogenous bases, there were found in the later stages of putrefaction two diamines of very powerfully poisonous effect, which, injected even in small doses in animals experimented on, produced death under paralysis. These two were presented in distinct crystals and isolated. A survey of the whole series of isolated ptomaïnes taken from corrupting nitrogenous substances showed that, contrary to the former assumption, they were all simply compound, that they were all diamines belonging to the series of fats. Their great resemblance to vegetable alkaloids rendered it necessary that in the case of chemical investigations only such alkaloids and bases should be deemed demonstrated to exist in a dead body which had been isolated and had been presented in their characteristic salt-crystals. In the endeavour to study the bases produced by pathogenic bacilli Prof. Brieger had examined artificial cultures of bacilli, and first the typhoid bacillus on peptone. This led to no positive result. It was the culture of the typhoid bacillus on meat infusion and meat jelly which first led to the isolation of two new intensely poisonous bases, one of which, being injected in small quantities into animals, acted similarly to neurine, producing death under a strong flow of saliva, paralysis and diarrhœa, while the other produced only violent exhausting diarrhœa. The small quantities of these poisons did not yet, however, allow them to be sufficiently characterised chemically. They appeared to be triamines, and should be further investigated. The method adopted in the course of this investigation promised additional important results.—Dr. H. Virchow communicated the observations he had made on the cells of the vitreous humour, regarding which the opinion had hitherto been entertained that they were lymph cells which had emigrated from the blood vessels, and which, by reason of their amœboid movements, presented the most various forms either on the surface or in the interior of the vitreous body. Dr. Virchow had first examined the vitreous body of very different species of fish, and in the case of these animals, which were provided with vessels of the vitreous humour, he had established that the cells were perfectly fixed, invariable formations, which manifested themselves so characteristically that it was possible to distinguish the particular species by the particular form of the cells of the vitreous humour. This conclusion determined the speaker to examine the vitreous humour of other cold-blooded animals, and he chose frogs for this purpose, and had, besides, examined the vitreous body in an Alpaca sheep and in the fowl. After a description of the methods of examination he had adopted, he described minutely the forms of the cells of the vitreous body he had found in these different animals. In the case of the sheep he found them ranged only on the surface in perfectly definite order; they here consisted of small, round nuclei surrounded by large masses of protoplasm manifoldly sinuated and branched. In the case of the fowl the cells likewise lay on the surface of the vitreous body in regular arrangement. The protoplasm surrounding the nuclei was, however, in part drawn out lengthwise and branched at the ends, in part stellate, divided into thin rays, in part irregularly arranged. In the case of the frogs the greatest multiplicity of forms was met with. The cells lay either between the blood-capillaries or on them, and in this case were to be recognised only with great difficulty. The nuclei were mostly longish, and around these nuclei extended the delicate protoplasm, often spun out in fine lines of fibres between the vessels, or covering them. In the case of a few cells long processes extended from the protoplasm, of which single pieces had detached themselves. In the case of others the protoplasm had spread itself out into a very wide, uncommonly delicate film covering the vitreous body. Other cells, again, had granular protoplasm, and were either round, with a large round nucleus, or were more or less lengthened to the degree even of a filiform shape. To relate these different forms of the cells of the vitreous humour each to an integral characteristic difference in the species to which it belonged, was more than the speaker had been able to accomplish. Towards the solution of this problem further investigations would be required.—Herr Aronsohn communicated the further experiences which, in conjunction with Herr Sachs, he had collected relative to the heat-centre in the cerebrum, discovered by him last year. When on a perfectly definite part of the cerebrum he pricked with a needle so deeply as to touch the parts lying under the cortex, then he observed a rise of temperature in the rectum, in the muscles, and in the skin of from about 1° to 2° C. The prick had to touch the corpus striatum in order to produce a rise of temperature, and in point of fact it was only the median part of the corpus striatum which, on being touched, gave rise to this result. No other part, however nearly situated to this spot, could, on being touched, produce this rise of temperature. The increase of temperature continued for about three hours after the prick, and affected the two sides even when the wounding of the brain was only one-sided. Electrical stimulation of the same limited spot produced a similar result. Whether there were ganglions lying on the spot in question, which influenced the production of warmth, or whether only definite nerve-tracts were touched, was a question which could not be decided. In order to ascertain the immediate cause of the increase of temperature, experiments regarding the respiration, and determinations of the urea were simultaneously carried out. These experiments showed that immediately after the corpus striatum was pricked the inhalation of oxygen and the exhalation of carbonic acid were increased, and that the secretion of urea was augmented. It was therefore clear that an increase in the metabolism generally followed the prick, an increase which, in the opinion of the speaker, was due to the heightened innervation of the muscular system caused by the prick or the electrical stimulation.

THE BIRDS OF LANCASHIRE

The Birds of Lancashire. By F. S. Mitchell, M.B.O.U. Illustrated by J. G. Keulemans, Victor Prout, &c. Pp. xviii. 224. (London: Van Voorst, 1885.)

IMPORTANT as are the services which the writers of county faunas have rendered to the study of British ornithology every one knows, or ought to know, that such works have a very variable value. In some cases the geographical position of the county concerned is such as to invest its avifauna with high interest quite apart from the manner of its treatment, which may be, and in a few instances that we could but will not name, has been of a slovenly character. Or again, local considerations may be comparatively insignificant, and yet the book, from the combined knowledge and skill of the author, will be a great and positive gain to zoological literature. Thus it follows that the most pretentious works not unfrequently fall short of even a moderate standard of excellence, while that is attained or even surpassed by others put forward with unpresuming modesty. It gives us great pleasure to express our opinion that the little book now before us, "The Birds of Lancashire," falls well within the latter category. Its author, Mr. Frederick Shaw Mitchell, is known to have been engaged in its preparation for several years, and that he has used those years of preparation to good purpose almost every page in the book testifies. We have especially to commend his introductory remarks, which prove that he has taken the proper and philosophical view of the duties of a faunistic monographer, while the rest of the book shows how efficiently he has discharged them according to that view.

In these days the county of Lancaster, or at least its southern half, with its swarming population, its tall chimneys expelling tons upon tons of soot, and, still worse, volumes of noxious vapours, its once limpid streams drunk up by countless manufactories and returned to their channels befouled with deleterious compounds, presents almost as poor a field for the outdoor naturalist as can well be found in the United Kingdom. Nor does its geographical situation offer the ornithologist much promise for the pursuit of his study. Its coast-line, though extensive as that of English counties goes, is formed by the recess of a land-locked sea; and notwithstanding that as yet we really know little of the routes taken by birds in their migrations, there is nothing to induce the belief that any much-frequented route will be found to skirt Morecambe Bay, the sand-hills of Blackpool, or the estuaries of the Ribble and the Mersey. Nor do the hills of its interior, though rising to the height of nearly 2000 feet, and even exceeding that in the northern detached district of Furness, which contains the much admired Coniston Water and Windermere, add greatly to the attractiveness of a county which has the disadvantage of lying on the wrong side of our island—for we take it to be undeniable that in England birds, both as individuals and as species, decrease in number as we pass from the eastern to the western coast.

"The vast increase of population, and the scientific farming which drains every marsh, substitutes for every bosky nook a rigid bank and paling mathematically drawn, are the chief causes of the decrease both in species and individuals which has taken place in the manufacturing districts; but it is astonishing how many still flourish among the teeming millions which dwell there, and should it be possible for air and water to become more pure, there is no doubt that, except in the immediate vicinity of buildings, little further diminution would occur.

"The way in which birds are driven away by the extension of buildings, and by the conversion of a rural into an urban locality, may well be instanced by the case of Peel Park, Salford, which is one in point. Mr. John Plant has kindly permitted me to use his notes, which have been carefully kept since 1850, and which show the following results:—

	Personally observed.	Breeding.
1850–60	71 species	34 species
1860–70	42 ,,	— ,,
1870–75	19 ,,	8 ,,
1876–80	15 ,,	— ,,
1881	13 ,,	— ,,
1882	5 ,,	2[1] ,,

Mr. Plant considers that the main causes are not so much simply the presence of more people and greater disturbance by them, as the destruction of natural food, and loss of protective foliage, from the vitiated atmosphere, and makes the melancholy prophecy that, if the same thing goes on for another ten years, there will not be a large tree alive in the park."—*Introductory*, p. iii.

Yet Mr. Mitchell does not think that on the whole birds in Lancashire are decreasing, and remarks that "the greater scarcity of the Goldfinch, for instance, which feeds on the thistles of waste lands, is balanced by the greater plentifulness of the Hawfinch, which prefers a more cultivated country." The extensive range and increasing numbers of the species last mentioned of late years throughout the whole of England is indeed a matter that is at present quite unaccountable. But Mr. Mitchell goes on to say that "if the game-preserver will lay aside some of his truculence in respect of species which occasionally diminish his stock, if the denizens of towns will discourage the bird-catching fraternity, and be content to only hear the Linnet and the Bullfinch in their natural haunts, and if the specimen hunter will try to be content with skins which are not *local*, there is no reason to expect any approach to extinction of species which are now on the list." Here we would remark that not much harm comes from bird-catching if the law now existing be obeyed, and that without it few "denizens of towns" would ever hear the song of any bird; but we quite agree with what our author says as to the game-preserver and skin-collector. From the results of somewhat extensive observation in many parts of England it is clear that the absolute extermination of both Kestrel and Sparrow-Hawk—the last of the birds-of-prey which can be said to inhabit this country generally—will be accomplished in a very few years, and even our three species of Owl—in spite of the Act which nominally protects them—are likely to suffer the same fate. Mr. Mitchell no doubt recognises the fact, as every impartial observer must do, that, birds-of-prey excepted, the system of strict game-preserving affords an incalculable amount of protection to all other birds; but the "local specimen-hunter" is usually a pestilent character indeed—one who without any counterbalancing merit simply flatters his own vanity, degrades an interesting not

[1] Starling and House Sparrow.

to say instructive study, and induces his fellow-subjects to break the law by the price he offers for his "rarities."

Passing to another part of our theme we wish to mention our author's remarks on the valueless nature of nearly all the ordinary records with regard to the migrations of birds. Many we are sure must have felt the truth of the following statements; but we do not recollect having before seen it so explicitly put forth, and congratulate Mr. Mitchell on perceiving its importance. He says:—

"The fact is, that very few of the observations, now so numerously made, as to the movements of summer migrants, are worth anything at all; and if data are to be collected on land of value commensurate with those now being collected on information from lighthouses, &c., by the committee appointed by the British Association, it will be necessary for the observer to fulfil something like the following conditions: firstly, that he should be continuously engaged out of doors; secondly, that he should be entirely familiar, not only with the plumage of the birds, but that he should be able to recognise most of them when flying, and be thoroughly acquainted with their song, their call and alarm notes; and thirdly, that he should have a knowledge of the food requirements of each species, and be able, for instance, to infer, from the plentifulness of such and such an insect, that such and such a bird may be expected to feed on it. Such a conjunction can only be found in few individuals; but if every man in his leisure field-walks would, and especially in connection with meteorological conditions, note the other natural circumstances at the time of his first seeing a spring arrival, a mass of information would be got together, invaluable for the discovery of the laws of geographical distribution; and until something of the sort is done, and such information sifted and compared, I believe those laws will remain, as they are now, dubious and conjectural."—*Introductory*, pp. ix. x.

In the bibliographical portion of his work Mr. Mitchell shows himself to be well read, and the selections he makes from the writings of his predecessors seem to be exceedingly judicious. If he errs at all, which we do not say is the case, it is on the side of conciseness, and we can imagine that many readers who have not access to a good library would be better pleased had his extracts occasionally been longer, so that, should his little book reach a second edition, as it well deserves to do, this point might be borne in mind by the author; though we cannot find it in ourselves to blame him on this account, knowing the tendency to superfluity which prevails among the ornithological writers of the present day. One unquestionable merit Mr. Mitchell possesses. He is free from the wish to exaggerate the importance of his subject, and is certainly not bent on making out a numerous list of the birds of his county, as so many compilers of local faunas have done, by giving fresh life to the most doubtful reports which profess to record impossibilities. In one case, indeed, he seems to us to have transgressed; but he may be pardoned for not being aware of the profound mistrust that was entertained nearly five-and-twenty years since by well-informed persons in regard to some statements that were then made in a certain auction-catalogue. The Swallow-tailed Kite should disappear from his list. Lancashire, however, indubitably boasts the possession of the only existing "British-killed" specimens of the Black-throated Wheatear and the Wall-Creeper—though an example of the latter is known to have been obtained in Norfolk nearly one hundred years ago—and accordingly a coloured figure (by Mr. Keulemans) of each of these species is introduced. Some carefully drawn illustrations of decoys, as well as several other ingenious modes of netting or snaring wild birds, are also given, and these add not a little to the interest of the book; for, with the exception of the plates in Rowley's not very accessible "Ornithological Miscellany," we are not aware of any representation of the mode of capture by "fly-nets," while we think neither the "douker-net" nor the "snipe-pantle" has ever been figured before; and with respect to this last term, which Mr. Mitchell derives "from the Anglo-Norman 'panter = a net or snare,'" we may observe that Olina in 1622, and Willughby after him, calls a certain kind of net used in taking starlings, woodcocks, and other birds *pantiera*—a word which seems to exist now in Italian as *pantera*.[1] Of course a work on the birds of Lancashire could not be complete without a reference to Gerarde and the Pile of Foulders, whereon bernacles turned to geese; but we are glad to see that Mr. Mitchell abstains from sneering at the old herbalist's credulity, as so many modern writers have done, though we must point out to him that in these days to speak of a bernacle as "a species of multivalve" is to use a somewhat vague if not inaccurate expression. Let us add that a map of the county and, so far as we have tested it, an excellent index are among the merits of this satisfactory little book.

A CATALOGUE OF CANADIAN PLANTS

Geological and Natural History Survey of Canada. Alfred R. C. Selwyn, LL.D., F.R.S., F.G.S., Director. "Catalogue of Canadian Plants. Part II. Gamopetalæ." By John Macoun, M.A., F.L.S., F.R.S.C. 8vo, 200 pp. (Montreal: Dawson Brothers, 1884.)

ALTHOUGH this is only a catalogue of names and localities, it is a work of much interest and one that has been greatly needed by European botanists and botanical geographers. The flora of the north temperate zone in both hemispheres is so very similar in general character that nearly half of the genera of the Canadian area and a large number of the species reach to it all the way from Britain across Europe and through Siberia, and the remarkable longitudinal differentiation of the flora of the United States renders it a matter of much interest to be able to trace out the dispersion of the species through the more northern areas of the Continent. The "Flora Boreali-Americana" of Sir Wm. Hooker is now forty years old, and all that has since been worked out about the Canadian species and their distribution has never been put together and published so that it was available for general use. The first portion of the present Catalogue, which was issued in 1883, contained the Polypetalous natural orders; including naturalisations the number of Polypetalous genera was 243, and of species 907. The present part contains the Gamopetalæ, and carries up the number of genera to 498, and of species to 1811. So that the total number of flowering plants now known in British North America may be estimated at about 3000 species against 10,000 or 12,000 now known in the United States. One of the most remarkable points

[1] See also Prof. Skeat's "Etymological Dictionary" (p. 415) *sub voce* "Painter," for instances of its use by Chaucer and others.

about the Canadian flora is how extremely few species enter into it that are not found in the United States. The general question of the characteristics of the North American flora was fully discussed by Dr. Asa Gray in an address to the biological section of the British Association at Montreal, which was published in the issue for November, 1884, of the *American Journal of Science*. Two of its leading characteristics as compared with Europe are the abundant development of peculiar types of Compositæ and Ericaceæ. It is to this present catalogue that we must turn for full details on such matters as these in application to the northern area. One of the most curious instances of a locality for a well-marked plant widely distant from its main area is furnished by the occurrence of *Calluna vulgaris* in very small quantity in Newfoundland, Cape Breton Island, and Nova Scotia. It is not known on the American continent, and the genus *Erica* is entirely absent. A large number of common European plants, such as *Bellis perennis*, *Chrysanthemum Leucanthemum*, *Tussilago Farfara*, *Hyoscyamus niger*, and *Anagallis arvensis* are fully naturalised in Canada. Some British species, such as *Gentiana Amarella* and *Hieracium umbellatum* are represented in Canada by varieties mostly readily distinguishable from the European type. Of plants alpine in their European range which are widely spread in British North America we have instances in *Loiseleuria procumbens*, *Arctostaphyllos alpina*, *Linnæa borealis*, *Lobelia Dortmanna*, *Vaccinium uliginosum*, and *V. Vitis-idæa;* and of plants of wide European and British dispersion at a lower level in *Campanula rotundifolia*, *Achillea Millefolium*, *Viburnum Opulus*, *Pyrola minor*, and *Andromeda polifolia*. Mr. Macoun has consulted Dr. Asa Gray and Dr. Sereno Watson on all points of doubtful identification, and used the same nomenclature and standard of specific limitation.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Zoology of Dr. Riebeck's "Chittagong Hill Tribes." —The Gayal and Gaur

In NATURE for June 25 (*ante*, p. 169) there appeared a review of the late Dr. Emil Riebeck's "Chittagong Hill Tribes." The contributions of the specialists who are entitled "the foremost naturalists of Germany" are mentioned as "separate monographs of great value."

This is no stinted praise, and as one of the separate monographs, that on the zoology, by Dr. Julius Kuhn, is especially noticed, I took the earliest opportunity of reading what I anticipated would prove a very interesting essay on the fauna of a rather imperfectly-known region.

I will only say that I was disappointed. The zoological "monograph" consists of four pages, two and a half of which are taken up by Dr. Kuhn's remarks on the gayal and gaur. These are the only portions deserving notice; the remaining page and a half contain notes, all trivial, and some seriously incorrect, on skulls of a rhinoceros, a bear, and a monkey, of only one of which a specific determination is attempted, and in that instance the name given is, I believe, wrong. Perhaps these notes are not by Dr. Kuhn, for his observations on the gayal (*Bos frontalis*, var. *gavæus*) and the gaur (*B. gaurus*, var. *cavifrons*) show some acquaintance, though an imperfect one, with the literature of the subject. Your reviewer credits Dr. Kuhn with the discovery that "the gayal or wild ox of Bengal, Assam, and Further India does not differ specifically from the gaur of India proper," and Dr. Kuhn writes apparently under the impression that the occurrence of the gaur east of the Bay of Bengal is not known. The range of the gaur throughout Assam, Tipporah, Chittagong, Burmah, and the Malay peninsula has, however, been well known for thirty years at least, and has been repeatedly described by Cantor, Blyth, Jordon, and other naturalists, whilst the head of a Tenasserim gaur was well figured nearly fifty years ago in the *Journal* of the Royal Asiatic Society (vol. iii., 1836, p. 50). The fact that the wild gaur is called gayal by the natives of some parts of India is also not new. The name by which the tame gayal, *Bos frontalis*, is generally known in the country is not *gayal*, but *mithan*.

Dr. Kuhn's principal object is to show that the gayal may be a domesticated race of the gaur. It would be impossible to do justice to the subject without going into considerable detail, but the first stage in the inquiry is one to which no reference is made by Dr. Kuhn. This is the question whether *Bos frontalis*, the gayal, exists as a distinct species in the wild state, as stated by Lambert, Colebrooke, Horsfield, Blyth, and others, or whether; as lately urged by Mr. J. Sachs (*Proc.* Z. S., 1883, p. 142), there is no such thing as a wild gayal. A very valuable contribution to the history of these animals was published twenty-five years ago by Blyth in the *Journal* of the Asiatic Society of Bengal, vol. xxix. p. 282, in a paper "On the Flat-horned Taurine Cattle of South-East Asia." This paper was, I think, subsequently republished in either *Land and Water* or the *Field*, but I am not certain. One most important circumstance mentioned by Blyth on apparently excellent authority is that the gaur is kept tame in the interior of the Chittagong hills, and, as a tame animal, is quite distinct from *Bos frontalis*. If this is the case hybrids are very likely to occur, for the gayal breeds freely with the much less nearly allied zebu, and such hybrids may account for the occurrence of forms intermediate between the gayal and gaur. An indication that such forms exist is, so far as I can see, the only evidence brought forward by Dr. Kuhn in favour of the gayal being a domesticated race of the gaur, his main argument; his supposed discovery that the tame gayal and wild gaur inhabit the same country being a singularly fine example of a *nidus equinæ*.

It will, I hope, be understood that these observations apply solely to the zoological portion of Dr. Riebeck's work; though, in connection with this, in another part of the book, I remark that Plate 14, Fig. 2, which represents a rodent's—probably a squirrel's—skull, is called in the explanation of the plate "the skull of a musk-deer"! Your reviewer's opinion of the work is doubtless founded on the anthropological and ethnological portions; I only dissent from the views expressed as to the zoological monograph.

"The Fauna of the Seashore"

IN the abstract of Prof. Moseley's interesting lecture on "The Fauna of the Seashore," published in the current number of NATURE (p. 212) several agents are referred to as competent to call into play the tendencies to vary which are embodied in each species. These, whether suggested by Prof. Lovén or the author of the lecture, include—light and shade, temperature, currents, food, enemies, favourable condition of water for respiration, and the variation of conditions produced by tides. I venture to think that one very important factor in the variation of the marine fauna, if not the most important, has been left out of the list: I refer to marine waves.

The action of waves on the littoral fauna is not only extremely severe, but it is of constant recurrence; and failure to resist it does not merely involve some minor disadvantage or inconvenience to the object attacked, but its very existence.

A point commonly overlooked by naturalists is the severity of the wave-action arising from the reciprocal character of the wave-currents. Human bipeds occasionally experience the inconvenience of a shifting current when encountering opposing blasts of wind at some street corner during a gale. The marine littoral fauna, living in a much denser medium, encounter two analogous currents for every passing wave heavy enough to affect the bottom, and have to encounter these currents without cessation for the days or weeks the storm may last. Any failure to resist this inexorable enemy on the part of the shallow water denizens of the sea or any encroachment on exposed areas during fine weather by animals unfitted to meet the storm will incur the penalty of death.

The prime necessity for every member of the littoral fauna is the power of resisting the attacks of waves; and every development and variation undergone by such littoral fauna must of necessity have been carried out under the immediate control of waves.

If, as Prof. Moseley tells us, it was in the "littoral zone . . . that all the main groups of the animal kingdom first came into existence," we may go further and say that these main groups were modelled by the ceaseless action of waves, as these in their turn were brought into being by winds raised by solar heat. Thus the early stages of evolution can be carried back directly, by the two short links of wind and wave, to the sun itself.

One point that I have never published myself or seen recorded by others, is the curious conflict that may be observed between wave- and tidal action. For example, a shell with a wide bathymetrical range, from tide-marks to, say, fifty fathoms, may evince a tendeney towards the elaboration of a useful form and sculpture, in the deeper water; whereas, between tide-marks the two daily checks to growth arising from the fall of the tide would immediately check any such variation in sculpture, and the altered form would no longer be best suited to the alongshore conditions.

Moreover, as the form best suited to tide-marks is often in conflict with that best suited to deeper water, the form of a species living between tide-marks might soon diverge from that of the same species frequenting deeper water. As a possible instance I would adduce the case of *Trochus zizyphinus* and *T. granulatus*. These gasteropods have always, I believe, been considered distinct species; but I have in my possession specimens from about fifteen fathoms, showing a distinct passage between the smooth zizyphinus and the sculptured granulatus, and this both in outline and sculpture.

I regret that I have been unable to obtain odontophores of the intermediate forms to ascertain if they confirm the passage from the one species into the other. It is, I think, evident that though *T. zizyphinus* can retain its form in deep water, *T. granulatus* could not retain its symmetrical granulated sculpture were it to invade the tidal strand.

The variety of method exhibited by the littoral fauna in resisting wave-currents affords a most interesting subject of research. Take for instance an exposed ledge of rock—no hypothetical one—with sturdy limpets living on it, the fragile *Pholadidea papyracea* living in it, and the hardy little *Littorina obtusata* clinging to the sea-weed. A storm attacks the trio, and tests their several methods of defence. The limpet is safe on the rock, the Pholadidea in it, and the Littorina, though at once washed off its feeble support, is safe, thanks to its solid shell, from the utmost violence of the storm. The tenacious hold of the limpet on the solid rock and the feeble adherence of the Littorina to the sea-weed indicate very opposite methods of meeting a common danger.

In conclusion I would put in a plea for working-models of the sea in some of our new aquariums. When one sees in a tranquil tank such a fish as the gurnard with its far-spreading feelers ready to steady itself amid swinging wave-currents, one would like to see its machinery brought into action. A gentle swinging motion could be easily imparted to the waters of a tank, and under such conditions the observer would see the animals use the special appliances they possess for resisting or evading their most formidable enemy. ARTHUR R. HUNT

Torquay, July 6

"New System of Orthography for Native Names of Places"

ALLOW me room for a few remarks on the Royal Geographical Society's "New System of Orthography for Native Names of Places," just published in your number for July 2. The Society has earned the thanks of the public for grappling with the neglected and vexatiously inconsistent question of place-name spelling. Attention was called by myself to this subject in *Notes and Queries* of May and July, 1884, and I can take no exception to the vowel and consonant system suggested by the Society, save to the retention of the un-English letter *x* and to one other particular.

This latter exception deals with the statement contained in paragraph (2) that "no change will be made in the spelling of names that have become by long usage familiar to English readers—as Calcutta, Cutch, Celebes, Mecca, &c." Now, why make even these exceptions to the excellent rules laid down? Exceptions are always a nuisance, and in the cases of justifiable reforms prove more often than otherwise the means whereby the benefits of such reforms are frustrated altogether. A little more boldness by the Society in grasping the nettle is wanted; and while an improved alternative spelling would soon become familiar to the public, the help given by this concession to logical consistency would encourage reforms both here and in other fields. The attempt to consider the public convenience here illustrated is, I believe, unnecessary; while the seeking to preserve historical spellings, as with other historical and venerable anachronisms, comes to this—that the progress of reform is continually becoming hidebound and stunted, if not stopped altogether, by the impossible attempt to energise distinct stages of growth at one and the same time. It is earnestly to be hoped that the Geographical Society, upon whom the mantle of "Bahnbrecher" in spelling reform has suddenly fallen, will do the wise thing here, and boldly declare against all "exceptions" to wholesome, justifiable improvement.

The need for, and the influence on other departments of spelling reform, of bold action on the part of the Society is illustrated by the retention of the letter *x*. In any reform scheme of the spelling of English place-names—the next urgent question to the above—the abolition of this letter will stand in the fore-rank of improvements. Witness its mischievous working in "Boxted" (Buckstead), "Hoxton" (Hogston in 1790), "Oxted" Ocksstead), Huxtable (Huckstable), &c.! N.

Recession of Niagara Falls in 133 Years

THE fallacy of Lyell's guess at the rate of recession was always plain if we referred to the first accurate account, that of the Swedish traveller Kalm, in *Gent. Mag.*, January, 1751; since which the gorge has both been enlarged full 100 acres, and had miles of its bed deepened many feet. In p. 16, col. 1, A, he said: "Canoes can go yet half a league above the beginning of the carrying place, . . . but higher up it is quite impossible, the whole course of the water, for two leagues and a half up to the great fall, being *a series of smaller falls, one under another*." Now plainly this whole series have so levelled their bed that the main falls now descend some 160 feet instead of the "137 feet" that he repeatedly maintained (col. 2, E) to be the utmost the engineers, "with mathematical instruments," then admitted. But as for the plan, he is yet more definite. P. 16, col. 1, E: "The river (or rather strait) runs here from south-south-east to north-north-west, and the rock of the great fall crosses it, not in a right line, but forming almost the figure of a semicircle or horse-shoe." (Prof. Tyndall has well remarked that, the upper stream having probably been always much wider than the gorge, the chief fall has always been concave; but Kalm's view makes it appear very slightly so, and we know that very flat segments are, by a perspective illusion, commonly thought semicircles or even "horse shoes.") "Above the fall, in the middle of the river, is an island, lying also south-south-east and north-north-west, or parallel with the sides of the river; its length is about 7 or 8 French arpents (an arpent being 120 feet). The lower end of this island is just at the perpendicular edge of the fall." He proceeds to tell how this island, once thought inaccessible, had been the scene of the heroic rescue, twelve years before, of two Indians by two others. Then, p. 18, col. 2, F.: "The breadth of the fall, as it runs in a semicircle, is reckoned to be about 6 arpents. The island is in the middle of the fall, and from it to each side is almost the same breadth" (barely 350 feet then, but in his engraving not half that). "The breadth of the island at its lower end is two-thirds of an arpent or thereabouts." His view makes it but *one*-third the height, *i.e.*, one-third of "137 feet."

Now this mere reef, about 900 feet by less than 80, was plainly one whose length the falls were reducing. Is there the least ground for holding they have ever reduced Goat Island (now ten times larger than that) or will reduce it one rood? But, prolong "Luna Islet" north-north-west till 900 feet long, and you will have the site, I submit, of Kalm's middle rock, barely 350 feet from the point Mr. Wesson marks, on Fig. 2, "New York Shore," and about as much from a Canadian point west-south-west of it. As for Goat Island, it cannot, in his time, have yet been touched by the falls, but may be one of those the hunters had habitually visited above. His description can be so well plotted on this last survey that the amount of gorge excavated since 1750 should be knowable to an acre. The west fall, then, only slightly the larger, has ever since been widening, lowering its edge, and getting more of the stream; so that the east one, comparatively stationary, retaining its height and decreasing in volume, must dry up, and its bed and all the isles become part of New York State. July 11

Sky Glows

EVER since the sunsets of 1883 and last year there has been at times an abnormal glare both before and after sundown. But I have seen nothing in the way of twilight effect so strange as that of Monday evening, the 6th, when about 10 p.m. a sea of luminous silvery white cloud lay above a belt of ordinary clear twilight sky, which was rather low in tone and colour. These clouds were wave-like in form, and evidently at a great elevation, and though they must have received their light from the sun, it was not easy to think so, as upon the dark sky they looked brighter and paler than clouds under a full moon. A friend who was with me aptly compared the light on these clouds to that which shines from white phosphor paint. This effect lasted for some time after 10 p.m., and extended from west to north, the lower edge of the clouds, which was sharply defined, was about 12° above the horizon. ROBT. C. LESLIE

6, Moira Place, Southampton, July 8

Black and White

MY daughter has two terriers, one black, the other white; she has noticed that in the dusk of the evening the black dog is much more visible than the white one, and has asked me the reason for this fact. I cannot properly explain why a white or light coloured garment shows much less in the dusk than a dark coloured dress, but this is a well-known fact to all sportsmen who shoot ducks at night, when it is their custom to wear a night shirt or other white dress over their ordinary costume. When the black and white dogs are playing together in the dusk of evening, the black dog can be distinctly seen when the white dog, at the same distance, is quite invisible. Will you please explain this? WM. E. WARRAND

Bught, Inverness, July 8

"Foul Water"

DURING a brief stay at Beaumaris in June 1883, and again in June 1884, I had frequent opportunities of observing the "gelatinous masses" mentioned by Mr. Shrubsole as occurring in large numbers at Sheerness-on-Sea. I first noticed them in 1883, while procuring a supply of water for my marine tanks at home. They then existed in very large numbers, and as I had no means of filtering the water before returning to Manchester, I almost expected to find it "foul" upon my arrival. I was, however, agreeably disappointed. The "gelatinous masses" had settled at the bottom of the jars, and were apparently dead. While at Beaumaris I subjected a few specimens to microscopical examination, but being busy with other work did not learn more than is given in Mr. Shrubsole's description.

Earthquake-Proof Buildings

UNLESS my memory plays me very false a number of lighthouses secured against earthquake shocks by saucers and balls were built in Japan just about twenty years ago from the designs of Mr. Stevenson of Edinburgh. WM. MUIR

The London Institution, Finsbury Circus, E.C.

THE QUESTION OF CIVIL AND ASTRONOMICAL TIME

ONE of the points made at the Washington Congress was that if Universal Time (surely Earth-Time or Prime Meridian Time would be a better term) were generally accepted, astronomical time might be abolished, astronomers accepting the new day of twenty-four hours commencing at midnight.

Since the Congress the question naturally has been well considered, and we think it desirable that we should now refer to some of the most important opinions which have already been given, not only as regards the desirability of the change, but as to the time at which that change should be brought about.

Among the first to accept the resolution was the Astronomer-Royal, for the internal use of the Observatory of Greenwich. Many opinions were collected at an early date and forwarded by Mr. Chandler, the Secretary of the U.S. Navy to the Senate. This action grew out of an order of Commodore Franklin, the Superintendent of the U.S. Naval Observatory, to adopt the new time on January 1, 1885; this was communicated to Prof. Newcomb, the Superintendent of the *American Nautical Almanac*, and drew a reply from Prof. Newcomb, from which we make the following extract:—

"(1) The Conference expresses the hope that as soon as may be practical the astronomical and nautical days will be arranged everywhere to begin at mean midnight.

"(2) That east longitudes shall be counted as plus and west longitudes as minus.

"The first of these recommendations proposes a change in the method of counting astronomical time which has come down to us from antiquity, and which is now universal among astronomers. The practice of taking noon as the moment from which the hours were to be counted originated with Ptolemy. This practice is not, as some distinguished members of the Conference seem to have supposed, based solely upon the inconvenience to the astronomer of changing his day at midnight, but was adopted because it was the most natural method of measuring solar time. At any one place solar time is measured by the motion of the sun, and is expressed by the sun's hour angle. By uniform custom hour angles are reckoned from the meridian of the place, and thus by a natural process the solar day is counted from the moment at which the sun passes over the meridian of the place or over the standard meridian. For the same reason sidereal time is counted from the moment at which the vernal equinox passes over the meridian of the place, and thus the two times correspond to the relation between the sun and the equinox.

"It would appear that the Conference adopted the recommendation under the impression that the change would involve nothing more than the current method of reckoning time among astronomers, and could therefore be made without serious inconvenience. A more mature consideration than time permitted the Conference to devote to the subject would, I am persuaded, have led that distinguished body to a different conclusion.

"A change in the system of reckoning astronomical time is not merely a change of habit, such as a new method of counting time in civil life would be, but a change in the whole literature and teaching of the subject. The existing system permeates all the volumes of ephemerides and observations which fill the library of the astronomer. All his text-books, all his teachings, his tables, his formulæ, and his habits of calculation are based on this system. To change the system will involve a change in many of the precepts and methods laid down in his text-books.

"But this would only be the beginning of the confusion. Astronomical observations and ephemerides are made and printed not only for the present time, but for future generations and for future centuries. If the system is changed as proposed the astronomers of future generations who refer to these publications must bear the change in mind in order not to misinterpret the data before them. The case will be yet worse if the change is not made by all the ephemerides and astronomers at the same time epoch. It will then be necessary for the astronomers of the twentieth century, using ephemerides and observations of the present, to know, remember, and have constantly in mind a certain date different in each case at which the change was made. For example, if, as is officially announced, the Naval Observatory introduces the new system on January 1, 1885, then there will be for several years a lack of correspondence between the system of that establishment and the system of the American Ephemeris, which is prepared four years in advance.

"It is difficult to present to others than astronomers who have made use of published observations the confusion, embarrassments, and mistakes that will arise to their successors from the change. The case can be illustrated perhaps by saying that it is of the same kind as—though in less degree than—the confusion that would arise to readers and historians in the future if we should reverse or alter the meaning of a number of important words in our language with a result that the future reader would not know what the words meant unless he noticed at what date the book was printed. The words would mean one thing if printed before the date of change, and another if printed after.

"It is worthy of attention that even the republican Government of France in 1790, which adopted a new calendar, did not venture to change the old system in its astronomical ephemeris.

"I see no advantage in the change to compensate for this confusion. If astronomical ephemerides were in common use by those who are neither navigators nor astronomers the case would be different. But, as a matter of fact, no one uses these publications except those who are familiar with the method of reckoning time, and the change from astronomical to civil time is so simple as to cause no trouble whatever.

"The change will affect the navigator as well as the astronomer. Whether the navigator should commence his day at noon or midnight, it is certain that he must determine his latitude from the sun at noon. The present system of counting the day from noon enables him to do this in a simple manner, since he changes his own noon into the astronomical period by the simple addition or subtraction of his longitude. To introduce any change whatever into the habits of calculation of uneducated men is a slow and difficult process, and is the more difficult when a complex system is to be substituted for a simple one. I am decidedly of the opinion that any attempt to change the form of printing astronomical ephemerides for the use of our navigators would meet with objections so strong that they could not be practically overcome.

"The second conclusion which I wish to consider is that which proposes to reverse our method of assigning algebraic signs to the longitudes by counting east longitudes as plus, and west longitudes as minus. The present system was adopted some forty years ago in Germany as being the most natural, because longitude was measured upon the earth by the apparent motion of the sun and stars from east to west, and it seemed most natural to count the direction of this motion as algebraically positive. This system has been adopted in the American Ephemeris since its origin, and all its tables and formulas which involve the application of longitudes have been constructed on this principle. To reverse this method will cause error and confusion to every one using the Ephemeris without, as far as I can see, the slightest compensating advantages. I am therefore of opinion that it should not be adopted.

"I respectfully submit that in view of these considerations no change should be made in the mode of reckoning time employed in the publications of this office until, by some international arrangement, a common date shall be fixed by all nations for the change."

Prof. Newcomb adds a list of changes in the *American Nautical Almanac* required when the astronomical day is reckoned from midnight.

"Page 1 of each month: The numbers on this page being given for Greenwich apparent noon, the question whether they shall remain unchanged or be given for Greenwich apparent midnight will have to be decided by competent authority.

"Page 2 of each month to correspond with the new mode of reckoning these numbers would be given for mean midnight, which would change the whole page.

"Page 3 of each month: Nearly the same remark applies to these pages as to page 2. When the change is made there will be a discontinuity of half a day in the comparison of the sun's longitudes before and after the change.

"Page 4 to correspond strictly to the new reckoning, the columns noon and midnight on this page would have to be interchanged. This might lead to errors on the part of the computer accustomed to the old system inadvertently forgetting the change which had been made. If not made the system would be a mixed one.

"Pages 5 to 12: All the numbers on these pages will be differently arranged when the hours are counted from midnight.

"Pages 13 to 18: The lunar distances will have to be given for midnight on the first column of the left-hand pages, and for noon on the first column of the right-hand pages, thus reversing the placing of the numbers on the two pages.

"Planetary ephemerides: These will naturally have to be given for midnight instead of noon, and the signification of all the numbers will therefore be different. There will also be a discontinuity of half a day in the progression of the series of epochs at the time the change is made.

"Moon's longitude and latitude: The indications of the times given in this part of the Ephemeris will be altered by half a day. The result would be that a computer inadvertently forgetting the change would take out a result half a day in error.

"Sidereal time of mean noon: Wherever this quantity was given throughout the Ephemeris it would, on the new system, have to be replaced by the sidereal time of mean midnight.

"Transit ephemerides: These would remain unaltered except the column of mean time of transit, which would be changed by 12 hours.

"Changes of nearly the same kind as in the planetary ephemerides would have to be made in giving the predictions of phenomena."

The following extract gives the gist of Commodore Franklin's reply to Prof. Newcomb's objections:—

"So far as the counting of astronomical time from antiquity is concerned, it is the argument of conservatism which desires no change in an existing order of affairs; yet, assenting to this argument, we might refer to a still remoter antiquity—to the time, not of Ptolemy, but of Hipparchus, the 'founder of astronomy,' who reckoned the twenty-four hours from midnight to midnight, just as the Conference has proposed.

"While it is unquestionably true that some confusion may occur, yet the liability to it will be almost entirely with the astronomer, who, through his superior education and training, could easily avoid it by careful attention to the ephemerides he was using. During the years of change, before the ephemerides are constructed in accordance with the new method, it will only be necessary to place at the head of each page of recorded observations the note that the time is reckoned from midnight, to call attention to the fact, and thus obviate the danger of error.

"It is an undeniable fact that the educated navigator finds the conversion of time a simple matter, yet experience has demonstrated that to the mariner who is not possessed of a mathematical education there is a decided liability to the confusion which is so greatly deprecated by all who are interested in this subject. I believe that to all navigators, at least to all English-speaking ones, the new method will prove itself decidedly advantageous.

"As is well known, for many years navigators kept sea time, by which the day was considered to begin at noon, preceding the civil day by twelve and the astronomical date by twenty-four hours. The change to civil time now kept on board ship was effected readily and without friction, so that the recommendation of the Conference regarding the commencement of the nautical day has already been largely anticipated. The navigator is concerned not with his longitude but with his Greenwich time, having obtained which he can take from the *Nautical Almanac* the data he seeks whether given for noon or midnight, and when the ephemerides shall have been made to conform to the new system there will be one time in common use by all the world.

"It seems to me eminently proper that the nation which called the Conference should be among the first to adopt its recommendations, and while it might possibly be better to wait until an entire agreement has been entered into by the astronomers of all nations, yet the fact that the first and most conservative observatory in the world has acceded to this proposal of the Conference would seem to be a sufficient reason why we should not wait for further developments. In deference, however, to the views so well advanced by Prof. Newcomb, and in view of the fact that the President has recently transmitted the proceedings of the Conference to Congress, as well also of the desirability of securing uniformity among the astronomers of our own country at least, I have suspended the execution of the order for the present with the view of communicating with those engaged in kindred work in order to ascertain their sentiments on the subject."

The replies received to Commodore Franklin's circular may be summarised as follows:—

Mr. STONE, Leander McCormick Observatory—

Change should be made completely on January 1, 1885.

Prof. NEWTON, Yale College—

Change desirable, may begin at once for internal use, and any communication from an observatory should state precisely what time is adopted.

Prof. PICKERING, Harvard College—

A general agreement more important than the mode of reckoning; will follow Greenwich absolutely.

Mr. HARRINGTON, Ann Arbor—
Will do as Greenwich does.

Prof. HOLDEN, Washburn Observatory—
Begin in 1890.

Prof. YOUNG, Princeton—
Begin January 1, 1885.

Mr. SWIFT, Warner Observatory—
Begin January 1, 1885.

Prof. LANGLEY, Alleghany—
Begin January 1, 1885.

Mr. PORTER, Cincinnati—
Begin January 1, 1885.

Prof. PRITCHETT, Washington University Observatory—
Wait a year at least for general concensus.

Prof. PETERS, Clinton. We extract his letter:—

"I have, from the beginning, attached very little importance to the object and the proceedings of the International Meridian Conference.

"The suggestions and recommendations which have been the result refer principally to things that are already in existence; for example, the reckoning of geographical longitudes east and west from Greenwich is in practice with most nations. The proposition to count the hours of the day from 0 to 24 also in civil life will scarcely ever be adopted, for nobody (except perhaps sick people lying in bed) will have patience enough to count the striking of the clock up to 24, not to speak of the greater liability of miscounting the strokes and of the difficulty in reading off the turret dial if the circle be divided into twenty-four parts. But what concerns astronomers directly is the change proposed by the Conference in the beginning of the astronomical day, in regard to the introduction of which you ask for my views. It is quite unimportant, of course, whether we begin from noon or from the preceding midnight; the reasons for taking the former as the starting-point exist no longer. Our clocks nowadays are not regulated, as in former times, by observing the culmination of the sun, and with the telescopes of increased size observations are continued not during the night alone, but are carried on as well in day-time, so that a break in the date at midnight is hardy more grievous than one at noon. While thus we might readily conform with the proposal of the Conference, and put our clocks back by twelve hours, we ought to hesitate nevertheless very much to do so at once, especially for two reasons: First, a general agreement and understanding among astronomers (not of the United States alone but of all nations) should be had; otherwise it would become necessary for avoiding confusion to add to every observation we publish some such words as 'old-style time' or 'new style time.' The subject undoubtedly will be discussed in the astronomical periodicals, and in societies representing our science. If authorities such as the Royal Astronomical Society, the German Astronomical Gesellschaft, the larger active observatories, &c., agree in favour of the change, the system of reckoning the astronomical day from midnight will soon be adopted universally. But a partial proceeding seems highly objectionable. Second, if we make a change in the time-keepers of the Observatory now, the use of the astronomical ephemerides, as they lie computed before us, will be made in many respects heavy. Take, for example, the places of the fixed stars, which are given for upper culmination from ten to ten days. When the sidereal day begins before noon, its date in the new arrangement of the solar day is changed. And every star place that we wish to take out of the ephemeris, therefore, requires some additional attention and reflection as to the corresponding date. In the *American Nautical Almanac*, where the tenths of the solar day are given, this inconvenience, to be sure, is not so great; we need only to diminish our argument by 0·5 day for having that of the table. A similar reduction of the argument must be made in using the lunar ephemeris, and of course in all the data expressed in solar time. In this way a source for at least possible mistakes is opened, and I think it therefore desirable that the change in the *Nautical Almanacs* should *precede* that in the observatories. The *American* as well as the *British Nautical Almanacs* are published as far as 1887, inclusive; the next or the next two following years may be under preparation.

"These considerations together lead me to the conclusion that it seems *not* advisable to introduce the change in the beginning of the astronomical day *before* the year 1890."

More recently two European astronomers have recorded their opinions. Prof. Struve in a pamphlet,[1] and Prof. Oppolzer in the *Monthly Notices*. The former thus expresses his views:—

"In regard to the change in the beginning of the astronomical day, thinks that the question before astronomers is not only of giving up a long-established custom, with consequent changes of rules of many years' standing, but it also involves a serious interruption of astronomical chronology. Without a doubt the astronomer would have to make a decided sacrifice in conforming to the wish of the Conference; but, after all, this sacrifice is no greater than our forefathers made when they changed from the Julian to the Gregorian calendar—a sacrifice to convenience of which we are still made sensible whenever we have occasion to go back to early observations.

"We need have little hesitation in making a similar sacrifice if it will prevent discordance between the civil and scientific custom of reckoning time, particularly troublesome where astronomical establishments come in contact with the outer world.

"Prof. Struve states that the Pulkowa Observatory is prepared to adopt the new time, the only question being as to the epoch when the change should be introduced in the publications of the Observatory. He is inclined to recommend that this should be deferred until some agreement can be reached by astronomers, and until the new time is adopted in the Ephemerides. This might be for the year 1890, or perhaps, better still, at the beginning of the next century."

Prof. Oppolzer's opinion is as follows:—

"When once such a universal time is introduced for all purposes it is quite natural that the question must arise, if there is indeed so great a necessity to retain in astronomy, and only in astronomy, a different reckoning of time. I fail to see this necessity, and I do not think that it would cause any serious trouble or confusion if a change were to be made in our astronomical reckoning; whilst a special mode of reckoning time in one science only, when all others use the generally-adopted standard, will, without doubt, be a source of error and confusion.' He then takes up in some detail the objections urged against the proposed change by Prof. Newcomb, and he discusses the changes which would be necessary in the Ephemerides. Prof. Oppolzer proposes to give practical effect to his views by adopting the new reckoning of time in an extensive list of 8000 solar and 5200 lunar eclipses which he is now preparing for publication."

Science, in an article on this subject, concludes as follows:—

"It is difficult to see how this matter will finally be decided. It is evidently a question for astronomers to settle among themselves; but so far they seem to be very evenly divided. For instance: out of some twenty-seven astronomers whose opinions, more or less decided, have been accessible for a count, thirteen seem inclined to favour the proposed change, while fourteen are opposed to it. And among the *pros* are Adams, Struve, and Christie; among the *cons*, Newcomb, Foerster, and Auwers."

MR. FREDERICK SIEMENS'S GAS LAMP

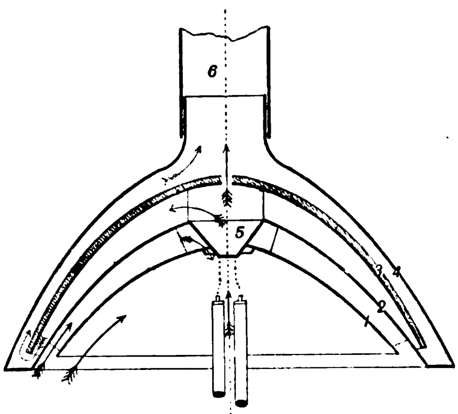
THE illuminating power of the most novel appliances for the production of light having, for economical reasons, been made more and more intense, and therefore more injurious to the eyesight, it follows that the eye must be protected as much as possible from the direct action of the light, with the least possible loss or diminution of effect. In other words, rooms should be lighted only by means of indirect rays or diffused light, the source of light itself not being directly visible. This is, in the author's opinion, a consideration of the highest importance as regards artificial illumination, which has only as yet received partial attention.

Until lately three main points only have been considered in any lighting application—viz. that the apparatus employed should be simple both in its construction and in its use; that the light should be of sufficient intensity for

[1] "Die Beschlüsse der Washingtoner Meridianconferenz."

the purposes required; and that the first cost and the maintenance of the plant employed should be very moderate. In public estimation, simplicity is the first *desideratum;* and hence a simple and direct form of illumination has always been preferred to a more complicated arrangement, even when the latter has been found more economical as regards first cost and maintenance, and more brilliant in its effects. At the present time, however, in addition to these requirements, a purer atmosphere and a more pleasant temperature in our apartments are desired, which matters received very little or no attention in former days, when people were content with a simple dim light, and took little interest in sanitary matters. The regenerative gas-burner may be regarded as a combined lighting and ventilating apparatus, by the employment of which the close oppressive atmosphere, so unpleasant at large gatherings, may be entirely avoided. In fact, it is the outcome of the demand for cooler and purer air in our apartments, combined with light of high intensity.

The lamp has been designed with a view to protect the eyesight from the direct action of the source of light, without diminishing its power; its construction will be understood from the following description:—Four hoods, 1, 2, 3, 4, of sheet iron or other suitable material, are arranged within one another in such a manner that the products of combustion travel downward between



2 and 3, and upward between 3 and 4, while the air to be heated for feeding the flame passes upward between 1 and 2. On the uppermost hood, 4, a chimney, 6, is provided, while the hood, 3, is shortened below so as to allow a clear passage for the products of combustion from the space between 2 and 3, to that between 3 and 4, and thus to the chimney. The hood, 2, carries at its apex an inwardly projecting outlet, 5, through which the products of combustion pass away as described, first downwards and then upwards, through the passages between the three upper hoods, into the chimney. The lowest or innermost hood, 1, is open, so that the air may pass upwards between the hoods, 1 and 2, as indicated by the arrows, to fill the inner space of the hood with heated air. The inner surface of this hood acts as a reflector, and in its focus are placed one or more fishtail burners of the usual type. As soon as the hood, 2, becomes sufficiently heated, through the action of the products of combustion passing between it and 3, the air between 1 and 2 will become heated, and, diminishing in its specific gravity, will automatically rise and fill the upper portion of the cone inside the hood, 1. By this arrangement the gas-jets burn within an atmosphere of heated air, with which they are consequently permanently supplied; the temperature of the air increasing with that of the gas-flames, and the brilliancy of the light increasing in the same ratio. The action is perfectly automatic, for, as the products of combustion pass away through the chimney 6, fresh heated air comes in at the same rate into the inner space of the hood 1 containing the gas-flames, to occupy the space which would otherwise be filled with cold air from the atmosphere below. The hot air which is supplied from the column of heated air formed between the hoods 1 and 2 will, on account of its *lower specific gravity*, always fill the upper space inside the hood 1, thus preventing the cold air of the atmosphere, which is at least three times as heavy, from rising inside the hood, 1, above a certain level, even in case of a disturbance in the atmosphere of the room. Thus no glass partition to exclude the cold air is required. The flame reflects its light directly downwards, as also from the inner surface of the hood, there being consequently an entire absence of shadows.

The light can be more or less concentrated or diffused, as desired, by varying the shape of the hood or reflector used. In some cases, where it is required to diffuse the light widely, or to diminish the downward radiation of heat, a bell-shaped glass, with its apex upwards, and its surface curving parabolically in the downward direction, may be employed, so as to cause all the rays of light it receives either to be refracted or to be reflected horizontally. If it is only desired to reduce the intensity of the downward radiation of heat, clear glass should be employed; if, however, it is also desired to diffuse the light, opaque glass is requisite, and the light may be thus more or less diffused, as may be required. The glass bell is suspended on a wire net of large mesh attached to a metal ring below, upon which and upon the netting the glass rests, so that, in case of accident, the broken glass would not fall below. It allows of free access to the flame, and does not form an integral part of the apparatus, so that its employment will not cause any particular trouble or inconvenience. As the intensity of the light depends entirely upon the up-current of heated air, the hoods may have any shape most suitable for the reflector and for the purpose of diffusing the light, provided that the height of the column of hot air between the hoods 1 and 2 be not relatively diminished.

The following tests of this lamp have been made:—The burners or jets removed from the dome were tested with the rays horizontal. The consumption of gas was 20 cubic feet per hour, and the illuminating power 57·5 candles, or 2·875 candles per cubic foot. They were then placed at an elevation of 1 foot 6 inches perpendicularly over a plain glass mirror placed at an angle of 45°, and in a line with the disk of the photometer. The distance from the standard light to the glass reflector was 18 feet 6 inches, which, added to the 1 foot 6 inches that the burners were placed above the reflector, made together 20 feet, the distance at which the light to be tested has to be fixed from the standard light in the photometer employed. In this case the consumption was again 20 cubic feet per hour, and the illuminating power was found to be 55 candles, or 2·75 candles per cubic foot; so that it would appear that there is an absorption by the glass in reflection of 4·35 per cent. The burners having been fixed in the dome reflector, the lamp, thus arranged, was tested again as in the last experiment. The consumption of gas was 20·5 cubic feet per hour, and the illuminating power 62·5 candles, or an average of 3·048 candles per cubic foot of gas, or 3·180 candles per cubic foot if the 4·35 per cent. found to be absorbed by the glass are added. The difference between 2·875 and 3·180 candles, or 0·305 candle, per cubic foot gives the increase of light due to the use of the reflecting cone. After burning for some time the lamp was again tested, the consumption of gas was found to be reduced to 15·5 cubic feet per hour, and the illuminating power to be increased to 115 candles, being an average of 7·42 candles per cubic foot; or, allowing for loss by absorption, 7·74 candles per cubic foot. The difference between this and 3·180 candles, or 4·560 candles, gives the gain in light per cubic foot of gas due to the regenerative arrangement, the gas burning within a highly-heated atmosphere.

Date.	Particulars of Burners.	Pressure of Gas.	Consumption in cubic ft. per hour.	Candle-power.	Candle-power per cubic ft. of gas.	Corrected for loss by mirror.
May 6, 1885.	Gas jets taken out of lamp	Ten-tenths	20·0	57·5	2·875	...
"	Same jets raised 18 inches to reflect light on mirror[1]	"	20·0	55·0	2·750	...
"	Same jets burning in cold lamp	"	20·5	62·5	3·048	3·180
"	Same jets burning in hot lamp	"	15·5	115·0	7·420	7·740

Of course light may be diffused or transmitted indirectly by other means than those described, though not perhaps in a more simple or economical way. The electric light has been to a certain extent already treated in a similar way by suspending arc lights at great altitudes, and by means of reflectors concentrating the light down upon certain areas. The intention has been, by this means, to illuminate whole towns or districts of towns from single sources of light. This can, in the author's opinion, be done if the concentration of the light is effected in a different way from what has been hitherto attempted—viz., by the employment of very much larger reflectors. In this way the loss of light sideways and the deep shadows that have been produced will be avoided. It matters very little at what height the light is placed, the chief question being what area has to be illuminated; and then the form of reflector suitable for the purpose can be easily determined upon.

In conclusion, it must be remembered that illumination from above downwards is in nearly all cases the preferable mode of distributing light, as Nature herself proves in having one light only, the sky being the diffusing agent by which the most perfect distribution of light is effected. Nature possesses, indeed, a gigantic reflector in the atmosphere and clouds; and the author has endeavoured to imitate Nature's reflector in a way suitable to our imperfect means and conditions, and to the circumstances of each individual case.

THE VOYAGE OF THE "CHALLENGER."[2]

II.

THE plan adopted in the narrative of the cruise gives the reader a good idea of the course of the voyage, the nature of the researches carried on, and the manner in which these researches have been followed up by the more detailed studies of the experts into whose hands the collections were afterwards placed. But it is necessarily desultory. We are led from station to station, from chemical to biological work, from physics to ethnology, from deep-sea temperatures to the anatomy of sea-slugs, with a rapidity and suddenness that are a little bewildering. Still, the general impression of the far-reaching aims of the expedition, of the skill and completeness with which the work was done, and of the enormous mass of new material obtained, is no doubt deepened by the difficulty or impossibility which the narrators have obviously experienced in giving within the brief compass of their chapters anything like a comprehensive digest of what the *Challenger* voyage accomplished in regard to the problems of the great deep. The reader must resign himself to be carried along as the naturalists of the expedition themselves were, and to listen to their story of what they saw and found.

In our notice of last week we left the *Challenger* at the Cape of Good Hope. From that station she strikes out boldly into the Southern Ocean, giving us glimpses of the Prince Edward and Marion Islands, with their proofs of recent volcanic action, the Crozet Islands and Kerguelen. In this part of the voyage the trawlings are extraordinarily rich, between one and two hundred animals coming up at each haul, representing nearly all the marine groups, and, with few exceptions, belonging to genera and species discovered now for the first time. Among the more interesting forms of life are various crinoids, the mention of which leads to a summary from Dr. P. A. Carpenter and Prof. L. von Graff of their Reports upon the additions to our knowledge of the recent crinoids made by the expedition Fig. 4). The figures of the living *Pentacrinus* remind the

Fig. 4.—*Metacrinus Wyvillii*, P. H. Carpenter.

[1] This shows a loss of 4·35 per cent. owing to absorption by mirror.

[2] "Report on the Scientific Results of the Voyage of H.M.S. *Challenger* during the years 1873-76." Prepared under the direction of the late Sir C. Wyville Thomson, and now of John Murray. "Narrative," vol. I., 1885. Continued from p. 207.

geologist of the familiar Liassic *Extracrinus*, and give a singularly antique aspect to the fauna. Not less interesting is the living *Rhizocrinus*, which is a dwarfed and degraded descendant of the well-known chalk fossil *Bourgeticrinus*, as this in turn appears to have been a dwarfed representative of the Pear-encrinites of the Jurassic rocks. The genus *Bathycrinus*, previously known only from a single immature specimen, is now shown to have a wide extension in the Atlantic, but is not known in the fossil state. While the stalked crinoids have been dying out, the Comatulæ, or Feather-Stars, are probably more abundant now than at any former geological period, no fewer than four hundred species being now known, and three of the six genera into which they are referable having been discovered by the *Challenger*. In connection with the subject of recent crinoids some interesting observations are given regarding the Myzostomid parasites that infest these creatures and produce singular mal-formations. The resemblance of these distortions to those found upon many fossil Palæozoic crinoids no doubt indicates the presence of similar parasites even in the waters of the Palæozoic oceans. From the rich trawlings below water we are led by the narrative to the abundant bird-life of the Southern Ocean and to the conclusions regarding the structure and affinities of the Petrels reached by that able and lamented naturalist, the late Mr. W. A. Forbes.

From the pages of the narrative a good notion of Kerguelen with its snowfields and lavas, and Heard Island with its ice-cliffs and glaciers can be obtained. The profusion of life in these southern waters is not a little remarkable—sponges, alcyonarians, holothurians, ophiurids, asterids, echinids, annelids, amphipods, polyzoa, gasteropods, cephalopods, and many other invertebrates. But the *Challenger* now pushes southward to the Antarctic ice-cliffs, and as these seas are but little known, full details of this part of the navigation are given, with the soundings, dredgings, trawlings, and temperature observations taken along the route. Numerous woodcuts, phototypes, and chromolithographs of icebergs observed in the Antarctic Ocean are inserted, and a special chapter is devoted to the history of exploration in these seas, and to an account of observations made by the scientific staff of the *Challenger* on Antarctic temperatures, the density of sea-water, the true composition of sea-water ice, Antarctic icebergs, the deposits formed on the sea-bottom in the icy tracts of the Southern Ocean, the surface organisms of these seas, and a detailed summary regarding the hexactinellid and tetractinellid sponges collected.

Fig. 5.—New Volcano, Camiguin Island.

Escaping from the perils of the ice-fields and Antarctic gales the vessel bears away to Australia, touching at Melbourne and Sydney and then, passing between the North and South Islands of New Zealand and northwards to the Fiji Islands, turns westwards again, through the Coral, Celebes and China Seas to Hong Kong. The account of this portion of the voyage is enriched with descriptions of numerous groups of animals collected during the expedition, particularly macrurous and brachyurous crustaceans, butterflies and moths, medusæ, star-fishes, amphipods, lamellibranchs, annelides, calcareous and horny sponges. The next track, from Hong Kong by Manila, Zebu, and the Admiralty Islands to Japan, takes up nearly 100 pages of the narrative. Among the more interesting observations recorded are those relating to the volcano of Camiguin Island, which burst forth upon a low plain in the summer of the year 1871 and in four years and a half rose to 1,950 feet in height, with abundant discharge of steam and with glowing lava at its summit (Fig. 5). The mountain is a dome-shaped mass rising from the seashore. It consists of various andesitic lavas but seems to possess no crater, resembling in this respect some of the trachytic domes of Auvergne. The lava is described as having apparently "issued from a central cavity and boiled over, as it were, till it set into the form of the dome." Probably the volcano is an example of the extravasation of viscous lava in successive shells, of which the outer are pushed outwards and upwards by the arrival of fresh material from below, as illustrated experimentally by Reyer. Mr. Busk supplies a *résumé* of his Report on the Polyzoa of the expedition. Professor E. Perceval Wright gives one on the Alcyonaria; Dr. Rudolph Bergh, one on the Nudibranchs; Professor Turner, one on the crania of the Admiralty and other Pacific Islanders; Professor G. O. Sars, one on the Schizopods and other crustaceans.

From Japan we are transported to the centre of the Pacific Ocean, and learn much by the way regarding the distribution of temperature in this vast expanse of water. A series of soundings taken from lat. 40° N. to lat. 40° S. affords a section of the very centre of the ocean through the volcanic peaks of Hawai and Tahiti. Perhaps no single part of the sounding work of the expedition offers a more impressive example than this of the boldness and success with which the problems of the deep sea can now be attacked. Down the middle of the widest and deepest ocean on the face of the globe a line of temperature soundings is taken with as much precision as if it had been an inland lake, and information is obtained that furnishes a clear picture of the depth of the water, the form of the bottom, and the manner in which the layers of different temperatures are superposed upon each other from the surface downwards. A careful survey of the coral-reef of Tahiti by Lieutenant Swire and Mr. Murray suggested to the latter observer the view which he has already published—that this reef and coral-reefs in general may be formed by the outward growth of the living coral upon a *talus* of coral-rock broken off by the waves, and do not prove subsidence as was believed by Darwin. Among the corals, briefly described by Mr. Moseley, probably the most beautiful of the madrepores is the delicately fragile *Leptopenus* trawled from a depth of 2,160 fathoms between Juan Fernandez and Valparaiso (Fig. 6). Prof. Hubrecht of Utrecht supplies some notes on the *Nemertea* in anticipation of his detailed Report on this subject. A summary is given of Mr. H. B. Brady's studies of the *Foraminifera*, which are so abundant in the surface waters and play so important a part in the formation of deep-sea deposits; and a digest of the Report of Dr. G. S. Brady on the copepod and ostracod crustaceans. But perhaps the most generally interesting section of this part of the narrative is that which treats of the nature of the organic deposits now forming on the floor of the deeper parts of the ocean. The important results obtained by the *Challenger* expedition in this novel department of enquiry have already been made familiar

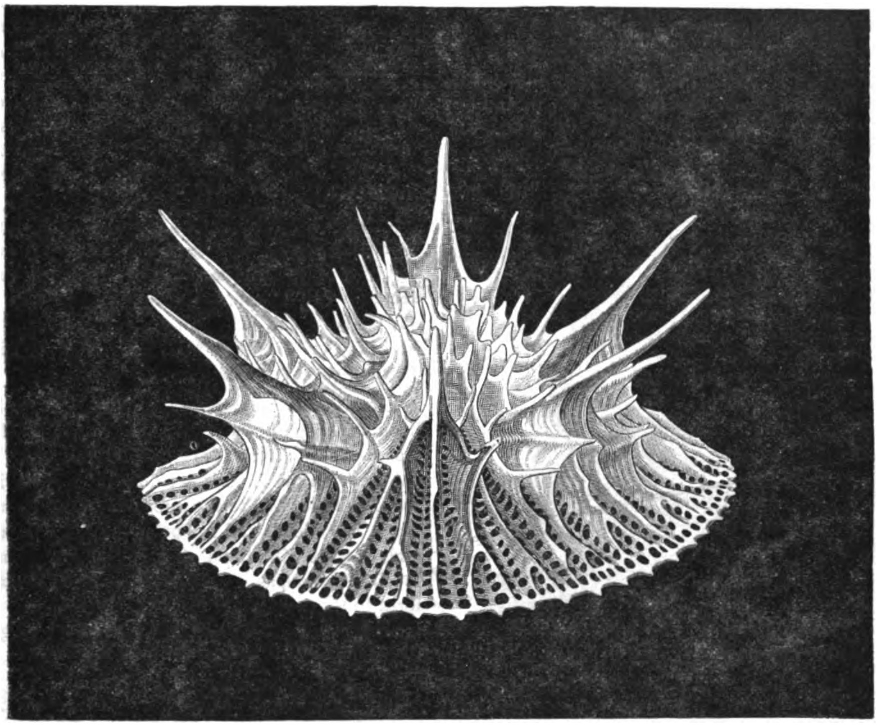


FIG. 6.—*Leptopenus hypocœlus*, Moseley.

by the writings of Messrs. Murray and Renard. But the reader will be glad to have them re-stated in the official account of the voyage, and to find them so admirably illustrated with woodcuts and a lithographic plate, which enable him to realise exactly the nature of the evidence for the extreme slowness of deposition at these great depths and so far from land. From no fewer than 116 sharks' teeth brought up with over two bushels of manganese nodules in a single haul from a depth of 2,385 fathoms, Fig. 7 has been selected for illustration. It differs in no essential particular from the tooth of *Carcharodon megalodon*, so common in Tertiary strata, except that it shows no large base.

Quitting Valparaiso, the *Challenger* pursues a southerly track to Port Otway, and then winding through the long line of sounds between the islands and the mainland passes through Magellan Strait to the Falkland Islands, and thence to Monte Video. During this part of the narrative we learn from Dr. Hoek what he has found out regarding the Cirripedes and Pycnogonids obtained during the cruise; from Mr. F. E. Beddard regarding the Isopods; from Mr. R. B. Watson about the Scaphopods and Gasteropods; from Mr. J. R. Henderson about the Anomurous Crustaceans; from Dr. Günther respecting the deep-sea fishes; and from Prof. E. Selenka regarding the *Gephyrea*. The course is then shaped eastward from Monte Video, across the South Atlantic to Ascension, and during the account of this *traverse* we are shown how the foraminiferal deposits of the deep sea were collected and investigated, and are supplied with a useful summary of the results arrived at by Messrs. Murray and Renard regarding deep-sea deposits in general, illustrated with an excellent coloured plate, which, in default of the actual objects themselves, brings their characters very clearly before the eye. As the narrative proceeds with the account of the homeward voyage from Ascension, we are told about pelagic diatoms, marine infusoria, coccospheres, rhabdospheres, bathybius, and the land-plants collected during the whole of the cruise, till at last the voyage ends at Spithead, on May 24, 1876. From the start on December 7th, 1872, till that date the vessel had traversed 68,890 nautical miles, and at intervals as nearly uniform as possible had established 362 observing stations.

The final chapter gives a summary of the results obtained by the officers of the Expedition, and by experts subsequently employed in the investigation of the density of sea-water, the composition of the salts of the ocean, the geographical and bathymetrical distribution of specific gravity, the carbonic acid, nitrogen, and oxygen present in sea-water, and a discussion of meteorological observations in their bearing upon oceanic circulation.

In this notice we have endeavoured merely to convey to the general reader some notion of the contents of the two portly volumes which contain the official narrative of the most important scientific expedition which has ever

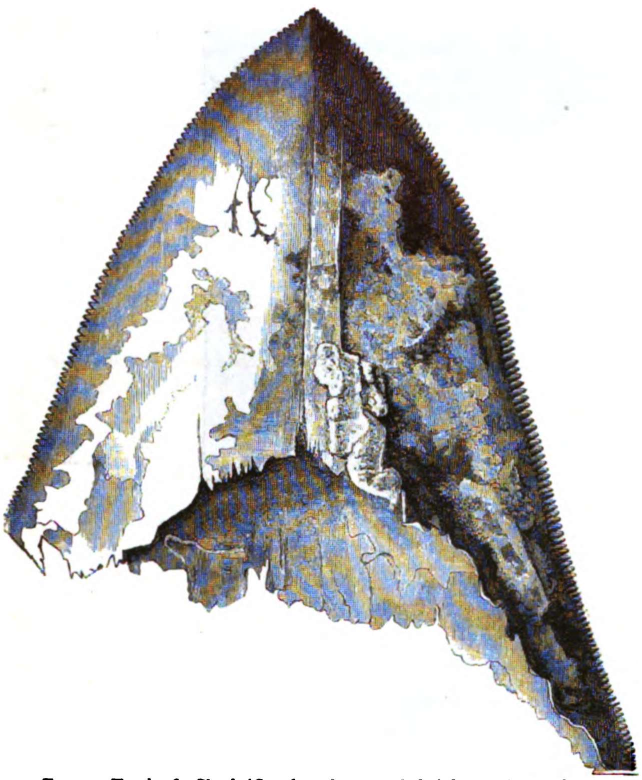

FIG. 7.—Tooth of a Shark (*Carcharodon megalodon*) from a depth of 2385 fms.

been despatched by any Government for the investigation of the depths of the ocean. The materials are not yet ready for a complete digest of the whole work achieved. But it would have been an important addition to the value of the Narrative had the authors endeavoured to give such a digest as far as the materials are now in their hands, marking those portions regarding which the final reports had not been received. Such a summary, carefully arranged in subjects and with precise references to the detailed Reports for fuller information, would have been of great service to those who cannot follow all the technical details of the Reports, as well as to the specialists who wish to learn to what source they have to turn for their own requirements. Let us hope that in a future edition of the narrative this want will be supplied. Meanwhile no one can rise from the perusal of these volumes without an admiration for the solid, painstaking, and conscientious way in which their compilation has been accomplished. They are not light reading, but they abound in material of general interest and form a fitting record of the great Expedition which they chronicle.

NOTES

THE fourteenth meeting of the French Association will take place on August 12 at Grenoble. M. Verneuil, Member of the Academy of Medicine, will be President. The public lectures will be "On the New Gallery of Palæontology of the Paris Museum," by M. Cotteau, ex-chairman of the Geological Society of France, and by M. Rochard, General Inspector of the Marine, on "The Victualling of France." A large number of medical questions will be dealt with in the several sections of the congress. The Ferran cholera experiments are sure to be discussed at full length. Numerous excursions will take place in the Alps under competent guidance as far as Chambery.

IN the course of the present summer the *Geological Magazine* will be twenty-one years old. During that period Dr. H. Woodward has been one of its editors, and for almost the whole time the principal editor, on whom the burden of the work has fallen. Further, the arrangement made with the publishers, in order to secure the continuance of the *Magazine*, would have actually resulted in pecuniary loss, but for illustrations presented by authors. Of the ability with which the *Magazine* has been conducted, and of its value to geologists, there can be no question. A committee has been formed, with Prof. Bonney as chairman, to give expression to their sense of the services which he has rendered to geology by presenting him with a testimonial, of which a piece of plate will, at any rate, form a part. The secretary and treasurer of the committee is Mr. G. J. Hinde, 11, Glebe Villas, Mitcham, Surrey, to whom subscriptions may be paid, or to the "Woodward Testimonial Fund," at the London and Westminster Bank, Limited.

ELABORATE preparations have been made in the neighbourhood of Niagara Falls for the formal transfer to-day to the Government of New York State of the strip of land adjoining the Falls on the American side. This strip will be thrown open for the future, free to the public, as "The Niagara International Park." Officials and troops representing both New York State and Canada will attend the ceremonies. This transfer attracts much attention, as it renders America's great cataract free henceforth to the world. We have already alluded at some length to the acquisition of the Falls and immediate neighbourhood by the State.

THE annual meeting of the Royal Archæological Institute will be held at Derby from Tuesday, July 28, to Wednesday, August 5, inclusive. The presidents of the three sections will be:—Antiquarian, the Rev. J. C. Cox, LL.D.; Historical, the Dean of Lichfield; Architectural, the Right Hon. A. J. Beresford-Hope.

THE observations made at the Ben Nevis Observatory have been received to the end of June. During the twelve months ending with June the rainfall, snow, and hail have been measured with all possible care every hour. During the year the whole of the rainfall, inclusive of melted snow and hail, amounts to 152·15 inches. Averaging the monthly falls from June, 1881, the mean annual rainfall on the top of Ben Nevis is 145·73 inches, which is thus the largest mean annual rainfall of any place at which rain has been observed in Scotland. The largest rainfall in any single month was 25·30 inches in December, 1884, and the smallest 4·85 inches in April, 1885. Falls of an inch a day, or upwards, are of comparatively frequent occurrence, having been recorded during one day in seven out of the 365 days. On two of the days upwards of four inches of rain was measured at the Observatory.

A TELEGRAM from Cooktown to Berlin, July 8, announces the arrival there of the New Guinea Company's steamship *Samoa*, with Dr. Finsch on board, who is returning to Europe from his recent exploring expedition along the unknown portions of the coast of Kaiser Wilhelm's Land (New Guinea) which are situated between Astrolabe Bay and Humboldt Bay. Dr. Finsch reports the discovery of several good harbours and of a navigable river. The land is suitable both for agriculture and stock-raising. The natives were friendly.

THE Comptroller-General of patents, designs, and trade marks has issued, in the form of a Parliamentary paper, his report, the second since the passing of the Act of 1883. That the new Act has worked well in the interest of inventors may be seen from the fact that the number of applications for patents, which had risen, with some variations, almost constantly in the course of thirty years, from 1211 in the year 1852, to 6241 in 1882, leaped with a bound to 17,110 in 1884. The increase is, in fact, as between the years 1883 and 1884, no less than 195 per cent. Seventy-nine per cent. of the applications were made by persons resident in the United Kingdom—namely, 12,356 being residents in England and Wales, 901 in Scotland, and 254 in Ireland. Of the rest the largest numbers were from the United States, 1181, from Germany 890, and from France 788. Residents from twenty-seven other countries also made application to the office, thirteen such countries being British possessions, from which 175 applications were made, and three, it may be added, were made from Egypt. Only three appeals were made in the course of the year against the decision of the Comptroller, so that it may be taken that his decision is almost invariably satisfactory to applicants. The receipts of this office amounted to 103,827*l.*, of which 88,996*l.* were for patents' fees, 3477*l.* for designs' fees and stamps, 7014*l.* for trade-marks' fees, and more than 4000*l.* for the sale of publications. The chief payments made were 36,225*l.* for salaries—all of which are set forth in detail in the report—and 17,000*l.* to Messrs. Eyre and Spottiswoode for printing. There was a surplus income of nearly 40,000*l.*

THE International Telegraph Congress, which meets in Berlin on August 10, will be attended by delegates from all the European states, and from Brazil, British India, Dutch India, Egypt, Algeria, Cochin China, Japan, Natal, New Zealand, Persia, Siam, Cape Colony, South Australia, and Victoria, as well as from all the great cable companies. The chief subjects of deliberation will consist of various technical questions, including more especially a general reduction of tariffs.

THE Council of University College, London, have instituted a Professorship of Electrical Engineering, and have appointed Dr. J. A. Fleming thereto. Dr. Fleming retains his connection as advising electrician with the Edison and Swan Electric Light Company.

WE give the following extracts from Prof. Adams's report to the Senate as to the proceedings in the Cambridge Observatory for the year ending May 26, 1885:—The total number of observations made with the transit circle during this interval, for determinations of right ascension and north polar distance, is 3253. These include 658 observations of clock stars made on 152 nights; 69 observations of Polaris at the upper transit involving 151 circle readings, and 73 observations at the lower transit involving 180 circle readings; 11 observations of stars compared with Wells's Comet; and 2442 observations of zone stars made on 100 nights, the greater number at five or seven wires, and all, without exception, read off with four microscopes. For instrumental adjustment the Nadir Point was observed 203 times, the level 203 times, and the collimation 207 times. Twenty pairs of observations for flexure of the transit telescope made June 18 to 23, 1884, give for the coefficient $-0''.651$; this will need confirmation, as it differs considerably from the former determination, $-0''.936$. The observations of clock stars and those of Polaris are completely reduced, and the mean places for January 1 obtained up to the end of 1884. The true apparent places of all the other stars observed in 1884 is also obtained both in Right Ascension and North Polar Distance. As regards the observations of former years:—The mean R.A. and N.P.D. of the Zone Stars are obtained up to December 12, 1877, and the true apparent R.A. and N.P.D. to the end of 1882, and the reductions are far advanced in 1883. The reductions from mean to apparent place at date are calculated to the end of 1882. The means of transits and microscope readings are deduced up to the present time. The intervals of R.A. wires used in the reductions for 1884 were obtained from 63 observations of Polaris made January 18 to July 10, 1884: (1), by taking the mean of the intervals for Polaris and the mean of the declinations, and using the formula $\sin E = \sin P \cos \delta$; (2) by deducing the equatorial intervals from each individual observation, and taking the mean of the results. The intervals by the two methods almost exactly agreed. The meteorological observations are communicated daily by telegraph to the Meteorological Office. The sunshine recorder has been regularly employed, and the records sent at intervals to the office.

COL. PRJEVALSKY telegraphed to St. Petersburg from Kiria, in Khotan, on June 20, that during April and May he and his party had explored the region between Lob Nor and Kiria, and that, leaving stores at the latter place, he was about to go into the neighbouring Tibetan mountains, whence he would return to Kiria at the end of August, and then come back to Russia.

PROF. THALÉN, whose classical researches on the spectra of the metallic elements have won for him such wide renown, has recently published a new memoir on, and a revised list of, the lines of iron, presented to the Royal Society of Upsala last September (published by Berling, Upsala). The new work has been done by means of a gramme dynamo, and much higher dispersion than that employed in 1864. An upper carbon pole being rejected on account of the spectrum of "acetylene," about which we have heard so much in this country, and which we now know to be due to carbon vapour, three tubes of iron 15 mm. in external diameter were used to prevent fusion of the points. The size of the laboratory did not permit the use of a lens, but the poles were placed in a horizontal position. The spectroscope employed had six and sometimes nine prisms of flint of 60°, the focal length of the object-glasses of collimator and telescope being 81 cm. and magnifying power 62. The wave-lengths have also been re-determined by a process which he gives.

Bulletin No. 8 (1885) of the U.S. Department of Agriculture (Division of Entomology) is occupied by a particularly interesting memoir by Prof. C. V. Riley on the occurrence of "Periodical Cicada" (*C. septendecim*). This insect is one of the marvels of entomology, because ordinarily a period of seventeen years elapses between the deposition of the egg and the appearance of the perfect *Cicada*, and practically all but a few weeks of that period are passed in the preparatory underground larval condition. But even such a Methusaleh amongst insects is liable to have its development hastened (and its whole life thereby shortened) by temperature, for Prof. Riley discovered that (principally in the Southern States) there is also a thirteen-year brood of the same species, although each condition impinges on the domain of the other. That the larva sometimes penetrates to a great depth is shown by the fact that the perfect insects, true to time, once came through the floor of a cellar 5 feet deep, a building having been erected over the site of their underground quarters; in another instance the larvæ were found 10 feet below the surface.

Occasionally, at very long intervals, the 17-year and 13-year forms appear simultaneously. Such an event as regards one of the largest broods happened in the year 1647, again in 1868, and will not again occur till 2089. But it must not be supposed that the broods are simultaneous over all the United States; they vary according to locality, so that somewhere or other there is nearly always a brood on the wing. Prof. Riley has, through his agents, collected information from many states, and for thirty-two different districts is able to predict the particular year of appearance during the next 13 and 17 respectively in these districts. 1887, 1890, and 1892 are the only years omitted as not likely to produce the Cicadas. One would imagine that in the course of 17 years a larval *Cicada* must occasion great damage to the roots of trees, &c., but it would seem that any damage in this way is as nothing compared with that inflicted on the foliage by the perfect insect during its brief existence.

AN air-balloon railway is about to be constructed on the Gaisberg, near Salzburg, a mountain of no great height, but offering a magnificent view over the beautiful neighbourhood of the town. The balloon, which will have grooved wheels on one side of its car, will ascend a perpendicular line of rails, constructed on the principle of the wire-rope railway invented years ago for the Righi, but never realised.

M. FOUQUÉ has established at Meudon Observatory, with the kind assistance of M. Janssen, an apparatus for registering electrically the propagation of earthquakes in underground layers. Experiments have been made by the fall of a weight of 600 kilogrammes from 7 metres; the results having been deemed satisfactory, measures are being taken for procuring the fall of 900 kilogrammes from 9 metres, which represents a shock of 81,000 kilogrammes. A steam elevator will be procured for further investigations.

AT the recent distribution of prizes at University College, Dundee, Prof. Gairdner, of Glasgow, strongly advocated the formation of a School of Medicine in Dundee. Dr. Gairdner not only urged the duty of setting a medical school afoot, but he showed how in some ways a new school may be made more attractive and more efficient than the old, so as both to supply the educational needs of its own neighbourhood and even to draw students from a distance also. Tradition, prejudice, and the vested interests of professors make all reform slow in the old Universities, and cause many changes which are admittedly desirable to seem well-nigh impossible of attainment. The matter in which Prof. Gairdner chiefly indicated the possibility of reform is the present separation of practical from theoretical instruction and the long delay in bringing a student face to face at the bedside with disease. In a new school, he thought, the attempt should be made to give men hospital instruction from the very beginning of their student life; to illustrate to them in the wards what they are at the same time learning in the lecture-room in chemistry, anatomy, and physiology; and to give the longest possible training to hand and eye and ear in the subtle discrimination of disease.

THE University College of Wales at Aberystwith was the scene of a destructive fire during Wednesday night last week, which resulted in the loss of two lives, including Prof. James Macpherson, and serious injury to three other persons. The College buildings were the largest and handsomest in the Principality, having been built at a cost of 80,000*l.*, and they include the necessary rooms and offices for the education of a large number of students. The flames spread with alarming rapidity, and in a short time had complete hold of the museum, library, professors' rooms, and students' apartments. By great exertions all the articles of value in the museum and library were removed. The Principal's residence and examination hall escaped, but the northern wing was gutted. The College was insured for 10,000*l.*, but the damage will amount to 40,000*l.*

A TELEGRAM from Simla, July 9, states that shocks of earthquake continue to be felt in Cashmere at intervals of two or three days. A severe shock occurred at Srinagar on the 4th inst.

A SEVERE earthquake, which lasted for some time, and was felt, with varying intensity, over the whole province, occurred at Calcutta on Tuesday morning, at twenty-three minutes past six. Some of the shocks were very serious, and the walls of a number of houses were cracked, causing the utmost alarm to the inhabitants.

THE death is announced, at the age of forty-seven years, of Mr. N. W. Posthumus, director of the Higher Burgher School at Amsterdam, one of the founders of the Dutch Geographical Society, and from the beginning its secretary and one of the editors of its *Journal*. Many contributions to the "Tijdschrift Aardrijkskundig-genootschap" are due to him.

WE have received from the Observatory of Brussels the volumes of the *Annales* of the Royal Observatory there, giving the documents and observations made on the Transit of Venus in 1882 by the Belgian party ordered to Texas. Drawings are given of the contacts, which require careful study; almost everything but the "black dip" was seen in a Dolland of 11 cm. aperture.

THE American Government have forwarded a consignment of catfish to the National Fish Culture Association with a view to their being acclimatised to the waters of this country. They arrived per s.s. *Britannic* in perfect condition, all being alive, which, considering the long voyage they had been subjected to, is remarkable. The catfish is a very valuable food-fish, and would assume a high rank amongst the freshwater fishes of our waters if cultivated. Pending their removal to the Fish Culture Establishment of the Association at Delaford, they are being exhibited at the Aquarium of the Inventions Exhibition, where they attract considerable attention.

SEVERAL of the picked dogfish in the tanks of the Aquarium at the Inventions Exhibition brought forth young last week. They lived for several days, but ultimately died.

A FURTHER stock of landlocked salmon were turned into the Thames on Thursday last by the Thames Angling Preservation Society, in the presence of various gentlemen interested in the matter. This species is exactly suited to this river, being non-migratory, for salmon once quitting for the sea the polluted water of the Thames are not likely to return thereto.

WE have received a new edition of Mrs. Lankester's "Wild Flowers Worth Notice," revised, improved, and increased in size. Allen and Co. are the publishers.

"FACE and Foot Deformities" is the title of a book of curious interest, by Mr. Frederick Churchill, C.M., published by J. and A. Churchill.

THOSE interested in glaciology should read Prof. Forel's little *brochure* on "Les Variations Périodiques des Glaciers des Alpes," separately reprinted from the *Jahrbuch* of the Swiss Alpine Club (Staempli, Berne).

DR. J. E. TAYLOR's latest contribution to popular science is "Our Common British Fossils and where to find them" (Chatto and Windus). A prettily illustrated book of a similar character is Mr. F. G. Heath's "Where to find Ferns," published by the S.P.C.K.

THE additions to the Zoological Society's Gardens during the past week include a Vervet Monkey (*Cercopithecus lalandii* ♂)

from South Africa, presented by Mr. G. C. Barnes; an American Badger (*Taxidea americana* ♀) from North America, presented by Mr. F. J. Thompson; a Common Fox (*Canis vulpes* ♀), British, presented by Mr. Christopher Heseltine; a Rufous Rat-Kangaroo (*Hypsiprymnus rufescens* ♀) from New South Wales, presented by Miss Laidlaw; a Red-throated Amazon (*Chrysotis collaria*) from Jamaica, presented by Mrs. S. Waite; three Rufous-vented Guans (*Penelope cristata*) from Central America, presented by Mr. G. H. Hawtayne, C.M.Z.S.; a Leopard Tortoise (*Testudo pardalis*) from South Africa, presented by Mrs. Henrietta Hodges; two Crowned Horned Lizards (*Phrynosoma coronatum*) from North America, presented by Master Chas. E. Napier; a Cinereous Vulture (*Vultur monachus*), European, a Nonpareil Finch (*Cyanospiza ciris*) from North America, deposited; an Axis Deer (*Cervus axis* ♂), a Mule Deer (*Cariacus macrotis* ♂), three Long-fronted Gerbilles (*Gerbillus longifrons*), seven Mandarin Ducks (*Œx galericulata*), four Chilian Pintails (*Dafila spinicauda*), bred in the Gardens.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, JULY 19-25

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on July 19

Sun rises, 4h. 7m.; souths, 12h. 6m. 1·2s.; sets, 20h. 5m.; decl. on meridian, 20° 47′ N.: Sidereal Time at Sunset, 15h. 56m.

Moon (at First Quarter) rises, 13h. 10m.; souths, 18h. 28m.; sets, 23h. 38m.; decl. on meridian, 10° 33′ S.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	6 3	13 34	21 7	16 27 N.
Venus	5 56	13 31	21 6	17 6 N.
Mars	1 18	9 33	17 48	23 23 N.
Jupiter	7 44	14 41	21 38	10 23 N.
Saturn	2 8	10 18	18 28	22 32 N.

The Occultations of Stars and Phenomena of Jupiter's Satellites are such as are visible at Greenwich.

A TEACHING UNIVERSITY FOR LONDON

An extraordinary meeting of the Convocation of London University will be held on the 28th inst., when the report of the Special Committee appointed on February 24 to consider the question of a Teaching University for London will be presented by Lord Justice Fry, who will also move the following resolutions:—

1. That the report of the Special Committee and the scheme therein comprised be received and adopted.

2. That the Senate be requested to consider and approve the said scheme, and to take such steps as they may think fit to carry the same into effect.

3. That a Committee of this house, consisting of five members, be appointed to confer with the Senate in respect of the said scheme in case the Senate shall desire such conference.

The following is the scheme for the constitution of the University proposed by the Special Committee:—

1. The University to consist of—(1) Senate; (2) Convocation; (3) Constituent Colleges; (4) Faculties; (5) Boards of Studies, with the Queen as Visitor.

I.—Senate

2. To consist of:—(1) Chancellor; and (2) Vice-Chancellor (to be appointed and retain office as at present); (3) the Chairman of Convocation *ex officio*; (4) and not more than thirty ordinary members (including the Vice-Chancellor), of whom six shall be nominated by the Crown, six shall be elected by Convocation, and three shall be elected by each of the four Faculties. And if and when the following bodies respectively shall become Constituent Colleges—one shall be nominated by the President of University College, London; one shall be nominated by the Principal of King's College, London; one shall be nominated by the President of the Royal College of Physicians of London; one shall be nominated by the President of the Royal College of Surgeons of England; one shall be nominated by the Chairman of the Council of Legal Education, and one shall be nominated by the President of the Incorporated Law Society.

3. The nominating bodies to determine for themselves on what recommendation the nominations shall be made.

4. One-third of each of the groups of six and three members of the Senate to retire each year; such one-third to be those who have been longest in office, or, when several have been in office for the same period, to be ascertained by ballot.

5. The six representatives of colleges to serve for three years.

6. Power to fill up occasional vacancies.

7. Power to re-nominate and re-elect.

8. In the first place, the faculty and college members to be added to the existing Senate; but no new members to be appointed by the Crown or Convocation till the number of Crown and Convocation members respectively has fallen below six, and then only so as to bring the number up to six.

II.—Convocation

9. To remain unchanged.

III.—Constituent Colleges

10. The Constituent Colleges to consist of the following bodies in or near London:—(*a*) such bodies as may be named in a schedule to be settled by a joint committee of the Senate and Convocation; (*b*) such other bodies being colleges or institutions incorporated by Royal Charter, or otherwise established on a permanent and efficient footing, in which the majority of the students are of the age of seventeen years at least, as the Senate with the concurrence of the faculty or faculties interested may from time to time admit.

11. Admission as a constituent college shall be subject to such terms as may be agreed upon between the body becoming a constituent college and the joint committee or the Senate with the concurrence aforesaid (as the case may be).

12. The constituent colleges shall be arranged in three groups —viz. (*a*), those colleges which are principally intended to occupy the entire time of their students; (*b*) those colleges in which lectures are given of the most advanced kind, whether professional, literary, or scientific; (*c*) those colleges which are intended to aid the evening studies of persons engaged in business, or otherwise do not fall under either of the preceding groups.

13. By the terms of agreement on the admission of such constituent college the following points shall be determined:—(*a*) The group to which it shall belong; (*b*) the faculty or faculties to which it shall belong; (*c*) the number of members of the faculties to represent the college; (*d*) the class or classes of professors or teachers in the college who are to take part in the election of members to represent the college.

14. In a college of the first and second group the number of its representatives on the faculties shall *prima facie* bear a larger proportion to the total number of professors and teachers in the college than in the case of a college in the third group.

15. A constituent college and the Senate with the concurrence of the faculty or faculties interested may revise the terms of the agreement between the University and the constituent college.

16. No person shall be eligible as a member of a faculty representing a college unless he be in the class of professors or teachers in that college and capable of taking part in the election of members to represent that college.

17. Power to be given to the Senate with the concurrence of the faculty or faculties interested—(*a*) to diminish or increase the number of teachers in a college who shall be members of a faculty or faculties; (*b*) for good cause to remove any college from being a constituent college.

18. The affiliation of colleges to the University to cease.

19. The institutions from which the University receives certificates for degrees in Medicine (hereinafter called the recognised Medical Institutions) to retain their right of giving such certificates whether they be or be not constituent colleges.

20. The list of recognised medical institutions to be subject to the existing power of revision, but so that the Senate shall not report thereon without the previous advice of the Faculty of Medicine (see Charter of January 6, 1863, section 37).

IV.—FACULTIES

21. There shall be four faculties—viz. (1) Arts; (2) Laws; (3) Science; (4) Medicine.

22. All departments of knowledge in which examinations may be held by the University, and not included in any of the other faculties, shall be included in the Faculty of Arts.

23. Each faculty shall consist of—(a) the representatives of the constituent colleges; (b) the examiners in the faculty during their periods of office and three years afterwards; (c) such persons eminent in the studies with which the faculty is concerned not exceeding six in number as the faculty may elect and for such periods as they may determine.

24. Each faculty shall elect—(a) a chairman for three years; (b) three members of the Senate; (c) members of a board of studies.

25. The persons to be elected under the last clause must be members of the faculty not being examiners in office, and on ceasing to be members of the faculty or accepting the office of examiner such persons will vacate their seats as chairman or member of the Senate or board.

26. On any matter connected with its subjects a faculty may—(a) make recommendations to its board of studies in all matters within the competence of the board; (b) represent its views to the Senate.

V.—BOARDS OF STUDIES

27. There shall be a board of studies in each faculty.

28. Each board shall consist of such a number of members being a multiple of three, and not less than six nor more than twenty-one, as the faculty shall from time to time determine, together with one member of Convocation to be elected by Convocation.

29. One-third of the faculty members shall retire each year.

30. The member elected by Convocation shall sit for three years.

31. Power to fill up occasional vacancies.

32. Power to re-elect.

33. Each board shall elect a chairman every year.

34. Each board of studies shall have the following powers and duties:—(a) To consider the recommendations of its faculty; (b) to consult together on all matters connected with the subjects of its faculty and the examinations therein and the teaching thereof; (c) to advise the Senate from time to time as to the institution of new degrees or any change in the degrees, or as to the regulations in force with regard to the degrees and examinations in its faculty (without which advice the Senate shall not act in the said several matters); (d) to consult with and advise the examiners in the faculty; (e) to represent its views on any matter connected with the subjects of its faculty to the Senate; (f) to make by way of report to its faculty such recommendations as it may think fit, with the object of insuring suitable and efficient teaching in the subjects of its faculty, and generally to report to its faculty on all matters connected with its subjects as the board may think desirable; (g) to summon a meeting of its faculty for the discussion of any matter relating to its subjects.

35. Boards of studies may, if they or any of them shall from time to time think it desirable, meet and act concurrently on particular subjects.

VI.—EXAMINERS

36. The examiners in each faculty may from time to time make such reports and recommendations to the faculty or its board of studies as they may think fit.

VII.—DEGREES

37. Candidates to be admitted to matriculation and all degrees other than degrees in the Medical Faculty without regard to the place of their education.

38. Candidates for degrees in the Faculty of Medicine to show that they have passed the required course of instruction in a constituent college in the Medical Faculty or in a recognised medical institution.

VIII.—GENERAL PROVISION

39. Except so far as altered by the foregoing provisions either directly or indirectly, the existing constitution of the University to be retained.

DANISH RESEARCHES IN GREENLAND

DURING the last few years the Danish Government have despatched several scientific expeditions to her great but sparsely populated dependency, Greenland, for the purpose of exploring it geographically, zoologically, botanically, and mineralogically, while efforts have also been made to learn something of the Norse archæological remains in South Greenland. Glacial researches, too, have been prosecuted and valuable observations made of the enormous ice-field—the inland ice, which fills the entire interior—and of its movements to the sea through the numerous fjords, the birth-place of the greatest icebergs in the northern hemisphere.

The results of these varied researches have only been published after a long delay. It should, however, be stated that the Danish Government have followed a carefully prepared plan on this point, as the Royal Commission appointed for the purpose of supervising the same, consisting of Prof. Johnstrup, Admiral Ravn, and Dr. Rink, have decided that the results of the researches should not be made public until their analysis was completed in every detail. These have been embodied in the work published by the Commission: "Videnskablige Meddelelser om Grönland" (Scientific Informations about Greenland), a publication which has gained one of the gold medals of the French Academy, and of which six or seven volumes have been published. In addition to this work we have received another, equally great, containing 109 tables, with facsimiles in colour of fossil plants found in North Greenland, defined and described by the late Prof. Oswald Heer, of Zurich, who also defined the fossils which Mr. E. Whymper, in 1867, brought home from the Disco Island and the peninsula of Noursoak, an account of which was published in the *Transactions* of the Royal Society, 1869, pp. 445-488, with eighteen lithographed plates.

Last year no less than three Danish expeditions were at work along the Greenland shores.

The first of these, under Lieut. A. Jenssen, known for his wanderings on the inland ice—was engaged in exploring and charting the district on the west coast, between Sukkertoppen and Holsteinborg (65¼°—67° N. lat.), where there is a network of little unexplored fjords, between mountains rising from 6000 to 7000 feet in height, penetrating upwards of 100 miles into the broad coast-land.

The results of this expedition were very important, as the flora, fauna, and geology of this part of Greenland were ascertained. Several new plants were brought home, and the flora on a "nunatak," viz. a mountain rising above the inland ice, was collected. Lieut. Jensen is still occupied in finally drawing and describing the explored part of the coast, embracing about 1000 square miles.

The second expedition, under Lieut. J. Holm, is, in its second year, engaged in penetrating from Cape Farewell, along the barren and difficult east coast, always encircled by pack-ice. It comprises four scientists, and has for its object the exploration of the country between the 63° and 70° lat. N., where the formation of the land is much like that of Iceland.
