Report on the Occupation of the Table, by Mr. William E. Hoyle.—I reached Naples on April 6, 1885, and left on the 28th of the same month. In so short a time it was obviously impossible to make anything of the nature of a complete investigation in a subject of such magnitude and difficulty as the embryology of the Cephalopoda; it seemed, herefore, that the opportunities afforded me could best be utilised by collecting material for subsequent examination. Of this I had an abundant and immediate supply, thanks to the kindly forethought of your secretary, who had given notice to the authorities of the station of the nature of the work I had undertaken, so that they had a quantity of ova ready for my use. The greater part of my time was spent in extracting embryos from the egg and preserving them in various fluids, and a fairly complete series of developmental stages of *Loligo* and a good many embryos of *Sepia* were thus obtained. When the young Cephalopods have reached a stage at which the rudiments of the arms are clearly visible, it is moderately easy, after a little practice, to extricate them by making an incision into the egg-membrane with a fine scalpel; but previously to this period they so nearly occupy the whole interior of the egg that it is almost impossible to obtain them uninjured. A quantity of such eggs I preserved whole by a method suggested to me by Dr. Jatta, who is at work upon a monograph of the Cephalopoda of the Bay of Naples. The strings of eggs are placed whole in weak solution of chromic acid (about 0·25 per cent.) for a few hours, and then in distilled water for twenty-four hours, after which they are preserved in alcohol. The embryos can then be extracted much more readily than when fresh. Some time was devoted to examining and drawing the embryos in the fresh condition, and in watching the process of segmentation in *Loligo* and *Sepia*. I observed the presence of the "Richtungsbläschen" in the former, which, so far as I am aware, has only been noted in a Russian memoir on the development of *Sepiola* by Ussow. A number of blastoderms in process of segmentation were preserved according to a method proposed by Ussow, for the knowledge of which I am indebted to Dr. Edward Meyer, who kindly translated it for me from the original. The egg, without removal of the membranes, is placed in 2 per cent. solution of chromic acid for two minutes, and then in distilled water, to which a little acetic acid (one drop to a watchglassful) has been added, for two minutes longer. If an incision be now made into the egg-membrane the yolk flows away and the blastoderm remains; if any yolk still cling to it, it may be removed by pouring away the water and adding more. The blastoderms thus prepared show, when appropriately stained, fine karyokinetic figures, of which I hope shortly to publish an account. The reduction of the collected embryos to serial sections and their examination will of course occupy some time, but I hope in a few months to prepare some account of the results obtained from them.

Report of the Committee, consisting of Prof. Huxley, Mr. Sclater, Mr. Howard Saunders, Mr. Thiselton Dyer, and Prof. Moseley (Secretary), appointed for the purpose of promoting the Establishment of Marine Biological Stations on the Coast of the United Kingdom.—The Committee has received the sum granted (150*l.*) from the Treasurer of the Association, and has paid it to the funds of the Marine Biological Association of the United Kingdom, as the most direct means of promoting the speedy establishment of a marine laboratory in a most favourable situation on the British coast—namely, Plymouth. An excellent site for a laboratory has been granted to the Marine Biological Association by Government, at Plymouth. A sum of 8000*l.* has been raised by subscriptions and donations, the Government has promised to aid the working of the laboratory by an annual subsidy, and there is every prospect of success. It is probable that the building of the laboratory will commence in November.

Report of the Committee, consisting of the Rev. Canon Tristram, the Rev. F. Lawrence, and Mr. James Glaisher (Secretary), appointed for the purpose of promoting the Survey of Palestine.—The Survey of Eastern Palestine has been carried on during the last year privately by Herr G. Schumacher, C.E., assisted by Mr. Laurence Oliphant, who has also furnished the Committee with valuable notes of personal exploration in the district now called Junlau—the ancient Gaulanitis. The portion surveyed by Herr Schumacher consists of about 200 square miles, and covers an area previously quite unknown. The map, which is now in the hands of the Committee, is accompanied by voluminous memoirs and a great number of sketches, drawings, and plans of ruins figured for the first time, which it is proposed to publish, with the memoirs, in October. The map of the Wady Arabah has been laid down in the Society's sheets; the geological memoirs compiled by Prof. Hule after his expedition of 1883-84 are nearly ready, and will be issued before the end of the year; and the Society has been enabled to secure Mr. Chichester Hart's

Natural History memoir, made from new observations during the same journey. In addition the Committee have received from Mr. Guy Le Strange, and published, observations and notes made by him during a recent journey east of Jordan. The results of the survey, so far as it has been completed, will appear in a map reduced to a scale of about three miles to an inch, showing the country on both sides of the river Jordan, instead of on the western side only. This portion of the work is under the direction of Col. Sir Charles Wilson, K.C.M.G., F.R.S. The Society has also issued during the last year a popular account, by Prof. Hule, of his recent journey, called "Mount Seir," and reprints of Capt. Conder's popular books, "Tent Work in Palestine" and "Heth and Moab." Finally, the Committee have completed the issue of their great work, the "Survey of Western Palestine," with the last volumes of "Jerusalem," the "Flora and Fauna," and a portfolio of plates showing the excavations and their results.

SECTION H

ANTHROPOLOGY

OPENING ADDRESS BY FRANCIS GALTON, F.R.S., ETC., PRESIDENT OF THE ANTHROPOLOGICAL INSTITUTE, PRESIDENT OF THE SECTION

THE object of the Anthropologist is plain. He seeks to learn what mankind really are in body and mind, how they came to be what they are, and whither their races are tending; but the methods by which this definite inquiry has to be pursued are extremely diverse. Those of the geologist, the antiquarian, the jurist, the historian, the philologist, the traveller, the artist, and the statistician, are all employed, and the Science of Man progresses through the help of specialists. Under these circumstances, I think it best to follow an example occasionally set by presidents of sections, by giving a lecture rather than an address, selecting for my subject one that has long been my favourite pursuit, on which I have been working with fresh data during many recent months, and about which I have something new to say.

My data were the Family Records entrusted to me by persons living in all parts of the country, and I am now glad to think that the publication of some first-fruits of their analysis will show to many careful and intelligent correspondents that their painstaking has not been thrown away. I shall refer to only a part of the work already completed, which in due time will be published, and must be satisfied if, when I have finished this address, some few ideas that lie at the root of heredity shall have been clearly apprehended, and their wide bearings more or less distinctly perceived. I am the more desirous of speaking on heredity, because, judging from private conversations and inquiries that are often put to me, the popular views of what may be expected from inheritance seem neither clear nor just.

The subject of my remarks will be "Types and their Inheritance." I shall discuss the conditions of the stability and instability of types, and hope in doing so to place beyond doubt the existence of a simple and far-reaching law that governs hereditary transmission, and to which I once before ventured to draw attention, on far more slender evidence than I now possess.

It is some years since I made an extensive series of experiments on the produce of seeds of different size but of the same species. They yielded results that seemed very noteworthy, and I used them as the basis of a lecture before the Royal Institution on February 9, 1877. It appeared from these experiments that the offspring did *not* tend to resemble their parent seeds in size, but to be always more mediocre than they—to be smaller than the parents, if the parents were large; to be larger than the parents, if the parents were very small. The point of convergence was considerably below the average size of the seeds contained in the large bagful I bought at a nursery-garden, out of which I selected those that were sown.

The experiments showed further that the mean filial regression towards mediocrity was directly proportional to the parental deviation from it. This curious result was based on so many plantings, conducted for me by friends living in various parts of the country, from Nairn in the north to Cornwall in the south, during one, two, or even three generations of the plants, that I could entertain no doubt of the truth of my conclusions. The exact ratio of regression remained a little doubtful, owing to variable influences; therefore I did not attempt to define it. After the lecture had been published, it occurred to me that the grounds of my misgivings might be urged as objections to the general conclusions. I did not think them of moment, but as the inquiry had been surrounded with many small difficulties and matters of detail, it would be scarcely possible to give a brief and yet a full and adequate answer to such objections. Also, I was then blind to what I now perceive to be the simple explanation of the phenomenon, so I thought it better to say no more upon the subject until I should obtain independent evidence. It was anthropological evidence that I desired, caring only for the seeds as means of throwing light on heredity in man. I tried in vain for a long and weary time to obtain it in sufficient abundance, and my failure was a cogent motive, together with others, in inducing me to make an offer of prizes for family records, which was largely responded to, and furnished me last year with what I wanted. I especially guarded myself against making any allusion to this particular inquiry in my prospectus, lest a bias should be given to the returns. I now can securely contemplate the possibility of the records of height having been frequently drawn up in a careless fashion, because no amount of unbiassed inaccuracy can account for the results, contrasted in their values but concurrent in their significance, that are derived from comparisons between different groups of the returns.

An analysis of the records fully confirms and goes far beyond the conclusions I obtained from the seeds. It gives the numerical value of the regression towards mediocrity as from 1 to $\frac{2}{3}$ with unexpected coherence and precision, and it supplies me with the class of facts I wanted to investigate—the degrees of family likeness in different degrees of kinship, and the steps through which special family peculiarities become merged into the typical characteristics of the race at large.

The subject of the inquiry on which I am about to speak was Hereditary Stature. My data consisted of the heights of 930 adult children and of their respective parentages, 205 in number. In every case I transmuted the female statures to their corresponding male equivalents and used them in their transmuted form, so that no objection grounded on the sexual difference of stature need be raised when I speak of averages. The factor I used was 1·08, which is equivalent to adding a little less than one-twelfth to each female height. It differs a very little from the factors employed by other anthropologists, who, moreover, differ a trifle between themselves; anyhow it suits my data better than 1·07 or 1·09. The final result is not of a kind to be affected by these minute details, for it happened that, owing to a mistaken direction, the computer to whom I first entrusted the figures used a somewhat different factor, yet the result came out closely the same.

I shall explain with fulness why I chose stature for the subject of inquiry, because the peculiarities and points to be attended to in the investigation will manifest themselves best by doing so. Many of its advantages are obvious enough, such as the ease and frequency with which its measurement is made, its practical constancy during thirty-five years of middle life, its small dependence on differences of bringing up, and its inconsiderable influence on the rate of mortality. Other advantages which are not equally obvious are no less great. One of these lies in the fact that stature is not a simple element, but a sum of the accumulated lengths or thicknesses of more than a hundred bodily parts, each so distinct from the rest as to have earned a name by which it can be specified. The list of them includes about fifty separate bones, situated in the skull, the spine, the pelvis, the two legs, and the two ankles and feet. The bones in both the lower limbs are counted, because it is the average length of these two limbs that contributes to the general stature. The cartilages interposed between the bones, two at each joint, are rather more numerous than the bones themselves. The fleshy parts of the scalp of the head and of the soles of the feet conclude the list. Account should also be taken of the shape and set of many of the bones which conduce to a more or less arched instep, straight back, or high head. I noticed in the skeleton of O'Brien, the Irish giant, at the College of Surgeons, which is, I believe, the tallest skeleton in any museum, that his extraordinary stature of about 7 feet 7 inches would have been a trifle increased if the faces of his dorsal vertebræ had been more parallel and his back consequently straighter.

The beautiful regularity in the statures of a population, whenever they are statistically marshalled in the order of their heights, is due to the number of variable elements of which the stature is the sum. The best illustrations I have seen of this regularity were the curves of male and female statures that I obtained from the careful measurements made at my Anthropometric Laboratory in the International Health Exhibition last year. They were almost perfect.

The multiplicity of elements, some derived from one progenitor, some from another, must be the cause of a fact that has proved very convenient in the course of my inquiry. It is that the stature of the children depends closely on the average stature of the two parents, and may be considered in practice as having nothing to do with their individual heights. The fact was proved as follows:—After transmuting the female measurements in the way already explained, I sorted the children of parents who severally differed 1, 2, 3, 4, and 5, or more inches into separate groups. Each group was then divided into similar classes, showing the number of cases in which the children differed 1, 2, 3, &c., inches from the common average of the children in their respective families. I confined my inquiry to large families of six children and upwards, that the common average of each might be a trustworthy point of reference. The entries in each of the different groups were then seen to run in the same way, except that in the last of them the children showed a faint tendency to fall into two sets, one taking after the tall parent, the other after the short one. Therefore, when dealing with the transmission of stature from parents to children, the average height of the two parents, or, as I prefer to call it, the "mid-parental" height, is all we need care to know about them.

It must be noted that I use the word parent without specifying the sex. The methods of statistics permit us to employ this abstract term, because the cases of a tall father being married to a short mother are balanced by those of a short father being married to a tall mother. I use the word "parent" to save a complication due to a fact brought out by these inquiries, that the height of the children of both sexes, but especially that of the daughters, takes after the height of the father more than it does after that of the mother. My present data are insufficient to determine the ratio satisfactorily.

Another great merit of stature as a subject for inquiries into heredity is that marriage selection takes little or no account of shortness or tallness. There are undoubtedly sexual preferences for moderate contrast in height, but the marriage choice appears to be guided by so many and more important considerations that questions of stature exert no perceptible influence upon it. This is by no means my only inquiry into this subject, but, as regards the present data, my test lay in dividing the 205 male parents and the 205 female parents each into three groups—tall, medium, and short (medium being taken as 67 inches and upwards to 70 inches)—and in counting the number of marriages in each possible combination between them. The result was that men and women of contrasted heights, short and tall or tall and short, married just about as frequently as men and women of similar heights, both tall or both short; there were 32 cases of the one to 27 of the other. In applying the law of probabilities to investigations into heredity of stature, we may regard the married folk as couples picked out of the general population at haphazard.

The advantages of stature as a subject in which the simple laws of heredity may be studied will now be understood. It is a nearly constant value that is frequently measured and recorded, and its discussion is little entangled with considerations of nurture, of the survival of the fittest, or of marriage selection. We have only to consider the mid-parentage and not to trouble ourselves about the parents separately. The statistical variations of stature are extremely regular, so much so that their general conformity with the results of calculations based on the abstract law of frequency of error is an accepted fact by anthropologists. I have made much use of the properties of that law in cross-testing my various conclusions, and always with success.

The only drawback to the use of stature is its small variability. One-half of the population with whom I dealt varied less than 1·7 inch from the average of all of them, and one-half of the offspring of similar mid-parentages varied less than 1·5 inch from the average of their own heights. On the other hand, the precision of my data is so small, partly due to the uncertainty in many cases whether the height was measured with the shoes on or off, that I find by means of an independent inquiry that each observation, taking one with another, is liable to an error that as often as not exceeds $\frac{2}{3}$ of an inch.

It must be clearly understood that my inquiry is primarily into the inheritance of different degrees of tallness and shortness. That is to say, of measurements made from the crown of the head to the level of mediocrity, upwards or downwards as the case may be, and not from the crown of the head to the ground. In the population with which I deal, the level of mediocrity is $68\frac{1}{4}$ inches (without shoes). The same law, applying with sufficient closeness both to tallness and shortness, we may include both under the single head of deviations, and I shall call any particular deviation a "deviate." By the use of this word and that of "mid-parentage," we can define the law of regression very briefly. It is that the height-deviate of the offspring is, on the average, two-thirds of the height-deviate of its mid-parentage.

If this remarkable law had been based only on experiments on the diameters of the seeds, it might well be distrusted until confirmed by other inquiries. If it were corroborated merely by the observations on human stature, of which I am about to speak, some hesitation might be expected before its truth could be recognised in opposition to the current belief that the child tends to resemble its parents. But more can be urged than this. It is easily to be shown that we ought to expect filial regression, and that it should amount to some constant fractional part of the value of the mid-parental deviation. It is because this explanation confirms the previous observations made both on seeds and on men, that I feel justified on the present occasion in drawing attention to this elementary law.

The explanation of it is as follows. The child inherits partly from his parents, partly from his ancestry. Speaking generally, the further his genealogy goes back, the more numerous and varied will his ancestry become, until they cease to differ from any equally numerous sample taken at haphazard from the race at large. Their mean stature will then be the same as that of the race; in other words, it will be mediocre. Or, to put the same fact into another form, the most probable value of the mid-ancestral deviates in any remote generation is zero.

For the moment let us confine our attention to the remote ancestry and to the mid-parentages, and ignore the intermediate generations. The combination of the zero of the ancestry with the deviate of the mid-parentage, is that of nothing with something, and the result resembles that of pouring a uniform proportion of pure water into a vessel of wine. It dilutes the wine to a constant fraction of its original alcoholic strength, whatever that strength may have been.

The intermediate generations will each in their degree do the same. The mid-deviate of any one of them will have a value intermediate between that of the mid-parentage and the zero value of the ancestry. Its combination with the mid-parental deviate will be as if, not pure water, but a mixture of wine and water in some definite proportion had been poured into the wine. The process throughout is one of proportionate dilutions, and therefore the joint effect of all of them is to weaken the original wine in a constant ratio.

We have no word to express the form of that ideal and composite progenitor, whom the offspring of similar mid-parentages most nearly resemble, and from whose stature their own respective heights diverge evenly, above and below. He, she, or it, may be styled the "generant" of the group. I shall shortly explain what my notion of a generant is, but for the moment it is sufficient to show that the parents are not identical with the generant of their own offspring.

The average regression of the offspring to a constant fraction of their respective mid-parental deviations, which was first observed in the diameters of seeds, and then confirmed by observations on human stature, is now shown to be a perfectly reasonable law which might have been deductively foreseen. It is of so simple a character that I have made an arrangement with one movable pulley and two fixed ones by which the probable average height of the children of known parents can be mechanically reckoned. This law tells heavily against the full hereditary transmission of any rare and valuable gift, as only a few of many children would resemble their mid-parentage. The more exceptional the gift, the more exceptional will be the good fortune of a parent who has a son who equals, and still more if he has a son who overpasses him. The law is even-handed; it levies the same heavy succession-tax on the transmission of badness as well as of goodness. If it discourages the extravagant expectations of gifted parents that their children will inherit all their powers, it no less discountenances extravagant fears that they will inherit all their weaknesses and diseases.

The converse of this law is very far from being its numerical opposite. Because the most probable deviate of the son is only two-thirds that of his mid-parentage, it does not in the least follow that the most probable deviate of the mid-parentage is $\frac{3}{2}$, or $1\frac{1}{2}$ that of the son. The number of individuals in a population who differ little from mediocrity is so preponderant, that it is more frequently the case that an exceptional man is the somewhat exceptional son of rather mediocre parents, than the average son of very exceptional parents. It appears from the very same table of observations by which the value of the filial regression was determined, when it is read in a different way, namely, in vertical columns instead of in horizontal lines, that the most probable mid-parentage of a man is one that deviates only one-third as much as the man does. There is a great difference between this value of $\frac{1}{3}$ and the numerical converse mentioned above of $\frac{3}{2}$; it is four and a half times smaller, since $4\frac{1}{2}$, or $\frac{9}{2}$, being multiplied into $\frac{1}{3}$, is equal to $\frac{3}{2}$.

Let it not be supposed for a moment that these figures invalidate the general doctrine that the children of a gifted pair are much more likely to be gifted than the children of a mediocre pair. What it asserts is that the ablest child of one gifted pair is not likely to be as gifted as the ablest of all the children of very many mediocre pairs. However, as, notwithstanding this explanation, some suspicion may remain of a paradox lurking in these strongly contrasted results, I will explain the form in which the table of data was drawn up, and give an anecdote connected with it. Its outline was constructed by ruling a sheet into squares, and writing a series of heights in inches, such as 60 and under 61, 61 and under 62, &c., along its top, and another similar series down its side. The former referred to the height of offspring, the latter to that of mid-parentages. Each square in the table was formed by the intersection of a vertical column with a horizontal one, and in each square was inserted the number of children out of the 930 who were of the height indicated by the heading of the vertical column, and who at the same time were born of mid-parentages of the height indicated at the side of the horizontal column. I take an entry out of the table as an example. In the square where the vertical column headed[1] 69- is intersected by the horizontal column by whose side 67- is marked, the entry 38 is found; this means that out of the 930 children 38 were born of mid-parentages of 69 and under 70 inches, who also were 67 and under 68 inches in height. I found it hard at first to catch the full significance of the entries in the table, which had curious relations that were very interesting to investigate. Lines drawn through entries of the same value formed a series of concentric and similar ellipses. Their common centre lay at the intersection of the vertical and horizontal lines, that corresponded to $68\frac{1}{4}$ inches. Their axes were similarly inclined. The points where each ellipse in succession was touched by a horizontal tangent, lay in a straight line inclined to the vertical in the ratio of $\frac{2}{3}$; those where they were touched by a vertical tangent, lay in a straight line inclined to the horizontal in the ratio of $\frac{1}{3}$. These ratios confirm the values of average regression already obtained by a different method, of $\frac{2}{3}$ from mid-parent to offspring, and of $\frac{1}{3}$ from offspring to mid-parent. These and other relations were evidently a subject for mathematical analysis and verification. They were all clearly dependent on three elementary data, supposing the law of frequency of error to be applicable throughout; these data being (1) the measure of racial variability, (2) that of co-family variability (counting the offspring of like mid-parentages as members of the same co-family), and (3) the average ratio of regression. I noted these values, and phrased the problem in abstract terms such as a competent mathematician could deal with, disentangled from all reference to heredity, and in that shape submitted it to Mr. J. Hamilton Dickson, of St. Peter's College, Cambridge. I asked him kindly to investigate for me the surface of frequency of error that would result from these three data, and the various particulars of its sections, one of which would form the ellipses to which I have alluded.

I may be permitted to say that I never felt such a glow of loyalty and respect towards the sovereignty and magnificent sway of mathematical analysis as when his answer reached me, confirming, by purely mathematical reasoning, my various and laborious statistical conclusions with far more minuteness than I had dared to hope, for the original data ran somewhat roughly, and I had to smooth them with tender caution. His calculation corrected my observed value of mid-parental regression from $\frac{1}{3}$ to $\frac{6}{17\cdot 6}$, the relation between the major and minor axis of the ellipses was changed 3 per cent., their inclination was changed less than 2°. It is obvious, then, that the law of error holds throughout the investigation with sufficient precision to be of real service, and that the various results of my statistics are not casual determinations, but strictly interdependent.

In the lecture at the Royal Institution to which I have referred, I pointed out the remarkable way in which one generation was succeeded by another that proved to be its statistical counterpart. I there had to discuss the various agencies of the survival of the fittest, of relative fertility and so forth; but the selection of human stature as the subject of investigation now enables me to get rid of all these complications, and to discuss this very curious question under its simplest form. How is it, I ask, that in each successive generation there proves to be the same number of men per thousand who range between any limits of stature we please to specify, although the tall men are rarely descended from equally tall parents, or the short men from equally short? How is the balance from other sources so nicely made up? The answer is that the process comprises two opposite sets of actions, one concentrative and the other dispersive, and of such a character that they necessarily neutralise one another, and fall into a state of stable equilibrium. By the first set, a system of scattered elements is replaced by another system which is less scattered; by the second set, each of these new elements becomes a centre whence a third system of elements are dispersed. The details are as follows:—In the first of these two stages, the units of the population group themselves, as it were by chance, into married couples, whence the mid-parentages are derived, and then by a regression of the values of the mid-parentages the true generants are derived. In the second stage each generant is a centre whence the offspring diverge. The stability of the balance between the opposed tendencies is due to the regression being proportionate to the deviation; it acts like a spring against a weight.

A simple equation connects the three data of race variability, of the ratio of regression, and of co-family variability, whence, if any two are given, the third may be found. My observations give separate measures of all three, and their values fit well into the equation, which is of the simple form—

$$v^2\frac{p^2}{2} + f^2 = p^2,$$

where $v = \frac{2}{3}$, $p = 1\cdot 7$, $f = 1\cdot 5$.

It will therefore be understood that a complete table of mid-parental and filial heights may be calculated from two simple numbers.

It will be gathered from what has been said, that a mid-parental deviate of one unit implies a mid-grandparental deviate of $\frac{1}{3}$, a mid-ancestral unit in the next generation of $\frac{1}{9}$, and so on. I reckon from these and other data, by methods that I cannot stop to explain, that the heritage derived on an average from the mid-parental deviate, independently of what it may imply, or of what may be known concerning the previous ancestry, is only $\frac{1}{2}$. Consequently, that similarly derived from a single parent is only $\frac{1}{4}$, and that from a single grandparent is only $\frac{1}{16}$.

The most elementary data upon which a complete table of mid-parental and filial heights admits of being constructed are (1) the ratio between the mid-parental and the rest of the ancestral influences, and (2) the measure of the co-family variability.

I cannot now pursue the numerous branches that spring from the data I have given, as from a root. I will not speak of the continued domination of one type over others, nor of the persistency of unimportant characteristics, nor of the inheritance of disease, which is complicated in many cases by the requisite concurrence of two separate heritages, the one of a susceptible constitution, the other of the germs of the disease. Still less can I enter upon the subject of fraternal characteristics, which I have also worked out. It will suffice for the present to have shown some of the more important conditions associated with the idea of race, and how the vague word "type" may be defined by peculiarities in hereditary transmission, at all events when that word is applied to any single quality, such as stature. To include those numerous qualities that are not strictly measurable, we must omit reference to number and proportion, and frame the definition thus:—"The type is an ideal form towards which the children of those who deviate from it tend to regress."

The stability of a type would, I presume, be measured by the

[1] A matter of detail is here ignored which has nothing to do with the main principle, and would only serve to perplex if I described it.

strength of its tendency to regress; thus a mean regression from 1 in the mid-parents to $\frac{2}{3}$ in the offspring would indicate only half as much stability as if it had been to $\frac{1}{3}$.

The mean regression in stature of a population is easily ascertained, but I do not see much use in knowing it. It has already been stated that half the population vary less than 1·7 inch from mediocrity, this being what is technically known as the "probable" deviation. The mean deviation is, by a well-known theory, 1·18 times that of the probable deviation, therefore in this case it is 1·9 inch. The mean loss through regression is $\frac{1}{3}$ of that amount, or a little more than 0·6 inch. That is to say, taking one child with another, the mean amount by which they fall short of their mid-parental peculiarity of stature is rather more than six-tenths of an inch.

With respect to these and the other numerical estimates, I wish emphatically to say that I offer them only as being serviceably approximate, though they are mutually consistent, and with the desire that they may be reinvestigated by the help of more abundant and much more accurate measurements than those I have had at command. There are many simple and interesting relations to which I am still unable to assign numerical values for lack of adequate material, such as that to which I referred some time back of the superior influence of the father over the mother on the stature of their sons and daughters.

The limits of deviation beyond which there is no regression, but a new condition of equilibrium is entered into, and a new type comes into existence, have still to be explored. Let us consider how much we can infer from undisputed facts of heredity regarding the conditions amid which any form of stable equilibrium, such as is implied by the word "type," must be established, or might be disestablised and superseded by another. In doing so I will follow cautiously along the same path by which Darwin started to construct his provisional theory of pangenesis; but it is not in the least necessary to go so far as that theory, or to entangle ourselves in any questioned hypothesis.

There can be no doubt that heredity proceeds to a considerable extent, perhaps principally, in a piecemeal or piebald fashion, causing the person of the child to be to that extent a mosaic of independent ancestral heritages, one part coming with more or less variation from this progenitor and another from that. To express this aspect of inheritance, where particle proceeds from particle, we may conveniently describe it as "particulate."

So far as the transmission of any feature may be regarded as an example of particulate inheritance, so far (it seems little more than a truism to assert) the element from which that feature was developed must have been particulate also. Therefore, wherever a feature in a child was not personally possessed by either parent, but transmitted through one of them from a more distant progenitor, the element whence that feature was developed must have existed in a particulate, though impersonal and latent, form in the body of the parent. The total heritage of that parent will have included a greater variety of material than was utilised in the formation of his own personal structure. Only a portion of it became developed; the survival of at least a small part of the remainder is proved, and that of a larger part may be inferred by his transmitting it to the person of his child. Therefore the organised structure of each individual should be viewed as the fulfilment of only one out of an indefinite number of mutually exclusive possibilities. It is the development of a single sample drawn out of a group of elements. The conditions under which each element in the sample became selected are, of course, unknown, but it is reasonable to expect they would fall under one or other of the following agencies: first, self-selection, where each element selects its most suitable neighbour, as in the theory of pangenesis; secondly, general co-ordination, or the influence exerted on each element by many or all of the remaining ones, whether in its immediate neighbourhood or not; finally, a group of diverse agencies, alike only in the fact that they are not uniformly helpful or harmful, that they influence with no constant purpose—in philosophical language, that they are not teleological; in popular language, that they are accidents or chances. Their inclusion renders it impossible to predict the peculiarities of individual children, though it does not prevent the prediction of average results. We now see something of the general character of the conditions amid which the stable equilibrium that characterises each race must subsist.

Political analogies of stability and change of type abound, and are useful to fix the ideas, as I pointed out some years ago. Let us take that which is afforded by the government of a colony which has become independent. The individual colonists rank as particulate representatives of families or other groups in the parent country. The organised colonial government ranks as the personality of the colony, being its mouthpiece and executive. The government is evolved amid political strife, one element prevailing here and another there. The prominent victors band themselves into the nucleus of a party, additions to their number and revisions of it ensue, until a body of men are associated capable of conducting a completely organised administration. The kinship between the form of government of the colony and that of the parent state is far from direct, and resembles in a general way that which I conceive to subsist between the child and his mid-parentage. We should expect to find many points of resemblance between the two, and many instances of great dissimilarity, for our political analogy teaches us only too well on what slight accidents the character of the government may depend when parties are nearly balanced.

The appearance of a new and useful family peculiarity is a boon to breeders, who by selection in mating gradually reduce the preponderance of those ancestral elements that endanger reversion. The appearance of a new type is due to causes that lie beyond our reach, so we ought to welcome every useful one as a happy chance, and do our best to domicile and perpetuate it. When heredity shall have become much better and more generally understood than now, I can believe that we shall look upon a neglect to conserve any valuable form of family type as a wrongful waste of opportunity. The appearance of each new natural peculiarity is a faltering step in the upward journey of evolution, over which, in outward appearance, the whole living world is blindly blundering and stumbling, but whose general direction man has the intelligence dimly to discern, and whose progress he has power to facilitate.

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE[1]

THE meeting of 1885 of the American Association for the Advancement of Science was held at the Ann Arbor University. The total attendance (according to *Science*) of members was not a large one, the number reaching only to 365; the number of papers was 176. Two changes in the organisation were made; by one, the section of histology and microscopy was abolished, as it has been urged for some time that a special science of microscopy does not exist, the microscope being rather a tool to be used by scientific men in various branches. The other change was in the name of the section of mechanics, the words "and engineering" being added to the title, that it may be more clearly understood by Americans that those interested in all branches of engineering are invited to take part in the proceedings. As this was the first meeting since the action of the Government in regard to the Coast Survey, the question was generally discussed. The matter was referred to a committee, which offered to a general session of the Association the following resolutions, which were unanimously accepted:—

WHEREAS, The attention of this Association has been called to articles in the public press, purporting to give—and presumably by authority—an official report of a Commission appointed by the Treasury department to investigate the condition of the U.S. Coast Survey Office, in which report the value of a certain scientific work is designated as "meagre."

AND WHEREAS, This Association desires to express a hope that the decision, as to the utility of such scientific work, may be referred to scientific men.

Resolved, That the American Association for the Advancement of Science is in earnest sympathy with the Government in its every intent to secure the greatest possible efficiency of the public service.

Resolved, That the value of the scientific work performed in the various departments of the Government can be best judged by scientific men.

Resolved, That this Association desires to express its earnest approval of the extent and high character of the work performed by the U.S. Coast Survey—especially as illustrated by the

[1] For early copies of the addresses and papers we are indebted to the editor of *Science*.

gravity determinations now in progress—and to express the hope that such valuable work may not be interrupted.

Resolved, That this Association expresses, also, the hope that the Government will not allow any technical rule to be established that shall necessarily confine its scientific work to its own *employés*.

Resolved, That in the opinion of the American Association for the Advancement of Science, the head of the Coast Survey should be appointed by the President, by and with the advice and consent of the Senate, should have the highest possible standing among scientific men, and should command their entire confidence.

Resolved, That copies of these resolutions shall be prepared by the general secretary, and certified by the President of the Association and by the permanent secretary, and shall be forwarded to the President of the United States, the Secretary of the Treasury, and given to the press.

Various improvements with the object of securing a more rapid despatch of business were either suggested or adopted; thus members are to be elected by a standing committee instead of in general session, and it is proposed to restrict general sessions of the Association to the beginning and close of the meeting, and to limit the public reading of committee reports in general session to such as seem to the standing committee specially desirable from their interest or importance. The next meeting will be held at Buffalo, beginning August 18, 1886, under the presidency of Prof. Edward S. Morse, of Salem.

We regret much that it is impossible for us to reproduce in full the President's address and the sectional reports; the obvious pressure on our space at the present time will only enable us to refer to a few salient topics. The President's address was delivered by Prof. J. P. Lesley, of Philadelphia. We find the following striking observations on the "dead-work" of science:—

There is a topic which I think should be frequently considered by all who engage in scientific pursuits, and by none so earnestly as by those who are ambitious to reach the higher points of view, from which to survey and describe those systematic combinations of phenomena which are more or less panoramic: I allude of course to generalisers or discoverers of natural laws, and the professional teachers of such laws: while those who deal in itemised science, the mere observers of isolated facts, discriminating specimens and naming genera and species in the animal, vegetable, or mineral worlds, and especially such as occupy themselves with geographical and geological studies in detail, stand in less need of having it pressed upon their attention, because in their case it insists upon its own necessity.

I allude to what is technically known among experts as "dead-work."

This topic has to be treated in the most prosaic style. To describe dead-work is to narrate all those portions of our work which consume the most time, give the most trouble, require the greatest patience and endurance, and seem to produce the most insignificant results. It comprises the collection, collation, comparison and adjustment, the elimination, correction, and re-selection, the calculation and representation—in a word, the entire first, second, and third handling of our data in any branch of human learning—wholly perfunctory, preparatory, and mechanical, wholly tentative, experimental, and defensive—without which it is dangerous to proceed a single stage into reasoning on the unknown, and futile to imagine that we can advance in science ourselves, or assist in its advancement in the world. It is that tedious, costly, and fatiguing process of laying a good foundation which no eye is ever to see, for a house to be built thereon for safety and enjoyment, for public uses or for monumental beauty. It is the labour of a week to be paid for on Saturday night. It is the slow recruiting, arming, drilling, victualling, and transporting of an entire army to secure victory in one short battle. It is the burden of dead weight which every great discoverer has had to carry for years and years, unknown to the world at large, before the world was electrified by his appearance as its genius. Let us examine it more closely: it will repay our scrutiny. Those of you who have been more or less successfully at work all your lives may get some satisfaction from the retrospect: and those who have commenced careers should hear what dead-work means, what its uses are, how indispensable it is, how honourable it is, and what stores of health and strength and happiness it reserves for them.

My propositions, then, are these:—(1) That, without a large amount of this dead-work, there can be no discovery of what is rightly called a scientific truth. (2) That, without a large amount of dead-work on the part of a teacher of science, he will fail in his efforts to impart true science to his scholars. (3) That, without a large amount of dead-work, no professional expert can properly serve, much less inform and command, his clients or employers. (4) That nothing but a habitual performance of dead work can keep the scientific judgment in a safe and sound condition to meet emergencies, or prevent it from falling more or less rapidly into decrepitude; and (5) That in the case of highly-organised thinkers, disposed or obliged to exercise habitually the creative powers of the imagination, or to exhaust the will-power in frequently-recurring decisions of difficult and doubtful questions, dead-work and plenty of it is their only salvation; nay, the most delicious and refreshing recreation; a panacea for disgust, discouragement, and care; an elixir vitæ; a fountain of perpetual youth. . . .

First, then, is it so that scientific truths cannot be discovered without a large amount of preliminary dead-work? Surely no one in this assembly doubts it who has established even one original theory for himself, or won for it the suffrages of judges capable of weighing evidence. Now the immense disproportion in numbers between theories broached and theories accepted is the best proof we could have, not only of the value and necessity of dead-work, but of the scarcity of those who depend upon it as a preparatory stage of theorising. And, moreover, not theories only, but simple statements of fact believed and disbelieved—that is, finally accepted or finally rejected—exhibit the like numerical disproportion, and betray a general carelessness or laziness of observers; at all events their manifest lack of appreciation of the value and necessity of the dead-work part of observation, which imperatively must precede any clear mental perception of the simplest phenomenon, before the attempt is made to establish its natural relationships, and present it for acceptance as a part of science.

No; dead work cannot be delegated. The man who cannot himself survey and map his field, measure and draw his sections properly, and perfectly represent with his own pencil the characteristic variations of its fossil forms, has no just right to call himself an expert geologist. These are the badges of initiation; and the only guarantees which one can offer to the world of science that one is a competent observer and a trustworthy generaliser. Nor has one become a true man of science until he has already done a vast amount of this dead work; nor does one continue in his prime, as a man of science, after he has ceased to bring to this test of his own ability to see, to judge, and to theorise, the working and thinking of other men. But enough of this.

My second proposition was that no teacher of science can be successful who does not himself encounter some of the dead work of the explorer and discoverer; who does not discipline his own faculties of perception, reflection, and generalisation, by field-work and office-work, independently of all text-book assistance; who does not himself make at least some of the diagrams, tables, and pictures for his class-room, in as original a spirit and with as much precision of detail as if none such had ever been made before, and these were to remain sole monuments of the genius of investigation. What the true teacher has to do first and foremost is to wake up in youthful minds this spirit of investigation *ab initio*. The crusade against scholastic cramming promises to be successful; but the crusade against pedagogic cramming has hardly yet been organised. How is the scholar to be made an artist if the teacher cannot draw? The instinct of imitation in man is irresistible. Slovenly drawing on the blackboard—sufficient evidence of the teacher's imperfect information and inaccurate conception of facts, the nature of which he only thinks he understands—can do little more than raise a cold fog of suspicion in the class-room, by which the tender sprouts of learning must be either dwarfed or killed. But even slovenly diagrams are preferable to purchased ones; for whatever diminishes the dead-work of a teacher enervates his investigating, and thereby his demonstrating, powers, and lowers him toward the level of his scholars.

Were I dictator I should drive all teachers of science out into the great field of dead-work; force them to go through all the gymnastics of original research and its description, and not permit them to return to their libraries until their notebooks were full of their own measurements and calculations, sketch-maps and farm-drawings, severely accurate and logically classified, to be then compared with those recorded in the books. What teachers fail to keep in mind is this: that learning is not knowledge; but as Lessing says: Learning is only our knowledge of the experience of others; knowledge is our own. No man really comprehends what he himself has not created. Therefore we know nothing of the universe until we take it to pieces for inspection, and rebuild it for our understanding. Nor can one man do this for another; each must do it for himself; and all that one can do to help another is to show him how he himself has morsellated and recomposed his small particular share of concrete nature, and inspire him with those vague but hopeful suggestions of ideas which we call learning, but which are not science.

My third proposition was that an expert in practical science can command the respect and confidence of his professional fellows, and through their free suffrages build up his own reputation in the learned and business worlds, only in exact proportion to the amount of good dead-work to which he voluntarily subjects himself. For, although the most of it is necessarily done in secrecy and silence, enough of it leaks out to testify to his honest and diligent self-cultivation; and enough of it must show in the shape of scientific wisdom to make self-evident the fact that he is neither a tyro nor a charlatan. More than once I have heard the merry jest of the Australasian judge quoted with sinister application to experts in science. When a young colleague, just arrived from England, asked him for advice, he answered: Pronounce your decisions, but beware of stating your reasons for them. Many an ephemeral reputation for science has been begot by this shrewd policy; but the best policy to wear well is honesty; and honesty in trade means selling what is genuine, well-made, and durable; and honesty in science means, first, facts well proved, and then conclusions slowly and painfully deduced from facts well proved, in sufficient number and order of arrangement to exhaust alike the subject and the observer. Reap your field so thoroughly that gleaners must despair. Fortify your position, that your most experienced rival can find no point of attack. Lay your plans with such a superfluity of patient carefulness that fate itself can invent no serious emergency. Demonstrate your theory so utterly and evidently that it shall require no defender but itself. Die for your work, that your work may live for ever. Forget yourself, and your work will make you famous. Enslave yourself to it, and it will plant your feet upon the necks of kings, and your mere Yes or No will become a law to multitudes. This is what the dead-work of science, when well done, does for the expert in science.

My fourth proposition—that only the habitual performance of dead-work can preserve the scientific intellect in pristine vigour, and prevent it from becoming stiffened with prejudices, inapt to receive fresh truth, and forgetful of knowledge already won—hardly needs discussion. Human muscles become atrophied by disuse. Men's fortunes shrink and evaporate by mere investment. I pray you to imagine what I wish to say, for it all amounts to this—that the grass will surely grow over a deserted footpath. Let me hurry to the close of this address, which I have found too serious a duty for my liking, and perhaps you also have found it too personal a preachment for yours. One more suggestion, then, and I have done.

My fifth proposition was that the wearied and exhausted intellect will wisely seek refreshment in dead-work.

The physiology of the brain is now sufficiently well understood to permit physicians to prescribe with some assurance for its many ills, and to regulate its restoration to a normal state of health. Its tissues reproduce themselves throughout life if no extraordinary over-balance of decay takes place, if there be no excessive and too long-continued waste. For the majority of mankind, nature provides for the adjustment between consumption and reproduction of brain matter, by the alternations of day and night, noise and silence, society and solitude; and also by the substitution of the play of fancy in dreams, for the work of the judgment and the will in waking hours. We follow the lead of nature when we seek amusement as a remedy for care. We bring into activity a rested portion of the brain, to permit the wearied parts of it to restore themselves unhindered.

In Section A Prof. Newton, of Yale, read a paper upon "The Effect of Small Bodies passing near a Planet upon the Planet's Velocity."

The former researches of Prof. Newton upon meteors are recognised among astronomers as our principal source of knowledge about the character, distribution, and motion of these minute bodies with which the solar system is filled, especially those which strike our atmosphere and are burned up as meteors. The possible effect of these upon the rotation of the earth, and the revolution of the earth and moon in their orbits, has been subjected to elaborate investigation at the hands of several mathematical astronomers. The recent publications of Mr. Denning, of Bristol, claiming the fixity of long-continuing radiant points of meteor streams, have raised the question of the existence of broad streams of meteoroids moving swiftly through stellar space outside of solar attraction; and any new investigation bearing upon any of these points is more than usually timely. In this paper Prof. Newton has discussed the effect upon the earth's motion of those bodies which do not pass near enough to the earth to be drawn into its atmosphere, but still near enough to be drawn out of their course, and swung for a time in hyperbolic orbits around it. He began by saying that the results of the investigation might perhaps be considered negative as far as measurable quantities in the solar system are concerned, but that they had a mathematical interest, and might possibly have a bearing upon somewhat similar questions in molecular physics, like the kinetic theory of gases. The mathematician and astronomer must be referred to the paper itself, and the results of popular interest may be briefly summarised as follows:—Considering, first, the case of a cylindrical stream of small bodies evenly distributed, and all moving in the same direction with a common velocity past the earth supposed to be in the axis of the cylinder, it is shown that they will communicate to the earth in each unit of time a velocity along the axis: (1) that is proportional to the density of the group; (2) that decreases as the velocity increases nearly inversely as the square of the velocity; (3) that increases as the logarithm of the radius of the cylinder, the radius being measured by a unit differing from the earth's radius by a small quantity, which is a function of the velocity. Second, in the case of a widely-extended group of small bodies evenly distributed in space, and having speeds all equal, but directed towards points evenly distributed over the celestial sphere with the earth moving in a right line through them, it is shown that, for those which do not strike the earth, but only affect it by their attraction, the effect will be an exceedingly minute acceleration of the earth's motion, if the latter *is less than that of the bodies*, even though the group is infinite in extent. If the earth's velocity *is greater than that of the bodies*, their total effect will consist of two parts: a very minute retardation of the earth's motion, depending in amount upon the absolute velocity of the bodies; and another retardation depending upon the assumed extent of the group. In conclusion, the effect of bodies *striking* the earth or moon is manifold greater than that of those only *passing near*; and since it has before been shown that any admissible magnitude of meteroids would make the effect upon the moon's mean motion of those which strike it only a minute fraction of the observed acceleration, still less can any action of those passing near the moon have any appreciable effect.

Papers were also read by Prof. Harkness on the flexure of transit instruments; by Prof. Hough, describing some improvements recently introduced in the printing chronograph, first designed and brought into use by himself at the Dudley Observatory in 1871, by Prof. Burkitt Webb, describing a method of using polar coordinates, by transferring the origin from the centre to the end of the unit radius, thus substituting $(r-1)$ for r, and then using the length of the arc and the distance out from its end upon the radius vector, as x and y are used in rectangular coordinates. He found this a very convenient transformation in the application of polar coordinates to the discussion of Amsler's planimeter; and, pointing out, that by substituting infinity for unit-radius in the equations thus transformed, they were reduced to those of rectangular coordinates, he thought this transformation of polar coordinates might be found generally useful.

In this section also Mr. Rockwell presented some results of his observations for time and latitude with the almucantar, an instrument devised by Mr. Chandler, of the Harvard College Observatory, a year or two ago, which promises at least to furnish an entirely new and radically different method of attacking the question of absolute positions of the stars, and very probably far to surpass all others in accuracy, on account of its freedom from systematic errors. The results thus far published by Mr. Chandler seem fully to confirm all that was expected of the instrument; and it is probably not too much to say, that it is the most important addition of the present century to the instruments and methods used in the determination of absolute star positions.

The sources of systematic error would seem to be almost wholly reduced to those of varying personal equation in the observation of transits at all speeds and at all inclinations and directions over horizontal wires, and to possible systematic difference in atmospheric refraction in different azimuths. Mr. Rockwell exhibited some results, simply copied from his observing-books, illustrating the methods of reduction for time and latitude observations, and showing the degree of accuracy that can be attained by the instrument in both these directions. They served to show that the instrument when duplicated will give equally good results with the one first constructed; and their consideration gave rise to a very interesting discussion, participated in by many members, as to the character of work the instrument might be expected to do, in the course of which Mr. Rockwell answered, in a very entertaining way, many questions, put by various members, as to the details of observing and reducing, which were not before clearly understood on account of the novelty of the work. One of the most important problems which the instrument is specially adapted to investigate, and one which we hope Mr. Chandler will soon find time to undertake, is the determination of the declination of fundamental stars south of the equator, tying them to northern stars at corresponding zenith-distances below the pole. This would seem to be by far the best, perhaps the only, method of connecting these together in a way that shall be free from systematic error.

In the Physical Section, the first paper read was by Prof. Langley, on the spectra of some sources of invisible radiations, and on the recognition of hitherto unmeasured wave-lengths. This was followed by one by Mr. Brashear on a practical method of working rock-salt surfaces for optical purposes.

Prof. H. S. Carhart presented a paper on surface transmission of electrical discharges, which was an ingenious revision of work by Prof. Henry. Prof. E. L. Nichols presented some further notes on the chemical behaviour of magnetic iron, a continuation of work described in a paper at the Philadelphia meeting. Major H. E. Alvord of Mountainville, New York, presented the results of telemetric observations at Houghton Farm. This is a method by which changes in temperature are transmitted and recorded electrically; and Major Alvord's results show that, with increasing experience, the records followed more and more satisfactorily the observations made on the mercurial thermometer.

Prof. T. C. Mendenhall called attention to the modifications and improvements already made or desired in electrometers, especially with reference to their use in observations on atmospheric electricity. Observations of this kind have been made regularly for the last year or two; but, as Prof. Mendenhall well said, the meaning of the variations recorded is still a mystery. Prof. A. E. Dolbear read three papers: in one he described a method of studying contact-theory of electricity by means of the telephone. He has found that a click is produced in the telephone every time the circuit is broken between two heterogeneous materials, as copper and zinc. In another paper he referred to his success in employing a Bernstein incandescent lamp for projection purposes; and in the third he described a new galvanic element of high electromotive force and great constancy, consisting of carbon in a saturated solution of bichromate of potash, and sulphuric acid and zinc in a saturated solution of ammonic chloride; nitric acid could be used in place of sulphuric. Mr. A. J. Rogers presented a paper on electrolysis of the salts of the alkaline earth.

Prof. E. D. Nicholls has, by means of a spectro-photometer, described at a previous meeting, compared the spectrum of the unclouded sky with that of the light reflected by magnesium carbonate, illuminated by direct sunlight.

Prof. Wead exhibited a combined spectro-photometer and ophthalmospectrcscope.

In the Chemical Section Prof. Nichols delivered an address on chemistry in the service of public health. Amongst the papers are:—Prof. Noyes, on para-nitrobenzoic sulphuride; Dr. Wiley, on a method of estimating lactic and acetic acid in sour milk or *koumiss;* Mr. Young, on the thermo-chemical reaction between potassic hydrade and common alum. A general discussion took place on the question of what is the best initiatory work for students entering upon laboratory practice, and also, To what extent is a knowledge of molecular physics necessary to one who would teach theoretical chemistry?

In the Section of Mechanical Science Prof. Webb delivered an address on the second law of thermo-dynamics. Mr. Wagner presented an elaborate paper on electric light tests, giving an account of his work in testing the efficiency of two electric-light plants. Prof. Cooley explained and illustrated a method of testing indicator-springs. Prof. Thurston's paper on cylinder condensation is described as being of great scientific and practical value.

In the Section of Geology and Geography the address was by Prof. Edward Orton, and the subject, Problems in the study of coal, with a sketch of recent progress in geology. There were, in all, twenty-seven papers in this Section, none being geographical. Stratigraphy received the lion's share of attention, the most important paper on this subject being one by Prof. Henry S. Williams.

The address to the Biological Section was by Dr. Wilder, on Educational Museums of Vertebrates.

The Section opened with two papers by Prof. L. E. Sturtevant as the result of observations and experiments at the New York agricultural experiment station. The first, on the hybridisation and cross-fertilisation of plants. In the second—"Germination Studies"—the author gives, as a result of many trials with commercial seeds of our common plants, that very extended series of trials must be made with each species in order to obtain the desired accuracy in results.

An interesting paper on the biological deductions from a comparative study of the influence of cocaine and atropine on the organs of circulation, by Dr. H. G. Beyer, U.S.N., was read before the Section.

"On the Brain and Auditory Organs of a Permian Theomorph Saurian" was the title of an interesting paper by Prof. E. D. Cope. The author called special attention to the morphology of the brain, the character of the cranial walls and the auditory apparatus.

The disputed question of the bisexuality of the pond-scums (Zygnemaceæ) was discussed by Prof. C. E. Bessey, of the University of Nebraska, who concluded that these organisms do not possess true bisexuality.

"On the Process of Cross-fertilisation in *Campanula americana*" was the title of a paper presented by C. R. Barnes.

A paper on aquatic respiration in soft-shelled turtles (Aspidonectes and Amyda) was presented by Profs. Simon H. and S. Phelps Gage as a contribution to the physiology of respiration in vertebrates.

Prof. C. E. Bessey read a paper on the inflorescence of *Cuscuta glomerata*.

Prof. Gage addressed the Section (G) on Microscopy and Histology on the limitations and value of histological investigation, and Mr. Dall discoursed to the Anthropological Section on the native tribes of Alaska. The papers in this section were very numerous, many of great interest, and all naturally devoted to anthropological questions connected with the North American continent.

NOTES

THE National Sanitary Congress commenced its autumn meeting at Leicester on Tuesday, when the president, Prof. De Chaumont, F.R.S., gave an address on the work of the Sanitary Institute.

THE portrait of the late George Bentham, subscribed for by several of his friends, has been presented to the Herbarium, Royal Gardens, Kew, on behalf of the subscribers, by Sir John Lubbock. The picture is a successful reproduction, by Miss Merrick, of the original in the possession of the Linnean Society.

WE regret to notice the death of M. Breton des Champs, one of the French Government engineers, a mathematician and scientific writer who played a prominent part in connection with the Newton forgeries. In combination with his friend Leverrier, M. Breton des Champs exploded these frauds, which were so disgraceful to the good name of the French Academy of Sciences. He discovered the books from which the so-called "forger with long ears" had copied the assumed letter sold to M. Chasles.

THE Essex Field Club will hold its sixth annual cryptogamic and botanic meeting in Epping Forest on Friday and Saturday, October 2 and 3. On the Saturday afternoon and evening there will be an exhibition of fungi and other plants, fresh and preserved, with micro-objects; and papers will be read by Dr. Wharton and Mr. Worthington Smith. The following botanists, among many others, are expected to be present, and will act as "referees" in various departments of plant-lore:—Prof. Boulger, Dr. Braithwaite, Dr. M. C. Cooke, Rev. J. M. Crombie, Rev. Canon Du-Port, Messrs. J. L. English, Henry Groves, F. J. Hanbury, E. M. Holmes, David Houston, A. Vaughan Jennings, Frederick Oxley, W. W. Reeves, Worthington G. Smith, C. A. Wright, Dr. Spurrell, Dr. H. T. Wharton, &c. Those wishing to attend should communicate with the hon. secretary, Mr. W. Cole, Buckhurst Hill, Essex, who will forward programmes giving full particulars.

THE Trustees of the Gilchrist Lectures Fund have arranged for courses of six lectures in each of five Lancashire towns—Blackburn, Lancaster, Chorley, Colne, and Padiham, and for similar courses in Greenock, Paisley, Stirling, Alloa, and Kilmarnock—all to be delivered during October and December. No lectures will be given during November in consequence of the General Election in that month. The lecturers entrusted with the work are: Prof. R. S. Ball, Rev. W. H. Dallinger, Prof. W. C. Williamson, Dr. Andrew Wilson, and Mr. W. Lant Carpenter. Each course includes three lectures on biological and three on physical subjects, oxyhydrogen lantern illustrations being freely used, and in some cases experiments also. As usual the charge for admission will be one penny, and the largest available rooms are secured for the lectures, special measures being taken to insure the attendance of working men. There will probably be similar courses in five Midland towns in the spring.

WE are informed that the vacant Chair of Physics and Engineering in University College, Bristol, has been filled by the appointment to the post of Prof. John Ryan, M.A., King's College, Cambridge, D.Sc. London, and Member of the Institute of Mechanical Engineers. Dr. Ryan, who is a practical engineer, has hitherto held the appointment of Professor of Mechanics and Engineering in University College, Nottingham. At Bristol he succeeds Prof. Thompson, now Principal of the Finsbury Technical College, and Prof. Hele Shaw, recently appointed to the Professorship of Engineering in University College, Liverpool.

MR. F. C. LEHMANN, a German botanist, who has travelled or over ten years in Central and South America for the purposes of scientific researches, has arrived safely at Panama, from Europe, which he lately visited in order to arrange with other scientific colleagues to assist him in the classification of his extensive collection of objects of natural history. Mr. Lehmann was about to proceed to the Cauca, where he intends to remain for several years, with his domicile in Popayan. He proposes the continuation of former labours and minute researches into the botanico-geographical conditions of the Flora of Tropical America.

THE exceedingly unusual character of the following announcement, coming from the United States, will attract attention. We take it from *Science*:—"On account of the lack of funds necessary to maintain its activity, the Astronomical Observatory of Beloit College, Wisconsin (Prof. J. Tatlock, jun., director), has been closed."

THE experiments for the electrical illumination of the Palais Royal are very successful. The number of incandescent lights used is 150. The Théâtre Français, Théâtre du Palais Royal, and Council of State have agreed to the deed of agreement signed by the shopkeepers, so that thousands of lamps will soon be in operation. But before taking a final decision, the subscribers are trying every description of incandescent lamp.

A SERIES of science lectures has commenced at the Royal Victoria Hall, Waterloo Bridge Road, and promises to be as successful as any previous one. On September 29, W. J. Harrison, F.G.S., will lecture on "Stone Tools and the Men who used them." On October 6, Mr. A. H. Fison will lecture on "Some Other Worlds." On October 13, Prof. H. G. Seeley, F.R.S., will lecture on "Coal."

WE learn from the *London and China Telegraph* that a work on which Dr. Dudgeon of Peking has been engaged for upwards of ten years, has just been issued in eighteen Chinese volumes. It comprises a translation of Gray's "Anatomy" and Holden's "Osteology." There are in addition two volumes of plates, comprising 600 cuts, which have occupied the time of two men for two years and a half. The whole of these cuts have been made at the expense of the Chinese Foreign Office, and the work has been published in a series issued by the Foreign Language College at Peking. It is proposed to establish in connection with this college a medical school and hospital to provide proper practitioners for the service of the army, navy, and palace.

A REPORT on carp-culture in China has been made by Dr. Macgowan to the Carp-Culture Association of the United States. Pisciculture, it appears, was cultivated at a very early period, being regarded as a branch of agriculture. The carp is, of all fish, the most frequently reared by artificial means in China, but nearly every species of *Cyprinidæ*, bream, tench, roach, gold-fish, &c., is so raised. A treatise on fish-rearing has been attributed to a Minister of the fifth century before our era, but it it appears to have been really written eight centuries later. The work says that of the five modes of rearing animals by far the most productive and valuable is fish-breeding. The pond used for this purpose (it goes on) should be an acre in extent (the depth is usually less than eight feet), and nine stone islets, each having eight inlets or bays, a yard below the surface of the water, should be constructed in it; then twenty gravid carp and four males, each three feet long, are to be deposited in it noiselessly in the month of March. Two months later a turtle should be placed in the pond, two months later a couple, and after a like period three more. By this time there will be 360 carp. The turtles are to prevent their being transformed into dragons and flying away. The object of the islets and bays is to afford greater space for the fish in their sinuous voyages, for the more a fish travels the fatter and bigger he becomes. The Chinese author then makes the following calculation: in the following year the pond will be found to contain 150,000 carp 1 foot in length, 450,000 3 feet, 10,000 2 feet. In the third year 100,000 1 foot, 50,000 2 feet, 50,000 3 feet, and 40,000 4 feet. A thousand of those that are 2 feet in length should be retained for replenishment, and all the rest be sent to market. In another year their number will exceed all calculation, and they require no feeding, hence the value of carp culture. All the varieties, we are told, come from the black species. Those destined to become white change to silver or yellow, while the others turn first red and then golden. Some of the white sort are so nearly transparent that their viscera are visible. Much of the art of rearing them consists in affording due amounts of shade and sunshine in the course of their growth, and in changing their water, not more than half of which is to be removed every fourth day. In the earliest times the practice, which continues to-day, was introduced of planting mulberries on the margins on which apiaries were placed, the droppings from which fed the fish, while the leaves of the trees first nourished silkworms and then goats. These droppings are said to impart a peculiar flavour to the fish.

A CONSIGNMENT of soles and brill has lately been despatched by the National Fish Culture Association to the American

Government as a slight recognition of the presentations of ova made by them to this country. There is a great dearth of flat fishes in the United States, and at the instigation of the Commissioners of Fish and Fisheries many attempts have been made to forward young specimens for propagation from England. Hitherto these efforts have not met with success, it being exceedingly difficult to transmit live soles, as they are less tenacious of life than their congeners. We hope that Prof. Baird, who has received notice of the despatch of this valuable gift, will not be again disappointed. The fish have been placed in charge of an experienced pisciculturist, who will accompany the s.s. *Republic*, by which vessel they have been sent, and who will bring back a number of American species with a view to acclimatising them in this country.

THE Royal Commissioners of the Colonial Exhibition, to be held next year at South Kensington, have issued circulars to the Governors of our Colonies requesting them to send the various species of fish indigenous to their respective countries for exhibition. Special preparations will be made at the close of October for receiving them. The arrangements will necessarily be of an elaborate nature, as the tanks will have to be constructed in such a manner as to provide for the exigencies of each species and the regulation of high and low temperatures according to the climatal necessities of the fish.

SPECIAL interest is just now centred at the Aquarium in the incubation of the ova of some of the dogfish which have recently spawned. The eggs, which resemble filbert nuts in shape, are to be seen in a special tank, which presents a sight of much edification. The formation of the fish inside the ova is plainly perceptible, every part of them being apparent. The fish in the Aquarium are now being fed at 6 o'clock, partly on a new dietary specially invented by Mr. W. Burgess, of Malvern Wells.

THE Marquis of Lorne has successfully planted some whitefish in a specially constructed lake on the Isle of Mull. The fish form part of those reared by the National Fish Culture Association this year. His Lordship reports that the fish are doing well.

AT a lecture delivered by Mr. W. Oldham Chambers, F.L.S., at the Hull Town Hall last week on fish culture, living specimens of the whitefish and other foreign species of fish were exhibited, and excited much interest amongst the audience.

A RECENT *Bulletin* of the United States Fish Commission contains the following interesting account of the destruction of young trout by mosquitoes: "In the middle or latter part of June, 1882, I was prospecting on the head-waters of the Tumichie Creek, in the Gunnison Valley, Colorado. About 9 o'clock in the morning I sat down in the shade of some willows that skirted a clear but shallow place in the creek. In a quiet part of the water where their movements were readily discernible, were some fresh-hatched brook or mountain trout, and circling about over the water was a small swarm of mosquitoes. The trout were very young, still having the pellucid sack puffing out from the region of the gills, with the rest of the body almost transparent when they would swim into a portion of the water that was lighted up by direct sunshine. Every few minutes these baby trout—for what purpose I do not know, unless to get the benefit of more air—would come to the surface of the water, so that the top of the head was level with the surface of the water. When this was the case a mosquito would light down and immediately transfix the trout by inserting its proboscis, or bill, into the brain of the fish, which seemed incapable of escaping. The mosquito would hold its victim steady until it had extracted all the life juices, and when this was accomplished, and it would fly away, the dead trout would turn over on its back and float down the stream. I was so interested in this before unheard-of destruction of fish that I watched the depredations of these mosquitoes for more than half an hour, and in that time over twenty trout were sucked dry and their lifeless bodies sent floating away with the current. It was the only occasion when I was ever witness to the fact, and I have been unable by inquiry to ascertain if others have observed a similar destruction of fish. I am sure the fish were trout, as the locality was quite near the snow line, and the water was very cold, and no other fish were in the stream at that altitude. From this observation I am satisfied that great numbers of trout, and perhaps infant fish of other varieties in clear waters, must come to their death in this way; and if the fact has not been heretofore recorded it is important to those interested in fish-culture."

A TELEGRAM from Rome, September 21, states that repeated shocks of earthquake have occurred in Benevento. The inhabitants are terror-stricken, and are encamped in the open country.

THE Russian *Official Messenger* states that the city of Namangan, in Ferghana, has been visited all through the summer by repeated shocks of earthquake, which have hitherto been of very rare occurrence there. The strongest shocks took place on April 17 and August 4, but no very serious consequences resulted.

ON September 12, at 9.30 p.m., a magnificent meteor passed over the city of Stockholm, going from south to north. Its light was very brilliant. On account of the limited area of observation it was impossible to tell whether it burst near the city or not.

DURING the month of August enormous swarms of ants passed over the town of Solothurn in Switzerland. They came from the Jura mountains, and formed a cloud, consisting of seventy-five perpendicular columns, in which the ants circled around in spiral form. The swarm lasted for twenty minutes, the height of the cloud being upwards of ninety feet. Millions of them fell to the ground, however, without making any visible change in the phenomenon.

ACCORDING to the *Bergen Adresseblad*, fishermen at the island of Mögster, on the coast of the province of Bergen, on the west coast of Norway, have lately seen large floating blocks of ice at sea, which are believed to be parts broken off from icebergs in the North Atlantic. Such a phenomenon has never before been observed in these parts.

THE Swedish journal *Norrbottens Kuriren* states that the water is falling rapidly in the Gulf of Bothnia, a phenomenon to which we have on several occasions referred. As a further proof of this the journal states that a stone in the archipelago by the coast which fifty years ago at lowest tide was barely visible above water is now at mean tide three feet above it.

WE have pleasure in noticing the issue of No. 43 of the first part and Nos. 29-31 of the second part of the well-known "Encyklopædie der Naturwissenschaften" from the house of Eduard Trewendt, Breslau. The former brings forward Dr. A. Reichenow's "Handwörterbuch der Zoologie, Anthropologie, und Ethnologie," from article "Heteronereis" to "Icteridæ." Among other articles embraced within this interval are valuable contributions on the development of the organs of hearing by Prof. Griesbach; on "Hypnotismus," by Prof. Gustav Jäger; on "Januten," "Japaner," "Javanen," by Dr. von Hellwald; on "Hissarlik," "Hohlefels," "Hohlkeit," by Prof. Mehlis. Nos. 29 and 31 of the second part, again, continue the "Handwörterbuch der Chemie," while the 30th number continues the "Handwörterbuch der Mineralogie

Geologie, und Paläontologie." The two chemical numbers treat with all the fullness and thoroughness characteristic of this estimable work "Dichte," "Didym," "Diffusion," "Dinte," "Diphenylverbindungen," "Dissociation," "Dünger," and "Eisen," and the accompanying woodcuts illustrating any difficult experiments in the text add materially to the practical value of the articles. The new number, finally, of the Mineralogical, Geological, and Palæontological Dictionary contains important contributions on "Reptilien" and "Rhizopoden," by Rolle; on "Salze," by Kenngott; on "Schichtenlehre" and "Schwankungen im Niveau vom Meer und Festlande," by von Lasaulx—articles distinguished not more by fullness and compactness of matter than by clearness of dan. ne

WITH unflagging vigour and learning the new Italian quarterly, *La Nuova Scienza*, prosecutes the mission it has undertaken of building up an exact philosophy on the foundation of the natural and historical sciences. In the last number for June, 1885, the articles of chief interest, all contributed by the indefatigable editor, Prof. Enrico Caporali, are: Modern Italian thought, German anticlerical evolution, and the Pithagoric formula in cosmical evolution. The last-mentioned paper deals with the evolution of gravitation, of heat, of electricity, chemical affinity, lower organic force, higher organic force, sentient force, social authority; fatalist and free evolution. It is held in general that all evolution is due more to internal energy than to outward conditions, in opposition to Herbert Spencer's theory of mechanical causes.

THE address of Mr. W. H. Dall, vice-president to the Anthropological Section of the American Association for the Advancement of Science at Ann Arbor, last month, has been printed as a separate pamphlet. The subject of the address was "The Native Tribes of Alaska."

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Mr. A. Cornet; a Red Kangaroo (*Macropus rufus* ♀) from Australia, presented by Mr. G. Wylie; a Bonelli's Eagle (*Nisaetus fasciatus*) from North Africa, presented by Capt. W. R. Taylor, s.s. *Empusa*; two Tawny Owls (*Syrnium aluco*), European, presented by Mr. H. Lee; a Nightjar (*Caprimulgus europæus*), European, presented by Mr. Cuthbeth Johnson; a Robben Island Snake (*Coronella phocarum*) from South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; seven Blue-bearded Jays (*Cyanocorax cyanopogon*) from Para, purchased; a Beisa Antelope (*Oryx beisa* ♀), born in the Gardens.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, SEPTEMBER 27 TO OCTOBER 3

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on Sept. 27

Sun rises, 5h. 56m.; souths, 11h. 50m. 51·3s.; sets, 17h. 46m.; decl. on meridian, 1° 48′ S.: Sidereal Time at Sunset, 18h. 13m.

Moon (three days after Full) rises, 19h. 0m.*; souths, 2h. 1m.; sets, 9h. 13m.; decl. on meridian, 10° 42′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	4 29	11 1	17 33	5 36 N.
Venus	9 34	14 12	18 50	16 17 S.
Mars	0 19	8 11	16 3	19 47 N.
Jupiter	4 33	11 1	17 29	4 46 N.
Saturn	22 1*	6 9	14 17	22 19 N.

* Indicates that the rising is that of the preceding day.

Occultations of Stars by the Moon

Sept.	Star	Mag.	Disap. h. m.	Reap. h. m.	Corresponding angles from vertex to right for inverted image ° °
28	48 Tauri	6	21 56	22 45	33 273
28	γ Tauri	4	23 46	0 43†	36 279
29	75 Tauri	6	4 41	5 41	149 268
29	θ¹ Tauri	4½	4 48	5 26	54 1
29	B.A.C. 1391	5	5 41	6 51	109 324
30	111 Tauri	5½	3 2	4 17	73 268

Oct.					
2	λ Geminorum	3½	0 38	1 32	30 248

† Occurs on the following day.

The Occultations of Stars are such as are visible at Greenwich.

Sept.	h.	
27	9	Mercury in conjunction with and 0° 52 north of Jupiter.
Oct.		
1	11	Saturn in conjunction with and 4° 15′ north of the Moon.
3	19	Mars in conjunction with and 5° 4′ north of the Moon.

THE ASTRONOMICAL ASSOCIATION

THE Astronomical Association held their eleventh general meeting this year at Geneva from Aug. 19 to 22 inclusive, and the representatives of so many nations were present that the meeting fully bore out the character of an international one. Among the fifty members, or thereabouts, attending were: Struve, from Pulkowa; Newcomb, from Washington; Christie, from Greenwich; Dunér, from Lund; Pechule, from Copenhagen; Tietjen, from Berlin; Krüger, from Kiel; Schur, from Strassburg; Tisserand, from Paris; Spörer, from Potsdam. The office-bearers were: Auwers, from Berlin, President; Schönfeld, from Bonn, and Seeliger, from Munich, Secretaries; Bruns, from Leipzig, Treasurer: while Bakhuyzen, from Leiden, Gyldén, from Stockholm, and Weiss, from Vienna, were honorary members of the Committee. Prof. Oppolzer, who was also a member of the Committee, was unable to attend.

The first sitting was opened by President Auwers in the aula of the University at 10 in the forenoon of the 19th. Among the scientific reports of the Committee the full communications of Prof. Weiss on the present state of the computations of the orbits of the comets were of special interest. Of the 12 periodical comets returned at different times to their perihelion, 8 had again been regularly determined by the same calculators. Of the remaining four three were removed from our present care: Biela's, which, as was known, had been lost to observation, and the comets of Halley and Pons-Brooks, whose next perihelion lay too remote in the future. There was, consequently, but one periodical comet—Brorsen's—to be taken account of. As to the remaining non-returning comets, of the 168 which had appeared in this century 41 were to be regarded as settled, 23 had their orbits pretty well determined; in the case of 58 comets a new calculation of the orbit was desirable for various reasons, and in all 46 had yet to be calculated definitely. There was, therefore, a wide field of labour open. Prof. Weiss accordingly sought to commend to the Society the establishment of a common calculation bureau for the settlement of the questions at issue, while the exact detailed treatment of a particular comet should in future, as hitherto, be left to the initiative of a single calculator. In the discussion following this address, Staatsrath Struve argued against the founding of such a bureau on the ground that the comets were of too peculiar a nature to accommodate themselves to the methodic treatment of a calculation bureau. No resolution was taken on the question.

This report was followed by communications of a business character on the great zone undertaking of the Society. These communications were of no great extent, the undertaking being already in near prospect of completion. The photometric survey of the heavens by Prof. Pickering, of Harvard College, read by Prof. Auwers, was heard with special interest.

Next followed the scientific addresses. Dr. Schram, Observer in the Austrian Triangulation, communicated a table calculated by him, which would shortly be published, a table which materially lightened the approximate calculation of an eclipse for a particular spot on the surface, according to Oppolzer's elements.

Prof. Weiss then communicated the publication of the second volume of the *Annals* of the Vienna Observatory, and followed this up with the remark that the meridian circle, which was sixty years old, was now very much in need of repair; but, unfortunately, there was no money at disposal for this purpose.

After the President had opened the second sitting at ten o'clock on August 20, he communicated a report on the photographic mapping of all the stars of the "Bonner-Durchmusterung" which Gill (of the Cape Observatory) had begun, and of which about 100 plates were already to hand. The time taken for the exposure of each plate amounted on an average to one hour.

After various deliberations of a more private character the discussion turned on Resolution VI. of the Meridian Conference of Washington. The President declared emphatically that the question could be considered in this assembly only from an astronomical standpoint. The question was simply whether it were desirable for the astronomer to transfer the beginning of the day to midnight, and to this question the discussion should be restricted. At the outset the President announced that the Committee of the Society, with the exception of one member not present (Oppolzer)—that is, in the proportion of seven to one—had voted against the adoption of the proposal.

Staatsrath Struve (from Pulkowa) at once opposed the restriction advanced by the President, which, he thought, involved a one-sided treatment of the matter. It was to their advantage, he asserted, not to seclude themselves from the rest of the world. Magnetic and meteorological observers, he said, counted their day from midnight. Many astronomers, moreover, he continued, worked by day, and most observations were made between six and twelve in the evening. The change was defended by men eminent in science. The reform assuredly met a deeply-felt want. The question was "Should they make this sacrifice or not?"

Prof. Spörer, of Potsdam, mentioned that he always counted his observations from midnight.

Prof. Newcomb, of Washington, spoke at considerable length on the question, and rather against than in favour of the adoption of the proposal of universal time.

Prof. Weiss, of Vienna, was of opinion that the sacrifices demanded of astronomers by this reform were too great, and that the advantages were more than counterbalanced by the disadvantages. He laid stress on the fact that astronomers were wont to make their calculation of time from the moment when the time-determining object—the spring point—the mean sun—passed the meridian. That was also the true point of commencement. The observations which were of interest to the public at large, might be given in universal time, whereas with their more esoteric observations they might adhere to the old reckoning. The astronomer should keep by himself, and pay no attention to claims of intercourse.

Prof. Safárik, of Prague, said, "Why should we make a sacrifice on behalf of the public that feels no concern with our labours?"

Prof. Krüger, of Kiel, thought that altogether there were but few necessary points of relation between the astronomer and the public—points, however, which could be readily taken account of if the public desired it.

Dr. Dunér, from Lund, argued that by a change of date it would be impossible not to make a sudden break in astronomical labours that had hitherto been carried on uninterruptedly, to whatever time of day or night the commencement of the day was transferred. He concluded by expressing his opinion that the sacrifices demanded were too great.

Geheimrath Auwers expressed himself as personally opposed to the change, principally in order to avoid a discontinuity in the calculation of time which might, later on especially, lead to sensible errors.

Prof. Bakhuyzen, of Leiden, was refused a hearing, because he wanted to speak of seamen, who have the reform specially at heart.

Staatsrath Struve remonstrated against this proceeding, and argued that the question ought not to be treated onesidedly. At the Washington Conference seamen had the majority of representation, and opinion had there been almost unanimously expressed in favour of the reform. He was swayed by the desire of rendering astronomy useful to the rest of the world.

Prof. Gyldén, of Stockholm, argued that the change must give rise to vexatious errors unless it were universally carried out on one line. As the realisation of this idea was, however, more than could be looked for at present, he would now have to vote against the universal time. He believed, nevertheless, that in twenty or thirty years hence the majority of astronomers would be in favour of the universal time.

Prof. Tietjen, of Berlin, thought that in the Berlin Year-Book at all events, no such change would find place before 1900.

Staatsrath Struve maintained that in the Royal Astronomical Society the majority were in favour of the universal time.

Dr. Pechule, of Copenhagen, was also of opinion that it would be well for astronomy to accommodate itself to the rest of the world; but only when all were of one mind should the innovation be simultaneously and universally introduced.

Prof. Folie, of Brussels, thought that in all reforms there were some stragglers, and in his opinion it was the duty of astronomers energetically to take the initiative in the good cause.

After some recapitulatory observations of the President the discussion closed. No resolution whatever was passed on the subject.

It may be worth while mentioning here in respect of this subject that in the reading of the protocol it was affirmed that all the members of the Committee who were present were opposed to the adoption of the universal time. Objecting to this declaration, Dr. Pechule stated that Prof. Gyldén had only voted against the *immediate* adoption, while he entirely approved the *principle* of the proposed reform. The protocol had accordingly to be altered so as to give effect to this statement.

The series of scientific addresses was resumed by Dr. Mittag-Leffler, from Stockholm, who communicated the mathematical prize exercises which, under the auspices of King Oscar II., had been instituted by a special Commission.

Staatsrath Struve handed, for circulation, photographs of the great refractor of 30 inches aperture, which a short time ago had been mounted in Pulkowa, and expressed his complete satisfaction with the result.

Prof. Newcomb had thoroughly studied the instrument for seven days continuously, and corroborated Staatsrath Struve's views regarding the value of the instrument, entering into various details on the matter.

Prof. Tisserand, of Paris, spoke of a purely theoretical examination of the rotation of the earth.

Dr. Steinheil spoke on the calculations of Galileo's telescopes of new construction.

Prof. Spörer, of Potsdam, gave a somewhat long address on the new views regarding the physics of the sun.

The following day was devoted to a common trip around the Lake of Geneva, Col. Emile Gautier, at present Director of the Geneva Observatory, engaging at his own cost the saloon steamship *Winkelried* for this purpose. The dinner, which was served on board ship, gave opportunity for expressing the warmly-felt thanks of so many guests to their generous host for the entertainment he had provided them during the continuance of the Congress.

On the last day of the meeting, Saturday, August 22, the proceedings of a business character were brought to a close. The statutory order respecting the raising of the fee for life-membership to 185 marks was adopted. As the place of meeting for 1887, Kiel was fixed on. The new election of a committee made no change in its former composition.

The scientific addresses were opened by Prof. Gyldén, who spoke of a graphic representation of planetary orbits.

Prof. Newcomb followed with an address on perturbations and their numerical calculation.

Prof. Bakhuyzen made communications respecting his treatment of Schröter's observations of Mars. He came to the conclusion that since Schröter's time "Huggin's Inlet" had probably changed considerably, whereby the hypothesis that Mars is in large part covered with fluid received material support.

Dr. Müller, of Potsdam, spoke on modern photometric apparatuses, and examined in particular those of Zöllner, Pickering, and Pritchard, entering into a searching criticism of them. The sources of error of the most considerable systematic deviations in the results obtained with these instruments were not yet sufficiently known, and it would therefore be well to mark out a number of stars of which thorough observations should be taken by the different observers with the use of all the three instruments.

Prof. Seeliger, of Munich, spoke of theoretical, and in part also practical, investigations he had commenced, which for the present had shown that the Lambert law respecting the reflective power of illumined surfaces, the basis hitherto of all photometric experiments, was entirely false. He reserved his more complete exposition of the matter till the close of his labours in this direction.

Prof. Safârik observed that some astronomers to whom he had communicated his "fluorescence plates," whose intermediate junction of eye-piece annulled the secondary spectrum, had given him a favourable report regarding their use. He was always ready, he said, to place other plates at the disposal of any who desired them.

Prof. Weiss announced that he was engaged in the preparation of a catalogue of 4500 stars which had formerly been observed at Geneva, a catalogue which was now approaching its completion.

President Auwers once more expressed thanks for the friendly reception the Association had met with at Geneva and proposed to the meeting that they should rise from their seats in honour of Col. Gautier. The proceedings were then declared to be concluded.

EDUCATION IN THE UNITED STATES

THE pride taken in popular education in the United States makes any digest of their experience valuable; and education, as carried on in their cities, the subject of a recent Circular of Information from the Bureau of Education, is necessarily the branch of it most interesting in our crowded island. Dr. Philbrick, the writer of it, has been, in Boston, a most successful school superintendent, an officer who undertakes the active duties of both School Board and Government Inspector, and one without whose services cities are here said to be behind the times. The uncertainty of a good choice of members for a School Board by popular election in the United States makes this office the more important; women having, as a rule, declined to counteract corrupt votes by their own. Every branch of education is treated upon here. Technical instruction, both as provided in Paris and in the United States, is largely and systematically considered; from the shape it takes in the school, where it simply replaces the gymnasium to boys over thirteen years of age, to the apprentice school which really attempts to supersede the worn-out system from which it gets its name by a more scientific and intelligent teaching of a few trades, among which building in its various branches, necessarily so important in a new country, is always one chosen. School museums are recommended, both of natural history and of technology; the decoration also of schoolrooms with statuary, &c., now provided for the purpose at low prices, a list of which is appended. The rules to be observed in building are a digest of both European and American experience, valuable to every one concerned with the architecture of schools of any class; and we may just note Dr. Philbrick's conclusions—that increased centralisation and permanency are found desirable; that *speaking* French or German is unnecessary to 90 per cent. of secondary scholars; and that high school education is bad for girls. "Free and uniform" is Dr. Philbrick's ideal. He believes that the work of elementary schools can be so revised that the higher subjects will be a simple continuation of the lower; so that a complete elementary course shall be just the same as the first few years of a university education. Higher stages are never to be commenced till after the age of fourteen. Free high schools, "the most truly democratic of all our institutions," are being used by youths who go back to farm work, contending that in no way does a classical education unfit a man for manual labour and attending meetings of "old boys" whose common interest in the school helps to obliterate social distinctions. Such schools are to be provided for the mechanic to carry on his studies therein in the evening; while for higher students manual labour, especially the use of carpenters' tools, is to replace the gymnasium, and be pursued afterwards in evening technical schools; and thus study and labour will complement each other, and the daily toil of the poor man is raised to the level of the rich man's recreation. Military and fire drill are to be taught, and replace out-door games. We fear that an elementary course complete in itself and different from university rudiments, although perpetuating class distinctions, will probably be a necessary evil for some time yet, and also that paralysis for lack of competition must be incurred where pupils are required to attend the school in their own district of their own city—this necessitating uniformity of books for the sake of families removing.

A PREHISTORIC CEMETERY

A DUNFERMLINE correspondent writes that another cemetery of prehistoric times has been discovered on the estate of Pitreavie. About two and a half miles to the north-east of the former discovery a number of workmen were, some days ago, engaged in collecting rough stones to form an embankment. Ere the work had proceeded far it was noticed that the stones, which lay on a moor, formed a circle, partly covering a mound 200 feet in diameter. In the centre of the mound, and about 36 inches below the surface, a cyst measuring 46 inches in length and 24 inches in width was found. The cyst was three-parts filled with a dark mould, and in it was discovered a beautifully-formed urn which stands 5 inches in height and measures 6 inches across the mouth. There was nothing in the urn but soil, but in the cyst some large calcined bones were found. Explorations were continued in the vicinity of the cyst and within the stone circle, with the result that no fewer than eleven other urns were found. All these urns contained calcined human bones and much vegetable charcoal, both in dust and in pieces, and numerous pieces of burnt bones were also found in the mound—a circumstance which indicates that a good many interments had taken place without urns. The urns measured from 5 to 12 inches in height, are hand-made, and of the type usually known as "food-vessels." They have everted rims, and are ornamented with varied designs, formed by oblique lines and dots on the upper part, and encircling projecting rings at the bulged part. The urns are of a reddish colour, but the pottery section shows a black interior with a mixture of coarse sand. There are several interesting features attached to the discoveries. In the first cemetery a row of cysts with an urn in each were discovered—circumstances which unmistakably indicate the predominance of inhumation over that of cremation. No bones were found in the urns. In the second discovery only one cyst was found, and eleven of the urns were simply buried in the mounds, and all contained burnt bones—facts suggestive of cremation. The second discovery corresponds more than the first with most of the prehistoric local cemeteries which have been laid bare in the county of Fife. The chronological relationship between the two kinds of interment—inhumation and cremation—as presented to us in the two Pitreavie cemeteries, opens up a most interesting field of inquiry to the enthusiastic archæologist. Dr. Worsaae, the late distinguished archæologist, says cremation was the outcome of higher and more advanced religious principles than characterised the people of the Stone Age, who were in the habit of burying their dead in dolmens and other megalithic tombs, with food-vessels, weapons, ornaments, and such articles as were supposed to be serviceable beyond the grave. Founding upon Dr. Worsaae's idea, it is not unreasonable to assume that the two discoveries under notice belong to the Stone and Bronze ages. The urns are all in the hands of the proprietor of the estate, Mr. Beveridge, and are likely to be handed over to the National Society of Antiquaries.

SCIENTIFIC SERIALS

Annalen der Physik und Chemie, No. 8, July 15.—This contains the following:—On the time-relations of the formation of the electric residuum in paraffin, by C. Dieterici.—On the quantity of electrical elementary particles, by E. Budde.—On the theory of thermo-electric forces, by the same.—On a deduction from the laws of electro-dynamic points, suggested by Gauss, by the same.—On some applications of theory of change of form in a body when it is magnetically or dielectrically polarised, by G. Kirchhoff.—Determination of some coefficients of friction and experiments on the influence of magnetisation and electrification on the friction of liquids. The values obtained from swinging disks were always greater than from an outflow-apparatus. Experiments in which sulphate of manganese solution was let flow from a capillary tube placed between magnetic poles, and others in which the capillary tube, of flint glass coated with shellac, was brought into the field of a condenser (the liquid being sulphide of carbon), showed no alteration of the coefficient of friction.—On the solubility of salt mixtures, by F. Rüdorff. Of the pairs of salts examined, some were found to be forced from their common solutions when an excess of one or the other salt acted on these, but in other cases only those pairs of salts were forced out which separate from the common solution either in double salts or in mixed crystals.—On the theory of fluorescence, by E. Lommel. He answers some objections of Herr Wüllner to his theory.—Spectral photometric researches on some photographic sensitisers. He finds the sensitising colouring-matters divisible into: (1) those which gradually absorb the spectrum from the violet onwards, and are like the ordinary photographic; (2) those which have a regular absorptive action over great parts of the spectrum from the violet, but photographically show a maximum of sensitisation in the yellow; and (3) those which show an absorption band in the spectrum and a local increase of sensibility to light thereabouts (coincidence not exact).—Correction of new formulæ, by W. Wernicke.—Remarks on Herr Melde's acoustic experimental researches, by A. Else.—Alteration of the influence machine, by E. Lommel. He gets a spark of 12 cm.—On an inaccuracy of the theory of the gold-leaf electroscope, by T. Häbler.

Proceedings of the Boston Society of Natural History, vol. xxiii., part 1.—Mr. Bouvé contributes notes on gems, especially the garnet, hiddenite (an unnamed gem of a light yellow colour, a representative of the mineral spodumene, of which hiddenite is a green variety), and others.—Dr. S. Kneeland read a paper, illustrated by the stereopticon, on the subsidence theory of earthquakes as evidenced by the Ischian catastrophes of 1881 and 1883.—Prof Crosby has a long paper on the relations of the conglomerate and slate in the Boston Basin; Mr. Bouvé on the genesis of the Boston Basin and its rock formations; Messrs. Dickerman and Wadsworth on an olivine-bearing diabase from St. George, Maine; Prof. Shaler on the origin of kames, a kind of gravel deposit, also known as Eskers, and often called in America, Indian ridges. He supposes that at the close of the glacial period the re-elevation of the land must have been accomplished with very great suddenness.—Finally, Prof. Hyatt contributes a lengthy paper on the larval theory of the origin of cellular tissues.

SOCIETIES AND ACADEMIES

Paris

Academy of Sciences, September 7.—M. Bouley, President, in the chair.—Researches on isomerism in the aromatic series: Action of the alkalis on the phenols of mixed function, by M. Berthelot.—Studies on the mode of action of the subnitrate of bismuth in the staunching of sores, by MM. Gosselin and Hérat.—Note on the fluorescence of some rare earths, by M. Lecoq de Boisbaudran. The author arrives at conclusions differing in several respects from those of Mr. Crookes, but reserves for the present an exposition of the grounds which induce him to infer that yttria is not the efficient cause of the fluorescence —On apparent anæsthesis and retarded sensations in hysterical, epileptic, and other nervous subjects, by M. V. Revillont.—Letter announcing the discovery of a new star in the nebula of Andromeda, by M. Lajoie.—Note on the changes recently observed in the nebula of Andromeda, by M. G. Bigourdan.—Observations of Brooks's new comet and of the new planet, 250, made at the Paris Observatory (equatorial of the west tower), by M. G. Bigourdan —Table of the chief elements of the ten regular polyhedric figures, one illustration, by M. Em. Barbier. — A new map of the solar spectrum, by M. L. Thollion. This work, which has occupied four years of incessant labour at the Observatory of Nice, comprises the whole of the solar spectrum between A and *b*—that is, about one-third of the prismatic spectrum. It is over ten metres long and includes 3200 lines, or double the number contained in Angström's Atlas. In the preparation of this plan the author's aim has chiefly been to determine as far as possible the present state of the solar spectrum, to serve as a starting-point for future observation. The physicist will by its means be able to record subsequent changes in the spectrum with the same certainty that the astronomer determines the changes taking place in stellar regions.—Account of the "Anemogene," an apparatus invented for generating aërial currents analogous to those of the terrestrial atmosphere, by Mgr. Rougerie, Bishop of Pamier. This instrument takes the form of a miniature globe, which, by rotating around its axis in the air, is made to produce by its mechanical action currents resembling those observed on the greater part of the oceanic basins. The currents are indicated by vanes placed at intervals of 5°, like the compass-cards of the thirty-two winds prepared for the French navy by M. Brault. A list is given of all the trade winds, ascending and descending currents, and other normal atmospheric phenomena reproduced with more or less accuracy by this apparatus.—On the period of latent excitation of some smooth muscles in the invertebrates, by M. Henry de Varigny. —On the so-called "vidian" nerves in birds, by M. F. Rochas. —On the anatomy and vital functions of *Truncatella truncatula*, by M. A. Vayssière.—On the marine annelids of the Bay of Algiers, by M. C. Viguier.—On the anatomical structure of the Ascidians (genera Saracenia, Darlingtomia, and Nepenthes), by MM. Edouard Heckel and Jules Chareyre.—Note on the black rot recently introduced from the United States into the vineyards of Hérault, by MM. P. Viala and L. Ravaz.—On the earthquake-shock felt at Orleans on August 16, by M. E. Renou. —M. H. Gadeau de Kervill announced that he had obtained a hybrid from a tame pigeon and a ring-dove, presenting in a modified form nearly all the special features of both parental types.

September 14.—M. Bouley, President, in the chair.—Discourses pronounced at the obsequies of the late M. Bouquet on September 11, by MM. J. Bertrand and Hermite.—On the fluorescence of some rare earths, continued, by M. Lecoq de Boisbaudran.—Description of the model of a new integraph serving to trace an integral curve ($y = \int f(x)\,dx + C$), any curve ($y = f(x)$) being given, one illustration, by MM. D. Napoli and Abdank-Abakanowicz. This integraph is capable of numerous applications, and may render great services to the engineer's art. It traces mechanically and with great precision the funicular curves or polygons which play so large a part in the problems of statics. Such problems as the centre of gravity, momenta of inertia, elastic curves and the like, are solved with great rapidity and accuracy.—On submarine countermines, by M. A. Trève.—On the new star in the nebula of Andromeda. Observations of Brooks' comet made at the Observatory of Paris (equatorial of the West Tower), by M. G. Bigourdan.—Numerical tables intended to facilitate the calculation of the ephemerides of the minor planets, by MM. O. Callandreau and L. Fabry.—On the mixed haloid and other derivatives of methylene, by M. Louis Henry.—On the fermentation of bread-stuffs, by M. Aimé Girard. From numerous researches instituted to determine the true character of the phenomenon by which the dough is changed into bread, the author concludes that the transformation is the result of alcoholic fermentation.—Researches on the morphology and anatomy of ferns, by M. P. Lachmann.—Disposition of the artesian waters in the Wed Rir' and throughout the Lower Sahara in general, by M. G. Rolland. In this paper the author sums up the results of observations continued for a period of six years on the underground supplies in the vast depression of the Shott Melrir in Algeria and Tunis.—Application of the laws of thermo-chemistry to geological phenomena: ores of manganese, by M. Dieulafait.—Note on a therapeutic operation, to which the name of "dielectrolysis" has been given, by M. A. Broudel.—Trigonometric study of a pyramid whose base is the triangle of Pythagoras, by M. G. Petrowitsch. The sides of the base being respectively related as the number 3, 4, 5, the faces of the pyramid satisfy the relation $3^3 + 4^3 + 5^3 = 6^3$, the number 6 being the measure of the right-angled triangle of the base.

Berlin

Physiological Society, July 17.—In consequence of a doubt expressed on a former occasion in the Society, Dr. H. Virchow had examined more minutely the eye of the frog, and had come to the conviction that it possessed a beautiful ciliary muscle with long fibres, which, as in the case of all other animals, composed the posterior and outer part of the ciliary body. The ciliary body, as was known, filled out the corner arising from the choroid, which closely adjoined the sclerotic, curving itself round to the iris at the point where the sclerotic passed into the cornea, and, besides the muscle, consisted of the pigmentary fold and a network of fibres, the ligamentum pectinatum iridis, which Dr. Virchow had searchingly investigated in a large number of animals. This network of fibres was so little developed in man as hardly to merit any consideration there. In other classes of animals, however, it attained a very remarkable development. The speaker gave a more detailed description of the course of the fibrous lines of the network, which presented a great multiplicity in the different animals. The fibres separated by larger interstices now pursued a principally posterior direction, now spread radiating from their place of origin at the union of the sclerotic and cornea, now they were developed more anteriorly, reaching far into the iris. By means of numerous diagrams and several preparations these anatomical relations were illustrated in greater detail. In regard to the physiological significance of this network of fibres the speaker was of opinion that they performed a mechanical function, but he dissented from the assumption put forth by some authors that the ligamentum pectinatum was the tendon of the ciliary muscle. Such an assumption was at variance with the fact that in the case of man, whose eye possessed powerful ciliary muscles, the ligamentum pectinatum was but weakly developed, whereas in other animals with a very weak ciliary muscle it was strongly developed. The fibres of the ligamentum pectinatum might operate as antagonists to the ciliary muscles in those cases in which they were especially directed posteriorly. In such cases, on the other hand, in which the fibres were developed more to the anterior side and passed into the iris, they would probably serve as antagonists to the musculus sphincter pupillæ. It was still more probable that by their radiation towards the membrana limitans they afforded support and hold to the fibres of the ligamentum suspensorium of the lens, establishing themselves at the other side of this membrane. This relation was brought very close by the course of the fibres, particularly in the case of the anthropoids.—Herr Aronsohn made some additions to his former communications on the physiology of the sense of smell. The most minimal quantities of clove oil and bromine, which dissolved in 0·6 per cent. of common salt solutions, he was yet able to smell distinctly, tallied very well with the most minute quantities which Valentin had found perceptible by the sense of smell in the air. By electrical stimulation of the olfactory nerve he had also been able to call forth distinct sensations of smell in some other trustworthy persons. The physiological common salt solution of the temperature of 40° C. he had previously found to be entirely indifferent to the olfactory nerves. Were a part of the common salt replaced by other salts, then, according to the nature of the salt, different, mostly somewhat large, quantities of the salt (osmodic equivalents) had to be taken in order to form an indifferent solution. These osmodic equivalents Herr Aronsohn had now exactly determined for a series of salts. Finally, in order to demonstrate that there were special fibres in the olfactories for special smells, he had hebetated his own sense of smell for a certain quality of smells, that, namely, of sulphuret of ammonium, and had convinced himself that, though, indeed, no longer able to perceive this smell, he was yet very well able to smell ethereal oils.—Dr. Benda spoke of a series of preparations of sensory and motory nerve-endings which he had exhibited in the Demonstrating Hall. They were prepared according to a new process recommended by Dr. Meys. The process consisted in adding arsenic acid to a chloride of gold and potassium. By means of this reagent the nerve-endings were made very beautifully visible, but in this way the epithelia were destroyed, and in order to preserve these likewise, Dr. Benda had further added to the fluid either chromic acid or alcohol. The exhibited preparations showed very clearly that the medullary motory nerves ended in Kühne's terminal plates, besides which in one case a marrowless, and certainly sensory, nerve-fibre, ending in a bifurcated ramification, could be distinctly traced. Marrowless fibres ended in an umbellate form, each single fibre on the muscle passing into a button-like swelling. These fibres, Dr. Benda held to be motory. There were further shown the nerve-endings in the papillæ of the tongue, in the Paccinian corpuscles, in the cornea, and in the skin of the neck.—Dr. Kossel spoke of some important chemical relations of the cell nucleus, of that constituent of it, namely, which morphologists denoted as chromatine, and chemists as nucleine. As products of decomposition of the nucleine he had formerly obtained three nitrogenous bases: xanthine, hypoxanthine, and guanine. Quite recently he had obtained, though, to be sure, only in very small quantities, from the nucleine, a fourth base, namely, adenine, discovered by him some time ago in the glands of the abdomen. After he had prepared 3 g. of this substance, he treated it with nitrous acid, and received as a product of the decomposition of adenine, hypoxanthine. When he treated guanine in the same manner he received xanthine. It was therefore probable that the first products of decomposition of the nucleine were adenine and guanine, and that from these, first hypoxanthine and then xanthine were formed. The chemical relations of these four bases were best rendered evident by their chemical formulæ:—

Adenine ...	$= C_5H_5N_5$	Guanine ...	$= C_5H_5N_5O$
Hypoxanthine	$= C_5H_4N_4O$	Xanthine ...	$= C_5H_4N_4O_2$

All the four bases stood in intimate relation to prussic acid, CHN, which by the action of caustic alkali was obtained from them in very large quantities, while other albuminous bodies under similar treatment yielded very little prussic acid, or none at all. It was doubtless of great importance that nuclei ne stood in such intimate relation to cyanogen. What part, however, the cyanogen bodies played in the cell nucleus was as yet unknown.

NORTH AMERICAN WATER-BIRDS

The Water-Birds of North America. By S. F. Baird, T. M. Brewer, and R. Ridgway. Two Vols., 4to. (Boston: Little, Brown, and Co., 1884.)

EXPECTATION was roused some years since when tidings came that the "North American Birds" of Prof. Baird, Dr. Brewer, and Mr. Ridgway, of which three volumes had been brought out in 1874, was in process of completion, and at last there appeared two quartos of goodly size under the title of "The Water-Birds of North America," which are not only the sequel to the work just named, but are also issued in continuation of the publications of the Geological Survey of California, of which a single volume on the land-birds of that State, edited by Prof. Baird from the notes of Dr. J. G. Cooper, saw the light in 1870. But, to complicate the matter further, the two quartos now before us form vols. xii. and xiii. of the "Memoirs of the Museum of Comparative Zoology" at Harvard. How all this came about is explained in the introduction by Prof. Whitney, the Californian State Geologist; but the only part that need concern us is the not surprising but still much-to-be-regretted fact that the cost of bringing out the volumes treating of the land-birds of North America was so great as to deter the publishers from continuing the work at their own risk. Most fortunately, then, the combination just mentioned was effected with the result we now see; but it still remains a reproach and humiliation to those interested in birds—not only in North America alone but all the world over—that so excellent a performance was not more encouraged by them. The obstinacy of the public in preferring a bad book to a good one is perhaps observable in almost every science, but that this obstinacy is nowhere more marked than in the case of natural history, and of ornithology in particular may be because it is one of the most popular branches of science, and because nine-tenths of those who pursue it hardly realise the fact that it is capable of serious study. Howbeit we may be sure that the old adage, "*Populus vult decipi*," was not first uttered by a man without worldly knowledge, and to this day experience tells us that it is as true as ever. It will take a long time yet to persuade people that they had better be well informed by an author who writes a book because he knows his subject, than by a badly-informed one who gets up his subject in order to write a book about it—though even this is perhaps saying too much, for many an author, on ornithology at least, has never taken the trouble to learn the rudiments of what he pretends to teach, and if he have but enough self-assurance he will get his claim to instruct allowed by those who are more ignorant than he is.

To all who have been concerned in the production of the text of the two volumes before us we must offer our hearty congratulations, as it is impossible for us to apportion to each anything like his proper share of merit. Besides the naturalists already named, Prof. Whitney states, in his introduction, that in revising the not wholly completed manuscript he has had the assistance of Mr. Allen, so long known as head of the ornithological department of the Harvard Museum, and that gentleman is therefore entitled to our thanks as much as any one of the others; but moreover it is also advisable to look back to the original preface of Prof. Baird, in which he states that "the most productive source" of the new information published in this work "has been the great amount of manuscript contained in the archives of the Smithsonian Institution in the form of correspondence, elaborate reports and the field-notes of collectors and travellers." The most important of these, he goes on to say, are those by the late Mr. Kennicott, and several residents in the then Hudson's Bay Company's Territory—Messrs. MacFarlane, Ross, Lawrence Clark, Strachan Jones, and others—besides Messrs. Dale, Bannister, and Henry Elliott in regard to Alaska and its islands. Now this being the case with respect to the former volume, which treated of the land-birds only, the importance of the labours of these gentlemen ought to be far more manifest in the present volumes, which deal with the water-birds, since an overwhelming majority of them have their home in the vast northern regions of the continent, and are only winter-visitants to most of the States and Territories of the Union. A good deal to our disappointment we find it otherwise. It may be that the late Dr. Brewer, who is believed to have been responsible for the "biographical" portion of these as of the former volumes, had not at his death completed the examination of the unpublished materials at his disposal; but certainly there is not so much information from American sources as we had hoped or even expected. On the other hand, European authors are freely, not to say redundantly, laid under contribution for such species as are common to the two continents, which it is needless to say are many. Of this we do not complain, though we confess we should rather have learned how these species behave themselves on the other side of the Atlantic; but there is a want of discrimination as to the opportunities possessed by the different observers quoted, and a lack of proportion as to the value of their observations. We do not say that this is not pardonable, perhaps it was unavoidable; but it is unfortunately no less a drawback; and, to make it worse, several instances might be cited in which absolutely contradictory assertions are reprinted without any attempt to indicate which is thought to be the more worthy of belief; while a good many of the statements to which this objection does not apply are but vain repetitions.

Passing to the descriptive part of the work, we do not hesitate to declare that, so far as we have been able to test it, it is excellent. The "specific characters" given seem really to deserve their name, since they indicate the species, and are not, as has lately become so common, drawn from an individual example. Moreover, they are sufficiently brief to be useful, for we have unfortunately entered upon days when specimens are described at a length that absolutely precludes the practical application of the description. Nothing marks more distinctly the difference between a naturalist and a book-maker than the being able to perceive and to tersely express the characters that are essential to the differentiation of a species. Among ornithologists, merely to cite the example of one who is gone, it seems to have been this faculty that gave the late Mr. Gould such a wonderful pre-eminence among his contemporaries. Others unquestionably far surpassed him as scientific ornithologists, indeed the scientific value of his works is very slight; but hardly any one had such an eye for a species, or could in a dozen words or so point out how it could be recognised. It is no doubt in consequence of this that so few of the species described by him have failed to be considered good by his successors.

The ornithologists of the New World are in one respect very fortunate. They are not encumbered by the enormous dead weight of synonomy that is so burdensome to their brethren of effete Europe; and, thanks to the steadfastness with which the North Americans follow the use of a nomenclature fixed by authority, they will probably be for ever exempt from much of the evil which afflicts the more independent writers of the Old World, almost each of whom likes to be a law unto himself. Whether the nomenclature now accepted in the United States and in Canada be founded on the best principle is a matter that need not be here discussed. It has been reduced to a practice the real advantage of which none can doubt. But that this state of things is possible arises in great measure from the fact that in one sense a very small number of North American birds have an ancient history such as is possessed by nearly all the European species, though of this ancient history the compilers of synonymy in general give but a feeble notion. Few things are more misleading than a long list of synonyms, such as is too often regarded as a test of an author's industry and knowledge. It almost always happens that in a list of this kind bad accounts and good are made to appear as though they stood, as it were, on an equal footing, and it not unfrequently occurs that a reference to the best account of a species may be wholly omitted, while a fantastic name introduced by some compiler or catalogue-maker, who perhaps never examined or even set eyes on a specimen, receives notice as if it were an important contribution to the history of the creature. If Americans suffered from this grievance to the same extent as Europeans do, we suspect that the ingenuity of the former would lead them to find some remedy for it, but they may bless their stars that they are comparatively free from it.

Every well-informed ornithologist knows that the systematic arrangement of birds presents a series of puzzles which as yet defy solution. Still, some steps towards the clearing away of the old trammels have been taken by various persons, and a few positions that may be looked upon as established have been gained. We are sorry to find so little in these volumes suggestive of further advance. The writers seem to be still enchained in the toils which the artificial system of Sundevall drew around the subject, and in the very brief space—barely two pages—thereto devoted, we have "altricial" and "præcocial," "gymnopædic," and "dasypædic" groups spoken of as if they were to be believed in. It is true that the arrangement adopted is said to be "not strictly natural;" but in the same paragraph are some other statements as to affinities or the reverse that we hope the author may live to repent. However we freely admit that the main object of these volumes is not to teach systematic ornithology, and therefore perhaps the less said on that contentious subject the better. They will, there can be no doubt, admirably fulfill the chief purpose for which they are intended, and enormously further the study of birds in English-speaking America. It would be out of place here to enter upon any minute criticism of their contents, and, while indicating in a general way, as we have attempted to do and as we conceive we are in duty bound, some of their shortcomings, we can strongly recommend them as on the whole justifying the high degree of expectation that had prevailed concerning them prior to their publication. Assuredly we shall have to wait long before another so comprehensive and, taking it all in all, so excellent an account of "The Water Birds of North America" is likely to make its appearance, and once more we tender our thanks to each and every one of those who have been concerned in the work, though we may perhaps make a reservation in regard to the wood-engraver.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

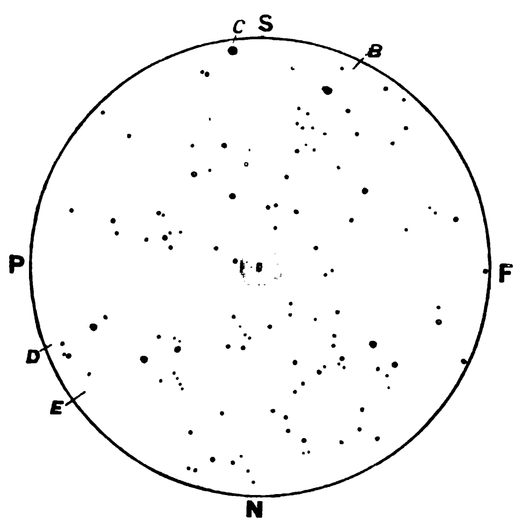
[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The New Star in Andromeda

THE information furnished by a photograph of the Great Nebula in Andromeda taken last year may be of value, particularly in relation to the presumed variability of the new star. An examination shows that no star brighter than about the 15th magnitude was then in the position now occupied by the new star.

This photograph was a trial plate taken on August 16 between 10h. and 11h., with an exposure of 30 minutes of the 3-foot reflector. With this exposure the impression of the nebula is very

FIG. 1.



Scale 0·1 inch = 100″.

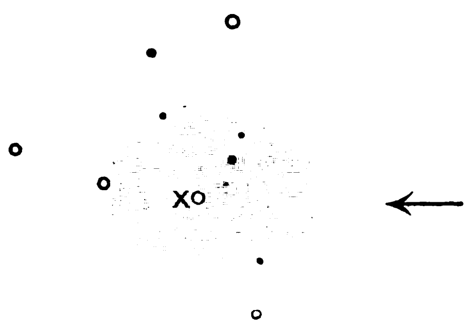
small for such a bright object as it appears in the telescope, being limited to about 2 minutes of arc around the nucleus (which was bright and round), not much more than is shown on a photograph of the Crab nebula with the same exposure, and not nearly so much as, though a little brighter than, a photograph of the Dumb-bell nebula taken a few days after. A great number of stars are to be seen. A defect in the apparatus then being used for the first time has caused a tilt of the plate and a consequent want of sharpness on one side, but the definition in the centre of the field is not injured.

To give some idea of the stars that can be seen and the value that may be given to photographic evidence of the existence or non-existence of faint stars, I give some particulars of this photograph. Without a magnifier 124 stars are to be seen within a radius of twenty minutes of arc from the nucleus.

I have traced these (see Fig. 1) so that they can be identified in the telescope; some of them may not be less than 13th magnitude, possibly fainter; the bright stars marked B, C, D, and E being shown in Argelander's maps of the Northern Heavens. B and C are at the present time about the same brightness as the new star, and can be well used to watch any variation in its light (when first seen by me on September 3 the new star was very much brighter than B or C, almost as bright as a star I have called A in my note-book that is just beyond the smaller nebula).

Using a magnifier to detect any fainter stars I find six near the nucleus: these I have shown as black dots on Fig. 2, using a

FIG. 2.



Scale 0·4 inch = 100″.

circle to show the stars near the nucleus that appear on Fig. 1, and a cross (×) to indicate the place of the new star. At this particular place there is not the slightest indication of any difference in the regular shading of the deposited silver from the denser part of the nucleus to the faint edge. The six stars indicated are extremely faint in the photograph and difficult to see, but I have no doubt of their real existence; from a comparison with other photographs I estimate them of about 15th magnitude, perhaps fainter. It may be that some of these may be identified at Birr Castle. From the absence of scale and orientation of the sketch given by Lord Rosse on p. 465 comparisons cannot be made, but a reference to the note-books would enable this to be done. A. A. COMMON

DURING last week I examined on three evenings the spectrum of this star apparently in the nebula. It appears to be continuous, extending from about D, as far as, or perhaps a little past F. Both Mr. Percy Smith and I are able to confirm Lord Rosse's conviction of the existence of a bright line or band. We compared its position with spark spectra, and feel satisfied that its position is not far from the bright line of the spark in air near to, and on the more refrangible side of D. The slit was of course necessarily wide, and the spectrum faint, so that this must only be considered as approximate.

GEO. M. SEABROKE

Temple Observatory, Rugby, September 29

IN the first evenings of September I observed the new nucleus of the nebula in Andromeda: I find it of the 8th magnitude. With a little Maclean's star spectroscope applied to the 10-inch refractor the spectrum of the nucleus is continuous, with suspected brighter bands. On the nights of Sept. 14 to 16, with 340 and 470 enlargements, I found to the east of the nucleus, and 15″ to 18″ distant from it, a faint object, probably a second nucleus, of 12th to 13th magnitudes. A. RICCO

Palermo Observatory

The Proposed Change in the Astronomical Day

IN your account of the proceedings at the recent meeting of the Astronomische Gesellschaft at Geneva (NATURE, vol. xxxii. p. 517) Dr. Struve is reported to have stated "that in the Royal Astronomical Society the majority were in favour of th universal day." There appears to be some mistake here: the Royal Astronomical Society as a body has not expressed any opinion on the subject. And, judging from the individual expressions of opinion which have been published, I should imagine that here, as at Geneva, the majority of real workers in our science (with the probable exception of those engaged on solar work) would be opposed to the proposed change. But how the majority of the Fellows of the Royal Astronomical Society could vote on the question it is impossible to say. My desire that a wrong impression on this subject, arising from a statement reported to have been made by such a high authority as Dr. Struve, should not be spread abroad, must be my excuse for trespassing thus far on your space.

A. M. D. DOWNING

Royal Observatory, Greenwich, S.E., September 26

A Tertiary Rainbow

PROF. TAIT remarks, in his recently-published work on "Light," that rainbows due to three or more internal reflections "are too feeble to be observed." It may therefore be worth recording that a tertiary bow was clearly visible from Thandiani Hill, Punjab, one evening last week (August 17). The bow extended over an arc greater than a semicircle, but was broken in two places. The colours were as distinct as in many an ordinary bow.

The condition of the sky was specially favourable for seeing a tertiary bow. The sun was low, and on nearly the same level with it there were several horizontal layers of cloud of considerable extent, whose nearer, unilluminated sides were therefore dark enough to serve as a good background for the bow. There was also a cloud in front of the sun itself, partially reducing its brightness. T. C. LEWIS

August 25

A White Swallow

ON August 3 I saw a white swallow flying among its fellows over a mill-pond at Garioch's Ford, Auchterless, Aberdeenshire. When I repassed on the following day it was still there, and it appeared to my brother and to me to be *entirely* white: otherwise I should suggest that the one seen in Westmoreland on September 4 (NATURE, No. 830, p. 500) might be the same bird on its southward pilgrimage. If it is true that the albino bird is never courted or paired ("Descent of Man," chap. xiv.) we are not likely ever to see many white swallows.

Mirfield, Yorks, September 28 ALEX. ANDERSON

THE enclosed paragraph from Yarmouth, in the *Norfolk News* of this day, will have interest for your correspondent at Milnethorpe. HUBERT AIRY

Stoke House, Woodbridge, September 26

Rara Avis.—A cream-coloured specimen of the swallow (*Hirundo urbica*) was shot on Caister Road, on Monday morning last, by Mr. A. Patterson. It is now in the hands of Mr. B. Dye of Row 60 for preservation.

DURING the summer of 1883 Mr. Cooper, of Bromwich, observed a white swallow throughout the season at a place within the city on the banks of the Severn. J. LL. BOZWARD

Worcester, September 28

THE ANNUAL CONGRESS OF THE SANITARY INSTITUTE OF GREAT BRITAIN

THE subjects dealt with by the Sanitary Institute of Great Britain at its annual meetings cover a wide field, and the Leicester gathering of this year, under the presidency of Prof. de Chaumont, F.R.S., forms no exception to the rule. The first aim of the Institute is, through its various agencies, to assist and indeed to lead in the improvement of public health, and the President did well to prove, by mortality statistics, how great a saving of life can be effected by the adoption of efficient sanitary measures, and how remunerative expenditure in this direction proves itself to be. The result of the sanitation carried out in the Army, and which is so much due to the labours of the late Dr. Parkes and to those of his successor, Dr. de Chaumont, is that, comparing the results of thirty years ago with those which now obtain, there is a saving in the home Army of two battalions per annum. Some substantial progress is also being made in the same direction as regards the general public, and when it is more fully understood that preventible diseases as a rule destroy those members of the population who are most remunerative in so far as the State is concerned, and that, speaking generally, each such premature death means a loss of at least 100*l*., even parsimonious members of sanitary authorities will not mind expending a little more of the public money in so good a cause.

Leicester was well chosen for this year's gathering, for in many respects the town has acquired some reputation in health matters. It may be regarded as the head-quarters of the anti-vaccination party; it prides itself, not without cause, on the efforts it has made to control the spread of infectious diseases; and it takes precedence amongst those English towns in which autumnal diarrhœa is so fatal to the infantile population. As regards the question of vaccination it would be premature to draw any general inferences from the Leicester results, for although during recent years only a comparatively small portion of the infantile population have been vaccinated, yet a vast majority of the inhabitants are fairly well protected against small-pox, and it is by no means so very strange that a disease which usually recurs in an epidemic form only after a lapse of years, should for a time remain absent from Leicester. Still, we frankly admit that the day of reckoning has been somewhat long in coming; but there are exceptional reasons for this. And in the first place we would note that Leicester is not so free from small-pox as is generally imagined. The Registrar-General's returns have, it is true, long shown an almost absolute blank as regards small-pox mortality there, but it must be remembered that the Leicester Small-pox Hospital, where the deaths from this disease take place, is not in the borough, and hence that the mortality occasioned is registered in altogether another district. Then again, the sanitary authority of Leicester, by the aid of a system of compulsory notification of infectious diseases, acquire the earliest knowledge as to the existence of cases of small-pox, and having provided themselves with an isolation hospital, the patients are at once removed, and their houses and clothing are efficiently disinfected. It may be said that any other town could do the same, and so vaccination would become unnecessary. But this is not so. Removal to hospital is only compulsory under conditions which, were objection raised to it by the people, would make this early isolation impracticable, and all populations are not so proud of their defiance of one of the laws of the country as to submit without resistance to the steps which are held necessary in order to prove that this law is a superfluous one. But Leicester goes much further than this. The authorities not only remove the sick, but they remove the healthy members of the sick person's family, and hold them in a species of quarantine until they know that they have escaped infection. Such a step may be very desirable from a health point of view, but it is altogether illegal, and it is quite certain that if any attempt were made to enforce such a system in other parts of the kingdom it would be resisted. The majority of the nation would also hold it to be unnecessary; and the recent publication by the German Government of the Report of a Commission showing that since re-vaccination was made compulsory in 1874 not a single death from small-pox has occurred in their Army, affords ample evidence that the simple operation of vaccination can fully meet all the difficulty.

But little further light was thrown, at the meeting, upon that obscure zymotic diarrhœa which annually causes so large a mortality in Leicester. But Dr. E. W. Buck, who has made the subject a special study, probably pointed out the essential cause of this fatality by showing how a large portion of the population of Leicester was exposed to the influence of a water-logged soil charged with decomposing organic matter. Temperature so largely influences this mortality that it was at one time regarded as its sole cause; but it is certain that a high temperature alone is powerless to produce it, whereas the effect of temperature on such conditions as obtain in Leicester must be very potent in favouring the development of organic germs, such as are now supposed to lie at the root of the evil. Extensive inquiry is needed as to this subject, and we hope that the results of the investigation which have been conducted for some years past by the Medical Department of the Local Government Board will soon be made public.

Amongst the many other matters of interest which were dealt with at the Congress is that of the provision of dwelling-accommodation for the working classes, and in view of the steadily extending practice of massing together vast numbers of human beings in great buildings where storey is piled upon storey, the warning uttered by Mr. Gordon Smith, President of the Engineering and Architectural Section, and the occupant of an important official appointment which adds weight to his opinion, should receive careful consideration. He asserts that in this class of buildings there has been an excessive infantile death-rate, and it is certain that the provision of ample open space about dwellings, which is, as regards ordinary dwellings, being more insisted on than ever, is especially necessary in the interests of child-life, which is so extremely sensitive to such insanitary surroundings as influence the quality of the air breathed.

The question of a rational system of burial was discussed at the last meeting of the Congress in connection with a paper by the Rev. F. Lawrence, who quoted the authority of the burial service of the Church of England as suggesting a system which would allow of the rapid action of the soil upon the dead, and who advocated burial at a depth of three or four feet only in coffins designed to ensure speedy perishability, and laid singly at a depth of three or four feet only from the surface. The advocates of cremation were naturally represented, but the progress of this method for the disposal of the dead is hindered by considerations which it is not easy to overcome. Foremost amongst these stands the difficulty of tracing cases of poisoning, and, even if the public were ready to assent generally to post-mortem examinations before the cremation was carried into effect, no such examination as is usually carried out could be trusted to decide whether this species of crime was the cause of death or not. Indeeed, in many cases of poisoning the most skilled pathological and chemical knowledge is required in order to avoid error. On the whole, such discussions as have taken place at Leicester tend to improvement in matters where change is desirable in the interests of public health, and the Institute may be congratulated on the results of their recent meeting.

INSECT RAVAGES

THE preservation of our garden and field crops from the attacks of injurious and destructive insects is a study which Miss E. A. Ormerod has made specially her own and which she has carried out with such signal success. Miss Ormerod's labours in popularising the subject so as to bring it within the knowledge of all classes in any way connected with agricultural and gardening pursuits are too well known to need even a reference, so thoroughly has she at heart the welfare of our food crops and field produce that she has taken other steps, besides the dissemination of her well known books, to bring the importance of the subject before those who are not likely to be reached by the works in question. We refer to the prize offered by her at an agricultural show held at Frome last year, the result of which was satisfactory in drawing a considerable amount of attention to the subject, and one of the outcomes of which has been the preparation of a series of object lessons, so to speak, which have been elaborated from the plan of Mr. W. H. Haley, who took the prize at Frome last year. The plan ot these lessons is as follows:—One insect is taken as an example and the life-history of this particular insect is illustrated by showing the creature in all its stages of development where practicable, or by neat and accurate-coloured drawings of pupa, larva. and perfect insect, each stage of which is carefully labelled, then a spray or twig of the plant attacked, or a model showing the insect's ravages is given, and in many cases also the parasites which attack the insect itself. Beneath this is carefully printed the life-history of the particular insect, and an enumeration of the plants upon which it feeds; and, finally, under the head of "Prevention and Remedies," some brief but concise instructions how to proceed to rid one's crops of the pest. All this is arranged on a cardboard mount 12 inches long by 8 inches wide, and placed in a box with a glass cover, so that one insect only is treated of in one case, thus making the information imparted very clear, and preventing all confusion. Of the insects treated in this way are the turnip and cabbage gall weevil, turnip moth, turnip fly, cabbage aphis, large white cabbage butterfly, cabbage moth, vine beetle, bean beetle, pea and bean weevil, winter moth, American blight on apple, magpie moth on gooseberry, celery-leaf miner, silver moth, beet or mangold fly, click beetle and wireworms, goat moth, lacky moth, daddy-long-legs, and onion fly.

Twenty of these cases have recently been prepared by Mr. Mosley, of Huddersfield, under the superintendence of Miss Ormerod, and are now in the museum at Kew, and a set of ten of a similar character are to be placed in the Aldersey School of the Haberdashers' Company at Bunbury, Cheshire, where plain teaching on such subjects is being satisfactorily carried on. J. R. J.

AMERICAN AGRICULTURAL GRASSES[1]

HOWEVER complicated the systematic synonymy of the Gramineæ may be, the popular nomenclature of the grasses is probably in an even more unsatisfactory state. In the former case the name of the author appended to the scientific name of the plant is usually sufficient to dispel any ambiguity as to what particular plant is meant, even though that plant may have received half a dozen systematic names from as many different botanists. In the case of the trivial name, however, even this means of identification is lacking, and it is no uncommon circumstance to find the same name applied to several different grasses, each one of which may, moreover, have one or two additional names. To those who are studying the grasses in their agricultural aspect this confusion is very perplexing, particularly as both the English and the American agricultural journals usually refer to a grass by its trivial name. The difficulties which surround this subject are well exemplified in the volume before us. For example, in American agricultural publications the term "salt-grass" is frequently met with, and we searched this volume in the hope of finding out the species so denominated. But instead of one we find no less than four distinct species, in as many genera, called "salt-grass," namely, *Vilfa depauperata*, *Sporobolus airoides*, *Brizopyrum spicatum* (*Distichlis maritima*), and *Spartina juncea*. To an English agriculturist foxtail means *Alopecurus pratensis* only, whereas in America the name is also given to *A. geniculatus*, *Hordeum murinum*, *H. jubatum*, and *Setaria setosa*. Rye-grass in England is *Lolium perenne*; in America the term is applied in addition to four species of Elymus. Blue grass is the name given to four distinct species of Poa, varying considerably in their agricultural value, and one of these, *P. pratensis*, often spoken of as Kentucky blue-grass, is also called "June grass," "spear grass," and "red top," the last name being equally applied to *Agrostis vulgaris*. Bunch grass is more vague in its application, for it embraces at least six species in five genera, while in Canada the same name is given to two other grasses, *Elymus condensatus* and *Kœleria cristata*, the former of which is known in the United States as "giant rye grass." The term "goose grass," which in England is restricted to the rubiaceous hedgerow weed *Galium Aparine*, is, in America, applied to *Poa annua*, which is also called annual spear grass, and to *Panicum Texanum*, further known as Texas millet. The grass *Holcus lanatus*, which to all English farmers is known as Yorkshire fog, is variously termed velvet grass, velvet mesquite, satin grass, and meadow soft grass, this last term being also current in England.

There are about 600 species of grasses in the United States, a few only of these having been introduced. The work under notice embraces descriptions of 120 species, each accompanied by a plate. Of these, about forty, included under twenty-six genera, are identical with British species. Five additional British genera are represented, but not by British species; these are Elymus, Melica, Spartina, Stipa, Triodia. About a dozen British genera do not appear, the most noteworthy among these being, perhaps, Brachypodium, Briza, and Cynosurus. Two dozen of the genera enumerated are extra-British; the chief ones are Andropogon, Aristida, Bouteloua, Buchloë, Danthonia, Muhlenbergia, Paspalum, Sorghum, Sporobolus, and Zizania. The so-called buffalo grasses are *Bouteloua oligostachya*, *Stipa spartea*, and *Buchloë dactyloides*; the first two may be gathered in quantity by any one who travels across the Canadian prairies, but the last-named, which is regarded as the true buffalo grass, does not extend into Canada.

In upwards of 100 pages of text we find collected much information both of botanical and of agricultural interest. The structural and economic characters of each grass figured are detailed at some length, but Dr. Vasey has, perhaps wisely in a work of this kind, made no attempt at classification. Though systematic synonyms are seldom given, there is a lavish display of trivial ones, for which the agricultural reader, at all events, will be grateful. Orthographic blunders are rather numerous, and the index might be more complete. The term *chartaceous* ("the texture resembling paper or parchment in thickness") is, we believe, not current on this side of the Atlantic; let us hope we may do without it.

The chemical analyses are of much agricultural interest, and readers should compare the results here given with those obtained by Wolff in his analyses of German grasses. The figures before us serve to show how considerably the same gramineous species may vary in composition according to the soil and climate in which it is grown, this point being specially illustrated by analyses of *Phleum pratense* and *Dactylis glomerata*, each from half a dozen different localities. How variable is the composition of gramineous herbage generally is well shown in the following table, in which are given the highest and lowest percentages of the constituents named, obtained in 136 analyses of different species of grasses:—

Dry substance	Highest	Lowest
Ash	19·24 ...	3·57
Fat	5·77 ...	1·48
Nitrogen free extract	66·01 ...	34·01
Crude fibre...	37·72 ...	17·68
Albuminoids	23·13 ...	2·80

[1] "The Agricultural Grasses of the United States." By Dr. George Vasey, Botanist of the Department of Agriculture; also, "The Chemical Composition of American Grasses," by Clifford Richardson, Assistant Chemist. (Washington: Department of Agriculture, 1884.)

A process which has been the means of throwing much light on problems in vegetable physiology and agricultural chemistry, namely, a comparison of the analyses of a plant and of its separate members in different stages of growth, has been applied to fifteen familiar species of grasses, and the results are tabulated and briefly discussed.

Many useful suggestions, some of them of the highest practical importance, are to be met with in these pages. Here is one by Prof. Asa Gray which refers to the Teosinte, or Guatemala grass, *Euchlæna luxurians*, a native of Mexico and Central America, and has the true ring of progress about it:—

"To make the *Teosinte* a most useful plant in Texas and along our whole south-western border the one thing needful is to develop early-flowering varieties, so as to get seed before frost. And this could be done without doubt if some one in Texas or Florida would set about it. What it has taken ages to do in the case of Indian corn, in an unconscious way, might be mainly done in a human lifetime by rightly directed care and vigorous selection."

This volume is highly creditable to its authors, and it adds one more to the many useful publications which have emanated from the United States Department of Agriculture. W. FREAM

THE DEVELOPMENT OF THE CÆCILIANS

IN a letter recently published in the *Arbeiten aus dem zoologisch-zootomischen Institut in Würzburg*, Messrs. P. B. and C. F. Sarasin give a preliminary account of the development of *Epicrium glutinosum* as observed at Peraderinia in Ceylon, where these naturalists have taken up their quarters near the celebrated Botanical Gardens. Since the original discovery by Johannes Müller of the larval form of the Cæcilians, almost the only information obtained on this important subject is a short account of the gilled larvæ of *Cæcilia compressicauda* by Peters, founded on specimens procured by Jelski in Cayenne.

The brothers Sarasin show that *Epicrium* is not viviparous, as is *Cæcilia*, but oviparous. In the most advanced stage before hatching the embryo is provided with very long blood-red external gill-filaments, and has also a distinct tail with a strong fin. The gill-filaments are shed previous to the hatching, after which the young Cæcilians make their way to the neighbouring stream, and live in the water, breathing by means of gill-slits. After they leave the water their gill-slits close up, and they breathe by lungs. The brothers Sarasin compare these Cæcilians to Urodeles, in that they pass through the perennibranchiate stage in the egg. As larvæ they are derotrematous, and in the adult stage become true land-animals like Salamanders. Our authors also show that the spermatozoon has a spiral filament, and that there is a fourth gill-arch, from which the pulmonary artery is given off. Both these facts tend to show that the Cæcilians are more nearly allied to the Urodeles than to the Anurous Amphibians.

THE BRITISH ASSOCIATION

REPORTS

Fifth Report of the Committee, consisting of Mr. R Etheridge, Mr. Thomas Gray, and Prof. John Milne (Secretary), appointed for the purpose of investigating the Earthquake Phenomena of Japan. (Drawn up by the Secretary).—On account of an excursion which I have the intention of making during the coming summer to Australia and New Zealand, I am compelled to draw up this report a month earlier than usual. As the only time when the work of attending to observations and experiments repays itself is during the winter months, I may safely say that my intention of shortening the time usually devoted to earthquake observations is not likely to involve any serious loss. The number of earthquakes felt during corresponding periods in two previous years and this last year were respectively twenty-six, thirty-nine, and eighty, and not only have the earthquakes been numerous, but some of them have been pretty stiff, as is testified by the fact that on several occasions chimneys fell and walls were cracked. The work done during the last year is briefly as follows:—

Seismic Experiments.—Seismic experiments were commenced in conjunction with Mr. T. Gray in 1880. The movements then recorded were produced by allowing a heavy ball, 1710 lbs. in weight, to fall from various heights up to thirty-five feet. Subsequently many experiments were made by exploding charges of dynamite and gunpowder placed in bore-holes. During the last year, whilst working up the long series of records which accumulated, several laboratory experiments were made to investigate the methods to be employed when analysing the diagrams of earth motion. The first of these experiments consisted in projecting a small ball from the top of a tall flat vertically-placed spring, and at the same time causing the spring to draw a diagram of its motion. From the distance the ball was thrown its initial velocity could be calculated. From the diagram, either by calculation on the assumption of simple harmonic motion or by direct measurement, the maximum velocity of movement could be obtained. These three quantities practically agreed. The most important result obtained by these experiments was that they indicated an important element to be calculated in earthquake or dynamite diagrams, and, further, that in these diagrams the first sudden movement, which invariably has the appearance of a quarter-oscillation, ought apparently to be considered as a semi-oscillation. The second set of experiments consisted in determining the quantity to be calculated from an earthquake diagram which would give a measure of the overturning or shattering power of a disturbance. For this purpose a light strip of wood was caused by means of a strong spiral spring and a heavy weight to move horizontally back and forth with the period of the spring. On this strip small columns of wood were stood on end, and it was determined how far the spring had to be deflected and then suddenly released to cause overturning. The more important results of all these experiments are:—

I. *Effect of Ground on Vibration.*—(1) Hills have but little effect in stopping vibrations. (2) Excavations exert considerable influence in stopping vibrations. (3) In soft damp ground it is easy to produce vibrations of large amplitude and considerable duration. (4) In loose dry ground an explosion of dynamite yields a disturbance of large amplitude but of short duration. (5) In soft rock it is difficult to produce a disturbance the amplitude of which is sufficiently great to be recorded on an ordinary seismograph.

II. *General Character of Motion.*—(1) The pointer of a seismograph with a single index first moves in a normal direction, after which it is suddenly deflected, and the resulting diagram yields a figure partially dependent on the relative phases of the normal and transverse motion. These phases are in turn dependent upon the distance of the seismograph from the origin. (2) A bracket seismograph indicating normal motion at a given station commences its indications before a similar seismograph arranged to write transverse motion. (3) If the diagrams yielded by two such seismographs be compounded, they yield figures containing loops and other irregularities not unlike the figures yielded by the seismograph with the single index. (4) Near to an origin, the first movement will be in a straight line outwards from the origin; subsequently the motion may be elliptical, like a figure 8, and irregular. The general direction of motion, is, however, normal. (5) Two points of ground only a few feet apart may not synchronise in their motions. (6) Earthquake motion is probably not a simple harmonic motion.

III. *Normal Motion.*—(1) Near to an origin the first motion is outwards. At a distance from an origin the first motion may be inwards. (2) At stations near the origin the motion inwards is greater than the motion outwards. At a distance the inwards and outwards motion are practically equal. (3) At a station near the origin, the second or third wave is usually the largest, after which the motion dies down very rapidly in its amplitude, the motion inwards decreasing more rapidly than the motion outwards. (4) Roughly speaking the amplitude of normal motion is inversely as the distance from the origin. (5) At a station near an origin the period of the waves is at first short. It becomes longer as the disturbance dies out. (6) The semi-oscillations inwards are described more rapidly than those outwards. (7) As a disturbance radiates the period increases. Finally it becomes equal to the period of the transverse motion. From this it may be inferred that the greater the initial disturbance the greater the frequency of waves. (8) Certain of the inward motions of "shock" have the appearance of having been described in less than no time. (9) The first outwards motion, which on diagrams has the appearance of a quarter-wave, must be regarded as a semi-oscillation. (10) The waves on the diagrams taken at different stations do not correspond. (11) At a station near the origin, a notch in the crest of a wave of shock gradually increases as the disturbance spreads, so that at a second station the wave with a notch has split up into two waves. (12) Near the origin the normal motion has a definite commencement. At a distance the motion commences irregularly, the maximum motion being reached gradually.

IV. *Transverse Motion.*—(1) Near to an origin the transverse motion commences definitely but irregularly. (2) Like the normal motion, the first two or three movements are decided, and their amplitude slightly exceeds that of those which follow. (3) The amplitude of transverse motion as the disturbance radiates decreases at a slower rate than that of the normal motion. (4) As a disturbance dies out at any particular station the period decreases. (5) As a disturbances radiates the period increases. This is equivalent to an increase in period as the intensity of the initial disturbance increases. (6) As we recede from an origin the commencement of the transverse motion becomes more indefinite.

V. *Relation of Normal to Transverse Motion.*—(1) Near to an origin the amplitude of normal motion is much greater than that of the transverse motion. (2) As the disturbance radiates, the amplitude of the transverse motion decreases at a slower rate than that of the normal motion, so that at a certain distance they may be equal to each other. (3) Near to an origin the period of the transverse motion may be double that of the normal motion; but as the disturbance dies out at any given station, or as it radiates, the periods of these two sets of vibrations approach each other.

VI. *Maximum Velocity and Intensity of Movement.*—(1) An earth particle usually reaches its maximum velocity during the first inward movement. A high velocity is, however, sometimes attained in the first outward semi-oscillation. (2) The intensity of an earthquake is best measured by its destructive power in overturning, shattering, or projecting various bodies. (3) The value

$$v^2 = \frac{4}{3} g \sqrt{a^2 + b^2} \times \left(\frac{1 - \cos\theta}{\cos^2\theta}\right)$$

used by Mallet and other seismologists to express the velocity of shock as determined from the dimensions of a body which has been overturned, is a quantity not obtainable from an earthquake diagram. It represents the effect of a sudden impulse. (4) In an earthquake a body is overturned or shattered by an acceleration, f, which quantity is calculable for a body of definite dimensions. The quantity f as obtained from an earthquake diagram lies between $\frac{v}{t}$ and $\frac{v^2}{a}$, where v is the maximum velocity, t is the quarter-period, and a is the amplitude. (5) The initial velocity given in the formula $v^2 = \frac{2a^2}{b}$ (for horizontal projection) used by Mallet as identical with v^2 in 3, are not identical quantities. (6) In discussing the intensity of movement I have used the values $\frac{v^2}{a}$. (7) The intensity of an earthquake at first decreases rapidly as the disturbance radiates; subsequently it decreases more slowly. (8) A curve of intensities deduced from observations at a sufficient number of stations would furnish the means of approximately calculating an absolute value for the intensity of an earthquake.

VII. *Vertical Motion.*—(1) In soft ground vertical motion appears to be a free surface-wave which outraces the horizontal component of motion. (2) Vertical motion commences with small rapid vibrations, and ends with vibrations which are long and slow. (3) High velocities of transit may be obtained by the observation of this component of motion. It is possibly an explanation of the preliminary tremors of an earthquake and the sound phenomenon (4) The amplitude and period of vertical waves as observed at the same or different stations have been measured.

VIII. *Velocity.*—(1) The velocity of transit decreases as a disturbance radiates. (2) Near to an origin the velocity of transit varies with the intensity of the initial disturbance. (3) The rate at which the normal motion outraces the transverse motion is not constant. (4) As the amplitude and period of the normal motion approach in value to those of the transverse motion, so do the velocities of transit of these motions approach each other. (5) That the ratio of the speed of normal and transverse motions is not constant is shown from a table of these velocities calculated for different rocks from their moduli of elasticity.

IX. *Miscellaneous.*—(1) At the time of an earth-disturbance, currents are produced in telegraph lines. (2) The exceedingly rapid decrease in the intensity of a disturbance in the immediate neighbourhood of the epicentrum has been illustrated by a diagram. (3) For the duration of a disturbance due to a given impulse in different kinds of ground, reference must be made to the detailed descriptions of the first four sets of experiments.

Experiments on a Building to resist Earthquake Motion.—In the Report of last year I described a house which rested at its foundations upon cast-iron balls. These balls were 10-inch shell. The records obtained from an instrument placed inside this house showed that, although it was subjected to considerable movement at the time of an earthquake, all *sudden* motion had been destroyed. Although the balls did very much to mitigate earthquake motion, wind and other causes produced movements of a far more serious nature than the earthquake. To give greater steadiness to the house, 8-inch balls were tried, and then 1-inch balls. Finally the house was rested at each of its piers upon a handful of cast-iron shot, each ¼-inch in diameter. By this means the building has been rendered astatic, and, in consequence of the great increase in rolling friction, sufficiently stable to resist all effects like those of wind. The shot rest between flat iron plates. That the house had peculiar foundations would not be noticed unless specially pointed out. From these experiments it seems evident that it is possible to build light one-storied structures of wood or iron in which, relatively to other houses, but little movement will be felt.

Observations in a Pit 10 *feet deep.*—The instrument placed in this pit is similar to all the other instruments, and is installed in a similar position. Comparing the maximum amplitudes, maximum velocities, and maximum accelerations obtained in the pit with those obtained at about thirty feet distance, they are for one particular earthquake respectively in the ratios of 1 : 43, 1 : 52, and 1 : 82. In most earthquakes the extent of motion has been too small to admit of measurement, and that there had been any movement could only be detected by holding the plate on which the record was written up to the light and glancing along it lengthways. This investigation tends to confirm the view which I have previously put forward, that an earthquake at a short distance from its epicentrum is practically a surface disturbance, principally consisting of horizontal movements. The vertical motion is small, and is best seen in the preliminary tremors either of an actual earthquake or of a dynamite explosion. From a practical point of view these results must be of the greatest importance to those who have to erect heavy structures in earthquake districts.

Buildings in Earthquake Countries.—As during the last few years so much destruction both to life and property has taken place in various parts of Europe, it seems that an epitome of the results of observations and experiments carried on in Japan relative to construction in seismic districts might not only be interesting, but possibly it might also be of practical value. When erecting a building it appears that we ought first to reduce as far as possible the quantity of motion which ordinary buildings receive; and, second, to construct a building so that it will resist that portion of the momentum which we are unable to keep out. To reduce the momentum which usually reaches a building the following may be done:—

(1) Institute a seismic survey of the district or area in which it is intended to build, and select a site where experiment shows that the motion is relatively small. (2) For heavy buildings adopt deep foundations (perhaps with lateral freedom), or at least let the building be founded on the hardest and most solid ground. It is perhaps because the tops of the hills in Tokio are harder than the plains that they have relatively the least motion. A building only *partially* isolated may be exceedingly dangerous from the fact that motion entering in the unprotected side will make the excavations (cuttings, valleys, &c.) upon the opposite side into free surfaces which will swing forward through a range greater than they would have swung had the excavations

not existed. (3) For light buildings, especially if erected on soft ground, where the range of motion is always great, if the structure rests on layers of fine cast-iron shot, it cannot possibly receive the same momentum as a building attached to the moving ground. To resist the effects of momentum which cannot be cut off a building: (1) Bear in mind the fact that it is chiefly stresses and strains which are applied horizontally to a building which have to be encountered. A vertical line of openings like doors or windows in a building constitute a vertical line of weakness to horizontally-applied forces. (2) Avoid coupling together two portions of a building which have different vibrational periods, or which from their position are not likely to synchronise in their motion. If such parts of a building must of necessity be joined, let them be so joined that the connecting link will force them to vibrate as a whole, and yet resist fracture. Brick chimneys in contact with the framing of a wooden roof are apt to be shorn off at the point where they pass through the roof. Light archways connecting heavy piers will be cracked at the crown. To obviate destruction due to these causes a system of construction similar to that to be seen in several of the buildings of San Francisco, Tokio, and Yokohama may be adopted. This essentially consists of tieing the building together at each floor with iron and steel tie-rods crossing each other from back to front and from side to side. (3) Keep the centre of inertia of a building or its parts as low as possible. Heavy tops to chimneys, heavy copings, and balustrades on walls and towers, heavy roofs and the like are all of serious danger to the portion of the structure by which they are supported. When the lower part of a building is moved, the upper part by its inertia tending to remain behind often results in serious fractures. All the chimneys in Tokio and Yokohama which have fallen in consequence of their ornamental heads have been replaced by shorter and thicker chimneys without the usual coping. The roof of a portion of the Engineering College rests loosely on its walls, and has therefore a certain freedom. In Manila many heavy roofs have been replaced by roofs of sheet iron. Walls may be lightened in their upper parts by the use of hollow bricks. Such vertical motion as may exist is also partly obviated by light superstructures. Vertically-placed iron tie-rods give additional security. If these and other rules which are the result of experiment and observation could be adopted in earthquake countries, it is certain that the loss of life and property might be greatly diminished.

Earth Tremors and Earth Pulsations.—Notwithstanding the untrustworthiness of level observations, they nevertheless have given results of interest. (1) The bubbles from time to time move back and forth without apparent reason. Considerable changes have sometimes been observed before an earthquake (2) The greatest movement of the bubble of a level takes place during the colder part of the year, which is the season of earthquakes, and also the season when the barometric gradient between Siberia and the Pacific is the steepest. (3) The bubble of a level continues to move long after the sensible motion of an earthquake has ceased, enabling us to study the slow movements which bring an earthquake to a close. (4) When the barometer is very low, as, for instance, during a typhoon, the bubble of a level may be distinctly seen to pulsate back and forth through a range of about ·5 mm. In September of last year, in conjunction with Mr. W. Wilson, C.E., and Mr. Mano, of the Imperial College of Engineering, I carried an instrument to the summit of Fujiyama, which is about 12,365 feet in height, where I succeeded after many failures in recording automatically earth tremors and earth pulsations. But we were unable to remain for more than five days.

The results of interest connected with these observations are:—(1) That the movements on the top of the mountain were much greater than those which I usually observe in Tokio. (2) The tremors, or slight swing-like movements of the instrument, did not necessarily accompany the wind. (3) That during the heavy south and south-east gales the direction of displacement of the pointer was towards the south-east, which is the same result as would be obtained if the bed-plate of the instrument were raised on the south-east side, or if the mountain had tipped over to the north-west. My colleague, Mr. T. Alexander, treating Fuji as a conical solid made of brick, with a wind-load of 50 lbs. on the square foot, found the slope and deflection of a point 100 feet below the apex of the cone. This calculated slope was two or three times greater than the greatest deflection which I measured. As it is difficult to imagine that a mountain could suffer deflection by a wind pressure, I will not insist upon the fact that deflection actually occurred. It is certainly curious that the results of calculation and observation should point in the same direction.

Report of the Committee on Electrical Standards, consisting of Prof. G. C. Foster, Sir W. Thomson, Prof. Ayrton, Prof. J. Perry, Prof. W. G. Adams, Lord Rayleigh, Prof. O. J. Lodge, Dr. John Hopkinson, Dr. A. Muirhead, Mr. Preece, Mr. H. Taylor, Prof. Everett, Prof. Schuster, Dr. J. A. Fleming, Prof. G. F. Fitzgerald, Mr. R. T. Glazebrook, Prof. Chrystal, Mr. H. Tomlinson, and Prof. Barnett, with Mr. Glazebrook as Secretary.—The Committee reported that the Secretary has had constructed a series of coils to serve as standards in terms of the legal ohm. These standards, in accordance with the resolution of the Committee, were constructed on the supposition that the value of the legal ohm is 1·0112 B.A. units. The comparisons were made by the methods given in the reports for 1885 and 1884, and the values found were—

No.	Resistance	Temperature
100	·999515	14·1
101	·998845	14·1
102	10·00415	16·7
103	10·00352	16·75
104	100·0304	16·05
105	100·0436	16·05
106	1000·694	17·4
107	1000·677	17·45
108	10006·8	17·35
109	10006·8	17·35

These standards have also been compared with mercury-tube resistances constructed by Mr. Benoit, of Paris, and a difference of ·00049 legal ohm was found. The legal ohm standards, as constructed by the Committee, exceed by this amount those constructed in Paris. Six coils have been compared with the standards during the year, and the values are given. The Committee hope that arrangements may be made for issuing standards of electromotive force, and for constructing and issuing standards of capacity. In conclusion, they ask to be reappointed, with the addition of the names of Prof. J. J. Thomson and Mr. W. N. Straw, with a renewal of the unexpended grant of 50*l*.

Report on Electrical Theories, by Prof. J. J. Thomson.—This report deals exclusively with those theories which only profess to give mathematical expressions for the forces due to a distribution of currents. Those theories which profess to give mechanical explanation of these forces are not considered. There was not sufficient time to consider both classes of theories, and it is evident that the mathematical theory must be settled before we can get a satisfactory mechanical one. As to the general result of the inquiry, we may say that all that has been proved is that it is absolutely necessary to take into account the currents in the dielectric; and that the action of these, as well as other currents, must be given by some form of the potential theory—that is, the theory propounded by F. E. Neumann and generalised by Von Helmholtz. But nothing definite is known as to what we should take as the measure of these electric currents, and which of the many forms of the potential theory is the right one. We hardly require experimental proof that alteration in the polarisation of the dielectric, at any rate if the dielectric be other than the ether, produce effects analogous to those produced by an ordinary current flowing through a conductor. For the polarisation of a dielectric by an electromotive force produces a change in the structure of the dielectric. This is shown by the alteration in volume experienced by glass and other bodies when placed in the electric field, and also by the breaking down of the dielectric when the strength of the field is great enough. Now, if we move a magnet we shall, since we produce an electromotive force in its neighbourhood, produce a change in the structure of the dielectric around it because we alter its state of polarisation. It follows, then, from the principle of action and reaction, that if we alter the state of polarisation of the dielectric we shall alter the state of motion of the magnet. So that an alteration in the polarisation of the dielectric produces a magnetic force. We can show in a similar way that an alteration in the polarisation must produce all the effects produced by an ordinary conduction current. We know nothing, however, about the magnitude of the current which is equivalent to a change in the state of polarisation. It seems natural to suppose that the intensity of the current is proportional to the rate of change of the electromotive force. Let us suppose that it equals η (rate of change of the electromotive force). The quantity η has never been experimentally determined, but two hypotheses have been made as to its value by Maxwell and Helmholtz. According to Maxwell $\eta = \kappa/4\pi$, where κ is the specific inductive capacity, and, according to Helmholtz, η is also a function of κ. There is very little experimental evidence for either of these theories. For Maxwell's theory, perhaps the best evidence is that, if we assume the electro-magnetic theory of light, the refractive index should, if $\eta = \kappa/4\pi$, equal the square root of a specific inductive capacity, which is very approximately the case for a good many substances. Maxwell's assumption has the great advantage of getting rid of all discontinuity in the currents; and, when this is the case, all forms of the potential theory lead to the same result. So that, if we could prove Maxwell's theory experimentally, it would be a complete theory of electro-dynamic action. If it should turn out, however, that Maxwell's theory is not true, then we should have to go on further and determine which of the several forms of the potential theory is the true one; as, if the currents are not closed, the different forms of the theory lead to different results. It would seem that the most important thing to be done in electro-dynamic theory is to determine whether $\eta = \kappa/4\pi$ or not, and the author has described two ways in which this may be done. If Maxwell's theory should prove not to be true, we must go on to determine the value of η for all dielectrics, and which of the forms of the potential theory is the true one.

Report on Standards of White Light.—Various experiments have been made by the Committee. The members have come to the conclusion that the standard candle as defined by Acts of Parliament is not in any sense a standard. The spermaceti used is not a definite chemical substance, and is mixed with other substances. Also the constitution of the wick is not properly defined. The Committee have considered the relative merits of different proposed standards, and have come to the conclusion that for *commercial* purposes the pentane standard of Mr. Vernon Harcourt is the best. Although the Committee wish their opinion on this point to be known to the Board of Trade and the public, they do not recommend the adoption of any particular standard until further experiments on radiation have been made. Several experiments are enumerated which they propose to make. They ask reappointment, with a grant of 50*l.* towards the proposed researches.

Report of the Committee on Meteoric Dust.—Experiments have been made at the Scottish Marine Station by means of an apparatus in which the wind blows through gratings of fine platinum wire. The moisture deposited is collected and examined for suspended particles. Funnels have also been placed at different localities for catching rain. The presence of carbonaceous matter is most marked. In smaller quantities occur quartz, felspar, mica, tourmaline, garnet, glassy particles resembling Krakatoa dust or pumice, and small round magnetic particles about 1-500th of an inch in diameter. They resemble similar larger particles got from deep-sea deposits at the greatest distance from continental land. None are of cosmic origin. Usually they have a small nucleus in the interior, but are frequently hollow. Further observations are to be made at various stations all over the world.

Report of the Committee on Meteorological Observations on Ben Nevis.—The chief additional observations made during the year were with regard to rainfall and wind. The amount of water substance deposited, in whatever form, has been collected by specially-designed gauges and measured every hour since June 24, 1884. In the end of October the anemometers designed by Praf. Chrystal were added to the instruments. But during seven months—November, 1884, to May, 1885—no anemometer could indicate results, with the exception of thirty days. This is owing to the deposition of ice-crystals. The greatest speed indicated during three days was on the night of April 24. The mean speed for 12 hours was 74 miles per hour, the speed for one particular hour being 81 miles per hour. The highest temperature reached, 60°·1 F., occurred at 2 p.m., August 9; and the lowest, 11°·1 F., at midnight, February 16. The coldest week—average temperature, 16°·2 F.—was the one ending on February 21. The changes of temperature, particularly in winter, were caused, not by direct solar influence, but by the passage of cyclones or anticyclones over the observatory. Indeed in the stormy months of winter this may be taken to be accurately the case. In summer the afternoon minimum of atmospheric pressure was 0·007 inches above the mean for the whole day, but in winter it was below the mean. During twelve months there were 464 hours of sunshine, being about 11 per cent. of the total possible amount. Heavy rainfalls frequently occur. The longest for one hour was on December 10, 1884. The largest daily fall occurred then also, being 4·264 inches. On an average, a fall of at least one inch occurred one day in seven.

Report of the Committee on Solution, Secretary Dr. W. W. J. Nicol.—The subjects discussed in this Report are:—(1) Molecular volumes, (2) saturation, (3) supersaturation, (4) vapour pressures, and (5) expansion of salt solutions. (1) The results of a series of experiments show the molecular volume of a salt in dilute solution to be a quantity composed of two constants: one for the metal and the other for the salt radical; hence the same volume change is produced by replacement of one metal or salt radical by another metal or salt radical. *Water of crystallisation* is not to be distinguished from the solvent water, but the *water of constitution* possesses a volume different from that of the rest of the water—results showing the existence in solution of the anhydrous salt in contradistinction to the view that a hydrate, definite or indefinite, is formed in solution. (2) Saturation is reached when the further addition of salt would produce diminution of the mean molecular volume of the molecules already present. (3) The so-called supersaturated solutions are simply saturated or non-saturated solutions of the anhydrous salts, the only truly supersaturated solutions being those which result from the fact that, when a hot solution is cooled, a finite time is required for the excess of salt to crystallise out.

The Report of the Committee appointed to investigate by means of Photography the Ultra-violet Spark Spectra emitted by Metallic Elements and their Combinations under Varying Conditions, drawn up by Prof. Hartley, F.R.S., was presented by him to the Section; in it an account is given of the results of the investigation of the changes in the character of the spectra of the metals produced by variation in the strengths of the solutions of their salts—*e.g.* chlorides, nitrates, or sulphates. The study of a very considerable number of the photographs of such spectra shows the strength of the solution to have a marked effect on their character, the more dilute the solution the smaller the number of lines; further, that under the same spark conditions, similar solutions of the same strength emit the same spectrum. Solutions containing 1 per cent., 1-10th, 1-100th, and 1-1000th of the metal were used; solutions of the latter strength seldom gave a spectrum of more than three or four lines, and with solutions containing less than 1-10th per cent. the diminution in the number of lines is usually very marked. The spectrum reaction may be utilised for the quantitative analysis of minerals, and yields results more reliable than those obtained by ordinary methods. The reaction is extremely delicate, and in the case of magnesium one part of the metal in 10,000 millions of solution can be detected by the appearance of two characteristic lines.

Third Report of the Committee, consisting of Profs. Williamson, Dewar, Frankland, Crum Brown, Odling, and Armstrong, Drs. Hugo Müller, F. R. Japp, and H. Forster Morley, and Messrs. A. G. Vernon Harcourt, C. E. Groves, J. Millar Thomson, H. B. Dixon (Secretary) and V. H. Veley, reappointed for the purpose of drawing up a Statement of the Varieties of Chemical Names which have come into use, for Indicating the Causes which have led to their Adoption, and for Considering what can be done to bring about some Convergence of the Views on Chemical Nomenclature obtaining among English and Foreign Chemists.—An account of the authorship of some of the various systems of nomenclature which have been devised for the purpose of distinguishing between compounds formed by the union of the same elements in different proportions has been given in the "Historical Notes" prefixed to the Second Report of this Committee. Among these systems the use of the termination *ous* and *ic*, to denote respectively lower or higher degrees of saturation of one element or group with another element or group, is perhaps that which has met with the widest acceptance. This system further directs that when electro-negative groups, the names of which end in *ous* and *ic*, unite with electro-positive groups to form salts, these terminations are to be changed into *ite* and *ate* respectively. It would be ill-advised to attempt on etymological grounds to change a system so firmly established as that involved in the present use of the prefixes *hypo* and *hyper*. No ambiguity can arise from the use of terms about the meaning of which every one is agreed, and their mere etymological accuracy is, in view of this all-important consideration, of secondary importance. As a metal rarely—if ever—forms more than two salifiable oxides, the *ous* and *ic* terminations generally suffice for purposes of distinction so far as the salts of metals are concerned. The practice of further employing these terminations in the case of acid-forming oxides does not lead to confusion, since these oxides are distinguished by the name *anhydride* (or *acid*). Thus we have

CrO	Cr_2O_3	CrO_3
Chromous oxide.	Chromic oxide.	Chromic anhydride. (Chromic acid.)

Indifferent oxides have frequently been classified and named by regarding them as compounds of salifiable, with acid-forming oxides, Cr_2O_4 being termed *chromic chromate.* For stages lower than *ous*, the prefixes *hypo* and *sub* are employed. Custom appears to have restricted *hypo* chiefly to acids and to acid-forming oxides, *sub* to salifiable and to indifferent oxides. With regard to the termination *ous*, the minor question arises, how far this termination ought to be written in the forms *ious* and *eous.* The answer is: as seldom as possible. "Cupreous" has generally given way to "cuprous"; no one writes "chromious" (although the name of the metal is "chromium"); and there is no reason why such names as "ruthenious" and "iridious" should not equally be shorn of their superfluous penultimate syllable. A further question, concerning which considerable difference of opinion has prevailed, is whether any *ous* or *ic* terminations ought to be employed in the names of salts of which only one class is known—thus *magnesic sulphate* instead of *magnesium sulphate.* There is something to be said here for both systems; and, as the diversity of practice does not lead to confusion, and consequently does but little harm (beyond in each case offending the ears of those accustomed to the opposite system), the question need not be regarded as a vital one. In the case of carbon compounds, however, there is a distinct advantage in affixing *ic* to the names of the positive radicals in ethereal salts. A neglect of this precaution leads to ambiguity—at all events in the *spoken* name. Thus, though there is no ambiguity in the name *ethyl phenylacetate* when written, yet the ear cannot distinguish between it and *ethylphenyl acetate.* This ambiguity is obviated by the use of the termination *ic*—thus, *ethylic phenylacetate* and *ethylphenylic acetate.* In the use of the terminations *ous* and *ic* to distinguish different series of *acids and acid-forming oxides*, with the exception of one or two isolated eases, almost perfect unanimity has prevailed. To sum up, the *ous* and *ic* terminations when employed for purposes of distinction in cases where two series of oxides, acids, salts, &c., are known, have been almost free from ambiguity, and for this reason deserve to be retained. On the other hand, in cases where only one series is known, those chemists who have employed one or other of these terminations have occasionally differed as to which ought to be used: the difficulty may be solved, as it has been done by some chemists, by avoiding the use of any termination in such cases. In complex cases where the above modes of naming prove inadequate, recourse may be had to numeral designations. These appear especially admissible in cases where an oxide occurs which is intermediate between the *ous* and the *ic* stage, and at the same time cannot be classed as a compound of oxides already classified and named. In applying numeral designations it is most important to select only such as are free from hypothesis and which afford correct information. In this respect chemists appear not to have been sufficiently careful of late years. As an example, *arsenious oxide* may be quoted; this compound is frequently termed "arsenic trioxide," the formula being written As_2O_3, and it is tacitly assumed that the molecule contains three oxygen atoms. There are three objections to this name:—(1) That, assuming the formula on which it is based to be correct, it affords no information as to the number of *arsenic* atoms associated with the *three* oxygen atoms; (2) that it involves the assumption that arsenious oxide does not vary in molecular weight, whatever its physical state; and (3) that the formula of *gaseous* arsenious oxide is As_4O_6. In employing numeral designations to indicate molecular composition in cases where this is established, it is therefore important to express the number of atoms of each constituent element, as *dicarbon hexachloride*, C_2Cl_6. But in the case of solid and liquid bodies of whichthe molecular weight is unknown, or which may vary with temperature, the name should merely indicate the relative proportions in which the constituents are associated; or, more explicitly, the name should indicate the proportion of the radical associated with what may be termed the characteristic element of the compound. No difficulty occurs in the case of the chloride, or analogous compound, of the monad elements generally, these being termed mono-, di-, tri-, tetra-, penta-, or hexa-chloride, &c., according as combination is in the proportion of 1, 2, 3, 4, 5, or 6 atoms of chlorine to 1 atom of the characteristic element. The application of this system would involve the use of the names tin dichloride and iron trichloride (not sesqui-chloride) for stannous and ferric chlorides respectively, names which accurately express the relative proportions of metal and of chlorine in these compounds without any hypothesis as to their molecular composition, which in the case of the former compound, at all events, certainly depends on temperature. It will, however, involve a slight departure from the existing practice when applied to oxides, sulphides, and other compounds of polyad elements; thus oxides of the type $(R_2)''O$ would be termed *hemi*-oxides, since they consist of the characteristic element and oxygen in the proportion of *one* atom of the former to *half* an atom of the latter. Oxides of the type $(R_2)^{vi}O_3$ would be termed *sesqui*-oxides, since the characteristic element and oxygen are present in the proportion of *one* of the former to *one and a half* of the latter. Oxides of the type R_2O_5 would be termed *sesterti*-oxides, as they contain oxygen and the characteristic element in the proportion of *two and a half* atoms of the former to *one* of the latter. Oxides of the types RO, RO_2, RO_3, and RO_4, would be termed respectively *mono-*, *di-*, *tri-*, and *tetr*-troxides.

The remainder of the report treats of the various systems which have been proposed for the naming of acid, basic, and double salts.

Report of the Committee appointed for the purpose of inquiring in to the Rate of Erosion of the Sea-Coasts of England and Wales, and the Influence of the Artificial Abstraction of Shingle or Material in that Action (*C. E. De Rance and W. Topley, Secretaries*).—The Committee has, during the past year, received several Returns relating to the south and east coasts of England. Most of those relating to the coast south of the Thames are printed. The thanks of the Committee are especially due to Major-Gen. Sir A. Clarke, who has instructed the officers of the Royal Engineers stationed around the coast to supply the Committee with such information as they may possess or be able to obtain. Further returns are expected from the same department and from other official sources; the Committee therefore think it best to defer any general Report until more complete information is obtained. The Memorandum drawn up by Mr. J. B. Redman so fully sets forth the work of the Committee, and the importance of the inquiry referred to it, that this is now printed. The Memorandum by Mr. G. Dowker, on East Kent, gives a sufficiently complete account of the changes of the coast in this district; changes which are of especial historical importance and interest. Mr. Whitaker has drawn up a list of works relating to the coast-changes of England and Wales, which will be of great service to the Committee and to those who may assist in the work. The Committee would again ask for the assistance of any who, by long residence or other means, have special knowledge of changes on any part of the English and Welsh coast. Printed forms of questions can be obtained from the secretaries or from any member of the Committee.

Third Report of the Committee, consisting of Sir J. Hooker, Dr. Günther, Mr. Howard Saunders, and Mr. Sclater (*Secretary*), *appointed for the purpose of exploring Kilima-njaro and the adjoining mountains of Equatorial Africa.*—In their last report, presented at Montreal, the Committee stated the arrangements that they had made with Mr. H. H. Johnston for undertaking an expedition to Kilima-njaro, and gave extracts from Mr. Johnston's letters showing the progress of his expedition up to May, 1884. Mr. Johnston gave an account of his expedition to the Royal Geographical Society at their meeting on January 26, 1885, in which he states that in consequence of the desertion of two natives whom he had taken out with him from Zanzibar as collectors, the collections were not so large as the Committee could have wished. Capt. Shelley prepared a report on the birds collected by Mr. Johnston, and Mr. F. D. Godman on the butterflies of his collection, after which the first sets in both these collections were handed over to the British Museum, as were also all the other zoological collections, with a request to the director that reports might be prepared for publication on such portions of them as seemed to be of sufficient interest. Reports on the zoological collections made by Mr. H. H.

Johnston have already been published in the *Proceedings* of the Zoological Society for this year. The botanical collections were handed over to the Royal Herbarium at Kew, where they were arranged, named, and a set sent to the British Museum. The report upon them is ready, and will be presented to the Linnean Society for publication. Prof. Bonney has kindly undertaken to report on the rock and mineral specimens collected by Mr. Johnston, and his report is presented herewith, and will be read in the Geological Section. Mr. H. H. Johnston has in preparation a volume containing a narrative of his expedition and a summary of the results arrived at, which will shortly be ready for issue. The sum of 25*l.* granted to the Committee at the Montreal meeting has been returned to the treasurer.

Report of the Committee, consisting of Dr. E. B. Tylor, Dr. G. M. Dawson, Gen. Sir J. H. Lefroy, Dr. Daniel Wilson, Mr. Horatio Hale, Mr. R. G. Haliburton, and Mr. George W. Bloxam (Secretary), appointed for the purpose of investigating and publishing Reports on the Physical Characters, Languages, Industrial and Social Condition of the North-Western Tribes of the Dominion of Canada.—The Committee have been in active correspondence with missionaries and others stationed among the Indians, but the unsettled state of the country during the past year has made it impossible to do more than collect materials for a preliminary report; the Committee, therefore, ask that they may be reappointed with a continuance of the grant.

Report on the Blackfoot Tribes. Drawn up by Mr. Horatio Hale.—The tribes composing the Blackfoot Confederacy, as it is commonly styled, have been until recently less known than any others. A correspondence was opened with two able and zealous missionaries residing among these Indians. The Rev. Albert Lacombe, widely and favourably known as Father Lacombe, Roman Catholic Missionary among the Siksika, or proper Blackfeet Indians, and the Rev. John McLean, Missionary of the Canadian Methodist Church to the Blood and Piegan (or Kena and Piekanè) tribes. Father Lacombe has been many years a missionary in the Canadian North-West, and has a very extensive knowledge of the tribes of that region. His elaborate work, the "Grammar and Dictionary of the Cree Language" ranks among the best contributions to American philology. Mr. McLean has been engaged in his missionary duties for five years, has prepared a grammar of the Blackfoot language, and is at present occupied in translating the Scriptures into that tongue. The unfortunate troubles of the past season have for a time interrupted the correspondence, and the principal portion of the report on these Indians will therefore have to be deferred for another year. Some other sources of information, however, have been examined, particularly the valuable official reports and maps of the Canadian and United States Indian Departments.

Fifty years ago the Blackfoot Confederacy held among the western tribes much the same position of superiority which was held two centuries ago by the Iroquois Confederacy among the Indians east of the Mississippi. The nucleus, or main body is still composed of three tribes, speaking the proper Blackfoot language: the Siksika, or Blackfeet proper; the Kena, or Blood Indians; and the Piekanè, or Piegans (pronounced Peegans), a name sometimes corrupted to "Pagan" Indians. To these are to be added the Sarcees from the north, and the Atsinas from the south. The Sarcees are an offshoot of the great Athabascan stock, which is spread over the north of British America, through Oregon and California into Northern Mexico. The Atsinas, who have been variously known as Fall Indians, Rapid Indians, and Gros Ventres, speak a dialect similar to that of the Arapohoes, who now reside in the "Indian Territory" of the United States. It is a peculiarly harsh and difficult language, and is said to be spoken only by those two tribes. None of the Atsinas are now found on Canadian territory, and no recent information has been obtained concerning them, except from the map which accompanies the United States Indian Report for 1884, and on which their name appears on the American Blackfoot Reservation. The five tribes were reckoned, fifty years ago, to comprise not less than 30,000 souls, the terror of all the western Indians on both sides of the Rocky Mountains. It was not uncommon for thirty or forty war parties to be out at once against the Salish (or Flatheads) of Oregon, the Upsarokas (or Crows) of the Missouri Plains, the Shoshonees of the far south, and the Crees of the north and east. The country which the Blackfoot tribes claimed properly as their own comprised the valleys and plains along the eastern slope of the Rocky Mountains, between the Missouri and the Saskatchewan, the favourite resort of the buffalo, whose vast herds afforded the Indians their principal means of subsistence. In the year 1836 a terrible visitation of the small-pox swept off two-thirds of the people, and five years later they were supposed to count not more than 1,500 tents, or about 10,000 souls. Their enemies were then recovering their spirits, and retaliating upon the weakened tribes the ravages which they had formerly committed.

In 1855 the United States Government humanely interfered to bring about a complete cessation of hostilities between the Blackfoot tribes and the other Indians, and framed a treaty for them, accompanying the act by a large distribution of presents. Dr. F. V. Hayden, in his account of the Indian Tribes of the Missouri Valley, states: "From my own experience among them, and from information derived from intelligent men who have spent the greater portion of their lives with them, I am convinced that they are among the most peaceable and honourable Indians in the West; and in an intellectual and moral point of view they take the highest rank among the wild tribes of the plains." This favourable opinion of Dr. Hayden is entirely in accordance with the testimony of the Indian agents and other officials of the Canadian North-West. At the present time, while constantly harassed on their reserves by the incursions of thievish Crees and other Indians, they forbear to retaliate, and honourably abide by the terms of their treaty, which binds them to leave the redress of such grievances to the Dominion authorities. Since the general peace the numbers of the Blackfeet have apparently qeen on the increase. Dr. Hayden reports the three proper Blackfeet tribes as numbering in 1855 about 7000 souls. The present population of the three Canadian Reserves is computed at about 6000, divided as follows: Blackfeet proper, 2400; Bloods, 2800; Piegans, 800. On the American Reservation there are stated to be about 2300, mostly Piegans. This would make the total population of the three tribes exceed 8000 souls. The adopted tribe, the Sarcees, have greatly diminished in numbers through the ravages of the small-pox. This tribe, now numbering less than 500 souls, have their Reserve near Calgary. They are reputed to be less cleanly and moral than the proper Blackfeet tribes. In this respect their habits and character correspond with those of other Athabascan tribes. During the past five years, as is well known, a great change has taken place in the condition of the north-western tribes through the extermination of the buffalo. The Blackfeet have been the greatest sufferers from this cause. The buffalo were their main dependence. Suddenly, almost without warning, they found themselves stripped of nearly every necessary of life. The change was one of the greatest that could well befall a community. The Governments both of the United States and of Canada came to the rescue; but in the former country the urgency of the case was not at first fully understood, and much suffering ensued. The agent on the Blackfoot Reservation in Montana (Major Allen) states in his official report that when he entered upon his duties in April 1884 he found the Indians in a deplorable condition. The supplies of food which had been sent for them had proved insufficient, and before these could be renewed many died from actual starvation. Some stripped the bark from the saplings which grew along their creeks, and ate the inner portion to stifle their sense of hunger. On the Canadian side, fortunately, the emergency was better understood. Col. McLeod, an able and vigilant officer, was in charge of the Mounted Police at that time, and through his forethought the necessary preparations were made. In 1879 and 1880 the buffalo disappeared from that region. Arrangements were at once made for settling the Indians on Reserves, and for supplying them with food and clothing, and teaching them to erect wooden houses and cultivate their lands. Daily rations of meat and flour were served out to them. Ploughs, cattle, and horses were furnished to them. Farm instructors were placed among them. The Indians displayed a remarkable readiness to adapt themselves to the new conditions. According to the reports of all the agents, they have evinced a quickness to learn and a persevering industry which place them decidedly in advance of the other Indian tribes of that region. In 1882 more than 500,000 lbs. of potatoes were raised by the three Blackfoot tribes, besides considerable quantities of oats, barley, and turnips. The Piegans had sold 1000 dollars' worth of potatoes, and had a large supply on hand. "The manner in which the Indians have worked," writes the agent, "is really astonishing, as is the interest they have taken, and are taking, in farming." Axes and other tools were distributed among them, and were put to good use. In November, 1882, log-houses had "gone up thick and fast on the Reserves, and were most creditable to the builders." In many cases the logs were hewn, and in nearly all the houses fireplaces were built. In the same year another official found comfortable dwellings, well-cultivated gardens, and good supplies of potatoes in root-houses. Most of the families had cooking stoves, for which they had sometimes paid as much as 50 dollars. He "saw many signs of civilisation, such as cups and saucers, knives and forks, coal-oil lamps, and tables; and several of the women were baking excellent bread and performing other cooking operations." Three years before these Indians were wild nomads, who lived in skin tents, hunted the buffalo, and had probably never seen a plough or an axe.

The Blackfeet have been known to the whites for about a century, and during that period have dwelt in or near their present abode. There is evidence, however, that they once lived further east than at present. The explorer Mackenzie, in 1789, found them holding the south branch of the Saskatchewan, from its source to its junction with the north branch. He speaks of four tribes—the Picaneaux, Blood, and Blackfeet. and the Fall Indians (Atsinas), which latter tribe then numbered about 700 warriors. Of the three former tribes he says: "They are a distinct people, speak a language of their own, and, I have reason to think, are travelling north-west, as well as the others just mentioned (the Atsinas); nor have I heard of any Indians with whose language that which they speak has any affinity. Mr. McLean's inquiries confirm this opinion of the westward movement of these Indians in comparatively recent times. "The former home of these people," he writes, "was in the Red River country, where, from the nature of the soil which blackened their mocassins, they were called Blackfeet." This, it should be stated, is the exact meaning of *Siksika*, from *siksinam*, black, and *ka*, the root of *oqkatsh*, foot. The meaning of the other tribal names, *Kena* and Piekanè, is unknown. This westward movement has probably been due to the pressure of the Crees, who, according to their own tradition, originally dwelt far east of the Red River, in Labrador and about Hudson's Bay. They have gradually advanced westward, pushing the prior occupants before them by the sheer force of numbers. This will explain the deadly hostility which has always existed between the Crees and the Blackfeet. M. Lacombe, however, expresses a doubt as to their former sojourn in the Red River region: "They affirm, on the contrary, that they came from the south-west, across the mountains—that is from the direction of Oregon and Washington Territory. There were" (he adds) "bloody contests between the Blackfeet and the Nez-percés, as Bancroft relates, for the right of hunting on the eastern slope of the Rocky Mountains." Mr. McLean, who mentions the former residence of the Blackfeet in the Red River country as an undoubted fact, also says: "It is supposed that the great ancestor of the Blackfeet came across the mountains." Here are two distinct and apparently conflicting traditions, each having good authority and evidence in its favour. One of the best tests of the truth of tradition is to be found in language. Mackenzie, well acquainted with the Crees and Ojibways, who speak dialects of the great Algonkin stock, recognised no connection between their speech and that of the Blackfeet. Another traveller (Umfreville), whose book was published in 1791, gave a list of forty-four words of the Blackfoot language. Albert Gallatin, whose "Synopsis of the Indian Tribes" appeared in 1836, examined this list of Umfreville, and pronounced it sufficient to show that the language of the Blackfeet was "different from any other known to us." A few years later, having received from an Indian trader a more extended vocabulary, he corrected his former statement, and showed that there was a clear affinity between the Blackfoot speech and the language of the Algonkin family. More recently the French missionaries made the same discovery. M. Lacombe writes to me: "The Blackfoot language, although far from, belongs to the same family as, the Algic, Ojibway, Santeux, Maskegon, and Cree. We discovered this analogy by studying the grammatical rules of these languages." Thus some of the ablest and most experienced of North American linguists have at first supposed the Blackfoot language to be distinct from all others, and have only discovered its connection with the Algonkin family by careful study. M. Lacombe has been good enough to send me a pretty extensive vocabulary of Blackfoot words, compared with the corresponding words in the Cree and Ojibway languages. He has added many paradigms of grammatical forms in the Blackfoot, compared with similar forms in the Cree and Ojibway tongues. The Blackfoot language is thus shown to be, in its grammar, purely Algonkin. The resemblance is complete in the minutest forms. But when we turn to the vocabulary, by which the first judgment of a language is necessarily formed, the origin of the early error becomes apparent. Many of the most common words are totally different from the corresponding words in the Algonkin languages. Others, found on careful examination radically the same as the corresponding Algonkin terms, are yet so changed and distorted that the resemblance is not at first apparent. Of this variation and distortion the numerals afford a good example. Other words in ordinary use show the total unlikeness in some cases and the distorted resemblance in others. The possessive pronoun "my" is expressed by the same prefix *ni* (or *n'*) in all three languages. Pursuing this trace we compare the personal pronouns, and find a close resemblance, the difference being mainly in the terminations. In the possessive prefixes the resemblance is still more notable. Thus in the Blackfoot language *n'otas* means "my horse, or dog" (the same word, oddly enough, applying in this form to both animals); and in Cree *n't'em* has the same meaning. These words are thus varied with the possessive pronouns and in the two numbers:—

	Blackfoot	Cree
My horse (or dog)	n'otas	n't'em
thy ,, ,,	k'otas	kit'em
his ,, ,,	otas	otema
our ,, ,,	n'otasinan	n't'eminan
your ,, ,,	k'otasinan	kitemiwaw
their ,, ,,	otasiwaw	otemiwawa
my horses (or dogs)	n'otasiks	n't'emak
thy ,, ,,	k'otasiks	kit'emak
his ,, ,,	otasiks	otema
our ,, ,,	notasinaniks	n't'eminanak
your ,, ,,	kotasiwaweks	kitemiwawok
their ,, ,,	otasiwaweks	otemiwawa

It will be seen that the close resemblance in grammar is as striking as the wide difference in the vocabulary. These facts admit of but one explanation. They are the precise phenomena to which we are accustomed in the case of mixed languages. In such languages—our English speech is a notable example—we expect the grammar to be derived entirely from one source, while the words will be drawn from two or more. Furthermore, wherever we find a mixed language we infer a conquest of one people by another. In the present instance we may well suppose that when the Blackfoot tribes were forced westward from the Red River country to the foot of the Rocky Mountains they did not find their new abode uninhabited. It is probable enough that the people whom they found in possession had come through the passes from the country west of those mountains. If these people were overcome by the Blackfeet, and their women taken as wives by the conquerors, two results would be likely to follow. In the first place, the language would become a mixed speech, in grammar purely Algonkin, but in the vocabulary largely recruited from the speech of the conquered tribe. A change in the character of the amalgamated people would also take place. The result of this change might be better inferred if we knew the characteristics of both the constituent races. But it may be said that a frequent, if not a general, result of such a mixture of races is the production of a people of superior intelligence and force of character. The circumstances thus suggested may account, not only for the peculiarities of the language and character of the Blackfeet tribes, but also for the different traditions which are found among them in regard to their origin and former abode. It would be very desirable to trace that portion of the Blackfoot vocabulary which is not of Algonkin origin to its source in the language of some other linguistic stock. The religion of these tribes (applying this term to their combined mythology and worship) resembles their language. It is in the main Algonkin, but includes some beliefs and ceremonies derived from some other source. "The primitive creation," writes M. Lacombe, "is attributed to a superior divinity, whom they call the Creator (*Apistotokin*). This divinity, however, is in some manner identified with the sun (*Natō*). The earth itself is believed to be a divinity of some kind, for, in their invocations, if they call the sun 'our father' (*Kinnon*), they call the earth 'our mother' (*Kikristonnon*). It seems also that the moon is considered to be one and the same divinity with the sun. At any rate, in the invocations it is designated by the same name, *Natōs*. Yet it is often said to be the 'old woman,' the consort of the sun. The whole of this is confused enough in the minds of the Indians to render them unable to give, when questioned, exact explanations. As to the secondary creation, the Indian account runs: At a certain time all the earth was covered with water. The 'Old Man' (*Napiw*) was in a canoe, and he thought of causing the earth to come up from the abyss. He used the aid of four animals. The musk-rat dived, and remained so long under water that when he came to the surface he was fainting, but brought a little particle of earth between the toes of his paw. This particle the 'Old Man' blew into the size of the whole earth. It took him four days to complete his work. The 'Old Man' worked two days more to make the first woman, for after the first day's work he had not succeeded in making anything graceful." This Napiw, or "Old Man," adds Father Lacombe, "appears again in many other traditions and legendary accounts, in which he is associated with the various kinds of animals, speaking to them, making use of them, and especially cheating them, and playing every kind of trick. According to the account of the Indians, the "Old Man" came from the south-west, across the mountains; and after a prolonged sojourn in these countries he went toward the north-east, where he disappeared, and nobody has heard of him since. Those who have read Schoolcraft's "Algic Researches," Mr. Leland's "Algonquin Legends," and, above all, Dr. Brinton's "Myths of the New World," will recognise in Napiw the most genuine and characteristic of all the Algonkin divinities. In every tribe of this widespread family, from Nova Scotia to Virginia, and from the Delaware to the Rocky Mountains, he reappears under various names—Manabosho, Michabo, Wetuks, Glooskap, Wisaketjack, Napiw—but everywhere with the same traits and the same history. While these beliefs are all purely Algonkin, the chief religious ceremony of the Blackfoot tribes is certainly of foreign origin. This is the famous "sun-dance." That this ceremony is not properly Algonkin is clearly shown by the fact that among the tribes of that stock, with the sole exception of the Blackfoot and a few of the western Crees, it is unknown. Neither the Ojibways of the lakes nor any of the numerous tribes east of the Mississippi had in their worship a trace of this extraordinary rite. The form of government among the Blackfeet, as among the Algonkin tribes generally, is exceedingly simple, offering a striking contrast to the elaborately complicated systems common among the nations of the Iroquois stock. Each tribe has a head-chief, and each band of which the tribe is composed has its subordinate chief; but the authority of these chiefs is little more than nominal. The office is not hereditary, the bravest or richest are commonly chosen; but in what manner the election is made is not stated. The term "confederacy" commonly applied to the union of the Blackfoot tribes is somewhat misleading. There is no regular league or constitution binding them together. "The tribes are separate," writes Mr. McLean, "and the bonds of union are the unity of religious belief, social customs, and language. They united against a common enemy, but I have never heard of their fighting against each other." Father Lacombe's account is similar. "The Blackfeet," he writes, "have no league or confederation, properly so-called, with councils and periodical reunions. They consider themselves as forming one family, whose three branches or bands are descended from three brothers. This bond of kinship is sufficient to preserve a good understanding among them." They can hardly be said to have a general name for the whole community, though they sometimes speak of themselves as *Sawketakix*, or "men of the plains," and occasionally as *Netsepoyè*, or "people who speak one language."

SECTION A.—MATHEMATICS AND PHYSICS

Discussion on the Kinetic Theory of Gases.—A most valuable and interesting discussion took place in this section on the kinetic theory. As at present applied the theory gives a much larger ratio for the specific heats of a gas than experiment allows. And the more complex a gaseous molecule becomes, the greater, according to theory, must be the ratio of its intrinsic to its translational energy. The object of the discussion was to determine whether the theoretical conclusions were legitimate, or the experimental facts incorrectly observed. It would seem that the theoretical conclusions are not correct, because they are founded upon inadmissible assumptions; and also that the facts require more thorough investigation.

Prof. Crum Brown opened the discussion upon lines already indicated in our present volume, p. 352. The ratio of the specific heat of mercury vapour at constant pressure to that at constant volume is 5/3. This gives, on the dynamical theory, only three degrees of freedom to the molecules: which must be the three translational freedoms. To prevent rotation, the molecules may be regarded as perfectly smooth, rigid, and spherical. But then the radiation cannot be accounted for. Similarly in diatomic gas the ratio is 7/5—giving three translational and two rotational freedoms; but again, not accounting for vibration of the atoms, either on the one hand, as parts of the molecules, or, on the other hand, in themselves.

Boltzmann's theorem asserts that the energy of a molecule is equally distributed amongst the different degrees of freedom. So if, in addition to the six degrees of freedom of a rigid body in space, the molecules have twenty or thirty others, it would seem that the dynamical theory must be abandoned, as there would not be sufficient energy for translational motion. The suggestion that radiation is caused not by vibration of the particles, but by disturbance of the ether due to the motion of the molecule through it, is scarcely admissible.

Difficulties again arise from the theoretical conclusion that energy of each kind is distributed among the molecules according to some form of the law of probability. For them, in a mixture of gases, we should always have some molecules in a condition favourable for combination. Also there should be no such sharp temperature and pressure limits for combination as exist—*e.g.* in the case of phosphorus and oxygen. Hydrogen and oxygen can be kept very long at a temperature near that of combination, without any chemical action occurring.

Prof. G. D. Liveing, in a paper on kinetic theory, said that the first doctrine leading to difficulties arises from assumptions, and is not a necessary part of the theory. The final distribution is the result not only of circumstances which vary, but of laws of force which are determinate. So there will be a tendency finally to limitation of the distribution of the energy in the different degrees of freedom. The dissipation of energy is the result of such laws limiting the reversibility of transmutations. Boltzmann's result will *not* follow if we consider other laws in addition to the conservation of energy. Indeed, the probability for it would be *nil*. Boltzmann also does not distinguish different kinds of motion—such as those of liquefaction, vaporisation, and dissociation. Those of translation and vibration even are often classed together. Yet the former three take place only after a certain accumulation of energy in the system; and the same may be true of the different vibrational degrees of freedom.

The constancy of the specific heats of some gases for large ranges of temperature indicates a constant *proportional* distribution of energy among the different degrees of freedom. But the proportion need not be that of equality. It is quite possible that mercury vapour at those temperatures at which its specific heat has been measured has no sensible vibrational energy. Experiments upon the emissivity of the more perfect gases show that they have, at ordinary temperatures, much less vibrational than translational energy; so that they may have only one, or, at most, two modes of vibration. The theoretical relation between the number of degrees of freedom in gases and their specific heats possibly requires revision. Still, it only limits the number of degrees sensibly exercised at the temperatures at which the specific heats were measured.

As regards the distribution of energy amongst the molecules, it is almost impossible to evade the conclusion that great differences of motion will exist, even although no particular law of distribution be assumed. Still, it is quite possible that there may be laws regulating the actions in encounters which prevent the excessive accumulation of any one kind of motion. Again, some molecules at 100° may have the average translational motion of molecules at 600°, but not that of vibration. So that very few molecules may have, at the same time, excess of motion of both kinds. Further, since this excess of energy is acquired at the expense of neighbouring molecules, the probability of there being at the same place two atoms of hydrogen and one of oxygen, in a mixture of these gases, in the average condition of those at the higher temperature, is infinitesimal. And yet again degrees of freedom exercised at the higher temperature alone may never be exercised by any molecule at the lower temperature on the average.

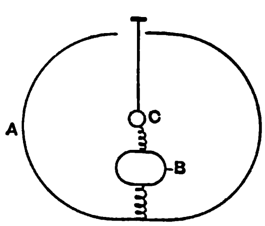
Differences of pressure in the two masses of the same gas at the same temperature are on the dynamical theory only differences of average free paths, so that it is difficult to imagine how any of the molecules in the more compressed gas can be said to be in the state, as to pressure, of the average molecules in the less dense gas. The free path of a molecule of the denser gas may at any instant be the same as the average free path of the molecules of the less dense gas; but its *average* free path will not be the same as theirs, and it is this that determines the pressure. In a system consisting of phosphorus and oxygen the possibility of chemical combination implies the possibility of an atom of phosphorus acquiring the same motion of translation, both as to speed and direction, as several atoms of oxygen, and of their jointly taking up the vibrational motions proper to an oxide of phosphorus at the temperature of the system, and that the transformations of energy involved in all this should be attended on the whole with a degradation. Since a diminution of the pressure of a gas means a degradation of its energy, this may facilitate combination when the mere fact of the molecules having instantaneous free paths of greater or less length would not suffice to produce such a result.

Sir W. Thomson remarked that Boltzmann's theorem was true in one particular case, but a proof of this case could be arrived at without the aid of the theorem, so that this does not prove the truth of the theorem. On the other hand, he had never seen any reason for believing in it at all. If we take an absolutely elastic globe and cause it to rebound between two parallel absolutely smooth and hard planes in a region where gravity does not act, it will go on moving between the two. But he does not believe that this will continue for ever. The translational energy of the ball will get transformed into energy of higher and higher modes of vibration, so that at last the ball will come to rest, as it will be impossible for this energy to be retransformed into translational energy.

Prof. J. J. Thomson said that he thought the reason that the ratio of the specific heats of a gas, as found by experiment, did not agree with the value given by Boltzmann's theorem, was because Boltzmann's theorem was not true.

Boltzmann, in his theorem about the distribution of energy in a gas the molecules of which consisted of dynamical systems with n degrees of freedom, assumed that there were no limits to the velocity which any co-ordinates could have, and therefore that the limiting velocity which any co-ordinate could have was independent of the velocity of any of the others. Now it was easy to see that in some cases there must be limits to the velocities, for, take the case of a molecule consisting of two atoms attracting each other with a force varying inversely as the square of the distance between them, then, if the relative velocity exceeded a certain value, the atoms would describe hyperbolas about their common centre of gravity, and the distance between them would increase indefinitely—in other words, the molecule would break up. Again, if we considered the case of a series of balls connected together by springs and fastened to a system which vibrated much more quickly than the natural period of vibration of the balls, then, if all the impacts fell on this system, the dynamics of the case, as investigated by Stokes and Sir William Thomson, showed that any disturbance would not be equally distributed among the balls, but that the energy in the balls would diminish in geometrical progression as we went away from the system at the end. It seemed, to say the least, rash in a case of this kind to assume that the velocity of any of the balls far away from the system was independent of those preceding it.

He had devised a molecule which it was easy to see would not obey Boltzmann's theorem. A was an envelope to the



bottom of which a feeble spring was fixed, the other end of which was attached to a heavy weight, B. To this weight a strong spring was attached, to the other end of which a light weight, C, was fixed. A rod of small mass was fastened to C, of such a length that it only extended beyond the envelope when the springs were stretched. This system would have two periods of vibration—a quick one corresponding to the upper sphere, and a slow one corresponding to the lower one. Then if all the molecules were stated, so that the amplitude of the quick vibration of C was much greater than the slow one, it was easy to see that the mean energy of the upper sphere would be greater than the mean energy of the lower ones, while, according to Boltzmann's theorem, these two quantities ought to be the same.

It might be mentioned that any co-ordinate which only entered the expression for the energy through its differential coefficient could be eliminated from the expression occurring in Boltzmann's theorem and the method applied to the remaining co-ordinates, so that, even if Boltzmann's method was unobjectionable the result need not apply to co-ordinates of this kind.

With regard to the second of the difficulties mentioned by Prof. Crum Brown, he thought that the point raised presented no difficulty if we took Williamson and Clausius's view of chemical combination. According to this view it was necessary to consider the number of molecules dissociated as well as the condition of the molecules; and though, if we took two gases at any temperature, it was true that there were a finite number of their molecules whose energy did not differ much from the mean energy of the molecules at the temperature at which these combined, yet it did not follow that a finite proportion of these were dissociated, and if there were not we could not expect them to combine. If the collision between two molecules in nearly the same condition was more efficacious in splitting up the molecules into atoms than a collision between molecules in widely different conditions, then we should not expect a finite proportion of the molecules in any state widely different from the mean to be dissociated.

Prof. W. M. Hicks said that one of the greatest objections to Boltzmann's theorem appeared to him to be the difficulty in believing that the mean energy of any vibration whatever of an atom was susceptible of unlimited increase, and referred to the case of a vortex ring inside a rigid spherical shell, where such energy could not be made to exceed a particular limit. As a matter of fact it was not proved that Boltzmann's theorem must correspond to the actual state, but only that an arrangement given by his theorem, if a possible one, was a permanent one. He stated that if the momenta could not exceed definite limits, Watson's proof could easily be modified to show that the energy was not distributed equally amongst the degrees of freedom. On the other hand, it was not permissible to assume all momenta consistent with the equation of energy as existent. As an example, the case of a system of mutually attracting spheres might be taken. Here the equation would admit of the infinite velocities due to infinitely near approach of the centres, which would in the actual case be prevented by the finite size of the spheres. Further, any particular system might possess other integrals of the equations of motion, which would introduce further limitations.

Prof. Osborne Reynolds remarked that the kinetic theory is only supposed to be true in as far as the assumptions on which it was based represented the actual circumstances. In these assumptions no account whatever was taken of any resistance to which the molecules in their motions might be subjected, other than that which arose from the mutual encounters. Whereas it was perfectly well known and certain that there must be such resistances connected with the radiation of heat—these resistances, applying only to motions of certain character, *i.e.* to the vibratory motions, whatever these may be. Neglecting these resistances, the kinetic theory points to the conclusion that the mean energy in each one of these vibratory motions would be the same as in each one of the translatory motions. In the same way, neglecting resistance, a pendulum continuously struck at varying intervals with a hammer of a given weight and moving at a given speed would possess the same mean energy whether the intervals were to be measured by years or seconds. But experience at once showed that with friction, the shorter the interval between the blows and the smaller the friction, the greater would be the mean energy of the pendulum. So, taking resistance into account, it would follow from the kinetic theory that the mean energy in the so-called degrees of freedom would be greatest in those in which the diffusion of energy was greatest and the resistance least, while it would be least in those in which the rate of communication was least and the resistance greatest. Hence, in any gas, the mean energies of translation, in which there is most rapid communication and no appreciable resistance, will be much greater than the mean energies of vibration to which there is all the resistance consequent on the radiation, and in all probability but little communication.

The same answer applies to difficulties raised as to the distribution of motion. The assumed distributions leave out of consideration all resistances, and resistance, however slight, would cut off the extreme velocities.

Mr. H. B. Dixon said that, by a series of observations made on a mixture of oxygen and hydrogen at intervals of 1000 hours, he had obtained evidence of combination at temperatures below that of dissociation.

Constant Gravitational Instruments. — Sir W. Thomson showed and explained constant gravitational instruments for measuring electric currents and potentials. In one instrument for measuring currents he employs the principle that a mass of soft iron of dimensions and shape not differing too much from a sphere, experiences, in a field of magnetic force, a pull from a place of weaker to a place of stronger force. The variation of the field is produced by variation in the dimensions of the conductor through which the current passes. In an instrument for measuring high potentials he used one pair of opposite quadrants placed vertically. The quadrants are connected to one pole of the instrument whose potential is required, and the needle, the lower end of which can be weighted, is joined to the other pole.

On the Dilatancy of Media composed of Rigid Particles in Contact, by Prof. Osborne Reynolds.—In the account which Prof. Reynolds gave of his paper, he did not submit a complete dynamical theory, but discussed a very fundamental property of granular masses. To this property he gives the name of *dilatancy*. It is exhibited in any arrangement of particles where change of bulk is dependent upon change of shape. In the case of fluid matter, as we know it, change of shape and volume are independent. In solids they are sometimes not separable. With granular masses the result is different—change of shape *always* produces change of volume. And further, in every case, if change of volume is prevented any change of form is impossible.

If we suppose the component granules to be spherical, no granule can change its position without disturbing the adjacent ones —for the granules are all supposed to be perfectly rigid, and to be absolutely in contact—and the internal particles are fixed if the external ones are. In illustration Prof. Reynolds showed a model of connected spherical bodies arranged in crystalline form. This model showed the arrangement of the particles corresponding to (say) the condition of least possible density of the whole mass (about one-half the density of the separate spheres). The shape could then be altered to that which corresponds to maximum density—the change taking place by sliding of the particles one upon another. Between the extreme states there are intermediate stages of equilibrium corresponding to maximum-minimum positions, where alteration in one direction produces decrease of density, and in the other increase of density.

In a complete treatment of the problem, friction must be closely considered; but in the experiment shown it is not of consequence, the result being independent. The above statements will be true of any continuous mass of granules if we hold the boundaries.

This principle of the dilatancy of such granular media explains many phenomena of common occurrence. For example, take a sack of corn; if set on end, it remains perfectly flexible, but if placed on its side it becomes hard, and its shape will not alter. Now take an indiarubber sack, fill it with corn—it remains perfectly flexible in all positions. The reason for this difference of behaviour is that in the former case the boundary of the granular mass is inextensible, while in the latter it allows increase of internal volume. So if it be possible with an extensible envelope, to impose a maximum volume upon the contents, effects similar to those obtained with the inextensible boundary may be expected: and this can be done. If we place some shot (No. 6 was used in the experiment) in a thin indiarubber bag, and add a certain amount of water, we obtain the result wished. For if the amount of water added be such that the spaces between the granules when in close arrangement are all filled by it, while with a wide arrangement the amount is not enough, a point will be reached in passing from the first to the second arrangement such that any further change of shape, and consequently of volume, would produce a vacuum. When this stage is reached the whole mass becomes perfectly hard. Prof. Reynolds illustrated this in a very beautiful manner by means of a ball of shot to which a glass tube open at the end was fitted. With a close arrangement of the shot, the water, which was coloured, stood high in the tube; but when pressure was applied to the bag, the level was lowered. This was shown also by the lecturer with a ball containing sand instead of shot. The water level sank till the whole was at maximum density, and, still more pressure being applied, the level again rose, the maximum having been passed. In these experiments about 6 per cent. of the water was free at the top of the ball with the close arrangement of granules. When another ball containing 20 per cent. of free water was used, the hard condition could only be approximated to by pressure, and then passed. So long as the maximum is not passed in this case the ball springs back to its original state when the pressure is released. But if the maximum be passed, it will not spring back. If some of the water be now let out, the maximum cannot be passed, except by shaking, and, if the flattened ball be then turned on edge, it will bear a pressure of a hundredweight without change of shape.

When the dilatant material, such as shot or sand, is bounded by smooth surfaces, the layer of grains adjacent to the surface is in a condition differing from that of the grains within the mass. This layer can slide between the one succeeding it and the surface, so that its displacement will cause much less dilatation than would be caused by the sliding of a layer within the mass. Hence, if two parts of the mass are connected by such a surface, certain conditions of strain may be accommodated by a streaming motion of the grains next the surface. Thus, if into a glass funnel partially filled with shot and held in a vertical position more shot be forced from below, the particles will flow up all around the sides—not rising in the centre as might have been thought.

As the foot presses upon the sand, when the falling tide leaves it firm, that portion of it immediately surrounding the foot becomes momentarily dry. When this happens the sand is filled, completely up to its surface, with water raised by capillary attraction. The pressure of the foot causes dilatation of the sand, and so more water is required. This has to be obtained either by depressing its level against the attraction or by drawing it through the interstices of the surrounding sand. As this latter requires time, for the moment the capillary forces are overcome, and the surface of the water is lowered below that of the sand, leaving it dry until a sufficient supply has been obtained from below, when it again becomes wet. On raising the foot we generally see that the sand under and around it becomes wet for a little time. This is because the sand contracts when the distorting forces are removed, and the excess of water escapes at the surface.

In referring to the results which might be expected to follow from a recognition of the property of dilatancy the author said that it places a hitherto unknown mechanical contrivance at the command of those who would explain the fundamental arrangement of the universe, and one which seems to promise great things besides possessing the inherent advantage of great simplicity. He then proceeded to explain, in a general way, how bodies in such a medium would—in virtue of the dilation caused in the medium—attract each other at a distance, with a force depending on the distance, which might well correspond with the force of gravitation. Further, owing to the existence of a region close to the body in which the density varies several times from maximum to minimum, the mutual force might undergo a change from attraction to repulsion, and this more than once as the bodies approach—a condition which seems to account for cohesion and observed molecular force far better than any previous hypothesis.

The transmission of distortional waves becomes possible if the medium be composed of small grains with large grains interspersed. The separation of two such sets of grains leads to phenomena closely resembling the phenomena of statical electricity. The susceptibility of such a medium for a state in which the two sets of grains are in conditions of opposite distortions may explain electrodynamic and magnetic phenomena, while the observed conducting power of a continuous surface for the grains of a simple dilatant medium closely resembles the conduction of electricity.

In remarking upon Prof. Reynolds's paper Sir W. Thomson pointed out an interesting question. Take a cube of spheres in the condition of maximum volume, and let every sphere touching the boundary be glued to it to prevent slipping. Other states are possible in the interior, but can we pass *continuously* to another condition, the boundary being held firm? Prof. Reynolds replied that he believed that he had got the result that it could not be done if we have a continuous medium. As other problems for solution, Sir W. Thomson suggested the theory of the hour-glass—what fixes the constant time for the sand running? and why does a substance sink deeper in a quicksand than in a viscous fluid of the same density?

On Calculating the Surface-Tensions of Liquids by means of Cylindrical Drops or Bubbles, by Prof. Pirie.—There are two methods by which the surface-tension of liquids are calculated. One involves the measurement of the height to which the liquid rises in a cylindrical tube of known diameter. The other involves the measurement of the height of a certain point of a drop of the liquid above a flat surface upon which it is placed. This point is the point of contact of the tangent plane when it becomes vertical. The former method is objectionable, because the results might be vitiated by the presence of a very small quantity of grease in the tube, or by electrification, &c. The latter, too, is not in a satisfactory state. Gay Lussac's results were in no degree different from those obtained by the ordinary method. Quincke's measurements are good, but his mathematics are misleading. To obviate the mathematical difficulties the author makes use of long drops—that is, drops obtained by placing portions of the liquid upon a concave cylindrical surface. The advantage is that the differential equation used in the calculation is immediately integrable. In remarking upon this paper Prof. Stokes said that Worthington has shown, by extending Quincke's result, that the theory agrees with experiment.

On the Surface-Tension of Water which contains a Gas dissolved in it, by Prof. Pirie.—This question is important, for no liquid is usually free from gas in solution. Prof. Pirie finds that the surface-tension is unaltered so long as the specific gravity of the water is unaffected by the dissolved gas. It is strongest in the pure liquid.

On the Thermodynamic efficiency of Thermopiles, by Lord Rayleigh.—The question has often arisen whether or not the dynamo may be replaced by an arrangement of thermopiles. There is a great difficulty due to the conduction of heat. Let t and t_0 be the temperature of the hot and cold junctions; e the electromotive force of one pair per degree Centigrade, and E the total E.M.F., hence we have

$$ne(t-t_0)=E.$$

From this equation the author obtains by means of Joule's law the expression

$$\frac{n^2e^2(t-t_0)^2}{4R_0}$$

for the useful work done externally. And again, if r_1, r_2, σ_1, σ_2, represent the specific electric resistance and the cross-sectional area of the metal bars, while l is their length,

$$R_0=nl\left(\frac{r_1}{\sigma_1}+\frac{r_2}{\sigma_2}\right).$$

To obtain the efficiency the above work must be compared with that done by the apparatus regarded as a perfect heat engine working between the same temperature. The ratio is

$$\frac{4J}{te^2}\left(\frac{r_1}{\sigma_1}+\frac{r_2}{\sigma_2}\right)\left(\frac{\sigma_1}{r'_1}+\frac{\sigma_2}{r'_2}\right).$$

where v'_1, v'_2 are the specific thermal resistances. The efficiency therefore is independent of $(t-t_0)$, of n, and of l; and also of the *absolute* values of σ_1, σ_2, r_1, r'_1, r_2, and r'_2.

Putting in numerical values for a thermopile of iron and German silver, Lord Rayleigh got 300 as the value of the above ratio. Since e^2 is involved, this number may be somewhat reduced; but high values of e are usually associated with high internal resistance. There is therefore no possibility of the thermopile becoming a useful generator of electricity on a large scale.

On Molecular Distances in Galvanic Polarisation, by Mr. J. Larmor.—Mr. Larmor's method involves the electro-chemical equivalent of the liquid used, and so differs from the two methods previously adopted. He has obtained extremely accordant results.

Cooling of Wires in Air and Vacuum, by Mr. J. T. Bottomley.—Mr. Bottomley finds that the medium has a most marked cooling effect. An electric current passed through a wire, when surrounded by air at atmospheric pressure, heated it only to 80° C. But when the air-pressure was $\frac{1}{19(10)^6}$ of an atmosphere, the wire became red hot. The temperature did not alter much until the pressure became 1-100th of an atmosphere.

An Account of Levelling Operations of the Great Trigonometrical Survey of India, by Major A. W. Baird.—This paper opened with an account of the methods formerly used in the determinations of relative height by the survey. The errors affecting these methods and the means adopted for their elimination were then pointed out. Various lines of level carried out to connect tidal stations lying north and south indicated a difference of sea-level at the stations. This difference cannot be due to false levelling of the instruments produced in consequence of the illumination of the spirit-level by the sun, for the same end of the line was not always brought out highest, and along one line no difference of level was perceptible. The discrepancy in one case amounted to three feet along the line from Bombay to Madras. The two weakest parts of this line were re-levelled, giving the same results as before. Consequently it would appear that the error is caused by local attractions influencing the instruments in greater degree than the more distant ocean.

On the Rainfall of the British Islands, by Mr. A. Buchan.—Mr. Buchan pointed out that the greatest differences in local climates arise from differences in the rainfall. For example: the mean temperatures of Skye and the Moray Firth coasts for any month are not much different, but the rainfall in Skye is about four times that at the Moray Firth. The former is one of the latest and poorest grain-producing districts in Scotland, and the latter is just the reverse. The inquiry was based on observations of rainfall made at 1080 stations in England and Wales, 547 in Scotland, and 213 in Ireland. They extend from the year 1860 to the year 1883. The regions of heaviest rainfall, giving an average of 80 inches or upwards annually, were four: Skye and a large portion of the mainland to the south-east as far as Luss, on Loch Lomond; the greater part of the Lake District; a long strip, including the more mountainous part of North Wales; and the mountainous district in the south-east of Wales. The West Highlands is the most extensive region of heavy rainfall in the British Islands. Its mountainous coast-line faces the rain-bringing winds of the Atlantic, and the air, being cooled in its passage up the lochs and valleys, the moisture is precipitated. At Glencoe, in this district, the heaviest rainfall in Scotland occurred—128·5 inches. The smallest rainfall was in a large portion of the south-east of England. The average rainfall for the last half of the period from 1860 to 1883 was comparatively high, chiefly in the eastern districts.

On a Remarkable Occurrence during the Thunderstorm of August 6, 1885, by Mr. W. H. Preece.—A house at St. Cuthbert's, ten miles from Wolverhampton, is connected with that town by telephone, and is also lighted by electricity. The dining-room was lighted by a single lamp in multiple arc with some others. The telephone wire was connected to the lightning-conductor as an earth. When the storm occurred, the dining-room lamp flashed up and went out, while a loud report was heard. The lightning-rod made bad earth, and it is believed that it had been struck, and that part of the discharge had entered the telephone circuit and then sparked across to the electric-light circuit. It did not seem to have divided, but to have passed entirely along the one branch, including the dining-room light, the platinum wire of which was volatilised and deposited on the interior of the glass, forming a good mirror.

Meteorology of Ben Nevis, by Mr. A. Buchan.—Mr. Buchan remarked that Ben Nevis possesses great advantages as a meteorological station because of its great height and its summit being only about four miles horizontally distant from a sea-level station. Also it is in the track of the Atlantic storms, which exercise so great an effect on the weather of Europe, especially in autumn and winter. The observations made on the mountain are for the purpose of determining more fully the great movements of the atmosphere and the dependence of the weather upon them. Mr. Buchan called attention to the great importance of abnormal values in the thermometric and hygrometric observations especially. The recurring periods of warmth characteristic of Ben Nevis do not occur at lower stations. The *föhn* peculiar to Switzerland occurs on Ben Nevis, and is always associated with heavy rainfall in the neighbourhood. When a cyclone prevailed at the foot of the mountain there is an anticyclone at the top, and *vice versâ*.

On some of the Laws which Regulate the Sequence of Mean Temperature and Rainfall in the Climate of London, by Dr.

Courteney Fox.—The laws enunciated in this paper are deduced empirically from observations extending over the last seventy years. Even as detached laws they are of great value; but their importance is more evident when we consider that, as the author remarks, it is from such material that the future science of meteorology must be built up by cautious induction. Given that a certain month of season is in certain condition as regards temperature or rainfall, Dr. Fox seeks to determine what may be predicted of the succeeding period as regards these qualities. He finds that, if a spring or a summer be very cold, the succeeding season will be cold; and warm autumns succeed very warm summers. The fact of a very dry August being followed by a wet September is unique. The following table shows other results obtained.

Characteristics.	Month.	Month following.
Very cold	Jan., April, June, July, Aug., Sept., Dec.	Cold
Very warm	Jan.	Dry
	June, July, Aug.,	Warm
Very dry	June, July,	Warm
Very wet	Jan., March. April,	Warm
	May, July	Cold

In addition the author records what follows when a given month has marked temperature and moisture characteristics simultaneously.

Characteristics	Month	Month following
Warm and wet	Nov., Dec.,	Wet
	Jan.,	Warm
Warm and dry	June, July,	Warm
	Aug.,	Wet
Cold and wet	July, Aug.,	Cold
Cold and dry	Dec.,	Cold
	Nov.	Dry

A very cold and very wet summer is succeeded usually by a cold autumn.

Domestic Electric Lighting, by W. H. Preece, F.R.S. Electrician G.P.O.—After referring to the full details of the lighting installation of his house in Wimbledon, given to the section at the meeting at Montreal, Mr. Preece referred generally to the experiences he had gained during the past twelve months. The secondary batteries upon which he had mainly relied exceeded his expectations in the services they rendered. They returned 70 per cent. of the energy put into them without any apparent diminution whatever in their E.M.F. They showed no signs of deterioration and gave no trouble whatever. He used his gas engine for charging only two days a week. He had experienced no fault with the wiring of his house. He had used only the very best materials, and had attended personally to the insulation of the system. It was periodically tested and found to be good. He referred in severe terms to the cheap and nasty wire which was so frequently and ignorantly used, and feared that the prejudice against the electric light would increase when failures from this cause arose. None but the very best materials should be used, and the joints should be seen to by experts. He had devoted considerable attention to the problem of distributing light, and had succeeded so far that while his rooms were beautifully illuminated the eye was not irritated by regarding a bright source of light. The lamp he used was a 50 volt 10 candle power glow lamp, and it was, as a rule, so fixed that the eye never saw it. He had arrived at the use of these lamps after careful consideration and many trials of other lamps. They secured greater safety in the leads, and involved less capital in batteries through the use of low E.M.F. He ran his lamp at an E.M.F. about 2 per cent. less than the normal E.M.F. He did this to secure long life to his lamps. The breakage had been very small. The E.M.F. and current which will give a lamp a normal life of 1,000 hours and a certain candle power should be determined by every maker. The sixth power of the current will give the candle power and the twenty-fifth power the life with any other current. The great advantage of batteries is that the proper current once determined can never be exceeded, and thus efficiency is ensured. If lamps are run too low there is a waste of power, if too high there is a waste of lamps. We are now gradually acquiring a thorough knowledge of the number of Watts which should be expended in each lamp to secure the maximum economic efficiency. He had introduced into the charging lead and into the discharging lead a Ferranti meter, so that he was able to record exactly the quantity of electricity passed through the batteries and that passed through the lamps. This beautiful meter is based on Ampere's laws which determine the attraction and repulsion of currents. A small phosphor-bronze vane is immersed in a bath of mercury, through which the current flows radially, fixed in a magnetic field. The mercury rotates and carries with it the vane. The rate of rotation varies directly with the strength of current and the number of rotations are recorded by a counter, which can be read off directly. So far he was perfectly satisfied with its performance. As regards expense, excepting the first cost, he did not find much addition to his expenditure for illumination. His electric light was costing him about 50*l*. a year for gas, wages, oil, and lamps. It was the cheapest luxury he indulged in. The great advantages were the comfort and cheerfulness it engendered, and as cheerfulness was the main element of health he thought that the electric light would prove a serious rival to the doctor. There was no one who valued health and comfort who should neglect to apply the electric light to his home, when it was brought, as it has been by the success of the secondary batteries, within his means. It was said that he, as an expert, could make things go which would fail in ordinary hands; but he mentioned several cases where coachmen, butlers, gardeners, and grooms had been found perfectly competent and intelligent enough to attend to everything.

Discussion on Standards of White Light.—This discussion was not so well sustained as the discussion on the kinetic theory. All the speakers agreed with the adoption of the pentane standard for commercial purposes. For scientific purposes a definition in terms of energy was deemed necessary. The eye cannot be used as an accurate instrument. On this point Prof. Stokes referred to the fact that if two equal areas differently coloured seem to have equally intense illumination, we have only to alter the size of the common area to destroy the apparent equality of intensity.

On Photometry with the Pentane Standard, by Mr. A. Vernon Harcourt.—Mr. Harcourt described the construction of the pentane standard light, and the method of using it for photometric purposes. In the course of his remarks he referred to the meaning of the expression "white light." Any so-called standard of white light is more nearly a standard of yellow light. He had never got a satisfactory definition of the expression, but supposed it to be such light as we have in ordinary daylight.

The Constitution of the Luminiferous Ether on the Vortex Atom Theory, by Prof. W. M. Hicks.—The simple incompressible fluid necessary on the vortex atom theory is quite incapable of transmitting vibrations similar to those of light. The author has therefore considered the possibility of transmitting waves through a medium which consists of this fluid modified so as to contain small vortex rings closely packed together. The rings are supposed to be composed of the same material as the rest of the fluid, to be very small compared with the wave-length, and to be at distances from one another also small compared with the wave-length. Their motion of translation is also taken to be so comparatively slow, that very many waves can pass over any one before it has much changed its position. Such a medium would probably act as a fluid for large motions. The vibration in the wave front may be (1) swinging, such as a ring oscillating on a diameter; (2) transversal vibration of the ring; (3) vibrations perpendicular to the plane of the rings; (4) apertural vibrations. Of these (3) seems to be impossible. If r be the radius of the rings, l the distances of their planes, w their cyclic constant, and v the velocity of translation, the author found

$$\text{For (1)} \ldots\ldots v \propto \frac{w}{l}\left(\frac{r}{l}\right)^4,$$

$$\text{For (2)} \ldots\ldots v \propto \frac{w}{l}\left(\frac{r}{l}\right)^2,$$

whilst for (4) in case of rings arranged parallel to a wave-front—

$$v \propto \frac{wr^2l^2}{(l^2 + 4r^2)^{\frac{5}{2}}}.$$

On a Photometer made with Translucent Prisms, by Mr. J. Joly.—In this photometer each side of the prism is illuminated by one of the lights to be compared, the edge being turned to the observer. The great advantage here is that the two illuminated parts are placed in sharp juxtaposition.

On a Point in the Theory of Double Refraction, by R. T. Glazebrook.—The author suggested that the theory of double refraction given by Lord Rayleigh, in which the ether is supposed to have an effective density different in different directions, might be modified so as to agree with Fresnel's theory, if it be not necessary to assume that the ether offers an infinite resistance to compression, but only that, as compared with its rigidity, its compressibility is very great, and further that in a crystal the light vibrations are normal to the ray, not to the wave normal, as was pointed out by Boussinesq and referred to by Ketteler in some of his papers.

On a New and Simple Form of Calorimeter, by Prof. W. F. Barrett.—The bulb of a thermometer is made in the shape of a double cup. In this cup is placed the substance whose specific heat (say) is to be determined. The stem of the thermometer is horizontal, and rests on a fulcrum so that the weight of the substance may be determined by using the apparatus as a balance. Special precautions are taken in determining the temperature of the substance when placed in the cup, and to prevent evaporation, &c. The specific heat is then given by the ordinary equation,

$$WS(T - \theta) = C(\theta - t),$$

the constant C being determined by experiment once for all.

Section B—Chemistry

On the Non-Existence of Gaseous Nitrogen Trioxide, by Prof. Ramsay.—After pointing out the inconclusive character of Lunge's argument in support of the existence of gaseous nitrogen trioxide, inasmuch as the use of any reagent may either decompose the gas or react with the products of its dissociation—viz. NO and $N_2O_4(NO_2)$, as though they consisted of N_2O_3 itself, the author shows the only criterion of the existence of this gas to be its vapour density. He finds that NO_2 may be mixed with NO without effecting any change in volume, and therefore no combination, or only a very slow combination, can take place between these gases. The vapour density of the first portion of the gas obtained by distilling liquid N_2O_3 is found to be 22·35, a result which accords fairly well with what the density should be, supposing it to be a mixture of N_2O_4, NO_2, and NO, having the empirical composition N_2O_3. Supposing the gas weighed to contain no N_2O_4, an assumption not warranted by facts, and consist of NO and NO_2, then, in order to make the specific gravity 22·35, 17·63 per cent. of N_2O_3 must be added to the mixture. These facts the author considers as deciding the point against the existence of gaseous nitrogen trioxide.

Observations on some Actions of a Grove's Gas Battery, by Prof. Ramsay.—The action of an ordinary Grove's gas battery can be explained by supposing that, at the point of contact between the platinum, hydrogen, and liquid, a decomposition of the water molecule takes place, its oxygen uniting with the hydrogen gas to form water, whilst the hydrogen is liberated from molecule to molecule until the free gas arrives at the point of contact of the platinum, the oxygen, and liquid; here it unites with the oxygen gas, forming water. If the liquid in the battery be coloured with indigo sulphuric acid, the author finds the indigo in contact with the hydrogen to undergo no changes, whereas that in contact with the oxygen is discoloured, a change probably due to the oxidation of the indigo to isatine. Hydrogen, therefore, in uniting with oxygen, does not bleach indigo. Now if, in the ordinary gas battery, the acid be replaced by a saturated solution of sodium chloride and hydrogen, and chlorine be substituted for hydrogen and oxygen, the indigo is found to be bleached on both sides, the bleaching taking place from above downwards, and taking place at once on admitting the chlorine, but some time is required before the reduction by the hydrogen is evident. These experiments show that when hydrogen unites with chlorine it is in a more active state than when it unites with oxygen. To explain this difference the author suggests that, when a molecule of hydrogen unites with a molecule of chlorine, atomic hydrogen exists for a moment, and this, in presence of indigo, reduces it to indigo-white. In the case of hydrogen and oxygen the union of two molecules of the former with one molecule of the latter may be effected without the hydrogen assuming the atomic condition, whereas the oxygen must assume the atomic or nascent condition, to which the bleaching of the indigo may be ascribed; or it may be that ozone or hydrogen peroxide are formed. These phenomena may, therefore, be regarded as chemical evidence corroborative of the following method of expressing the union of these gases with one another:—

$$H_2 + Cl_2 = HCl + HCl. \qquad 2H_2 + O_2 = H_2O + H_2O.$$

On the Spontaneous Polymerisation of Volatile Hydrocarbons at the Ordinary Atmospheric Temperatures, by Sir H. E. Roscoe, LL.D., F.R.S.—The attention of the author was drawn by Mr. Staveley, of West Bromwich, to a camphor-like solid, formed from the more volatile liquid hydrocarbons, produced by decomposing crude phenol at a red heat. The change from the liquid to the solid state was, at first, supposed to be due to the influence of the oxygen of the air, but investigation has shown the solid to be a hydrocarbon having the formula $C_{10}H_{12}$, and the change to be one of polymerisation. This solid hydrocarbon undergoes a further polymeric change when heated in a sealed tube at 180°. The author finds also that the first runnings of ordinary coal tar, which distil below 30°, are, on keeping in sealed tubes, converted spontaneously into this solid hydrocarbon $C_{10}H_{12}$.

On some New Vanadium Compounds, by J. T. Brierley.—The compounds described form a series of well-defined crystalline salts of purple or dark green colour, possessing a metallic lustre, which contain both the oxides V_2O_4 and V_2O_5, and may be regarded as vanadate-vanadites. These salts are formed by adding a caustic alkali to the dark green liquid formed by adding hypovanadic sulphate to a solution of an alkaline metavanadate. The composition of the sodium, potassium, and ammonium salts are represented by the following formula:— $2V_2O_4 . V_2O_5 . 2Na_2O + 13H_2O$., $2V_2O_4 . V_2O_5 2K_2O + 6H_2O$, and $4V_2O_4 . 2V_2O_5 . (NH_4)_2O + 14H_2O$.

The Essential Food of Plants, by T. Jamieson, F.C.S., F.I.C.—Whilst no doubt exists as to the essential character of the elements of carbon, hydrogen, oxygen, and nitrogen as constituents of the food of plants, the evidence in support of the elements phosphorus, potassium, magnesium, calcium, sulphur, iron, and chlorine to be regarded in this light cannot be considered conclusive. A little consideration shows the two elements, iron and chlorine, have but little claim to be considered as essential to the food of plants, and the experiments, of which an account was given in this paper, were made by the author with the view of vindicating the right of the five remaining elements to be so considered. These investigations were conducted at an experimental station in Sussex and also at one in Aberdeenshire, the nature of the soil in both cases being specially favourable. The method adopted consisted in observing the effects on plants grown in similar soil and under similar conditions, when supplied with manures, containing all these elements and comparing the results with those obtained when one or other of these elements was withheld. These experiments seem to provide proof that sulphur must be discarded from the list of essentials, while some doubt is thrown on even lime and magnesia. At the same time striking confirmation is afforded of the essential characters of both phosphorus and potassium.

A Plea for the Empiric Naming of Organic Compounds, by Prof. Odling, M.A., F.R.S.—Verbal translations of the structural formulæ assigned to organic compounds possess certain advantages as names for the several compounds. Thus, they are applicable to all organic compounds of which the structural formulæ are made out; they are the only sort of names applicable to complex isomeric compounds; and their use cannot be dispensed with wholly in the case of even less complex compounds. Notwithstanding these advantages, structural names constitute unsuitable names for general use, more especially as applied to fundamental hydrocarbons, alcohols, and acids. They are objectionable for this use by reason of their length, complexity, and want of ready indicativeness; by the circumstance of their being based on conceptions of chemical constitution of a kind pointed out by experience as eminently liable to change; and by the further circumstance of their representing a one-sided and, so far, an untruthful notion of the bodies designated. Structural names, expressing other than a distorted view of the constitution of all but a few of the most simple of organic bodies, are impracticable by reason of their length and complexity. Hence, to avoid the distortion inseparable from the use of any single structural name for an organic body, the only expedient is the assignment to each body, in proportion to its complexity, of an indefinite number of structural names, a proceeding almost tantamount to not assigning it any particular name at all. Although from their number and complexity, organic bodies can only be designated by names which do in some measure describe and characterise them, the primary purpose of a name is undoubtedly to designate, and not to describe. Accordingly, with a view to the prompt mental association of object with name, brief empiric names, based on the origin and properties of bodies, are, wherever practicable, to be preferred to structural names. As regards isomeric bodies, they may to a large extent be advantageously distinguished from one another by means of significant letters or syllables prefixed to the name common to the different isomers. But the suggested use of the particular letters α, β, γ, each in a special sense; also a general resort to the particles hydro-, oxi-, and hydroxi- as name-components; and, more especially, the innovation of substituting the word "hydroxide" for the long-established word "hydrate" are practices open to grave objection.

The Periodic Law, as illustrated by certain Physical Properties of Organic Compounds, by Prof. Thos. Carnelley, D.Sc.—In this paper the author shows that the physical properties of the normal halogen and alkyl compounds of the hydrocarbon radicals exhibit numerous relationships, which, with one exception, are similar to those which he has shown to exist between the normal halogen or the alkyl compounds of the elements. It appears that the physical properties of the following four classes of compounds obey the same rules:—(1) The halogen compounds of the elements—*i.e.* of elements with elements. (2) The alkyl compounds of the elements. (3) The halogen compounds of the hydrocarbon radicals. (4) The alkyl compounds of the hydrocarbon radicals—*i.e.* of hydrocarbon radicals with hydrocarbon radicals. The relationships referred to have been tested in no less than 6117 cases, 5 per cent. only of which are exceptions.

Suggestions as to the Cause of the Periodic Law, and the Nature of the Chemical Elements, by Prof. Thos. Carnelley, D.Sc.—The truth of the periodic law of the chemical elements is now generally allowed by most chemists. Nevertheless, but little has been done towards attaining a reasonable explanation of the law. The object of this paper, therefore, is to offer a few suggestions on this subject. Granting the truth of the periodic law, we cannot help theorising as to its cause, and thence by a natural step as to the nature of the elements themselves. Even long before the discovery of the law many chemists had pointed out certain numerical relationships existing between the atomic weights of bodies belonging to a given group, and had hence supposed that the elements belonging to the several natural groups were not primary, but were made up of two or more simpler elements. These conclusions, however, were more or less fragmentary, and referred only to particular groups of elements. In the light of the periodic law the author has made a general extension of the fragmentary conclusions of Dumas, and has brought that law into juxtaposition with an extended generalisation of the analogy of the elements with the hydrocarbon radicals. His conclusions are based on the relationships which he has observed to obtain between certain physical properties and the atomic weights of the elements, and those of their compounds (see previous paper). A careful consideration of the points submitted leads almost irresistibly to the conclusion that the elements are analogous to the hydrocarbon radicals in both form and function. This is a conclusion which, if true, would further lead us to infer that the elements are not elements in the strict sense of the term, but are built up of (at least) two primary elements, A (= carbon at. wt. 12), and B (ether at. wt. −2), which by their combination produce a series of compounds (viz. our present elements), which are analogous to the hydrocarbon radicals. If the above theory of the constitution of the elements be true, the periodic law would follow as a matter of course, and we should therefore be able to represent the elements by some such general formula as $A_n B_{2n+(2-x)}$, analogous to that for the hydrocarbon radicals, $C_n H_{2n+(2-x)}$, in which n = the series, and x the group to which the element or hydrocarbon radical belongs.[1] Assuming the truth of the theory here advanced, it is interesting to observe, that whereas the hydrocarbons are compounds of carbon and hydrogen, the chemical elements would be compounds of carbon with ether, the two sets of bodies being generated in an exactly analogous manner from their respective elements. There would hence be three primitive elements—viz., carbon, hydrogen, and ether. Finally, it may be stated that this theory would remove the chief objections which have been urged against the periodic law, whilst the existence of elements of identical atomic weights and isomeric with one another would be possible. May not Ni and Co, Ru and Rh, Os and Ir, and some of the rare earth metals be isomers in this sense?

The Value of the Refraction Goniometer in Chemical Work, by Dr. J. H. Gladstone, F.R.S.—The principal points illustrated and enforced in this communication were (1) that the index of refraction and length of spectrum are important physical properties of any substance; (2) the specific refraction and specific dispersion may be serviceable: (*a*) in determining the purity of a substance, (*b*) in the analysis of such a mixture as ethyl and methyl alcohols, (*c*) as a guide in the investigation of organic compounds, (*d*) as arbiter between rival views as to the constitution and structure of particular chemical compounds.

Refraction of Fluorine, by G. Gladstone.—From a comparison of the observations on fluorspar, cryolite, and several artificial fluorine compounds, the author shows the refraction equivalent of fluorine to range from 0·3 to 0·8, the mean of the whole series of determination being 0·6. Thus, taking the highest estimate, the specific refraction of this element is scarcely equal to half that of any other substance.

Note on the Conditions of the Development and of the Activity of Chlorophyll, by Prof. Gilbert, LL.D., F.R.S.—An account of some experiments made in conjunction with Dr. W. J. Russell, which show a close connection to exist between the formation of chlorophyll and the amount of nitrogen assimilated by plants; the amount of carbon assimilated is not, however, in proportion to the chlorophyll formed, unless a sufficiency of mineral substances, required by the plants, is available. In cases where both nitrogenous and mineral manures were applied a lower proportion of nitrogen assimilated and chlorophyll formed over a given area was observed, which is no doubt due to the greater assimilation of carbon and consequent greater formation of non-nitrogenous substances, although the amounts of nitrogen assimilated and chlorophyll formed were as great, if not greater.

On the Action of Sodium Alcoholates on Fumaric and Maleic Ethers, by Prof. Pardie, Ph.D., B.Sc.—By the action of *sodium methylate* on *ethylic fumarate*, *methylic methoxysuccinate* is formed, from which *methoxysuccinic acid* can be obtained, a crystalline solid melting at 101°–103°; this same acid is obtained from the products of the reaction of sodium methylate on *ethylic maleate* or *hydric methylic maleate*. Similarly an *ethoxysuccinic acid* is obtained by the action of sodium ethylate on *ethylic fumarate*, also by its action on *hydric ethylic maleate*. Thus fumaric and maleic acids yield alkyloxy-succinic acids, which are identical with one another, or, if not identical, resemble one another so closely that their isomerism must be of the same character as that of substances which differ from one another only in their optical and crystallographic characters.

On Sulphine Salts derived from Ethylene Sulphide, by Orme Masson, M.A., D.Sc. (Edin.).—Ethylene sulphide, when heated at 160°, is converted into diethylene sulphide $S(C_2H_4)_2S$, an ethereal solution of which, when mixed with methyl iodide, unites with the latter to form *diethylene sulphide methyl sulphine iodide* $S(C_2H_4)_2S.CH_3I$, which is a crystalline compound soluble in water, but insoluble in alcohol or ether. From this compound a series of the *sulphine* salts have been prepared, which resemble the salts of trimethyl sulphine in their behaviour when heated, but differing from these compounds in the ease with which they are decomposed by caustic alkalis with the formation of *diethylene sulphide methyl sulphine hydroxide* $(C_2H_4)_2S_2CH_3OH$. The compounds obtained by Dehn (*Annalen*, Supp. iv. 83) by heating together ethyl sulphide, ethylene bromide, and water together in sealed tubes, and styled "sulphinic salts" by him, were, in all probability, dimethylene sulphine-methyl-sulphine derivatives.

On an apparently new Hydrocarbon from Distilled Japanese Petroleum, by Dr. Divers and T. Nakamura.—A description of a yellow solid hydrocarbon found amongst the final products of the distillation of the petroleum from the wells at Sagara. The hydrocarbon melts at 280°-285°, and has a composition expressed by the formula $(C_4H_3)_n$.

The Composition of Water by Volume, by Dr. A. Scott, M.A., D.Sc.—After pointing out the desirability of renewed determinations of the exact proportions in which hydrogen and oxygen combine with one another, inasmuch as neither of these

[1] Cf. Abney's researches on the infra-red absorption spectra of carbon compounds (*Proc.* Roy. Soc., 31, 416), also the article on the Decomposition of Didymium by Welsbach in NATURE, vol. xxvii. p 435.

gases obey Boyle's law exactly, the author gave a description of the apparatus he had employed in making such determinations, which allowed the use of considerable volumes of these gases. The results obtained show the ratio not to be exactly that of 1 vol. of oxygen to 2 vols. of hydrogen ; but the proportions are 1 : 1·994 or 1 : 1·9935 ; or, if the impurity be supposed to exist in the oxygen alone, then the ratio is 1 : 1·996. The gases were examined as to their purity, the results indicating the presence of ·2 c.c. to ·3 c.c. of foreign gas in the 450 c.c. used.

In a communication entitled *On Solutions of Ozone and the Chemical Action of Liquid Oxygen*, Prof. Dewar gave a description of the apparatus and method employed by him in the liquefaction of such gases as oxygen, &c., and after discussing the conditions required for the successful conversion into the liquid state of the so-called permanent gases, he gave an account of some experiments made with liquid oxygen. At – 130° liquid oxygen loses the active characters possessed by this element in the gaseous state ; it is without action on phosphorus, sodium, potassium, solid sulphuretted hydrogen, and solid hydriodic acid. Other substances appear to undergo similar changes at very low temperatures ; thus liquid ethylene and solid bromine may be brought in contact without any action taking place, whereas gaseous ethylene and liquid bromine unite directly at the ordinary temperatures. Hautefeuille and Chapuis by subjecting a mixture of carbonic anhydride and ozone to great pressure obtained a blue liquid, the colour of which is due to the ozone. If ozonised air be passed into carbon disulphide at – 100°, the liquid assumes a blue colour, which disappears if the temperature be allowed to rise, and at a certain point a decomposition, resulting in the production of sulphur, takes place. The best solvent for ozone is a mixture of silicon tetrafluoride and Russian petroleum. These solutions of ozone are without action on metallic mercury or silver. Prof. Dewar, in remarking on the liquefaction of nitric oxide, stated that a comparison of its curve of liquefaction with that of methane shows the pressure to increase more rapidly with the temperature in the case of nitric oxide than in other gases, a fact which would appear to indicate, that at low temperatures the molecule of nitric oxide is of greater complexity, and probably exists as N_2O_2. An account was given of some of Cailletet's experiments on the electrical conductivity at low temperatures, which seemed to indicate that as the limit – 220° was approached ordinary electrical conductors become almost perfect conductors.

On the use of Sodium or other Soluble Aluminates for Softening and Purifying Hard and Impure Water, and Deodorising and Precipitating Sewage, Waste Water from Factories, &c., by F. Maxwell Lyte, F.C.S., F.I.C.—The advantages attending the use of sodium or other soluble aluminates for the above purposes are dependent upon their easy decomposition with the production of a precipitate of hydrated alumina, which removes organic matter, and further by their use the temporary hardness may be completely destroyed, and the permanent hardness reduced.

Some New Crystallised Combinations of Copper, Zinc, and Iron Sulphates, by J. Spiller, F.C.S.—The author gave an account of the preparation of a large series of double sulphates of copper and iron, zinc and iron, and copper and zinc.

In a communication on *Barium Sulphate as a Cementing Material for Sandstone* Prof. Clowes pointed out that, although Bischof mentioned instances of foreign sandstones in which the material cementing the sand grains together was barium sulphate, it appeared that up to the present time no such sandstone had been met with in the United Kingdom. Having learned that opinions differed regarding the calcareous nature of certain new red sandstone beds in the neighbourhood of Nottingham, he undertook to examine the chemical composition of these sandstones, and procured specimens of the sandstone from different levels. On being analysed, the sandstone was found to contain barium sulphate in varying proportions, at present being determined, while some of the lower beds also contained calcium carbonate. In some of the sandstone beds the barium sulphate was very unequally distributed, forming a network or a series of small masses more or less spherical in shape. In such sandstone the sand grains between the sulphate streaks and patches were quite loose, the result being that the weathered surface presented a honeycombed appearance. To explain the presence of the barium sulphate he suggested that it might have been deposited along with the sand ; but if such had been the case it had certainly undergone a physical change, as it now existed in a firm, compact, and crystalline condition. It would, therefore, appear that it had been either deposited from aqueous solution or that it had been rendered crystalline by a slow percolation of a solvent liquid through the sedimentary deposit, or owed its origin to the action of water containing calcium sulphate passing through sandstone cemented originally with barium carbonate.

NOTES

BOTANISTS will learn with very great regret of the death of Mr. Edmond Boissier, the learned and indefatigable author of the "Flora Orientalis," and many other important works on Systematic Botany. We have received no particulars, but we imagine his death must have been somewhat sudden, for the event was quite unexpected by his friends in this country. As recently as the month of August Prof. Oliver heard from him, the communication relating to the Supplements to the "Flora Orientalis," on which the deceased botanist has been for some time engaged, and in which he wished to incorporate the botanical results of Dr. Aitchison's latest investigations in Afghanistan. Boissier's career as a botanist may be said to have commenced with his travels in Spain in 1837, when he collected the materials published in his "Voyage Botanique dans l'Espagne," a richly illustrated work which appeared at intervals from 1839 to 1845. He subsequently travelled and botanically explored various parts of South-eastern Europe and Asia Minor. Independently of his larger works he published, separately, diagnoses of the exceedingly large number of undescribed species he found from within the limits of his "Flora Orientalis," the first volume of which appeared in 1867, and the last in 1881. This work alone is sufficient to place the author in the first rank of a school of distinguished systematists, now alas fast disappearing without leaving a corresponding rising generation to take up the work where they have left it. Like the late Mr. Bentham, M. Boissier was in a position to give his undivided attention to the science he had chosen, and like him he laboured unceasingly; and it is to be hoped that the supplement to the "Flora Orientalis" is in a sufficiently forward state for publication. Among other things the vast genus *Euphorbia* furnished materials for several valuable works, including a monograph of all the species, and a folio volume containing figures of 120 species. Mr. Edmond Boissier was a Foreign Member of the Linnean Society, having been elected in 1860: and from his constant readiness to give others the benefit of his extensive knowledge, he enjoyed the esteem and admiration of a wide circle of botanists.

THE death is announced, at the age of seventy-eight years, of Mr. John Muirhead, one of the very few survivors of the early days of telegraphy, and closely connected with its practical development. Mr. Muirhead, in conjunction with Mr. Latimer Clark and Mr. W. M. Warden, of Birmingham, founded the house now known as Latimer Clark, Muirhead, and Co., more than a quarter of a century ago. It was from this manufactory that Mr. Muirhead introduced the form of battery which bears his name, a form so eminently portable and practical that it has become the model for most of the existing batteries, while continuing itself to be largely employed.

A *Times* telegram dated Philadelphia, September 27, states that the President of the United States has asked Prof. Alexander Agassiz to accept the post of Superintendent of the Coast Survey.

A REMARKABLE memoir on the development of the sternum in birds, prepared by Miss Beatrice Lindsay, of Girton College, and communicated to the Zoological Society of London by Dr. H. Gadow at their meeting on June 16 last, will appear in the forthcoming number of the Society's *Proceedings*. Miss Lindsay, after close investigation of the embryonic condition of different stages in five types of bird-structure (the ostrich, guillemot, gull, domestic fowl, and gannet), has come to the conclusion that the keel of carinate birds is a special outgrowth of the true sternum peculiar to birds, and is not homologous with the episternum or interclavicle of reptiles, as has been held by Götte and others. There are no traces whatever in the embryonic stages of the ostrich, according to Miss Lindsay's observations, of the existence of any rudiments of the clavicles or keel. It follows that the view held by some morphologists that the ostrich may be a degraded descendant of some carinate form can no longer be supported.

THE Edinburgh International Industrial Exhibition will be opened on May 4 next.

A CORRESPONDENT of the *Times* in a recent article on the new Electorate, describes the fishermen at Staiths, a village on the Yorkshire coast, lying between Whitby and Saltburn. The people, he says, are imbued with all manner of quaint superstitions. They have a firm belief in witchcraft, the witch being wholly unconscious of his or her power of evil. Until recently—and it is said that the custom is still secretly maintained by some of the older inhabitants—it was customary, when a smack or coble had had a protracted run of ill-fortune, for the wives of the crew and owners of the boat to assemble at midnight, and, in deep silence, to slay a pigeon, whose heart they extracted, stuck full of pins, and burned over a charcoal fire. While this operation was in process the unconscious witch would come to the door, dragged thither unwittingly by the irresistible potency of the charm, and the conspirators would then make her some propitiatory present. Again, it is of frequent occurrence that, after having caught nothing for many nights, the fishermen keep the first fish that comes into the boat and burn it on their return home as a sacrifice to the Fates. All four-footed animals are considered by the Staiths folk as unlucky, but the pig is the most ill-omened of quadrupeds. If when the men are putting their nets into the boats the name of pig is by accident mentioned, they will always desist from their task and turn to some other occupation, hoping thus to avert the evil omen, and in many cases will renounce the day's expedition altogether. The sight of a drowned dog or kitten, too, as he goes towards his coble will always keep a Staiths fisherman at home; and, what is still more curious, if as he walks to his boat, his lines on his head or a bundle of nets on his shoulder, he chances to meet face to face with a woman, be she even his own wife or daughter, he considers himself doomed to ill-luck. Thus, when a woman sees a man approaching her under these circumstances she at once turns her back on him. If a fisher sends his son to fetch his big sea boots, the bearer must be careful to carry them under his arm. Should he by inadvertence place them on his shoulder his father will inevitably refuse to put out to sea that day. An egg is deemed so unlucky that the fishermen will not even use the word, but call it a roundabout; and, fearless as are the fishers in their daily struggling with the dangers of the sea, yet so fearful are they of nameless spirits and bogies that the writer was assured he could not find in the whole fishing colony of Staiths a volunteer who for a couple of sovereigns would walk by night to the neighbouring village, a couple of miles distant.

WE have received the report of Miss Pogson, the meteorological reporter to the Government of Madras, for the year 1884-85. It contains remarks on the various stations scattered over the Presidency, together with the usual tables. Part of the observer's work is to train learners, who afterwards take charge of the local stations. One of these, it is interesting to notice, is on the Laccadives, which islands are inaccessible during a great part of the year. The assistants in most cases are native officials.

ALL the legal steps have been taken by the French Government for entering into possession of the late M. Giffard's fortune, which is to be devoted to the good of science. The fortune is valued at 200,000*l.*, after paying about 100,000*l.* in legacies to friends, family, or scientific societies. The decree is ready and will shortly appear in the *Journal Officiel*. Several projects have been proposed already for utilising this large sum of money, but it is very likely nothing will be done before taking the advice of the French Academy of Sciences.

ON September 12, just after sunset, a remarkable mirage was seen at Valla, in the province of Sudermania, Sweden. It appeared first as a great cloud-bank, stretching from south-west to north, which gradually separated, each cloud having the appearance of a monitor. In the course of five minutes one had changed to a great whale blowing a column of water into the air, and the other to a crocodile. From time to time the clouds took the appearance of various animals, and finally that of a small wood. Subsequently they changed to a pavilion, where people were dancing, the players being also clearly visible. Once again the spectacle changed, now into a lovely wooded island with buildings and parks. At about nine o'clock the clouds had disappeared, leaving the sky perfectly clear. The air was calm at the time of the display, the temperature being 6° C.

THE aquarium at the Inventions Exhibition has lately been entirely restocked, the latest arrivals being a fine selection of bass weighing 10 lbs., some large specimens of Crustaceans, and an assortment of flat-fish of all descriptions. There is also on view a diversified collection of foreign freshwater fish presented by the General Import Company.

CAPT. VIPAN'S aquarium of foreign fishes at Stibbington Hall, Wansford, is a most valuable one, and includes unique and rare specimens of fish from all parts of the world, which are retained with the utmost care, the temperature of the water being regulated to suit the natural necessities of the various fish. This aquarium is considered to be one of the most unique in the United Kingdom, and increases in value annually on account of periodical additions to the collection.

THE taxidermist who has had charge of the work upon the body of "Jumbo," who was recently crushed between two trains, states that the elephant's stomach contained many English coins—gold as well as silver and bronze. His tusks had by the collision with the train been driven nearly through the skull. According to later accounts as to the accident, Jumbo at the last moment faced and charged the locomotive. The elephant's skin was found to be an inch and a half thick, and it weighed 1537 lbs. The skeleton weighs 2400 lbs., and the total weight of the body was over 6 tons.

MESSRS. SWAN SONNENSCHEIN AND CO. announce, for the season 1885-6, the following publications:—"A Treatise on Animal Biology," by Prof. Adam Sedgwick, Fellow and Lect. of Trin. Coll., Camb. (illustrated); "Practical Botany," by Prof. Hillhouse, of Mason Coll., Birm., based upon the work of Prof. Strasburger (largely illustrated); a translation of Profs. Nægeli and Schwendener's work, "The Microscope in Theory and Practice," with several hundred woodcuts; an "Alpine Flora," a pocket handbook for botanists and travellers, by Mr. A. W. Bennett, B.Sc., M.A.; an illustrated "Handbook of Mosses," by Mr. J. E. Bagnall; a "Star Atlas," by the Rev. T. H. Espin; further parts of Mr. Howard Hinton's "Scientific Romances"; an entirely new and partly re-written edition of Prof. Prantl and Vines's "Text-Book of Botany"; "From Paris to Pekin over Siberian Snows," an account of the Asiatic wanderings of M. Meignan, by Mr. William Conn; "The Wanderings of Plants and Animals," an adaptation from the German work of Prof. Victor Hehn, by Mr. James Stallybrass, tracing (chiefly by means of etymology) the history and the migration of European plants and animals to their home in Asia.

MESSRS. CROSBY LOCKWOOD AND CO. make the following announcements for the approaching publishing season:—"Electro-Deposition," by Alexander Watt, author of "Electro-Metallurgy"; "The Prospector's Handbook, a Guide for the Prospector and Traveller in Search of Metal-bearing or other valuable Minerals," by J. W. Anderson, M.A., F.R.G.S.; "The Engineman's Companion, a Practical Educator for Enginemen, Boiler Attendants, and Mechanics," by Michael Reynolds; "The Combined Number and Weight Calculator," by Wm. Chadwick, Public Accountant; "Our Temperaments, their Study and their Teaching, a Popular Outline," with illustrations, by F.R.C.S.E.; "The Artist's Tables of Pigments," by H. C. Standage; "Land and Marine Surveying," by W. Davis Haskoll (entirely new edition); "The Metal Turner's Handbook, a Practical Manual for Workers at the Foot Lathe," by Paul N. Hasluck (second edition, revised), being the first volume of a new series of "Handbooks on Handicrafts."

THE "Sun" Knife-cleaner has some points which deserve notice. It is supported on a light cast-iron standard, the upper portion of which is bored out and faced to make the bearing where alone perfect fit is required. A cast-iron spindle is fitted into this bearing, and supports upon a flattened face two spring disks made of cast steel finely tempered, dished in the centre and having rays upon them like the spokes of a wheel, which turn slightly outwards at their ends, so as to form a tapered space adapted to the wedge form of the length of the knife. These springs are so mounted upon the spindle that the rays of the one are opposite to the space, between the rays of the other. The spindle is terminated by a screw upon which a thumb nut is fixed to hold the handle in position and keep the working parts together. By means of this screw the springs can be pressed more or less closely together as required. Leather rings are riveted to the inner faces of the springs, and form the surfaces upon which the knives are cleaned and polished; the rivets are in the dished portion of the springs and so out of the way of the knife-blade; the polishing powder is supplied through a hole in the face of the front spring. The knife whilst being cleaned is supported below a wrought-iron piece cast into the standard and passed in and out of the machine. The difficulty in cleaning a knife is due to its double wedge form. A knife is a long wedge from the tip to the shoulder, and a short wedge from the edge to the back, and it is evident that the pressure brought to bear upon it must be of an elastic character, so as not to grind the knife away. As regards the length of the knife this is effected by the outward taper of the rays of the springs. The two leather rings between which the blade is passed in and out being pressed against the blade of the knife by the rays of the springs as described, it is evident that there is an elastic pressure upon it; the spring on the one side diminishes in its bearing pressure, as that on the other side increases, and hence an equable pressure is applied to all parts of the blade, as is proved by the excellent polish produced. A small portion of powder being supplied through the hole in the front spring, the knife is placed with its edge downwards below the wrought-iron support and passed slowly in and out of the machine between the leather disks with the left hand, whilst the right hand is employed in turning the handle of the machine in the direction of the hands of a clock. In this way from one inch to two inches in depth of the surface of each leather (depending upon the size of the machine) presses elastically upon the blade. This being the reatest frictional resistance at any moment between the blade nd the polishing surfaces, the labour of cleaning is reduced to a minimum, while the knife can be polished to the shoulder owing to the leathers being bevelled. Special to ls have been designed for cutting and bending the wrought-iron supports in one operation, for cutting and bevelling the leathers, and riveting and fitting them to the springs. These machines are supplied in four sizes.

IN contrast to the weather in Southern Norway during May and June (NATURE, vol. xxxii. p. 354) the weather of July was warmer and more normal, the mean temperature of the month—viz. 17·1° C. being 0·5° above the normal, 16·6°. This is chiefly due to the southern winds prevalling in the first part of the month. On July 21, however, the weather changed, northern and north-western winds prevailing, with clear and dry air, and in consequence of the great radiation, the temperature fell several times very low during the second part of the month. The minimum temperature—viz. 6·4° C.—was registered at Christiania on the night of the 22nd., and the highest—viz. 29° C.—on the 6th. The rainfall was 40 per cent. below the normal. With the exception of the coast towards the Naze, the month has been cold throughout the land on the whole, the most unfavourable parts being the west coast, where the temperature was 1° C. below the normal mean. In the mountains and in East Finmarken it sank several times below 0°. The rainfall in the southern and eastern parts was below the average, but in th northern and north-western parts it was above it. The greatest rainfall was registered in Finmarken, where, in Alten, for instance, it was 142 per cent. above the average.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Mrs. Paterson; a Humboldt's Lagothrix (*Lagothrix humboldti*) from the Upper Amazons, presented by Mr. F. J. Hammond; two Macaque Monkeys (*Macacus cynomolgus*) from India, presented respectively by Mr. F. Debenham and Miss Lucy McArthur; two West Indian Agoutis (*Dasyprocta cristata*), seven Crab-eating Opossums (*Didelphys cancrivora*), two Rough Terrapins (*Clemmys punctularia*), two Brazilian Tortoises (*Testudo tabulata*), two Teguexin Lizards (*Teius teguexin*), two Tuberculated Iguanas (*Iguana tuberculata*), nine Giant Toads (*Bufo aqua*) from Trinidad, presented by Mr. F. J. Guy; two Palm Squirrels (*Sciurus palmarum*) from India, presented by Mr. A. Bellamy; a Great Kangaroo (*Macropus giganteus* ♂), a Rufous Rat Kangaroo (*Hypsiprymnus rufescens*) from New South Wales, a Roan Kangaroo (*Macropus erubescens* ♀) from South Australia, presented by Mr. C. Czarnikow, F.Z.S.; a Common Crossbill (*Loxia curvirostra*), British, presented by Mr. H. S. Eyre; a Green Lizard (*Lacerta viridis*) from Jersey, presented by Mr. G. V. Colliver; a Guinea Baboon (*Cynocephalus sphinx*) from West Africa, two Bonnet Monkeys (*Macacus sinicus*) from India, two Ælian's Wart Hogs (*Phacochærus africanus* ♂ ♂) from Africa, deposited; a Garnett's Galago (*Galago garnetti*) from East Africa, a Harnessed Antelope (*Tragelaphus scriptus* ♀), an Elate Hornbill (*Ceratogymna elata*) from West Africa, a Puff Adder (*Vipera arietans*) from South Africa, a Lacertine Snake (*Cœlopeltis lacertina*), European, an Aldrovandi's Lizard (*Plestiodon auratus*) from North-West Africa, purchased; a Leopard (*Felis pardus*), born in the Gardens.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, OCTOBER 4-10

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on October 4

Sun rises, 6h. 8m.; souths, 11h. 48m. 37·5s.; sets, 17h. 29m.; decl. on meridian, 4° 31′ S.: Sidereal Time at Sunset, 18h. 29m.

Moon (New on October 8) rises, 1h. 10m.; souths, 8h. 31m.; sets, 15h. 41m.; decl. on meridian, 12° 2′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	5 10	11 18	17 26	0 43 N.
Venus	9 55	14 17	18 39	19 4 S.
Mars	0 15	8 0	15 45	18 47 N.
Jupiter	4 13	10 38	17 3	4 12 N.
Saturn	21 35*	5 43	13 51	22 18 N.

* Indicates that the rising is that of the preceding day.

Oct.	h.	
6	17	Jupiter in conjunction with and 1° 25′ north of the Moon.
7	20	Mercury in conjunction with and 0° 29′ north of the Moon.

HEREDITY

At the February meeting of the Swedish Anthropological Society Prof. Wittrock read a paper on the hereditability of colour of the eyes. The speaker had been requested by Prof. Alphonse De Candolle, of Geneva, to make observations on this point, which, together with those made in Switzerland, North Germany, and Belgium, had formed the material for M. De Candolle's paper, "Hérédité de la couleur des yeux dans l'espèce humaine" (*Archives des Sciences Physiques et Naturelles*, 3e période, t. xii., Genève, 1884). From the same the remarkable fact was derived that brown eyes were more common in men than women; of the individuals examined 41·6 per cent. of men and 44·2 per cent. of women had brown eyes. Further, in families where the parents had the same colour of eyes 80 per cent. of the children of parents with brown eyes had brown eyes, whilst of children of parents with blue eyes 93·6 per cent. of them had eyes of that colour. The unconformity was no doubt due to atavisme or the hereditary influence of ancestors. Of the children of parents of whom the father had brown and the mother blue eyes 53·3 per cent. had brown, whilst where the reverse was the case 55·9 per cent. had blue eyes. As the percentage of brown-eyed children of parents with bi-coloured eyes was highest, it seemed as if brown eyes were always on the increase to the detriment of blue ones. It appeared also from these researches that women with brown eyes have better prospects of marrying than those with blue. 52 per cent. of the married women had brown eyes, and only 48 per cent. of them blue—a circumstance which is the more remarkable as the number of women with brown eyes in Italian Switzerland is only 44 per cent. Another remarkable discovery was that the average number of children of parents with eyes similar in colour was 2·7, whilst that of those with different colour was 3·18, which was an additional proof of the fact that children of parents with similar organisation were as a rule of weak constitution. Comparing the colour of the eyes of the children where the parents were bi-coloured, with those of each of the latter, it was discovered that the eyes of the father were inherited by 48·8 per cent. of the children, and those of the mother by 51·2 per cent., which, divided between sons and daughters, showed that 47 per cent. of the former and 49·5 per cent. of the latter inherited the eyes of the father, whereas 53 per cent. of the sons and 50·5 per cent. of the daughters inherited those of the mother. Since Prof. Candolle had published his paper, he (the speaker) had continued his researches in Sweden, and from the material he had collected he had discovered results differing from Prof. Candolle's. Of the individuals reported to him 29·6 per cent. of the men and 30·7 per cent. of the women had brown eyes, so that even in that country the latter were more numerous than the former, but this was no doubt due to the circumstance that he had been most anxious to obtain particulars from bi-coloured parents. In accordance with Candolle's results, 75·6 per cent. of children of parents both with brown eyes inherited this colour, whilst of those with blue eyes 97 per cent. inherited that colour. It was but natural that this should be the case in Sweden, where blue eyes predominated. As regards the bi-coloured parents the case was different in Sweden too. If the father had brown and the mother blue, 59·9 per cent. of the children had brown eyes, whilst where the reverse was the case 53 per cent. of them had brown ones. These figures were the reverse of Candolle's. But of *all* bi-coloured parents 56 per cent. of the children had brown eyes, *i.e.* that in Sweden too the latter are on the increase. He could not say what *rôle* the colour of the eyes played in the selection of a wife in Sweden, as he had no statistics of the distribution of brown eyes in general, but there was a tendency similar to that stated above, as, of the parents embraced by these researches, the majority of wives had brown eyes. With reference to the number of children in Sweden of con-coloured and bi-coloured parents, that of the former was 4·49 and that of the latter 4·03, whilst 52·6 per cent. of the children inherited the eyes of the father and 47·4 per cent. those of the mother; of the sons 51·8 per cent. inherited the eyes of the father, and 48·2 per cent. those of the mother, which figures as regards the daughters were respectively 53·5 and 46·5 per cent. This shows that in Sweden the eyes are not predominantly inherited from the mother alone, and that the offspring of equally-constituted parents should not be weaker. The speaker stated in conclusion that he is continuing his researches. He excludes children under ten years of age from the same, and classifies blue-grey or grey eyes as blue.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

Prof. W. Grylls Adams, F.R.S., will deliver a Course of Lectures at King's College, London, on Heat and Light, during the Academical Year 1885-6. A Course of Practical Work in Electrical Testing and Measurement, with especial reference to Electrical Engineering, will be carried on under his direction in the Wheatstone Laboratory. There will also be a Course of Lectures on Mechanics and the Principles of Energy. The Wheatstone Laboratory is open daily from 1 to 4, except on Saturdays. For further particulars apply to Prof. Adams, King's College, London.

The following appointments have recently been made at the Victoria University, Owens College, Manchester:—To the Professorship of Mathematics: Mr. Horace Lamb, M.A., F.R.S., late Fellow of Trinity College, Cambridge, and Professor of Mathematics in the University of Adelaide. To the Professorship of Anatomy: Mr. Alfred H. Young, M.B., F.R.C.S.

SOCIETIES AND ACADEMIES

Paris

Academy of Sciences, September 21.—M. Bouley, President, in the chair.—On the development of cholera in India, by M. Gustave Le Bon. In support of Prof. Peter's view that European differs from Asiatic cholera only in the greater intensity of the causes producing it, the author argues that both forms might break out spontaneously in any country through the volatile germs arising from putrified organic matter. In his former researches he showed that, apart from these germs, there exists a series of volatile alkaloids which, when introduced by respiration, produce almost fulminating effects. These researches throw much light on the accidents attending the exhumation of bodies long buried and on the spread of typhoid or analogous fevers. The facts recently observed by M. Le Bon during a sudden outbreak of cholera at Kombakonum, in the south of India, tend to confirm this hypothesis. In India itself cholera rages almost exclusively amongst the native populations; the English, who reside in large cantonments, where sanitary arrangements are scrupulously attended to, being seldom attacked. That cholera and intermittent fevers are propagated chiefly by bad water is a point on which opinion is unanimous in that country, and the author's personal experience places it beyond all reasonable doubt.—Elements of Brooks's comet, by M. R. Radau. These elements, according to observations made at Cambridge and Paris, are found to be:—

$$T = 1885\text{, August } 10{\cdot}30457\text{; mean Paris time.}$$

$$\left.\begin{array}{rl} \pi - \Omega = & 43\ \ 0\ 47 \\ \Omega = & 204\ 33\ \ 7 \\ i = & 59\ 22\ 30 \end{array}\right\}\text{ Mean equinox of } 1885{\cdot}0.$$

$$\log q = 9{\cdot}87694$$

—Note on a new stellar spectroscope, by M. Ch. V. Zenger. This instrument is constructed on a new principle, and chiefly intended to measure simultaneously and accurately the angle of position and the distance of double stars situated very close together.—On the process of fertilisation in the Cephalopods, by M. L. Vialleton.—On the anatomical organisation of the urns in *Cephalotus follicularis*, by MM. Jules Chareyre and Edouard Heckel.

BERLIN

Physiological Society, July 31.—Prof. Fritsch spoke on the functions of the sebaceous glands, raising a protest against the conception, represented quite recently by Herr Unna, that these glands served only to lubricate the hairs, while the globiform glands, commonly called the sudoriparous glands, lubricated the skin and induced the formation of the subcutaneous fat, and that, finally, the perspiration was discharged by the sweat-pores, or, rather, the extreme ends of the straight canals into which the sweat found its way out from intercellular spaces through the stomata. A whole series of anatomical, histological, and physiological grounds were brought forward against this view both by the speaker and, in the course of the discussion on the subject, by Prof. Du Bois-Reymond, Prof. Waldeyer, Dr. Gad, and Dr. Lassar. All known observations and experiments were, on the contrary, they maintained, in favour of the view that the sebaceous glands provided fat for the skin, while the globiform glands had the production of sweat assigned to them.—Dr. Weyl reported on the results of a chemical examination of the cholesterin, the composition of which had not hitherto been ascertained, although this substance had been discovered more than a hundred years ago, and had since been traced in the most varied organs of the animal body and even in plants. The most searching investigation down to the present of cholesterin had been made by Herr Zwenger, who, by treatment with sulphuric acid and nitric acid, had found combinations which he had distinguished and chemically characterised as cholesterylene and cholesterone. By repeating these experiments Dr. Weyl had achieved much purer derivatives of the cholesterin, in particular chloric and bromic combinations, in very pure crystals, which rendered exact elementary analysis possible. This led to the result that the derivatives of cholesterin were found to be hydrocarburets belonging to the great class of the terpenes—that is, they were products of condensation or polymerisations of the simple terpene (C_5H_8). Even though it were not yet possible to state precisely the number of the C_5H_8 which had become polymerised in the several cholesterin derivatives, the speaker yet thought he had sufficient ground for assuming that the composition $(C_5H_8)^5H_2O$ was the one proper to the cholesterin itself. Substances which, both by their reactions and their percentage compositions, were denotable as terpenes, might also be obtained from the choleic acid, a circumstance which pointed to the more intimate relation between cholesterin and choleic acid.—Dr. Biondi communicated the results of an investigation carried out by him in the Institute of Prof. Waldeyer with a view to throwing light on the origin of the spermatozoids in the seminiferous canals—a question on which the views of physiologists were so widely divergent. By appropriate use of appliances for hardening, fixing, and colouring, among which the advantages of Flemming's fluid had to be mentioned with quite special prominence, Dr. Biondi arrived at results which corroborated none of the views formerly put forth, but which explained the earlier observed facts. In accordance with these results it had been endeavoured diagrammatically to distribute the contents of the seminiferous canals into columns, which, proceeding from the wall towards the central cavity, might be grouped into three layers. In the first stage of development, a stage always met with, in particular, in animals not yet ripe, the extreme layer lying on the wall of the canal consisted of round, primitive cells, the second layer, proceeding inwards, of round mother-cells, which were very rich in caryokinetic figures, and the third innermost layer consisted of a larger number of small round daughter cells. In a second stage of development observable in ripe glands the nucleus of the daughter cells were seen converted into spermatozoids, the exterior half of the nucleus becoming the head and the other interior half the middle part and tail of the spermatozoon. The protoplasm of the daughter cells took no part in this transformation, and enveloped the bodies of the spermatozoa, making them cohere into bundles from which the tails of the spermatozoa projected towards the central canal. These masses of protoplasm enveloping the bodies of the spermatozoa altogether resembled the figures described by the earlier observers as "Spermatoblasten." In this stage the above diagrammatically assumed column consisted, from the outside inwards, of the primitive cell, the mother cell, and the bundle of spermatozoa. In the next stage of development the formation of the spermatozoa, arising always in the same manner from the nucleus of the daughter cells, was pushed farther outwards, so that the column now consisted of but one large round cell on the outside and bundles of spermatozoa on the inside. The formation of the seminal corpuscles advanced still further, and at last the whole column, as far as the wall of the canal, consisted of spermatozoa, the bodies of which were agglutinated into bundles by masses of protoplasm, their tails being directed inwards. Primitive cells out of neighbouring columns now intercalated themselves between the wall of the canal and the spermatozoa, pushing the latter towards the middle. By the development of the mother and daughter cells the spermatozoa were quite pressed and discharged into the central canal. The process thus described then began anew. It must, however, be observed that in nature there was no separation into columns and layers such as was here diagrammatically described. It was only for the sake of clear representation that the processes succeeding each other in time were thus exhibited as divided in space. Dr. Biondi had examined this structure of the seminiferous canals, and this development of the spermatozoids in the bull, the swine, the cat, the rabbit, the guinea-pig, the rat, and other mammalia; and in all these cases he had found alike the same results. Prof. Waldeyer testified that Dr. Biondi had attained to these results quite independently and had communicated and demonstrated them to him as early as February of this year. It was only on his advice that Dr. Biondi had further examined a longer series of animals before publishing his results. A few days ago, continued Prof. Waldeyer, he had received a letter from Prof. Grünhagen in Königsberg, in accordance with which he (Prof. Grünhagen) had attained to the same results on spermatogenesis as had Dr. Biondi, to whom, of the two independent discoverers, was due the title of priority.—Dr. Blaschko briefly explained a series of microscopic preparations he exhibited, which served to show that between the epidermis and the cutis there lay no cementing substance; but just as it was long known that in the case of the epidermis cells they had processes grooving themselves digitately into one another, so here, too, the processes of the epidermis and cutis cells were seen to intertwine with one another and form a network, the meshes of which were particularly large in an œdematous skin.—Dr. Lassar demonstrated microscopic preparations of skin which he had excided from a patient suffering under lichen ruber. In the copious protoplasm (the exudation of the inflammation) surrounding the canals of the epidermis there were seen, after colouring with fuchsine and Bismarck-brown, an uncommonly large number of micrococci, distinguishing themselves particularly by their remarkable smallness.

MR. GRIEVE ON THE GAREFOWL

The Great Auk, or Garefowl (*Alca impennis*, Linn.), *its History, Archæology, and Remains.* By Symington Grieve, Edinburgh. 4to, pp. x. 141, and Appendix, pp. 58. (London: Jack, 1885.)

AGREEABLY to the wish of the editor of NATURE that I should notice in its pages the lately-published volume whose title stands above, I undertake a responsibility of a kind which is for me as delicate as can be imposed upon anybody. It has long been no secret that for more than five-and-twenty years—since, indeed, the premature death, in 1859, of my friend and fellow-traveller, the late Mr. JOHN WOLLEY—I have had it in hand to prepare and eventually to produce a monograph of the presumably extinct species of bird, into the investigation of whose history he had thrown himself with all the energy of his character. During that time I am not conscious of having ever lost an opportunity of adding to my store of information on the subject, in doing which I was for several years assisted by the zeal of the late Mr. G. D. Rowley; and, though always having in view the ultimate publication of the monograph originally contemplated by Mr. Wolley, I never hesitated to supply any inquirer with the particulars for which he asked—as may be seen on reference to the publications of Dr. Victor Fatio[1] and of Prof. Wilhelm Blasius[2]—both of whom I rejoice to think I was able in some measure to help. Nevertheless, each attempt to elucidate the natural history of the Garefowl only added to the number of still unanswered or unanswerable questions relating to it; and, amid numerous other occupations or duties, I have with difficulty been able to keep myself abreast of the ever-increasing contributions to the subject—many (I may say most) of them proving on investigation to have little or no foundation; and those which had the least, or none at all, generally giving the greatest trouble.

Apology, I feel sure, is needed for an introduction so egotistical as that contained in the foregoing paragraph; yet without it, or something like it, I fear my remarks on the book before me may be misunderstood. The force of circumstances has compelled me to set up a very high standard; and, when that standard has not been approached by any writer on the subject, it is almost impossible for me not to see his shortcomings, though many another man might find in him no fault at all. I therefore wish at once to record my opinion that in the present work the author has done the best that in him lies, and especially that his book, so far as it goes, is an honest book. If, after working at the subject for more than a quarter of a century, a man still finds himself unable, from one cause or another, to publish the results of his labour, it does not follow that he should be hard upon anybody else who, with perhaps as many distractions, makes a praiseworthy attempt to set before the world what is known of the lost species, though he may not have devoted to the task a tenth of the time. Moreover, Mr.

[1] *Bull. Soc. Orn. de la Suisse*, ii. pt. 1, pp. 5-70, 73-85.

Grieve begins his preface with the words: "In submitting these pages to the public, the author has fears that they will not bear severe criticism." I regret to say that regard to truth obliges me to declare that this is so; but I have no wish to be the severe critic, and it will be best here to describe the plan and scope of the work, which is obviously well chosen. Mr. Grieve begins with a very appropriate dedication to Prof. Steenstrup, that venerable biologist who first wrote a history[1]—he modestly called it only a "contribution" to a history—of *Alca impennis* that was in accordance with facts, and was worthy of the subject, of science, and of himself. The amount of indebtedness to him, due from all his successors in the investigation—but not always acknowledged—is not to be overrated. Hard as they may have found their work, it has almost entirely lain in clothing the form that he constructed; and, though there has been plenty of false tailoring, his outlines have proved to be true in almost every particular. In the dedication Mr. Grieve very justly states that he has not "much to relate that is new to British ornithologists;" but his desire has been "to bring within the reach of all, materials that at present are difficult of access."[2] These preliminaries over, the geographical range of the species—first in American and then in European waters—is entered upon, care being taken to warn the reader against the popular misconception that it was ever a bird of the high north, and then is given a description of its remains as found in the New World and in the Old. Under the last category come four chapters treating respectively of the discovery of its bones in Caithness, and in Oronsay, of the period to which the kitchen-midden on that island containing them presumably belongs, and of the single fragment found near Whitburn-Lizards, on the coast of Durham, by Mr. Hancock, which fragment, being the greater portion of the maxilla of what seems to have been an exceptionally large example, now in the Museum at Newcastle-on-Tyne, is very delicately figured (p. 64). After this Mr. Grieve enters upon a consideration of the bird's habits and of the regions in which it lived, and then proceeds to catalogue at some length (pp. 76-114) its existing remains—whether bones, skins, or egg-shells. Then follow three chapters on the uses to which the bird was put by man, on the names by which it has been known, with their possible origin and meaning, and on the period during which it lived. No fewer than nine appendices are added—all more or less of the nature of *pièces justificatives*—while an excellent index, with remarks on the accompanying chart, completes the volume, which is illustrated by several woodcuts and a couple of coloured plates representing the two eggs that doubtless came to Edinburgh in 1819 with Dufresne's collection, when it was bought by the University there, and, having been transferred to the Museum of Science and Art in the northern capital, were first publicly noticed by Major Feilden in 1869.

There cannot be a dispute as to the great pains which the author has taken with this work, but it would be inexpedient here to attempt any criticisms of its details, to an abundance of which exception may be taken. The

[2] Here may be added that, if report speaks truly, so strong has been this desire on the part of the author, that the book is sold to the public at less than cost price.

A A

fact seems to be that up to a certain point the story of the Great Auk can be worked up and told by any one willing to labour at it. Beyond that point the difficulties begin. Mr. Grieve appears to be hardly aware of the existence of these difficulties, though some of them have been hinted at, if not pointed out, by his predecessors. The most serious charge that can be brought against him is that he has needlessly raised fresh difficulties for future investigators. Mistakes that have taken years of labour to correct, and the correction of which has been published, are again set agoing, just as if no progress in that direction had been made; and, even worse than this, some new assertions, or at least suggestions, are hazarded that have, I am persuaded, no firm ground. No doubt on some of these points I may be prejudiced; but according to my knowledge I perceive that on too many questions Mr. Grieve has been unable to distinguish between good evidence and bad. However, there is in this book a distinct gain to all historians of the Garefowl, and that is the information here first placed on record by Mr. Champley of Scarborough, who is known to have interested himself for many years in all that concerns this species.

I most sincerely wish that I could accord higher praise to this work than I have been able to do, for Mr. Grieve's enthusiasm in the cause deserves greater success. It is seldom that any one but a Fennimore Cooper or a Charles Kingsley feels the romance that clings around the history of an expiring race. Most men—men of science especially—nowadays believe in the survival of the fittest, and are content to let the dead bury their dead. The moral lesson I do not venture to draw, and in conclusion have only to ask pardon of the readers of NATURE for putting myself so forward in this article.

ALFRED NEWTON

"THE WAVE OF TRANSLATION"

The Wave of Translation in the Oceans of Water, Air, and Ether. By John Scott Russell, M.A., F.R.S. (London: Trübner and Co., 1885.)

THE late Mr. J. Scott Russell was one of the most prominent and gifted naval architects which this country possessed in the middle of the present century. His name will long be remembered as the builder of the *Great Eastern*, the early advocate of the longitudinal system of framing iron and steel ships: the ingenious and eloquent expounder of the "wave-line" principle of design; and for many improvements in the theory and practice of iron steamship construction. His personality was at once striking and attractive, and his abilities were of an original and versatile kind. He was the author of a massive work upon naval architecture; and of numerous papers read before various learned societies. No one exercised greater influence than Mr. Scott Russell in promoting the cause of scientific education in naval architecture, and in stimulating and helping students, by numerous speeches and writings, to acquire a general and clear knowledge of the laws upon which the qualities of ships depend.

Mr. Scott Russell's writings were always interesting. He possessed the rare faculty of making the driest and most complicated of subjects intelligible, and even fascinating. Where he may not be correct in the hypotheses, or justified in the sweeping generalisations, he sometimes hastily put forward, he is usually suggestive, and provocative of thought upon the part of his readers. He was a vigorous and clear—though with a tendency to be a too rapid—thinker; and there are no writings upon naval architecture which have the power of fixing the attention and stimulating the intellect in a greater measure than those of Mr. Scott Russell.

We regret to say that the present work is not likely to add to the reputation of its author. It exhibits *les défauts de ses qualités* in their most pronounced form; and if we were asked for an example of Mr. Scott Russell at his very weakest and worst we could hardly do better than refer to that portion of this book which has not been before published. One-half of the volume is devoted to a reprint of the Report made by Mr. Scott Russell to the British Association in 1842-43, in which a description is given of the "solitary wave of translation," which he discovered for himself in 1834, and the properties of which he did much to investigate and make known. This Report is not only printed *in extenso*, but Part I. of the work consists exclusively of extracts from it. The same matter appears twice over—once as Part I. of the book, and once as portions of the British Association Report. The Report describes the knowledge possessed by Mr. Scott Russell in 1843 of "the varieties, phenomena, and laws of waves, and the conditions which affect their genesis and propagation." This may be interesting from a biographical point of view, but its present scientific value is not great. Many things have happened since the date of this Report, such as the theoretical investigations of Airy, Stokes, Rankine, Froude, eminent French mathematicians, and others; and numerous observations have been made of the forms and properties of waves by scientific officers of our own and foreign navies. These constitute a mass of information which the present work completely ignores.

One half of the book is taken up with the reprint of the British Association Report referred to, and with those extracts from it of which Part I. is made up. The remaining half contains the only new matter now published. This is divided into two sections, one being "on the analogy between the solitary wave in water and the sound wave in air," and the other "on the great ocean of ether and its relation to matter." The less said of these chapters the better. The following is an instance of how Mr. Scott Russell frames a theory or invents a hypothesis: "I am so impressed with the truth of this law, that the velocity of this solitary wave in any fluid is due to the depth of the fluid in which it moves, whether thick or rarefied, that I hazard the hypothesis, that in the unknown element which pervades the universe, and which, though unknown, is the cause and medium of the most familiar phenomena of everyday life, proceeding on the same basis of calculation as in the air and water occurs, we shall find that the ethereal ocean should be given a height of 5,000,000,000 miles, and that the corresponding velocity of the solitary wave through that ocean would be 1,000,000,000 feet per second."

An atomic theory is framed upon the following basis: "The law of attractive force in the atom, in conformity with the law of Newton, is according to the *square of the* *nearness*, and I propose to take as the law of repulsive force, the *cube of the nearness*. I think I am justified in taking this as the true law of repulsion of atoms of matter, because I find from the researches of eminent chemists that all free gases do so expand as to double their bulk by an increase of the distance of the particles, in the ratio of the cube of their nearness, or as 111 cube to 367." Then the theory of heat that is put forward appears to be a kind of material theory: "We may therefore define heat as *the effort of ether to resist crowding*. . . . Ether existing all around us in a normal state may be called *free ether*. Ether enclosed by force in limited space surrounded by material atoms is imprisoned or stored ether; its greater or less degree of crowding or storing means degrees of heat, and the quantity of crowding among the atoms indicates the specific heat of these atoms, and sometimes the specific heat of that kind of matter."

One more extract and we have done:—"Even Sir Isaac Newton's calculations of the speed of sound fell 100 feet short of the truth, and therefore corresponded to an error of a mile in the height of the atmosphere, and he could invent nothing better to account for the error than this sudden inflammation of the atmosphere. To this the reply is that the existence of the solitary wave of translation was not known to Newton, that the nature of its genesis and propagation could not therefore be calculated; but that present knowledge of the nature and laws of this wave completely explain and accurately measure its phenomena without the introduction of any hypothesis contradicted by fact."

We have said enough to show the character of this treatise, and we will conclude by repeating that we are sorry to see a posthumous work by so eminent a man as the late Mr. Scott Russell, containing nothing more to justify its publication than a reprint of his well-known, and imperfect, views in 1843, upon wave motion, and a fanciful interpretation of great physical laws. It is a pity that greater skill and discretion were not brought to bear upon the production of this volume.

OUR BOOK SHELF

Publication of the Norwegian Commission of the Measurement of Degrees in Europe. (1) Geodetical Operations, Part IV. (2) Tidal Observations, Part III.

THE first of these publications contains an account of the northern portion of the trigonometrical work undertaken to connect the side Stokvola-Haarskallen with the side Spaatind-Næverfjeld. The former side is directly connected to the base measured in 1864 near Levanger, as described in Parts I. and III. of the "Geodetical Operations."

A trigonometrical survey of this part of the country had already been made in 1835-6 by Gen. Broch, and it was at first hoped that this survey could be utilised, but on closer investigation it was found that the observations were not of sufficient precision to meet the requirements of the Commission for the Measurement of degrees in Europe, for which this work was to a great extent undertaken. The old stations were, however, utilised in the northern part of the triangulation; there the signals were well-built masonry cylinders. In the southern portion, however, the stations had in many cases entirely disappeared and had to be reconstructed. A careful description of each station is given, and in every case, with one or two exceptions, the signal could not be placed at the centre of the station; the usual measurements for reduction were therefore made, and apparently with more than usual care. The observations were taken with a 10-inch universal instrument made by Olsen and with a 12-inch theodolite made by Reichenbach. It would appear that the graduation of these instruments is not of a very high order; at any rate, the differences in the readings are rather large, frequently exceeding 10″: but in extenuation it must be said that the instruments were too small for the work and that the observations were made under considerable difficulties, owing to sea-fog and snow. There is nothing special to remark in the method adopted to adjust the observations, it being the usual method founded on the principle of least squares. It is shown that the mean error of the finally-adjusted angles is

$$0''\cdot547 \pm 0'\cdot029.$$

A diagram of the triangulation is given, from which it is seen that most of the triangles are well-conditioned; a few, however, are more elongated than they should be for good work, the triangle Munken, Stokvola, Haarskallen, especially so; for instance, the angle at Munken is $5^{\circ}\ 12'\ 57''\cdot416$. It should also be observed that several of the stations are determined by only two intersections. The longest side measures about sixty miles.

The second publication is the third report of the Norwegian tidal observations, and contains the results of the work done at Oscarsborg in 1880-1 and at Stavanger, Bergen, Kabelvaag, and Vardö in 1883. This report is simply a continuation of Reports I. and II., already noticed in NATURE; it contains nothing but tables, and there is nothing in it that calls for special notice.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

On the Influence of Wave-Currents on the Fauna of Shallow Seas

FOR many years past I have endeavoured, without much success, to call attention to the widely-spread influence of waves on the bottoms of shallow seas. To the geologist this action signifies denudation, and accounts, among other things, for the wholesale destruction of marine fauna so often exemplified in the rocks. To the zoologist it signifies a factor in evolution of immeasurable magnitude.

On seeing the abstract of Prof. Moseley's lecture on the fauna of the sea-shore in NATURE, I troubled you with my letter of July 6; now that the full report has appeared, equally reticent as to the significance of wave-currents, I ask leave to add somewhat to my former letter.

The difficulty in arousing interest in this subject arises from the fact that, though the phenomena of wave-disturbance are well known to mathematicians, natural history text-books commonly agree in asserting either the non-existence, or unimportance, of such disturbance. Thus the question has remained unheeded.

My own experience in the matter is as follows:—Holding the orthodox view of the peaceful repose existing on the sea-bottom, I commenced cruising, some twenty years ago, on that excellent natural experimental tank, Torbay. I soon found, to my surprise, that the local fishermen and dredgers were as confident that the waves greatly disturbed the bottom as naturalists were of the reverse. Having kept my eyes open in this direction, I submitted a paper to the Devonshire Association in 1878, descriptive of the levelling action of the waves on the six-fathom area of Torbay (*Trans. Dev. Assoc.*, vol. x. p. 182).

With the kind assistance of Lord Rayleigh I was enabled to show that theory and observation were in complete accords a to the energy evinced by the waves in the particular instance under consideration.

Having learned from Lord Rayleigh that wave-action at the sea-bottom takes the form of reciprocal currents, I was led to make some experiments and observations on the formation of ripple-mark. In the course of this investigation I was soon impressed with the conviction that these alternate currents held at their mercy the marine fauna exposed to their attacks, and that the zoological side of the problem was at least as important as the geological. Accordingly, an outline of the subject in its zoological aspect was included in a paper on ripple-mark read to the Royal Society in 1882 (*Proc.* R.S., vol. xxxiv. p. 1).

Having come into possession of confirmatory evidence of the action of waves at a depth of forty fathoms in the English Channel, I submitted the facts to the British Association at Southampton in the same year, 1882. This paper, sent in to Section A, was handed on to Section C, a mathematical friend suggesting to me the reason, and a very good reason too, that mathematicians required no evidence on the point contended for. However, the transfer only went to prove that the geologists were as sceptical as to the existence of wave-action at forty fathoms, as the physicists were satisfied as to that fact. This paper, amplified, appeared in the *Transactions* of the Devonshire Association for 1883 (vol. xv. p. 353).

The zoological aspect of the question was submitted to the British Association at Southport in 1883; and again to the Linnean Society in 1884, in a paper "On the influence of wave-currents on the fauna inhabiting shallow seas." In this paper, profiting by experience, I made no attempt to prove the fact of wave-action from observation, but relied entirely on a valuable letter with which I had been favoured by Prof. Stokes, Sec. R.S. Neither at the British Association nor at the Linnean Society was any exception taken to my arguments in support of the importance of wave-action on the fauna affected; nor, so far as I am aware, has my position been shaken since. Now that Prof. Moseley's important lecture has appeared, discussing the fauna of the sea-shore without reference to the ever-regulating wave-currents, there is considerable risk that less experienced students of natural history will in like manner pass over this promising field of research as not worthy of their attention.

Prof. Moseley states, and states truly, that the littoral fauna is adapted in various ways to withstand "the action of the surf, the retreat of the tides, the numerous enemies"; but, beyond the reach of surf and tidal fall, agents which only affect the narrow belt of sea contiguous to the shore, the alternate currents set up by ocean waves search out the armour and test the defences of all small animals living on those extensive marine areas, exposed to the ocean swell, where the depth of water does not exceed fifty fathoms.

With respect to enemies, the waves themselves are perhaps the most formidable, as they attack and occasionally destroy whole colonies at once, whereas predatory foes rather affect the individual. For instance, let such helpless mollusks as *Aplysia* or *Pleurobranchus* wander over the sandy bottom of Torbay, as they sometimes do: the first easterly gale will sweep them out of existence. In fact, the waves so invariably prevent *Aplysia punctata* growing to its full size on the British coast, that a full-grown specimen taken in protected Guernsey waters has been considered a distinct species—viz. *A. depilans*. Similar large specimens have occurred under the shelter of the Torquay harbour works, but these, by a series of odontophores and shells, I have been able to connect with the common *A. punctata*.

Prima facie it would appear that the shells of certain mollusks are more especially adapted to resist animate foes; but a close examination will often prove the contrary. Take the cases of the oyster, mussel, venus, and limpet: these mollusks are all helpless in the presence of their living enemies: the oyster perishes by the attacks of boring-sponges; the mussel is destroyed wholesale by starfishes; the venus is perforated by carnivorous gastropods at their leisure; whilst the limpet, easily detached when taken unawares, is said to be destroyed by birds. All four are, however, admirably adapted to resist wave-currents, each in its respective habitat.

The conclusion that the shells of mollusks are so constructed as to have comparatively but little reference to living foes is supported by the interesting fact mentioned by Prof. Moseley, that hard shells tend to disappear in pelagic and deep-sea regions. That is to say, they disappear where predatory enemies abound, but where the great non-predatory enemies, the waves, are powerless or not existent. Occasionally we find the supposed protection against living enemies to be greatly in excess of requirements—*e.g.* the case of the solen, whose power of burrowing is far greater than requisite for escape from birds, but which is none too great for the evasion of waves and currents tearing away the sand in which the mollusk dwells.

Wave-action tends to differentiate species. This can be seen in such obvious cases as *Cardium aculeatum* and *C. norvegicum*, *Venus dione* and *V. chione*. One of each of these pairs has chosen the mooring method of defence with anchor-like spines, the other that of facile penetration with smooth, unresisting shell surfaces. As these two methods are opposite in action and any compromise tends to inefficiency, the wave-currents must necessarily influence the mollusks in the direction of divergence.

Instances of habits and forms protective against wave-currents could be multiplied almost *ad infinitum*, and, as the subject is a very interesting one, I still live in hopes that it may yet be taken up and worked out by trained observers qualified for the task.

ARTHUR R. HUNT

Torquay, September 28

Prehistoric Burial-Grounds

THE account given in this week's NATURE (p. 518) of the discovery of a prehistoric burial-ground at Pitreavie has recalled to my memory the description of a similar find made in the eleventh or twelfth century by the monks of Noyon, and related to us us by Guibert, who was abbot of this foundation at the time. I believe that it is the earliest detailed account of any such discovery that has come down to our days; and it will be noticed that the leading features of this cemetery are almost exactly identical with those of the Pitreavie one. I am not aware that this passage has attracted the attention of modern writers upon prehistoric times.

Guibert, the author quoted, was born in 1053 and died in 1124, having been Abbot of Noyon for about twenty years. After stating his own conviction that his monastery was extremely old, he continues:—

"Quam opinionem, si nulla litteralis juvaret traditio, suppeteret profecto affatim peregrina, et non, putamus, Christiani nominis sepulchrorum inventa contextio. Circa enim ipsam et in ipsa basilica tantam sarcophagorum copiam conjunxit antiquitas, in multam loci famositatem tantopere expetiti, cadaverum inibi congestorum commendat infinitas. *Quia enim non in morem nostrorum ordo disponitur sepulchrorum, sed circulatim in modum corollæ sepulchrum unius multa ambiunt, in quibus quædam reperiuntur vasa, quorum causam nesciunt Christiana tempora.* Non possumus aliud credere nisi quod fuerunt gentium, aut antiquissima Christianorum, sed facta gentili more."

GUIBERTI Novig. *de Vita Sua*, L. ii. cap. i.

I may add that in Guibert's time there was a very old written tradition which ascribed the foundation of Noyon to a certain "rex insulæ Britanniæ," who was (so ran the legend) a contemporary of our Lord's. This tradition is, of course, worthless from a historical point of view, but certainly testifies to the extreme antiquity of the place; and shows that, long before Guibert's time, the inhabitants of Noyon had dim recollections of their prehistoric greatness, which naturally, in an age of Christian credulity, centred around the era of our Lord.

MARS, JUPITER, AND SATURN

WITH Mars, Jupiter, and Saturn in the morning sky the telescopist has a varied assortment of brilliant objects to which he may devote his attention. The great distance of Mars during the ensuing opposition will have the effect of limiting the apparent diameter to a low value, but the chief markings are so conspicuous as to be visible notwithstanding this inimical effect. Indeed during the preceding opposition, which was equally unfavourable, some of the more delicate features appear to have been recovered. At Milan Signor Schiaparelli has partly confirmed his previous results as to the singular duplication of the "canals," and Mr. Knobel has obtained a series of valuable sketches, which are reproduced in the last volume of the *Memoirs* of the Royal Astronomical Society. With regard to Jupiter the declination of the planet will be somewhat less than during the opposition of 1884-5, but the configuration of the belts and the peculiarities of the variable spots will doubtless continue to be exhibited with nearly similar prominence as in previous years. Saturn, situated in Gemini, and having considerable N. declination, will present a grand display, the rings being still widely open and inviting that close and systematic scrutiny which is so much needed either to affirm or negative some of the questionable details suggested by recent observations.

Observers of Mars are extremely fortunate in possessing such valuable memoirs and charts as those of Schiaparelli, Terby, Green, and others, which form a comprehensive and accurate basis of future reference and comparison. The seeming permanency of the chief lineaments on Mars and their distinctness of outline have permitted observers to assign their forms and positions with great nicety. But this has been found practically impossible in respect to any of the other planets of our system. Their markings are of so variable a tendency or so uncertain and ill-defined, owing probably to their atmospheric character, that it is out of the question to frame representative views that will serve to express the appearances observable at any future time. We have accumulated a vast number of delineations, including many peculiar forms, but these exhibit so much discordance as to prove that any attempt to arrange them with the same consistency as those of Mars must for the present be utterly futile.

What is essentially required in furtherance of our knowledge of areographic features are delineations in which the more delicate alternations of light and shade are faithfully portrayed. The ensuing opposition, though not offering the most favourable inducements for attaining this end, may yet be utilised as likely to afford its share of corroborations to old features and perhaps indicate some modification of the outlines attributed them by former observers. Mr. Marth's valuable ephemerides in the *Monthly Notices* supply the data wherewith the passages of certain prominent markings across the central line may be readily calculated from night to night. Drawings effected at the telescope and subsequently attested by the charts, or independent projections made on the basis of the new drawings and then compared with previous work will be important as furnishing fresh confirmations and additions to old records. Whatever plan is adopted, observers must not regard existing delineations as *perfectly* reliable and prejudice the judgment by endeavours to discern the outlines of the spots precisely as they have already been figured. Our work should be pursued apart from such influences, the aim being rather to correct and extend past results, than to follow them with implicit faith and mould our new seeings on the same pattern. Though much has been accomplished by the consecutive labours of the many able and earnest students of Martian features, the present state of our knowledge is not only incomplete, but considerable uncertainty exists as to the more difficult formations comprised in the physical aspect of this planet.

Jupiter, with so great a diversity of atmospheric phenomena, some of them rapidly variable, and all influenced by the quick rotation of the planet, gives prospect of being the subject of increased investigation. Late in the preceding opposition the great red spot which had so nearly disappeared and had, during the winter of 1884-5, assumed the appearance of a red ellipse with interior light cloud, showed unmistakeable evidences of increasing condensation. The ellipse grew perceptibly darker, and the central light cloud disappeared, so that at the end of the opposition the spot had almost regained the striking aspect it presented a few years ago. The question now is has this well-known feature continued to gain ascendancy during the time the planet has been lost in the sun's rays? Observations in October will furnish a definite answer to this question, and the planet should be confronted with our best telescopes as early as possible, so that the necessary evidence may be obtained. The spot will pass the central meridian of Jupiter at about the following times, and ought to be well seen in small instruments unless some great changes in an unexpected direction have affected its position or appearance in the interim since the last observation made here on the evening of July 8:—

Date 1885		Red Spot Central h.	m.	Date 1885		Red Spot Central h.	m.
Oct. 7	...	18	34	Oct. 29	...	16	48
12	...	17	43	31	...	18	26
17	...	16	52	Nov. 3	...	15	56
19	...	18	30	5	...	17	34
24	...	17	39	7	...	19	13
26	...	19	17	10	...	16	43

With reference to the white spots bordering the dark belts, and the other definite markings, they will doubtless be remarked as heretofore. Their singular vagaries of motion and appearance call for renewed study. The varying intensity and colour of the belts and their disposition in latitude should be carefully assigned on several dates during each opposition. If this method could be persistently followed during many years it would supply the material either for tracing out periodical recurrences, or proving such changes to be intermittent in character.

During the past opposition of Jupiter much attention was directed to the transits of the satellites and their shadows. When near mid-transit, III. and IV. are often seen as black spots, I. is visible as a grey spot, while II. is rarely, if ever, visible otherwise than as a bright spot. These anomalies have never received a satisfactory explanation, and further observations are much required as to the relative tints of the satellites when on Jupiter and the variations noticeable in different transits.

Saturn, though not presenting such an extent of conspicuous detail as Jupiter, is yet equally deserving of systematic study. The rings and numerous array of satellites compensate for lack of detail in the belts. The outer division in the ring, called after Encke, supplies us with a crucial test object, and one which perhaps has originated more difference of opinion amongst observers than any other planetary detail of which the existence is well assured. Either this division must be liable to fluctuate at short intervals or the evidence afforded by various telescopes is most conflicting, and suggests how careful we should be before accepting individual results when not corroborated or supported by undeniable testimony.

During the last few oppositions a very definite narrow dark belt has bounded the southern side of the equator, and this has attracted more comment than usual owing to its compact and very obvious appearance. This belt exhibits no distinct spots, though one or two observers have delineated it with marked condensations. The fainter belts nearer the pole are so very feeble that their existence is sometimes questionable. Indeed the features of this planet are of extreme delicacy, and require not only very steady air but a thoroughly good eye and instrument to trace them in their more minute forms. Some of them are doubtless variable and have given rise to the contradictions we have referred to. As to the satellites they comprise test objects for telescopes of all calibre. The identification of these bodies may be suitably effected at any hour by means of Mr. Marth's ephemerides (*Monthly Notices*, June, 1885).

W. F. DENNING

RADIANT LIGHT AND HEAT[1]

III. (Continued)

Absorption—Terrestrial Applications.

LET us next consider the absorption spectra of substances, that is to say, the absorption lines which substances at ordinary temperatures produce in the spectrum of light from a high temperature source, such as the sun or the electric arc. This absorption may either be general or selective; it may be spread over a large portion of the spectrum, or it may act specially over a very limited district or line. It is in the latter case that we derive most advantage by studying absorption spectra, and there are many substances which may be known at a glance by means of their peculiar absorption. Professor Stokes has shown, for instance, that blood may at once be distinguished from other solutions of similar tint by means of the characteristic dark bands which it produces. By means of a spectrum microscope Mr. Sorby thinks that the thousandth part of a grain of blood may be detected, and the same observer asserts that wines of different vintages can easily be distinguished from one another in the same way. It thus appears that the absorption spectrum may in many cases furnish us with an efficient and simple means of ascertaining adulteration, for the presence of inferior substances which escape detection by the taste or sight will at once be recognised when spectrum analysis is employed. Russell, Gladstone, Abney, Festing, and others have studied with much success the spectra of solid and liquid bodies.

The absorption spectra of gases and vapours at low temperatures have been studied by various physicists, and amongst them by Janssen, Roscoe, Schuster, and Lockyer. Brewster, as we have seen, was the first to observe the effect produced on the solar spectrum by nitrous acid gas; other gases have since been tried in the same way, and many of these give out channelled or fluted absorption lines similar to those given out by nitrous acid gas. In fine, various researches lead us to conclude that gases, and more especially vapours, are in a state of greater molecular complexity at a low than at a high temperature, for at a low temperature they have a prominent absorption for many kinds of rays, whereas at a high temperature they have no such strong absorptive power, but absorb and radiate only a few definite spectral lines.

This simplification produced in spectra by the rise of temperature has been greatly insisted on by Lockyer, and will again come under our review when we have discussed the celestial applications of spectrum analysis.

Meanwhile, I cannot do better than quote the words of Lockyer in his Treatise on the Spectroscope and its applications (NATURE Series):—"We may state generally (says that observer) that beginning with one element in its most rarified condition, and then following its spectrum as the molecules come nearer together, so as at last to reach the solid form, we shall find that spectrum become more complicated as this approach takes place, until at last a continuous spectrum is reached."

Before concluding this division of my subject, it will be necessary to allude to the absorptive effect produced by the earth's atmosphere on the light and heat of the sun. This is a point of great practical as well as scientific importance, more especially if we reflect that the atmosphere is a covering of variable composition, and that the variable element (aqueous vapour) is one which no doubt exercises a large absorptive influence upon the rays of the sun. But there is another element of variability in the sun itself, for we more than suspect that the amount of radiant energy which we receive from our luminary depends to some unknown extent upon the state of his surface, and may thus be different in years characterised by a maximum number of sun spots, and in years characterised by a small number of these phenomena. An additional complication is introduced by the suspicion that one of these causes of variability may react upon the other in such a way that in those years when the radiation of the sun is intrinsically most powerful (if there be such) an abnormally large amount of aqueous vapour may be dissolved in the air, so that we may have on such occasions an increased absorption as well as a large intrinsic radiation, and the one of these causes may thus, to a great extent, cover or conceal the other.

Bearing these points in mind, I shall divide my remarks into two sections. I shall treat, *in the first place*, of the means which we have at our disposal for estimating the whole amount of radiant energy which reaches us from the sun at any station, whether this be near the level of the sea or at an elevation above it.

In the second place, I shall allude to the means we have at our disposal for estimating the amount of any one kind of radiant energy that reaches us from the sun.

An instrument by means of which we may ascertain the amount of the sun's radiant energy is called an *Actinometer*.

I have recently suggested such an instrument for measuring the heating effect of the sun, which has been tried at various stations, and appears to work well. It consists of a thick hollow cube of brass, surrounded with felt, and then again with a covering of polished brass. Into the interior of this chamber a suitable thermometer is inserted, its bulb being exactly in the centre. There is a small hole in one of the sides, through which the heat of the sun condensed by a lens is made to fall upon the bulb of the thermometer, the instrument having a motion in altitude and azimuth so as to enable it to catch the sun readily. The exposure is made for a definite time, as given by a good chronometer.

Instruments of this kind have been established in various places and at various elevations, and we shall certainly be able to derive from them information of importance as regards the meteorology of the place. To what extent we shall be able by their means to separate between the two apparent causes of solar variability, namely, that due to an intrinsic change in the sun itself, and that due to a change in the constitution of the earth's atmosphere, is perhaps an open question. It may be hoped that such an instrument may at least enable us to advance the problem, even if it prove insufficient to bring it to a complete solution.

Again, Professor Sir Henry Roscoe has invented an instrument intended to record the effect of the sun in blackening chloride of silver. He is able to prepare a paper of a standard sensitiveness, which, by an automatic arrangement, is exposed for known intervals of time. This is an instrument from which we shall no doubt obtain valuable information, more especially as the more refrangible rays of the sun play an important part in terrestrial economy. Still, however, it does not at first sight escape the objection above mentioned, or enable us to discriminate between the two apparent causes of solar variability—the celestial and the atmospheric.

It has been remarked by the Solar Physics Committee, in their report to the British Government (page 66) that by comparing with a standard certain definite regions of the solar spectrum, unabsorbed by any of the constituents of the earth's atmosphere, we might be able to ascertain any variation in the quantity or in the quality of the true solar radiation. This leads me to inquire what means we have at present of estimating the amount of any particular kind of ray which we receive from the sun. In the first place, we have the recent extension by Captain Abney of the powers of photography, in virtue of which it is not too much to assert that we can now obtain a complete map of the solar spectrum, with its absorption lines extending greatly beyond the visible spectrum on either side. We have also the invention and successful construc-

[1] Continued from p. 425.

tion by Professor Langley of his Bolometer, which is an instrument for detecting and measuring small quantities of radiant heat much more sensitive than the thermopile. It depends upon the fact that the electrical resistance of a metal is increased as it rises in temperature. Suppose, now, that two circuits conveying equal and opposite currents meet in a galvanometer, the needle will of course remain at rest. If, however, a portion of one of these two circuits be heated, its resistance will be increased, and the current passing through it will thus be diminished. The two opposing currents will now no longer balance each other, and in consequence the galvanometer needle will be deflected.

In the bolometer the two circuits each contain a sheet of extremely thin platinum foil, so that a very small quantity of radiant heat falling upon these may produce a considerable result. These sheets may be compared to the two faces of the pile, and if the one be heated we shall have a current in the one direction, while if the other be heated we shall have a current in the opposite direction. By this instrument Professor Langley has determined with much precision the exact distribution of energy in the solar spectrum. But he has done more than this: he has carried his instrument up to the top of Mount Whitney, in America, and has thus procured us much information regarding the absorbent effect of the various constituents of the earth's atmosphere.

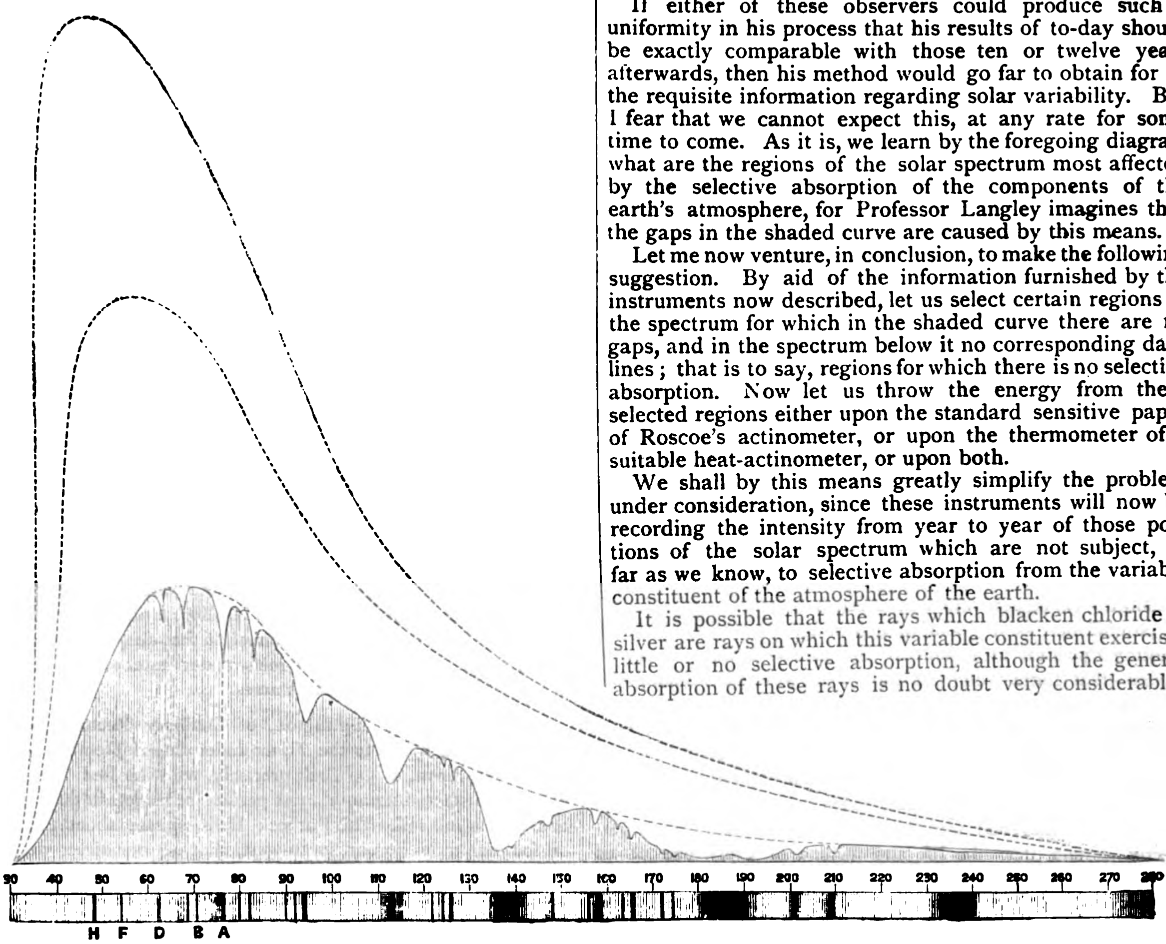

Fig. 10.

The following diagram (Fig. 10) exhibits the result of his researches. In it the lower band represents the solar spectrum as obtained by a perfect method. The shaded curve above the spectrum represents the observations made by Professor Langley with his Bolometer at the foot of the mountain. We have next a dotted curve derived from observations at the top of the mountain, and, finally, another representing the probable curve of solar energy above the limits of the atmosphere. It follows from these curves that if we could view the sun beyond the limits of the atmosphere the light would be decidedly blue.

There can be no doubt that the improved process of photography devised by Captain Abney, and the Bolometer of Professor Langley, furnish us with excellent differential instruments by which we may compare at any place and moment the relative distribution of solar energy over the various parts of the spectrum.

If either of these observers could produce such a uniformity in his process that his results of to-day should be exactly comparable with those ten or twelve years afterwards, then his method would go far to obtain for us the requisite information regarding solar variability. But I fear that we cannot expect this, at any rate for some time to come. As it is, we learn by the foregoing diagram what are the regions of the solar spectrum most affected by the selective absorption of the components of the earth's atmosphere, for Professor Langley imagines that the gaps in the shaded curve are caused by this means.

Let me now venture, in conclusion, to make the following suggestion. By aid of the information furnished by the instruments now described, let us select certain regions of the spectrum for which in the shaded curve there are no gaps, and in the spectrum below it no corresponding dark lines; that is to say, regions for which there is no selective absorption. Now let us throw the energy from these selected regions either upon the standard sensitive paper of Roscoe's actinometer, or upon the thermometer of a suitable heat-actinometer, or upon both.

We shall by this means greatly simplify the problem under consideration, since these instruments will now be recording the intensity from year to year of those portions of the solar spectrum which are not subject, as far as we know, to selective absorption from the variable constituent of the atmosphere of the earth.

It is possible that the rays which blacken chloride of silver are rays on which this variable constituent exercises little or no selective absorption, although the general absorption of these rays is no doubt very considerable; in this case no special adaptation to the chemical actinometer would be necessary.

To conclude, I think we may entertain a well-grounded hope that by patience and persistence in these or similar means, we shall ultimately arrive at a definite solution of this very interesting and important problem.

Balfour Stewart

(*To be continued.*)

NOTES

The Geological Congress met last week at Berlin. England was represented by Messrs. Geikie, Hughes, Bauermann, Hinde, Marr, Topley, White, Woodall, Lieut.-Col. Tabuteau, and

Capt. Shelley. Altogether there were 248 members, representing Germany, Austria, Belgium, Spain, the United States of America, France, India (Mr. Blanford), Italy, Japan, Norway, Holland, Portugal, Roumania, Russia, Sweden, and Switzerland.

MR. W. H. WHITE, who has succeeded Sir N. Barnaby as Director of Naval Construction, has entered upon his duties at the Admiralty.

WE regret to learn of the death of Walter Weldon, F.R.S., the eminent technical chemist, in his fifty-third year. Mr. Weldon's name is well known in connection with the Weldon process for the regeneration of the manganese peroxide used in the generation of chlorine, and with the consequent revolution in the production of bleaching-lime, affecting favourably such important industries as the cotton and paper trades.

THE Annual Exhibition of the Photographic Society was opened on Monday; the exhibits are up to the average of recent years.

SIR JOHN LUBBOCK unveiled on Thursday last, at Birmingham, a marble statue of the late Sir Josiah Mason, which has been placed in the square between the Science College and the Town Hall. Referring to the Mason College, Sir John said that such an institution was all the more needed on account of the extraordinary manner in which science is still neglected in our public schools. There were, indeed, according to the Technical Commission, only three schools in Great Britain in which science is fully and adequately taught. The majority of schools devoted to it less than three hours out of forty. Scientific men claimed for it six hours, which, with the same number for mathematics, ten for modern languages, and two for geography, would still leave no less than sixteen for classics. He advocated the general teaching of science, because it would add to the interest and brightness of life, would purify and ennoble the character, and because, with our rapidly-increasing population, it was almost a necessity, if our people were to be maintained in comfort. As regards the first point, it was quite a mistake to regard science as dry and uninteresting. Sometimes it might destroy a poetical idea, such as the ancient Hindoo theory of rivers—that Indra "dug out their beds with his thunderbolts and sent them forth by long continuous paths." But the real causes of natural phenomena were far more striking, and contained more real poetry than any that had occurred to the untrained imagination of mankind. Not our happiness only, but in many cases our very life itself depended on our knowledge of science. Huxley had well asked, "Whether, if it were perfectly certain that the life and fortune of every one of us would one day depend on our winning a game of chess we should not all learn something of the game. Yet it is a very plain truth that the life and fortune of every one of us depend on our knowing something of the rules of a game infinitely more difficult. It is a game which has been played for untold ages, every man and woman of us being one of the two players. The chessboard is the world, the pieces are the phenomena of the universe, the rules of the game are what we call the laws of nature. The player on the other side is hidden from us. We know that his play is always fair, just, and patient. But also we know, to our cost, that he never overlooks a mistake, or makes the smallest allowance for ignorance. To the man who plays well the highest stakes are paid with overflowing generosity, but one who plays ill is checkmated—without haste, but without remorse." The national necessity for science was most imperative. Even now we required to purchase food to the amount of 150,000,000*l.* a year. A century hence our coal would be approaching exhaustion, our population would be trebled, and we should require, to speak moderately, 400,000,000*l.* to pay for food. Nothing but the development of scientific training and appliances would enable us, under these circumstances, to maintain our population in happiness and comfort. We had, in fact, the choice between science and suffering.

MR. H. H. JOHNSTON appeals in the *Times* for subscriptions to make good the loss which Mr. H. O. Forbes has sustained while embarking at Batavia for his exploring journey in New Guinea. The boat which was carrying all his baggage on board ship suddenly capsized, and the unfortunate explorer in a few seconds lost all his equipment, a loss which it would probably take about 1000*l.* to replace. Mr. Forbes, it may be remembered, was subsidised by the Royal, the Scottish, and the Australian Geographical Societies, while the British Association at Aberdeen has made a grant of 150*l.* to help to replace his loss. What excellent work Mr. Forbes is capable of doing for science is shown in his recently-published work on the Malay Archipelago. He lost no time in getting to Brisbane, and has doubtless there obtained on credit such articles as will enable him to go on with his work, as according to the latest news he is again on his way to New Guinea. Subscriptions may be sent to the Secretary, Royal Geographical Society, Savile Row, W.

IN a few days the rock in the Hell Gate entrance to New York harbour, from Long Island Sound, is to be blown up by a party under the command of General Newton, United States Engineer. For nine years the work of excavation has been in progress. The rock has been honeycombed with chambers, the surface being still supported by columns of rock, into which dynamite cartridges have been fitted. Some 45,000 of these cartridges cased with copper have been laid. The work of distributing the cartridges began in July, 1884, and has just been completed, 275,000 lbs. of dynamite having been used. The explosion is to be brought about by means of an automatic detonator, placed upon Flood Rock, an electric connection with the land being established. It is expected that the explosion will pulverise the whole of the rock, without making much commotion in the water, or doing harm beyond a distance of 1000 feet. The *débris* will afterwards be removed, so as to make a channel 26 feet deep at low water. Flood Rock and the adjacent reefs under water which will be destroyed cover a space of nine acres.

THE Rev. M. F. Billington, of Chalbury Rectory, Wimborne, Dorset, writes to the *Times* under date September 29:—"This afternoon, at 5 o'clock precisely, we witnessed from this hill, of 360 feet altitude, a most perfect reflection in the clouds of a ship in full sail. The Purbeck Hills, situate about thirteen or fourteen miles to our south-west, shut out our direct view of the sea in that direction, and in all our long experience of many beautiful views of the coast line we have never before observed this curious phenomenon. It lasted for about three minutes, and then slowly faded out of sight."

ON September 29, between 8 and 9 p.m., a mirage somewhat similar to that described last week (p. 541) was again observed by many persons at Valla in Sweden. The entire lower part of the north-western horizon shone with a lurid glare, above which was a cloud-bank assuming the most remarkable forms. From time to time animals, trees, and shrubs were seen. Soon a bear changed into an elephant, and soon a dog into a horse. Later on groups of dancers were seen, men being distinguished from women. Further north the cloud formed an oak forest, in front of which was a valley, and nearer still a park with sanded paths. At about 9.30 the cloud sank into a mass, and the phenomenon disappeared.

THE Royal Microscopical Society will meet at King's College, W.C., on Wednesday, the 14th inst., at eight o'clock, when the following papers will be read:—Dr. Maddox: On the Feeding of Insects with Bacilli. Mr. T. B. Rossiter: On the Gizzard of the Larvæ of *Corethra plumicornis*.

ARRANGEMENTS are being made for the establishment of a Zoological Garden in Christiania.

DURING last week a series of experiments were carried out upon North Sea trawling vessels with a view to lighting them by electricity. The attempt was on the whole satisfactory. The introduction of electric light into fishing-boats would prove invaluable, but the heavy expenditure involved in such a scheme would exclude its general usage.

THE United States Fish Commission report a great decrease in the halibut and cod fisheries of America. The cause for this is attributed either to low temperatures of water or the destruction of fry by reckless fishing. A general falling off of flat-fish is reported from Germany this year, and a diminution in the herring fishery is recorded from Belgium. The increased number of fishermen off Holland and the destruction of immature fish has produced a bad effect upon the fishery of that place.

THE National Fish Culture Association have made arrangements to import a large consignment of carp from Germany for the purpose of acclimatising them to the waters of the United Kingdom. Numerous applications have been made from all parts for supplies of these fish, which are far superior to our own species. In Germany, China, France, and America carp farming is extensively prosecuted with highly satisfactory and remunerative results.

WE have received the report for the summer session of 1885 of the Queenwood College Mutual Improvement Society. It describes in detail the various excursions of the session, and would make an admirable guide for the parts of Hampshire and the Isle of Wight visited.

WE have received from the author a pamphlet containing a geological sketch of the Island of Antigua, by Mr. Purves, which was originally contributed to the *Bulletin* of the Royal Museum of Natural History of Belgium. Prior to this paper the only information on the subject was contained in a paper by Dr. Nugent, published in 1819, and by Prof. Hovay, published in the *American Journal of Science* in 1839. The pamphlet is illustrated by a geological sketch map.

THE Queen has been pleased to grant to Prof. W. Chandler Roberts, F.R.S., of the Royal Mint, authority to use after his paternal name the name of his uncle, the late Major N. L. Austen, J.P., of Haffenden and Combourne, in the county of Kent.

THE additions to the Zoological Society's Gardens during the past week include a Toque Monkey (*Macacus pileatus* ♂) from Ceylon, presented by Mr. Septimus Smith; a Green Monkey (*Cercopithecus callitrichus* ♂) from West Africa, a Macaque Monkey (*Macacus cynomolgus* ♀) from India, presented by Mr. S. T. K. D. Potter, F.R.G.S.; six Indian Fruit Bats (*Pteropus medius*) from India, presented by Mr. W. Jamrach; two Canadian Skunks (*Mephitis mephitica*) from North America, presented by Dr. C. Hart Merriam, C.M.Z.S.; a Common Badger (*Meles taxus*), British, presented by Lord Egerton of Tatton, F.Z.S.; a Ring-necked Parrakeet (*Palæornis torquata*) from India, presented by Mrs. Douglas; a Common Barn Owl (*Strix flammea*), British, presented by Miss Linda Raven; two Common Guinea-Fowls (*Numida cristata*), British, presented by Mr. C. H. Hopwood, M.P.; a Loggerhead Turtle (*Thalassochelys caouana*) from the Atlantic Ocean, presented by Mr. A. Duncan Fraser; four Hog-nosed Snakes (*Heterodon platyrhinos*), a Say's Snake (*Coronella sayi*), two —— Snakes (*Coluber alleghaniensis*), an American Black Snake (*Coluber constrictor*) from Indiana, North America, presented by Mr. F. J. Thompson; a Greater Sulphur-crested Cockatoo (*Cacatua galerita*) from Australia, a Great Bird of Paradise (*Paradisea apoda*) from the Aroo Islands, a Common Cormorant (*Phalacrocorax carbo*), British, an Emu (*Dromæus novæ-hollandiæ*) from Australia, a Gigantic Salamander (*Megalobatrachus maximus*) from Japan, deposited.

OUR ASTRONOMICAL COLUMN

THE SATELLITES OF URANUS AND NEPTUNE.—In Appendices I and II. of the Washington Observations for 1881, Prof. Asaph Hall has published the results of his investigation of the orbits of the outer satellites of Uranus, *Oberon* and *Titania*, and the satellite of Neptune. The satellites of Uranus were amongst the first objects observed with the 26-inch refractor of the Naval Observatory, after it was mounted in November, 1873. The first series during the oppositions of 1874 and 1875 were discussed by Prof. Newcomb, with the view to the determination of the mass of the planet, and the formation of tables of the motions of the satellites, which were published in the Washington Observations for 1873. Remarking that as the earth would be nearly in the plane of the orbits in the year 1882, and observations made about that year would probably afford a good determination of the position of this plane, Prof. Hall commenced a new series in March, 1881, which were continued through the four oppositions until the end of May, 1884; these observations were made with magnifiers of 606 and 888; in fair conditions of the atmosphere the outer satellites are stated to be easily observable with the Washington instrument. A comparison of the measures with Prof. Newcomb's tables showed that those tables required but small corrections, which were found by equations of condition in the usual manner. It should be mentioned that the tables were founded mainly upon Prof. Newcomb's own measures; those by Prof. Hall in the years 1875 and 1876 are included in his recent discussion.

For the position of the nodes and inclination of the orbits of the satellites, Prof. Hall finds—

$$N = 165^\circ{\cdot}81 + 0^\circ{\cdot}0142t$$
$$I = 75^\circ{\cdot}30 - 0^\circ{\cdot}0014t$$

t being the number of years from 1883·0.

The mean value of the mass of Uranus by the observations of *Oberon* is $\frac{1}{22603}$, and by those of *Titania*, $\frac{1}{22833}$, or, combining the values with their respective weights, the final result is $\frac{1}{22682}$. This value, though somewhat smaller than those previously obtained, Prof. Hall thinks is as good as he could obtain with the filar-micrometer of the large refractor, and he does not consider that there would be much gained by a continuation of the measures. He mentions that during the oppositions of the planet from 1881 to 1884, which were especially favourable for the search after new satellites, he made careful examination on several good nights along the orbit plane of the known satellites, without finding any new ones.

The orbits of *Oberon* and *Titania* appear to be sensibly circular.

Prof. Hall's discussion of the elements of the orbit of the satellite of Neptune is founded upon his own observations during the oppositions of 1875 and 1876, and those of 1881—84; in addition, he has made use of Prof. Holden's measures in the interval 1874 December—1878 November, and has also discussed those of Lassell and Marth taken at Malta in 1863 and 1864. Prof. Newcomb's elements are corrected by the formation of equations of condition and their solution, as in the case of the satellites of Uranus. The following are the principal results:—

$$N = 184^\circ{\cdot}32 + 0^\circ{\cdot}0095t$$
$$I = 120^\circ{\cdot}05 + 0^\circ{\cdot}0005t$$

t being counted from 1883·0.

Comparing the observations of 1881—84 with those of Lassell and Marth, the periodic time is found to be 5·876839 mean solar days; that deduced by Mr. Hind, which was adopted by Prof. Newcomb in his tables, is 5·8769 days; the small difference would produce a change of about 5° in the true position of the satellite in its orbit at the beginning of next century, and Prof. Hall leaves it to future observations to decide whether his correction is required.

The values of the mass of Neptune from his measures at different oppositions, and from those of Lassell and Marth and of Holden differ sensibly. The mean result from Hall's own observations is $\frac{1}{19092}$; he remarks that his distances are generally smaller than those of other observers, and believes that, in order to eliminate the effect of such personal equation from the determination of the mass of a planet, the only way will be to increase the number of observers and to take a mean of their results. Hall's value approaches nearly to that found by Prof. Newcomb, $\frac{1}{19380}$.

On favourable nights examinations of the region about Neptune were made, but no other satellite was detected.

VARIABLE STARS (1).—The following Greenwich times of geocentric minima of Algol have been deduced from elements corrected by the later observations of Schmidt:—

		h. m.			h. m.
November	8	15 7	December	7	7 16
	11	11 56		18	18 33
	14	8 45		21	15 22
	17	5 34		24	12 11
	28	16 49		27	9 0
December	1	13 38		30	5 49
	4	10 27			

(2) R Leonis will now be approaching a maximum; there would appear to be indications of a sensible perturbation in the period during the last twenty years or more. (3) V Piscium, one of Argelander's supposed variables, is now favourably placed for observation; his estimates vary from 6·7 m. to 9 m.; the position of this star for 1885·0 is in R.A. 1h. 48m. 18s., Decl. + 8° 12′·9. (4) Argelander's formula of sines makes a maximum of *Mira Ceti* due on December 19, but it may probably occur earlier.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, OCTOBER 11–17

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on October 11

Sun rises, 6h. 20m.; souths, 11h. 46m. 41·8s.; sets, 17h. 14m.; decl. on meridian, 7° 11′ S.: Sidereal Time at Sunset, 18h. 36m.

Moon (three days after New) rises, 9h. 40m.; souths, 14h. 28m.; sets, 19h. 13m.; decl. on meridian, 15° 18′ S.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	5 55	11 35	17 15	4 35 S.
Venus	10 17	14 23	18 29	21 28 S.
Mars	0 11	7 49	15 27	17 44 N.
Jupiter	3 54	10 16	16 38	3 38 N.
Saturn	21 8*	5 16	13 24	22 18 N.

* Indicates that the rising is that of the preceding day.

The Phenomena of Jupiter's Satellites are such as are visible at Greenwich.

Oct.	h.	
11	12	Venus in conjunction with and 6° 23′ south of the Moon.
16	10	Mercury in superior conjunction with the Sun.
17	2	Venus at greatest distance from the Sun.

GEOGRAPHICAL NOTES

ACCORDING to the report by Lieut. Wissmann on his last exploration in the Congo region, the Lower Kassaï constitutes a magnificent fluvial artery, frequently of enormous breadth, and leads without obstacle into the heart of the new Congo State. Between the station of Kwamouth and the confluent of the Lulua and above the station of Luluaburg the Kassaï, with a breadth of about 600 kilometres, is everywhere open for navigation. It runs through a country of wonderful fertility, presenting alternately plains and virgin forests, and inhabited by a dense population. With about one exception the travellers have been received everywhere with eagerness by peaceable tribes, all disposed to trade. During the forty-two days employed in the voyage from Luluaburg to Kwamouth the health of the expedition was excellent. There was no loss of life, except that two natives were drowned in the rapids of the Lulua. The five white men and the 200 Negroes of the Expedition arrived all in good health at Léopoldville on July 16.

THE current number of *Petermann's Mittheilungen* contains the conclusion of M. Thoroddsen's paper on a lava desert in the interior of Iceland. It supplies certain geographical and scientific observations of the writers, such as the superficial dimensions, height, &c., hydrography, climate, geology, volcanoes, glaciers, botany, and zoology of the interior of Iceland. Herr Hassenstein describes, with a large map, Bohndorff's journeys in Central Africa between 1874 and 1883. The usual geographical information for the month, and account of the literature concludes the number.

THE most interesting contribution, however, to *Petermann* this month is a short prefatory sketch on the history of the great geographical house of Perthes of Gotha, September 11 being the centenary of its foundation. In 1801 the first geographical work was published by Perthes, and in 1809 he published a large atlas by Prof. Heusinger. Under the second proprietor, Wilhelm Perthes, who was head of the establishment between 1816 and 1853, the publications of the house assumed their geographical and cartographical character. In 1817 appeared the first edition of Stieler's Atlas, consisting of fifty maps, and between 1823 and 1831 a supplement of twenty-five more was added This Atlas has now for nearly seventy years been the principal work published by the house of Perthes. It has been kept up to date, and the number of the maps, which in 1862 was 84, grew in 1871 to 90, and in 1879 to 95. The total number of maps, old and new, amounts to 197. Besides Stieler, Berghans (1797-1884), Spruner and Sydow supported Perthes. In 1832 Berghans's great atlas of the extra-European countries appeared. It was a financial failure, but it carried the name of the house abroad, and laid the foundation of its world-wide fame. In 1838 the publication of the same author's Physical Atlas in 93 maps was completed. Between 1837 and 1852 Spruner's Historical-geographical Atlas appeared, and was followed by various editions. Wilhelm Perthes died in 1853, and Bernhardt Perthes reigned in his stead for only four years, leaving a posthumous son, the present Justus Perthes. Petermann, who died in 1878, commenced his celebrated *Mittheilungen* in 1855. The publications of the house since that date are well-known to all geographers; Behm's "Geographical Year-Book," and Behm and Wagner's "Population of the Globe," are works of world-wide celebrity.

ON Friday last, after an absence of nearly three years, the Danish exploration expedition to the east coast of Greenland, under Lieutenants Holm and Garde, returned to Copenhagen in the ship *Constance* from Godthaab. We have from time to time given particulars of the progress of this expedition, the chief object of which was to penetrate as far north along the east coast as possible, and to attempt to reach certain native settlements known to exist between latitudes 65° and 66° N. The expedition has fulfilled all expectations, besides the collection of a valuable scientific material, Lieut. Holm having wintered in lat. 65°-66°, the highest point reached being lat. 66°08′ N., the northernmost ever reached by Europeans. Lieut. Holm is stated to have made some very valuable geographical and ethnographical discoveries, having spent last winter among East Greenlanders never before visited by Europeans. He has named the stretch of coast explored, King Christian IX.'s Land.

A WRITER who has travelled widely through Tonquin and Southern China describes, in a recent number of the *République Française*, the route from Lao-Kai, on the Red River, to Mengtsze in Yunnan. Premising that the river from the mouth to Lao-Kai, on the Tonquin border, is tolerably well known, he refers to the various routes for getting into South-Western China, but is far from enthusiastic about any of them, although he thinks that France in Tonquin has as much chance of getting the China trade as any of her rivals in the south. The writer then describes the route along the river from Lao-Kai to Manhao, the head of the Red River navigation. From this point the road to the plateau of Yunnan is said to be mountainous and difficult in the extreme. The article is of special value at the present moment, when the question of trade routes into South-Western China has assumed so much prominence.

THE BRITISH ASSOCIATION

SECTION C—GEOLOGY

Some Results of a Detailed Survey of the Old Coast-Lines near Trondhjem, Norway, by Hugh Miller, F.G.S., H.M. Geological Survey.—During a short visit to Norway in October, 1884, it appeared to the author that the best way to help to a solution of the vexed questions connected with the coast-terracing of Norway was to execute a careful survey of a few square miles of some suitable coast-region upon a sufficiently large scale. The neighbourhood of Trondhjem is remarkably well suited to this purpose. The map employed was partly a municipal chart on the scale of 1-10,000, and partly an enlargement of the Ordnance map. The limit of all the terraces and marine deposits is the famous "strand line" west of the town, a double range of old coast-cliff cut in the rock of the mountain-side. Its upper line is 580 feet above the sea, and answers to the "marine limit" over Norway generally. Numbers of level terrace-lines have been incised—chiefly in greenish clays, like brick-clays—all along the arable slopes east of the town between this rock-terrace and the sea. Above the Bay of Leangen, two miles east of town and river, and far beyond all erosive influence of the latter, thirty of these lines were mapped one above another in the first 300 feet of ascent, a distance of one and a half mile. Many of these are small but extremely distinct, the earthy clays being well suited to retain sharp impressions of successive sea-margins, which these unequivocally are. The present coast-line, neatly etched out by the waves in Trondhjem and Leangen Bays, is the key to these tiers of older ones. It also resembles them in having made little or no impression where the coast becomes rocky, the lines of incision in both cases stopping short at once when they reach the harder material. The old coast-lines are most numerous in well-sheltered positions. Thus a single pair of large terraces in an exposed situation east from Christiansten, where they face the open water of the fjord and the prevalent north-westerly storms, is represented in the recess above Leangen Bay by ten or twelve. The same fact is brought out on rising from this recess to the higher and more exposed ground. Thus, while thirty-three or thirty-four terraces are mapped below 350 feet (approximate) elevation, only nine or ten appear between that level and the rock-terraces of the upper marine limit, the numerical average height of the terraces thus rising by more than a half. In recesses of the coast further east, but beyond the map, these upper terraces seem to be preserved in considerably greater numbers. The number actually mapped was forty-three, or, with the two rock-terraces, forty-five. The largest number of terraces hitherto described at any one place in Norway seems to have been eighteen. Some of the general conclusions of the author are as follows:—(1) These terraces are all post-glacial, *i.e.* formed since the rock-glaciation of the district. This is confirmed by the condition of the high coast-cliff, which has been cut in ice-rounded rock, but is not itself glaciated. It appears, however, from the fauna of the raised shell-banks of the country (as worked out by Sars and Kjerulf), in which recent shells do not rise above 380 feet, that the seas of the upper levels were still glacial; and, though the Trondhjem fjord was free from land-ice, other deeper fjords and higher coasts may still have had glaciers coming into conflict with the sea, and producing the glaciated rock-terraces described by Sexe. All the evidence obtained discountenances Sexe's view that these rock-terraces were cut out by glaciers, as well as Carl Petersen's that they were rasped out by floating ice coasting the shores. On the clay terraces coast-ice has left no more sign of its presence than the winter freezing of our British rivers leaves upon our river-terraces. (2) If the country was upraised by a succession of elevatory jerks, as supposed by most geologists from Keilhau downwards, most of these would seem to have been small—much smaller, at least, than is supposed by Kjerulf. It is improbable that even Leangen Bay was secluded enough to contain a record of all the original coast-lines. The longer pauses and greater storms may have effaced an unknown number by a process of excision exemplified in all its stages by the map. It is hard to say, in fact, where the subdivision would end if all were preserved. The smaller terraces remind the eye of the incised lines and little planes engraved on the sandbanks bordering the rivers after a flood, in which case there is no periodicity in the subsidence of the waters. (3) The preservation or excision of the terraces thus seems to depend as much upon local circumstances—exposure to storms, resistance of coast-line, &c.—as upon anything else. It is impossible at present to predicate which of them shall in any given place remain. Whether elevation by jerks, therefore, be postulated or not, all hope of correlating these terraces throughout the country must be deferred until their heights have been accurately determined by level. The measurements hitherto made, not even excepting those of Profs. Kjerulf and Mohn, are probably inadequate for the purpose. This observation seems to apply also to the terraces graven in rock. In their aneroid measurements of the upper strand-line at Trondhjem these observers differ by 55 feet. (5) On entering the mouth of the Trondhjem Valley the terraces come under an influence other than that of the sea-waves. The valley was worked out, in deposits partly levelled out by the sea, according to the laws of river-terracing under the accelerating influences of a falling sea-level. The processes of automatic river-terracing are beautifully exemplified within the district mapped in the deep lobe-shaped curve of the river just before it enters the sea. The terraces have been added one after another to the point of the lobe of land thus surrounded, which is known as Oen.

The Glacial Deposits of Montrose, by Dr. J. C. Howden.—These consist, in order of age—(1) a marine clay containing fossils of a purely Arctic type, apparently the bottom of a deep sea. Above this is seen the estuarine clay, beneath which, however, are often found deposits of peat. Over the estuarine clay is a bed of stratified sand, and above that a dense non-fossiliferous Carse Clay, varying in thickness from 4 to 6 feet. The sequence of these deposits was held by the author to indicate interglacial periods.

Irish Metamorphic Rocks, by G. H. Kinahan, M.R.I.A.—This paper is an epitome of what is known as to the age of the Irish Metamorphic rocks.

Barium Sulphate as a Cementing Material in Sandstone, by Prof. Frank Clowes, D.Sc.—The author described the "Hemlock stone" and other similar blocks of Lower Keuper sandstone in the neighbourhood of Nottingham. They stand out in hard masses from the more easily denuded sandstone around them. Analysis has shown that the cementing material of the upper part is barium sulphate. This being practically insoluble withstands denudation and protects the lower part from waste, this lower part being mainly cemented by calcareous matter. Bischof has proved the occurrence of barium sulphate as a cementing material in some foreign sandstones, but the fact is probably new in Britain.

On Deep Borings at Chatham. A Contribution to the Deep seated Geology of the London Basin, by W. Whitaker, B.A., F.G.S., Assoc.Inst.C.E.—A few years ago the Admiralty made a boring in the Chatham Dockyard extension, to the depth of 903½ feet, just reaching the Lower Greensand, and in 1883-84 followed this by another boring near by. After passing through 27 feet of Alluvium and Tertiary beds, 682 of chalk, and 193 feet of Gault, the Lower Greensand was again reached; but, on continuing the boring, was found to be only 41 feet thick, when it was succeeded by a stiff clay, which, from its fossils, is found to be Oxford clay, a formation not before known to occur in Kent. At its outcrop, about seven miles to the south, the Lower Greensand is 200 feet thick, and is succeeded, a little further south, by the Weald Clay, there 600 feet thick. Not only, however, has this 600 feet of clay wholly disappeared, but also the whole of the next underlying set of deposits, the Hastings beds, which crop out everywhere from beneath the Weald Clay, and are also some hundreds of feet thick. More than this, the Purbeck Beds, which underlie the Hastings Beds near Battle, are absent, and also the Portlandian, Kimmeridge Clay, Corallian, &c.; beds which have been proved above the Oxford Clay in the sub-Wealden Boring, to the great thickness of over 1600 feet. We are therefore faced with a great northerly thinning of the beds below the Gault, a fact agreeing in the main with the evidence given of late years by various deep wells in and near London. Three other deep borings have been made or are being made near Chatham, all of which have passed through the Chalk into the Gault, and one has gained a supply from the sand beneath. The practical bearing of the Chatham section is, however, to enforce the danger of counting on getting large supplies of water in the London Basin from the Lower Greensand by means of deep borings at any great distance from its outcrop. Even if Lower Greensand occur at all in such places, it will probably be in reduced thickness, and therefore with reduced water-capacity.

American Evidences of Eocene Mammals of the "Plastic Clay" Period, by Sir Richard Owen, K.C.B., F.R.S., G.S., &c.—In the year 1843 a fragment of a lower jaw with one entire molar of a mammal was dredged up off the Essex coast. A canine tooth of the same was found in a well-sinking near Camberwell, in piercing the "plastic clay." The author had described the above as belonging to an animal of the Lophiodont family, and proposed for it the generic name Coryphodon. Shortly afterwards De Blainville had noticed certain fossils as "probably Coryphodont," but had referred them to *Lophiodon anthracotherium*. Ten years later Prof. Hébert had recognised two species of *Coryphodon* in the plastic clay of France. Explorations by Leidy, Marsh, and Hayden, in the "Mauvaises Terres" of Nebraska had led to the discovery of a large hoofed mammal allied to *Coryphodon*, to which the name *Titanotherium* had been given, and Prof. Cope has now recognised, from Evanstown, Wyoming, seven species of *Coryphodon*. From these materials, which have been rendered accessible to European palæontologists by the superb volume of reports recently issued by the United States Government, the author is enabled to give a general description of this family of hoofed mammals of large size which flourished in early Eocene times. To the details of this the major part of the paper is devoted.

Some Results of the Crystallographic Study of Danburite, by Dr. Max Schuster.—In studying the characters of the faces and the structure of the Danburite crystals found in Switzerland the author has met with vicinal faces of a peculiar kind, for which he proposes the term "transitional faces" (*Tschermak Min. Mittheil.*, vi., 1884, p. 511). Attention is called to the fact that these faces are easily affected by those causes which produce an unequal development of faces otherwise symmetrically disposed, and an illustration is given of the way in which their indices are numerically related to those of the principal faces of the crystal.

Notice of an Outline Geological Map of Lower Egypt, Arabia Petræa, and Palestine, by Edward Hull, LL.D., F.R.S., F.G.S.—The map exhibited was enlarged from that which accompanies the author's book, "Mount Seir, Sinai, and Western Palestine," giving a narrative of the expedition sent out into these countries by the Palestine Exploration Society in 1883-84. It embraces a region extending from the valley of the Nile on the west to the table-land of Edom (Mount Seir) and Moab, including the Jordan, Arabah Valley, and the mountains of Sinai. Its northern limit is the Lebanon. The main lines of fault and dip of the strata are also indicated. A topographical and geological map of the Arabah Valley on a scale of about six miles to one inch was in preparation, and would accompany the Geological Report now in the press for the Palestine Exploration Society.

A Preliminary Note on a New Fossil Reptile recently discovered at New Spynie, near Elgin, by Dr. R. H. Traquair, F.R.S.—Of this most important fossil the author had as yet only seen a photograph submitted to him by Prof. Judd, the President of the Section. This photograph represents pretty nearly a vertical longitudinal section of a reptilian skull, of which one very prominent feature is the presence of a large conical tusk in the upper jaw, projecting downwards and forwards, immediately behind the premaxillary part of the skull. This tusk is seen only in impression, but the cast of the internal cavity which is well shown indicates that it grew from a permanent pulp. No evidence of any other teeth is visible, and the whole appearance of the skull as seen in the photograph, with the position and shape of the tusk, indicate that the reptile here represented, if not actually belonging to the genus Dicynodon, is certainly a member of the group of Dicynodontia. Geologists will not underrate the importance of this discovery in its bearing on the question of the age of the reptiliferous sandstone of Elgin.

On the Average Density of Meteorites compared with that of the Earth, by the Rev. E. Hill, M.A., F.G.S.—The average density of the meteorites which fall on the earth is attempted to be calculated. Different methods give as results 4·55, 4·58, 4·84, 5·71, the last value being influenced by the size of one particularly large metallic specimen. The average density of the earth is usually regarded as 5·6. Meteorites are samples of the materials of space. A mass of them would aggregate into a body of density not widely differing from that of the earth. The densities of the other planets are not inconsistent with a like origin. Consequently any theory of the genesis of the earth from pre-existing materials involves a probability that an important part of its nucleus is metallic.

On the Occurrence of Lower Old Red Conglomerate in the Promontory of the Fanad, North Donegal, by Prof. Edward Hull, LL.D., F.R.S., Director of the Geological Survey of Ireland.—The district in which the Old Red Conglomerate occurs is formed of ridges and valleys of metamorphic rocks, consisting of beds of quartzite, schist, crystalline limestone, and trap, chiefly diorite. It lies between Lough Swilly and Mulroy Bay, and is washed on the north by the waters of the Atlantic. The remarkable tract of the Old Red Conglomerate, recently discovered by the officers of the Geological Survey, is far remote from any mass of the same formation, and it is unrepresented on any geological map hitherto published. The beds consist of red and purple sandstones and conglomerates, made up chiefly of quartzite pebbles and blocks, but also containing others of limestone and trap; all derived from the surrounding metamorphic series. They occupy an area of over two miles in length and half a mile across, extending along the northern base of Knock Alla, a ridge of quartzite which traverses the promontory from side to side. The beds dip against the base of the mountain, against which they are let down by a large fault, and they terminate along their northern edge by an unconformable superposition on beds of quartzite and limestone. They reach a total thickness of about 800 feet. From the position of these beds it becomes evident that they are unconnected with any of the recognised basins of Lower Old Red Sandstone, either in Scotland or Ireland, and may, therefore, be regarded as having been formed in an isolated basin, which, following the example of Dr. Geikie, I may be allowed to name "Lake Fanad." The tract will be a new feature on geological maps of Ireland.

On Bastite-Serpentine and Troktolite in Aberdeenshire; with a Note on the Rock of the Black Dog, by Prof. T. G. Bonney, D Sc., LL.D., F.R.S., Pres.G.S.—Bastite-serpentine (as noticed some time since by Prof. Heddle) occurs near Belhelvie and on the shore near the Black Dog. The author describes the microscopic structure of this, showing that it consists of olivine and its alteration products, enstatite in various stages of alteration, and a mineral of the spinellid group. Associated with this in the Belhelvie district is a fairly normal troktolite, consisting of a plagioclastic felspar allied to anorthite, olivine, more or less altered, and a little diallage. It closely resembles the typical Volpersdorf rock, but has rather less magnesia and more alumina, corresponding chemically more nearly with a rock described by the author from Coverack Cove, Cornwall. He is of opinion that the two rocks differ somewhat in age, though probably the earlier was still at a high temperature when the latter was intruded, and he inclines to the view that the serpentine is the older rock of the two. The Black Dog has been incorrectly described as consisting of "crystals of *talc* matted in such confusion as to form both a tough and hard rock." The rock really consists of quartz, sillimanite, two kinds of mica, an iron oxide (hematite?), and most probably some dichroite, with perhaps a little kyanite. In short, the rock presents a very close resemblance under the microscope to some specimens of the well-known "cordierite gneiss" of Bodenmais.

On the Re-discovery of Lost Numidian Marbles in Algeria and Tunis, by Lieut.-Col. Playfair, H.M. Consul-General for Algeria and Tunis.—The author explained that the name itself was a misnomer, as they are not found within the limits of Numidia proper, but in the province of Africa and in Mauritania. Most of the "Giallo antico" used in Rome was obtained from *Simittu Colonia*, the modern Chemton, in the valley of the Medgérda, the quarries of which are now being extensively worked by a Belgian company; but the most remarkable and valuable marbles are found near Kleber, in the province of Oran, in Algeria. There, on the top of the Montagne Grise, exists an elevated plateau, 1500 acres in extent, forming an uninterrupted mass of the most splendid marbles and breccias which the world contains. Their variety is as extraordinary as their beauty. There is creamy white, like ivory; rose colour, like coral; Giallo antico; some are as variegated as a peacock's plumage; and on the west side of the mountain, where there has been a great earth-movement, the rock has been broken up and re-cemented together, forming a variety of breccias of the most extraordinary richness and beauty.

On some Rock-Specimens from the Islands of the Fernando Noronha Group, by Prof. A. Renard, LL.D.—The rock-specimens described in this communication were collected by Mr. J. G. Buchanan, during the voyage of the *Challenger*. The islands have been described by Darwin in his "Geological Observations on Volcanic Islands" (2nd edition, p. 27). The author, after having explained the geological structure, gives lithological descriptions of the chief types of the rocks, which may be referred to the phonolites (St. Michael's Mount). These phonolites are composed of sanidine, augite, nepheline, hornblende, magnetite, nosean, and titanite. The rocks of Rat Island are basalts with nepheline. The constituent minerals are augite and olivine. The ground-mass is almost entirely composed of nepheline. Biotite and apatite occur as accessory constituents. The little island known as Platform Island is also basaltic, with a doleritic texture. It is composed of labradorite, augite, olivine, magnetite, and biotite. This rock has undergone alterations.

Preliminary Note on some Traverses of the Crystalline District of the Central Alps, by Prof. T. G. Bonney, D.Sc., LL.D., F.R.S., Pres. G.S.—During the past four years I have made several traverses of the Central Alps from north to south, and venture to lay before the Section the general results as bearing in some respect on the geology of the Highlands. (1) The ordinary rules of stratigraphy as learnt from most lowland districts are commonly quite inapplicable to the Alps. The most highly crystalline and the older beds often form the higher parts of a mountain region, the newer the lower. The newer beds frequently appear to underlie and dip regularly beneath the older. Gigantic folds, overturns, and overthrust faults abound. The true stratigraphy of a district can only be worked out by the exercise of patient and cautious induction from observations extended over a wide area. (2) The non-crystalline rocks of the Alps are of various ages. There are some of Carboniferous age, but the great period of continuous deposition generally begins with some part of the Trias. The conglomerates, which often occur at the base of the non-crystalline deposits, indicate that the principal metamorphism of the crystalline series was anterior to both these epochs. There is at present no reason to suppose that either in the Central Alps or for some distance on each side are there any representatives of the earlier Palæozoics. I believe that the conglomerates at the base of the Carboniferous contain fragments of the later crystalline rocks of the Alps as well as of some of the earlier—though I do not assert that these crystalline rocks have undergone no modifications since Carboniferous times. (3) In the heart of the principal Alpine chains, and apparently at the base of everything, are coarsely crystalline gneisses. These differ little from granites, except that they generally—almost always—exhibit a certain foliation, and occasionally seem to be interbedded with thin seams of micaceous schists or flaggy fine-grained beds. (4) On examination we find reason to believe that both the latter are generally due to crushing. Their strike agrees with that of the apparent foliation in these older rocks, and with that of a foliation which is also present in the newer crystalline rocks. This corresponds with the strike of the main physical features of the district, and with the cleavage in the included troughs of sedimentary rock. It runs for great distances with remarkable uniformity. (5) This apparent foliation is due to the devolopment of extremely thin films of a micaceous mineral. In many cases it causes the rock to bear the aspect of a highly micaceous schist; yet, on examining a transverse section, the rock is distinctly seen to be a crushed gneiss—*i.e.* though so conspicuous, it is a mere varnish. As it thus differs materially from a true foliation, it would be convenient to give it a name, and I should propose to call it the "sheen surface." It is, in fact, a kind of "cleavage foliation," that is, a foliation due to cleavage, and subsequent to it. (6) The pressure which has produced this "sheen surface" has in many cases affected the orientation of the minerals, which are present in the true "foliation" layers of the more distinctly foliated, *i.e.* mineral-banded, rocks. (7) In the crystalline schists very commonly the "sheen surface" corresponds with the original foliation surface, as in the slates the cleavage sometimes does with the bedding. This is due to the fact that the axes of the great folds often make a very high angle with the horizon. (8) Thus a non-foliated crystalline rock may be rendered to some extent foliated by pressure (followed by a certain amount of mineralisation): *i.e.* some gneisses may be formed by crushing from granites, some schists out of other igneous rocks. It may obliterate an earlier foliation, or it may intensify it, or it may produce an independent and more fissile foliation. In this sense gneiss may be said to pass into granite, because a rock which is now, both macroscopically and microscopically, a gneiss may prove to be a granite which has in some parts yielded to pressure more than in others. (9) As we pass outwards from the great central granitoid masses we come to gneisses and schists where the evidence of some kind of stratification becomes more marked; bands of crystalline limestone, quartzite, and granulite being associated with mica schist of many kinds—simple, garnetiferous, staurolitic, actinolitic, and the like—the bands of different mineral character and composition varying from mere streaks to layers up to many yards in thickness. In fact the above-named rocks are associated exactly as limestones, sandstones, and clays are associated in the ordinary sedimentaries. (10) Although the crushing of a crystalline rock *in situ*, or the squeezing and shearing of a breccia or conglomerate of crystalline fragments, occasionally gives rise to local difficulties, these are on a small scale, and sedimentary beds belonging to the Palæozoic or later periods of deposition are generally readily distinguishable from the whole of the crystalline series. Though folded and faulted in the most extraordinary manner, the members of the two series can generally be separated and in the Alps there is no evidence of a mingling of the one with the other in the process of rolling out or squeezing together; so that, after patient study and microscopical examination, we can generally decide without hesitation whether a particular set of rocks has originated from the crystalline or the sedimentary series. I do not say that we can always decide whether a schist or a gneiss has originated from an igneous rock or from an older schist or gneiss, but I think that in the Alps we can say that it has originated from one of these. Fortunately, intrusive rocks are very rare in the Palæozoic and later deposits in this part of the Alps. (11) Thus, although the Tertiary metamorphism of the Alpine rocks is very important, it is more pretentious than real, and its effects seem to have been the greatest where it has found a rock already crystalline to act upon. Hence I believe that every true gneiss and schist in the Alps is much older than the Carboniferous, and is probably older than any member of the Palæozoic period.

The Direction of Glaciation as ascertained by the Form of the Striæ, by Prof. H. Carvill Lewis.—As there seemed to be a disagreement between certain Scotch geologists and the Irish geologists regarding the inferences as to direction of glaciation to be deduced from the form of glacial striæ, the author was led to bring forward some observations of his own, made in America and in Great Britain, which threw light upon the disputed point. Well-preserved striæ are frequently blunt at one end and tapering at the other, the shorter ones sometimes resembling the characters used in the cuneiform inscriptions. This form may be seen in striæ of all sizes—from those several yards in length, when the blunt end may be an inch or more in breadth, to the finest scratches, where a microscope is necessary to detect any difference between the two ends. As shown in the Reports of the Boulder Committee of the Royal Society of Edinburgh (Fifth Report, pp. 18–20, 29, 58; Seventh Report, p. 18) and elsewhere, certain Scotch geologists regard the blunt end as the point of impact of the striating agent, and as therefore facing the direction from which the motion came. On the other hand the Irish geologists ("Memoirs of the Geological Survey of Ireland," Explanation to sheets 86, 87, 88, p. 55; Explanation to sheet 193, p. 18, &c.) interpret the shape of the striæ as indicating motion in the opposite direction, believing the tapering end to point to the direction from which glaciation proceeded. The point at issue is of importance, especially in outlying islands and elsewhere, where other indications of the direction of glaciation fail. In Pennsylvania, which is crossed from east to west by the terminal moraine of the great ice-sheet, and where the glaciation is uniformly in a southward direction, the author had observed that the blunt ends of the striæ, where flat surfaces were studied, were always to the south ("On the Terminal Moraine in Pennsylvania and Western New York." Report Z, Second Geological Survey of Pennsylvania, pp. 33, 85, 86, 107, 275). In certain instances the mode of formation of the striæ was also indicated by their shapes, which showed that a stone pushed along under the glacier had ground in deeper and deeper until in some cases it stopped or hopped out, in other cases was ground down to another cutting edge, and in others *turned over*, and began its work of engraving by a fresh and sharp corner. The peculiar gorges at the farther end of certain striæ showed a sort of slow rocking motion in some stones before they finally turned over. The author's observations in Ireland, both at localities where there could be no doubt as to the direction of glacial movement, and at localities where such direction was not previously known, led to conclusions entirely in harmony with those already reached in Pennsylvania and with those held by the Irish geologists. One of the best examples falling under the former category was among the local glaciers in the mountains of the Dingle promontory, a region not invaded by the great confluent ice-sheet of central Ireland. The striated beds of these small glaciers, beginning in a "corey" and bounded below by a semicircular terminal moraine, are beautifully defined and afford good opportunities for striæ study. It was found that *on upward slopes or in flat surfaces the striæ as a rule are blunt at the end towards which the motion was directed, but that in downward slopes the reverse is generally the case.* While this rule does not hold good for every individual scratch at a given locality, it has been found most useful when applied to striated surfaces in general. At Glengariff, where some finely striated surfaces occur, a number of tracings were taken directly from the rock, which clearly show the broader ends of most of the striæ to be to the south, the direction towards which the glacial stream advanced. Similar observations were made at several localities south of the Shannon. Finally, as an instance where the direction of glaciation was previously unknown, certain striæ were described which the author had observed on the top of the cliffs facing the Atlantic at Kilkee. These point N. 58° W. and S. 58° E., and the question to be determined was whether the glaciation proceeded from the Atlantic towards the land or whether it went north-westward and out to sea. The form of the striæ alone decided it. Their broad blunt ends were as a rule toward the north-west, the surface being horizontal, a fact which, taken in connection with other observations made about the mouth of the Shannon, showed that a great ice stream had flowed westward along the valley of the Shannon, and had opened out fan-shaped as it plunged into the sea.

The Geology of Durness and Eriboll, with special Reference to the Highland Controversy, by B. N. Peach, F.R.S.E., and J. Horne, F.R.S.E., Geological Survey of Scotland.—With the permission of the Director-General of the Geological Survey, the authors gave an outline of the geological structure of the Durness-Eriboll region, illustrated by a series of horizontal sections. They showed that the Silurian strata of Durness are arranged in the form of a basin, bounded on the east side by powerful faults disconnecting them from the same series in Eriboll. The order of succession in the two areas is identical, from the basal quartzites to the horizon of the limestone group. On the west side of Loch Eriboll the basal quartzites rest unconformably on the Archæan gneiss, but on the eastern shore there is conclusive evidence of the repetition of various members of the Silurian series by a remarkable system of reversed faults, culminating in a great dislocation which has thrust the Archæan gneiss over the truncated edges of the quartzites, fucoid beds, serpulite grit, and basal limestone. Reference was made to the effects of these mechanical movements on the Silurian rocks, and to the developments of new planes of schistosity in the gneiss above the thrust-plane. At intervals small patches of the basal quartzites are met with throughout this mass of Archæan gneiss, which are abruptly truncated by great reversed faults; but in the district between Eriboll and Assynt the whole Silurian succession from the basal breccia to the lowest limestone occurs repeatedly above the first great thrust-plane, separated by wedges of highly-sheared gneiss. It was shown that the alteration produced by each successive displacement gradually becomes more pronounced as the observer passed eastwards across the area. The old north-west strike of the Archæan gneiss gave place to a new foliation running more or less parallel with the strike of the thrust-planes; the felspathic basal quartzites and the "pipe-rock" pass into quartz schists and mica schists, and the Silurian limestone is felted with the crushed Archæan gneiss. Reference was next made to the outcrop of the great thrust-plane extending from the Whitten Head coast far to the south, which ushers in a highly schistose series with a north-north-east and south-south-west strike. After describing the lithological characters and order of succession of the eastern schists, the authors stated that the new planes of foliation had been superinduced by the mechanical movements that took place between Lower Silurian and Old Red Sandstone time, and that along these new planes a re-arrangement and recrystallisation of mineral constituents took place, resulting in the production of crystalline schists. Applying the knowledge thus obtained from the study of the eastern schists to the undisturbed Archæan masses, they had found conclusive evidence of similar mechanical movements. Each plane of schistosity exhibits the parallel lineation like slickensides trending in the same direction over a vast area, while the minerals were oriented along these lines. From a consideration of these phenomena the authors inferred that regional metamorphism need not necessarily be confined to any particular period, and further that the planes of foliation or schistosity in those areas which had been subjected to regional metamorphism were evidently due to enormous mechanical movements which had induced molecular changes in crystalline and clastic rocks.

The Highland Controversy in British Geology: its Causes, Course, and Consequences, by Chas. Lapworth, LL.D., F.G.S., Professor of Geology and Physiography, Mason College, Birmingham.—The author gave a *résumé* of the views of the earlier geologists respecting the geological age and possible mode of formation of the Highland metamorphic rocks; and sketched, in brief, the rise and progress of the controversy between Sir Rod. Murchison and his followers on the one hand, and Prof. Nicol, of Aberdeen, on the other, till its temporary close in 1861, by the publication of the Highland Memoir of Murchison and Geikie. He then reviewed the reopening of the controversy by Dr. Hicks in 1878, and the work of the Archæan geologists, up to the date of publication of Dr. C. Callaway's paper in 1883, in which Nicol's view of the great physical break between the Palæozoic rocks and the Eastern or Upper Gneissic series was shown to be correct, but the so-called Eastern gneiss was provisionally erected into a new Archæan system, the Caledonian, having the Arnaboll gneiss as its lower member. The author next gave a summary of his own views as deduced from his personal study of the Durness Eriboll district in 1882 and 1883, and published in 1884, illustrating these by coloured maps and sections. He held that (exception being made of the local Torridon Sandstone) the only rock-formations in the Durness-Eriboll area are, as Nicol originally contended: (1) The Archæan or Hebridean gneiss; and (2) The Palæozoic quartzites, fucoid beds, and limestones. But the so-called upper gneiss or eastern metamorphic gneiss appears to be composed of elements derived from one or other of the foregoing. There is no conformable ascending succession from the Palæozoic rocks into this Eastern Metamorphic series. The line of contact is, generally speaking, a plane of dislocation, and where this is wanting the Palæozoic rocks rest unconformably upon one of the members of the eastern gneiss. The present physical relations of the eastern metamorphic series are the effect of lateral crust creep, by which the eastern metamorphic rocks have been forced over the Palæozoic rocks in grand overfaults to the west, often for many miles. This Eastern Metamorphic series is composed of two petrological members, the *Arnaboll gneiss* to the west, and the *Sutherland schists* and gneisses to the east, having between them a series of *variegated schists* possessing characters common to both. The Arnaboll gneiss is simply the easterly extension of the Hebridean of the west The remaining gneisses and schists of the eastern metamorphic series are mainly composed of re-metamorphosed Hebridean, with included patches of igneous and Palæozoic material. The planes of schistosity which divide the layers of the Upper Gneissic series are not planes of bedding, but planes of dislocation. The dip and strike of these planes have been given to them since Silurian times by the agency of the great earth-movements. In some instances the original structures of the rocks are still recognisable; usually, however, they are wholly obliterated: the old minerals have disappeared as such, and new minerals have been developed. The Eastern Gneissic series has thus no pretension whatever to the title of a sedimentary rock-system. It is a petrological rock-massif, a metamorphic compound, composed of local elements of very different geological ages. In all their essentials these views appear to agree with the far more contended and minute results worked out independently, and published by Messrs. Peach and Horne in November 1884.

In the second part of his paper the author gave a summary of the work accomplished among the metamorphic rocks of the Alps and Eastern Germany by Heim and Lehmann; and described the several types of rock-metamorphism found in the Eriboll district, as worked out by himself. The Arnaboll (Hebridean gneiss) can be traced stage by stage from spots where it retains its original strike and petrological characters, to others where it acquires the normal strike and mineralogical features of the ordinary Sutherland schists. The old planes of schistosity become obliterated, and new ones are developed; the original crystals are crushed and spread out, and new secondary minerals, mica and quartz, are developed. The most intense mechanical metamorphism occurs along the grand dislocation (thrust) planes, where the gneisses and pegmatites resting on those planes are crushed, dragged, and ground out into a finely-laminated schist (*Mylonite*, Gr. *mylon*, a mill) composed of shattered fragments of the original crystals of the rock set in a cement of secondary quartz, the lamination being defined by minute inosculating lines (fluxion lines) of kaolin or chloritic material and secondary crystals of mica. Whatever rock rests immediately upon the thrust-plane, whether Archæan, igneous, or Palæozoic, &c., is similarly treated, the resulting mylonite varying in colour and composition according to the material from which it is formed. The variegated schists which form the transitional zones between the Arnaboll gneiss and Sutherland mica-schists are all essentially mylonites in origin and structure, and appear to have been formed along many dislocation planes, some of which still show between them patches of recognisable Archæan and Palæozoic rocks. These variegated schists (Phyllites or Mylonites) differ locally in composition according to the material from which they have been derived, and in petrological character according to the special physical accidents to which they have been subjected since their date of origin—forming frilled schists, veined schists, glazed schists, &c., &c. The more highly crystalline flaggy mica-schists, &c., which lie generally to the east of the zones of the variegated schists, appear to have been made out of similar materials to those of the variegated schists, but to have been formed under somewhat different conditions. They show the fluxion-structure of the mylonites; but the differential motion of the component particles seems to have been less, while the chemical change was much greater. In some of these crystalline schists (the augen-schists) the larger crystals of the original rock from which the schist was formed, are still individually recognisable, while the new matrix containing them is a secondary crystalline matrix of quartz and mica arranged in the fluxion-planes. While the *mylonites* may be described as microscopic pressure-breccias with fluxion-structure, in which the interstitial dusty, siliceous, and kaolinitic paste has only crystallised in part; the *augen-schists* are pressure-breccias, with fluxion-structure, in which the whole of the interstitial paste has crystallised out. The *mylonites* were formed along the thrust-planes, where the two superposed rock-systems moved over each other as solid masses; the *augen-schists* were probably formed in the more central parts of the moving system, where the all-surrounding weight and pressure forced the rock to yield somewhat like a plastic body. Between these augen-schists there appears to be every gradation, on the one hand to the mylonites, and on the other to the typical mica-schists composed of quartz and mica. Like the mylonites, the crystalline augenites and micalites present us with local differences in chemical composition (calcareous, hornblendic, quartzose, &c.), suggestive of Archæan, igneous, or Palæozoic origin. They also show similar structural varieties due to secondary physical changes (frilled, veined, glazed, &c.), as well as others due to the presence of special minerals (garnet, actinolite, &c., &c.).

On certain Diatomaceous Deposits (*Diatomite*) *from the Peat of Aberdeenshire*, by W. Ivison Macadam, F.C.S., F.S.C., &c., Lecturer on Chemistry, School of Medicine, Edinburgh.—The material was found below the peat in certain districts of Aberdeenshire, but principally in the basin in which lie Lochs Kinnord and Dawin. After removal of the surface peat-fuel, the lower and more highly mineral portion was cut in blocks and air-dried. The substance then consisted of almost pure Diatomacea bound together by the remains of Spragnum, Equisetacea, &c. Besides being found underlying peat the substance was also obtained on the shores of Loch Kinnord, and the more pure Diatoms were thickly distributed over the bottom of the deeper portions of the lake; these latter, however, from the want of the binding obtained from the marsh plants above mentioned could not be rendered readily available for market. An interesting point regarding these deposits was that whilst in Loch Kinnord an abundant supply of the Diatoms could be obtained, in the neighbouring Loch Dawin scarcely a single Diatom (recent or fossil) was found. This was probably due to the fact that whilst the feeding waters of Loch Kinnord flowed from hills consisting of a coarse and much disintegrated granite, and consequently contained a considerable portion of soluble silica, the Loch Dawin waters were obtained from hornblendic mountains, and held much less soluble silica in solution. The material was principally used for the manufacture of dynamite, and a considerable quantity had been forwarded to the works for this purpose. Unfortunately, however, dynamite had fallen to a great extent out of use, being replaced by the more powerful blasting gelatine, and thus what had at one time appeared as if it would prove an important local industry had entirely fallen away. Other uses, however, could be found for the material, such as the manufacture of ultramarine, for which, from the very small proportion of iron present, the diatomite has more especially to be recommended. As an absorbent it was of fully double the value of the ordinary German varieties of "kieselguhr."

On Some Recent Earthquakes on the Downham Coast, and their Probable Causes, by Prof. G. A. Lebour, M.A., F.G.S.—For the last two years frequent slight shocks, resembling those of earthquakes, and accompanied by rumbling noises, have been felt at Sunderland. Much discussion has arisen as to the cause of these, but that they are due to natural causes is now quite certain. Sunderland stands upon magnesium limestone, from 300 to 400 feet thick beneath the town; the rock is riddled with cavities of every size, some so small as to give a vesicular character to the stone, some large and forming true caverns. These cavities are partly due to the washing out of marly matter, partly to solution of the limestone. Every thousand gallons of Sunderland water contains one pound of stone; in this manner about forty cubic yards of magnesian limestone are yearly pumped up by the Water Company, and of course a much larger quantity is removed by natural channels. This action enlarges the cavities; the sides and roof fall in, thus accounting for the shock. The same explanation applies to the "breccia gashes" which are exposed along the shore. These are fissures filled with breccia. Quite recently similar shocks to those here referred to have been observed at Middlesborough. Pumping the brine from the salt deposits, 1000 to 1200 feet below the surface, may produce cavities into which the rock falls.

Some Examples of Pressure-Fluxion in Pennsylvania, by Prof. H. Carvill Lewis.—The three localities in Pennsylvania described in this paper lie in an area which had been especially studied by the author for some years back and had led him to conclusions similar to some of those recently announced as the result of studies in North-Western Scotland, which have justly attracted widespread attention. (1) a zone of ancient crystalline rocks extends across South-Eastern Pennsylvania, near Philadelphia, which is generally believed to underlie the lowest Cambrian strata and to be of Archæan age. This zone is about a mile wide where it crosses the Schuylkill River, south of Conshohocken, and it is from this point to Westchester, some twenty miles westward, that the present remarks especially apply. Although in many portions exhibiting a distinct gneissic lamination, the rocks of this zone are held by the author to be of purely eruptive origin, consisting of syenites, acid gabbros, trap granulites, and other igneous rocks, often highly metamorphosed. It is the outer peripheral portion of this zone to which attention is here directed. While the rocks are massive in the centre, this outer portion has been enormously compressed, folded, and faulted, with the result of producing a tough-banded, porphyritic *fluxion gneiss* identical with the "milonite" of Lapworth or the "sheared gneiss" of Peach and Horne. So perfect is the fluxion structure that the rock resembles a rhyolite. As in the "banded granulite" of Lehmann, elongated feldspar "eyes" lie in flowing streams of biolite grains and broken quartz, the streams often parting and again meeting around the porphyritic "eyes." Occasional crystalline eyes of hornblende remain, but most of it has been converted into biotite. A point of especial interest is that the feldspar of the eyes is quite colourless and free from inclusions, like the sanidine of recent lavas, while, on the other hand, the feldspars of the inner and massive portions of the zone, out of which this outer portion has been reformed by pressure fluxion, are full of inclusions and have the "dusty" appearance so common in ancient feldspars. The fresh-looking feldspar eyes are therefore believed to have been subsequently formed as a result of a *recrystallisation* of the old material under the influence of *pressure fluxion*. In similar manner the biotite has been made out of the old hornblende, garnets have been developed, and the quartz has been granulated and optically distorted by pressure. The influence of pressure is also seen in certain Cambrian strata in the immediate vicinity, where a sandstone containing cylindrical casts of *scolithus linearis*, apparently identical with the "pipe-rock" of North-Western Scotland, has, like it, been compressed to such a degree that the vertical casts are flattened out and elongated in the direction of lamination to several times their original length. In the same sandstone quartz pebbles have been pulled out and flattened, while sericite has been largely developed along the cleavage planes. The pressure can be shown to have been directed mainly from the south-east. (2) The second locality is in the midst of the Laurentian area of Buck's County, and is known as Van Artsdalen's Quarry. A mass of crystalline limestone is here mingled with an eruptive diorite in such manner as to show that it had actually flowed like an igneous rock, and had caught up inclusions. The results of extreme metamorphism are exhibited in the development in the limestone of graphite, wollastonite, and other minerals. The chemical changes and interchange of elements which might result from a loosening of molecular combinations under extreme pressure and their subsequent "regulation" into new compounds were discussed as among the phenomena of mechanical metamorphism. (3) As an American instance of the conversion of an intrusive diabase dyke into amphibolite schist, analogous to the case recently described by Teall, a long narrow belt of sphene-bearing amphibolite schist in the City of Philadelphia was adduced. This belt with distinctive mineralogical characters cuts across the metamorphic mica schists of the region unconformably, and is believed by the author to be a highly metamorphosed intrusive dyke of Lower Silurian age. The original augite or diallage has been completely converted into fibrous hornblende, and the influence of pressure is shown in the perfectly laminated character of the schist in the close foldings produced, and in the minute structure of the rock. Some interesting details of the latter having been photographed, diagrams constructed from these were exhibited. These showed that the rock was traversed by a parallel series of slips and crushings, and that about such lines of faulting and crushing there was a peculiar arrangement of the lines of hornblende crystals, not very unlike the arrangement of iron filings about the poles of a magnet, such as could not be satisfactorily explained by any theory of aqueous deposition, but pointed to a lamination by pressure.

SECTION D—BIOLOGY

On the Cause of the extreme Dissimilarity between the Faunas of the Red Sea and Mediterranean notwithstanding their recent connection, by Prof. Edward Hull, LL.D., F.R.S.—The faunas of the Mediterranean and of the Red Sea are so unlike that if the beds of the two seas were upraised, and their contents examined, naturalists would probably refer them to distinct geological periods. The dissimilarity is greater than was formerly supposed. In Woodward's "Manual of the Mollusca" it is stated that seventy-four species of mollusks are common to the two seas, but Prof. Issel, of Genoa, places the number at eighteen, or about 2 per cent. Equal differences exist if we compare other great groups of life; in fact, as Prof. Haeckel well observes, the fauna of the Red Sea is related to that of the Indian Ocean, the fauna of the Mediterranean to that of the Atlantic. This extreme dissimilarity would not surprise us if it were not for the proofs of recent connection between the two seas. Evidence of old sea margins, up to about 220 feet above the present sea-level, are frequently found along the Nile and in the valleys and plains of Philistria. As many of the marine forms found in these deposits still exist, the date of the submergence may be safely referred to that of the Pliocene; but it continued to a later period, and (in the author's opinion) it to some extent remained to the time of the Pharaohs. The existing fauna probably dates back to Eocene times, when the ocean spread widely over the area in question. In the Miocene period the main outlines of land and sea as we now find them were marked out, the deposits of this age being here small and local. Under the extremely different conditions existing in the two areas, the fauna during and after the Miocene period became differentiated. The connection re-established during and after the Pliocene period was insufficient to destroy these differences, although it allowed a mingling of forms to some extent. The maximum submergence was about 220 feet; but as the summit level between the two seas is about 50 feet, the depth of water would only be about 170 feet at the maximum. Only littoral and shallow-water forms would cross in the adult state; but many forms inhabiting deeper water in the adult state might have crossed when in the free-swimming larval state. When the land again rose, and the marine straits were finally effaced, the different physical conditions of the two seas would again come into effect. The difference of temperature is now very considerable, and probably was much greater during the Glacial period, especially if, as appears probable, the eastern or Levant basin of the Mediterranean were separated from the others; for into this would flow the cold waters of the Black Sea and of Central Europe, whilst the Red Sea would receive warm water, and be itself exposed to the rays of a tropical sun. It would be an interesting subject of inquiry—Which of these faunas most closely resembles that of the original stock?

On the Tay Whale (Megaptera longimani) and other Whales recently obtained in the District, by Prof. Struthers.—Prof. Struthers gave a description of the various parts of the anatomy of the whale. In addition to the Tay whale members of three other whales recently obtained in the district were exhibited for the purpose of comparison, and the analogy of its structure to that of other animals was specially referred to in order to show its identity with the mammal. Prof. Flower joined in the discussion which followed, and remarked that they now had an idea at least as to the origin of the whale: it carried its pedigree in every part of its body. It had been thought that the mammals that live upon land had been derived from progenitors that formerly lived in the sea, and that the mammals may have passed through an aquatic or marine stage before they took to land, but the observations of anatomy showed that this cannot have been the case. There was no doubt that the whale had been derived from a four-footed land mammal. All observations, for example, had shown that at some period of their life whales have a hairy covering, generally in the region of the mouth, that hairy covering being functionless and very often lost even before birth. In the same way whales at an early stage of their existence are furnished with a complete set of teeth, the rudiments of the teeth of the land mammal. The organ of smell, although in a rudimentary state and in some species almost entirely gone, also points to the origin of the whale.

Some Points in the Anatomy of Sowerby's Whale, by Prof. Turner.—Prof. Turner remarked that *Mesoplodon bidens*, or Sowerby's whale, of which he had dissected two specimens, was now for the first time dissected so that the viscera of this whale were seen by any anatomist, or that its tail and paddle, or fin, had been figured. The tail presents a very material difference from the customary tail in the cetacea in having the posterior border smooth instead of notched. Dr. Turner called attention in detail to the intestinal and limb structure of this species of whale, showing the affinity or resemblance of the cetacea to the reptilious and the amphibious, particularly in reference to the corpus. Prof. Flower said he was glad to find that Prof. Turner had found some intention for the muscles of the corpus. For all that they were very rudimentary as compared with the same muscles in other animals, and he thought that he might have to modify his views on this point as he had had to do in regard to many other things throughout life. Prof. Marsh, of Yale College, said the intermediary bone pointed out by Prof. Turner interested him much.

On the Cervical Vertebræ of the Greenland Right Whale, by Prof. Struthers.—The reduced condition of the upper and lower transverse processes was commented on, and the meaning of their different parts explained; also the completely fused condition of the bodies of the seven vertebræ. A nearly similar condition of the neck of the Pilot Whale (*Globicephalus melas*) was demonstrated, showing in the young condition the two body epiphyses on the rudimentary vertebræ. Other specimens illustrated the fibrous condition of the transverse processes in the Narwhal and Beluga.

On the Development of the Vertebræ of the Elephant, by Prof. Struthers.—The point was that in the anterior vertebræ the neural arches meet behind the body, covering it deeply, and shutting it entirely out from forming any part of the wall of the spinal canal.

On the Development of the Foot of the Horse, by Prof. Struthers.—Dr. Struthers called attention to the fact that the epiphysis of the rudimentary metacarpal and metatarsal bones is not at the upper or functional end, but at the reduced end or "button," from which only a slender ligament proceeded. This he considered a most interesting fact, one which completed the chain of evidence of the descent of the horse. There was a reason why the epiphyses should be there in the hipparion and previous forms from which the horse of the present day was descended. The development of the corresponding bones in man, the cetacea, and various other mammals, was given in illustration.

A specimen was shown of a two-toed horse. The valuable researches of Prof. Marsh on the descent of the horse were specially alluded to. Dr. Struthers demonstrated another fact connected with the development of the foot of the horse—that the first phalanx, or pastern bone, has an epiphysis at both ends.

On the Viscera of Gymnotus electricus, by Prof. Cleland.—Independent of its electric organs, this fish has a number of remarkable internal peculiarities. The curious spongy protuberances of the mucous membrane of the buccal cavity are well known to zoologists. The two swimming-bladders are remarkable for their relation to the kidneys; the anterior swimming-bladder being a small structure between their anterior extremities, and the larger posterior swimming-bladder being situated altogether behind their under hinder ends, while the duct of the latter ascends by the left side of the renal outlet, to be joined by the duct of the other bladder before entering the gullet. The pylorus also is remarkably contracted. But the most striking and altogether curious arrangements are seen on the ventral wall of the abdomen. The intestine passes forward the whole length of the abdominal cavity to the vent, and on its under side is a long renal duct as wide as itself, and opening immediately behind the vent; while, opening into this duct close to its outlet, are the ducts of the two ovaries, which lie one on each side, their morphologically anterior extremities placed posteriorly, as if in process of development these organs had been pulled around from their proper sub-vertebral position until completely inverted.

The Spiracle of Fishes in its relation to the Head, as developed in the Higher Vertebrates, by Prof. Cleland.—A very extraordinary mistake can be shown to be prevalent among embryologists, to the effect that the spiracle corresponds with the tympanum and external auditory meatus in the higher vertebrates. This is not the case. The spiracle is pre-oral; the tympanum is post-oral. The apparent sequence of the spiracle with the branchial clefts occurs, as Balfour described it, in the embryo of the dog-fish; but for all that, and although it has rudimentary external gills attached to its margins in the embryo, it is in front of the mandibular arch and above the maxillary lobe. Between the middle and lateral frontal processes is the nostril; between the lateral frontal process and the mandible is the space into the upper part of which the eyeball projects, and from which the lachrymal duct is developed; while between the first and second visceral lobes is the external ear; and it is highly probable that the upper part of the first branchial cleft is homologous with the clefts in front of and behind the lateral frontal process. Thus a certain amount of homology would exist between the spiracle of fishes and the lachrymal duct.

Is the Commissural Theory of the Corpus Callosum Correct? by D. J. Hamilton, M.B., Professor of Pathological Anatomy, Aberdeen University.—The results recorded by the author were obtained by certain special methods of preparation. They went to prove that the corpus callosum is not an inter-hemispherical commissure, as is generally supposed, but that it is in reality the decussation of a particular system of fibres on their way downwards to join the inner and outer capsules. These fibres are not to be confounded with the motor and other direct fibres derived from the cerebral cortex, and which decussate at some point lower down.

The Evidence of Comparative Anatomy with regard to Localisation of Function in the Cortex of the Brain, by Alex. Hill, M.A., M.B. Cambridge.—The object of the paper was to show that the theory of the localisation of function in the cortex of the brain must be submitted eventually to comparative anatomy for proof. The key to the arrangement of the lower parts of the central nervous system is to be found, as the author had elsewhere shown, in its segmental disposition: the grey matter is disposed in clumps the cells of which bear a definite numerical relation to the fibres of body nerves. The problem discussed in the present paper was the relation of the grey matter of the cortex to this lower grey matter, and therefore to the body nerves. Is each region of the cortex equally in relation with all the segments of the "central grey tube"? or is the cortex also divided up into areas, the superficies of each of which varies as the amount of grey matter in the clump of the lower system with which it is related, and therefore as the number of fibres in its associated nerve. For this investigation guides to the delimitation of the cortex are necessary, and no others are available for the purpose if the fissures fail. The homological value of the fissures is, however, established by the study of adult and fœtal brains. They are remarkably constant in their arrangement throughout animals of the same type, and in animals of different type they are very constant with regard to the order of their appearance, their progressive extension and permanent depth. The author of the paper expressed himself content, on account of the precision with which the fissures respond to the ordinary tests of homology, to place himself unconditionally in their hands, and the boundaries of the various regions of the cortex being thus marked out, it remains to devise a system of mensuration by which the superficial area of each region of the cortex may be determined for comparison with the cross-sections of the several nerves. As yet no satisfactory method of measurement has been devised, but even in the absence of exact data important results can be obtained by the observation of the brains of such animals as are conspicuous for excess or deficiency in the development of the muscular system or of one or more of the senses. As examples of such results Mr. Hill exhibited diagrams of the brains of the sheep, cat, pig, dog, and otter, enlarged from tracings of the pictures in Leuret and Gratiolet's Atlas. It was shown that, although it is impossible, as yet, to map out the brain into areas associated with the several nerves, it is quite possible to predict from the appearance of the brain the principal sensory and motor endowments of the animal to which it belonged. In the main Mr. Hill's results confirm those already obtained by Ferrier and other experimental physiologists; they seem, however, to show that they are open to correction in certain important points with regard to the areas allocated to the senses of smell, hearing, and facial sensation.

The Action of Cold on Microphytes.—Prof. M'Kendrick, Glasgow, gave an interesting account of the methods of trying to destroy small organisms like bacteria, not as is commonly done by heat, but by cold. It is known that by means of Coleman's cooling machine meat may be kept from putrefying for a considerable time, but in attempting to sterilise a putrescible solution by means of cold, it was found that, though in some cases putrescence was delayed, in no case were the organisms completely destroyed. Organic fluids were exposed to temperatures more than 120° below 0° F., but on thawing they were found to contain living organisms still. Thus the hope of preserving putrescible matter by means of cold—an important economical result—is, so far as investigation yet goes, destroyed. The organisms under cold seem to be in a nearly solid state, though we cannot call it a crystalline state. In a paste solution the water is crystallised under cold, the paste remaining spongy. Possibly cold may separate from these minute organisms the water they contain, and this water is again absorbed on thawing. Meat under cold becomes very friable, while yet minute fragments of it show the same microscopic constitution of muscle. It is well known that frogs have been found in blocks of ice and been revived. Frogs have been frozen at 20° F. in about half an hour. On thawing slowly the animal, in two instances, completely recovered. When it was frozen for longer than half an hour it did not recover; but, though reflex action was gone, there remained some irritability both in nerves and muscles. It was found also that certain vital functions may be arrested by cold, and thus conceivably higher organisms may be kept vitally inert for an indefinite time. Experiments were also tried on warm-blooded animals. A rabbit subjected to a temperature 100° below 0° F. recovered. No temperature lower than 73° below 0° F. has been obtained in free atmosphere. Prof. M'Kendrick gave a short sketch of the literature of the subject.

The Action of Ozonised Air upon Micro-Organisms and Albumen in Solution, by J. J Coleman, F.I.C., F.C.S.—This paper described a number of experiments conducted by the author in conjunction with Prof. McKendrick, F.R.S., being supplementary to their joint investigation upon the influence of cold on microphyles. Air artificially impregnated with ozone by means of a Ruhmkorff coil, so as to contain a much larger percentage of ozone than any natural atmospheric air, was passed continuously through a 1 per cent. solution of white of egg placed in a glass flask, the inlet and outlet tubes of which were carefully plugged with cotton wool previously to commencing the experiment. It was found that a stream of air containing an amount of ozone equal in weight to the albumen in solution passed through 100 c.c. of the liquid for thirty hours, failed in producing the slightest trace of oxidation, and that the ozonised air passed through the liquid quite unaltered. During the course of the experiment and for six days following the development of micro-organisms ceased, but at the end of that time, and notwithstanding the cotton wool plugs, the liquid became slightly turbid from the presence of organisms. As dilute hydrogen peroxide is without action upon albumen, the conclusion seems inevitable that albumen is practically indestructible by any atmospheric agency without previous splitting up by micro-organisms, and further, that whilst micro-organisms cannot develop, and are probably killed in an ozonised atmosphere, these spores are not easily destroyed by its agency. These results confirm the surmise of the late Dr. Angus Smith that putrefaction is a necessary preliminary to oxidation in all cases of *natural* river purification. Prof. Burdon Sanderson, Dr. W. B. Carpenter and Capt. Douglass Galton all commented upon the practical value and interest of this paper, Capt. Douglas Galton observing that the sooner organic matter of sewage is got on to land the better.

The Use of Graphic Representations of Life-Histories in the Teaching of Botany, by Prof. Bower.—This was a paper referring to a series of diagrams prepared by the author to bring in review the chief facts in the life-history of the moss, fern, equisetum, *Selaginella*, a conifer, and an angiosperm. Prof. Bower pointed out that these diagrams could be extended to include lower forms, and that they are only intended for use *after* the student has mastered the facts in detail in the laboratory. Having described the diagrams and referred to some interesting processes of vegetative reproduction in the mosses and ferns, the author then proposed for discussion a series of questions as to the advisability of employing such diagrams, or of extending their use. The discussion which followed was taken part in by Sir J. Lubbock, Profs. Bailey Balfour (Oxford), M'Nab (Dublin), Trail (Aberdeen), Mr. Marshall Ward (Owens College), and others, and several suggestions were proposed for rendering Prof. Bower's graphic representations still more graphic.

A New Theory of the Sense of Taste, by Prof. J. Berry Haycraft.—The author showed that "quality" in this sense depends upon the nature of the atoms found in the sapid molecule. A study of the periodic law demonstrates that similar tastes are produced by combinations which contain elements such as lithium, sodium, potassium, which show a periodic recurrence of ordinary physical properties. Among the carbon compounds those which produce similar tastes are found to contain a common "group" of elements. Thus organic acids contain the group CO.OH, the sweet substances CH_2.OH. There is no relation between quality of sensation and gross molecular weight, except that substances of either very small or very great molecular weight are not tasted at all.

On the Hybridisation of Salmonidæ at Howietoun, by Francis Day.—During the last eleven years Sir J. R. Gibson-Maitland, at Howietoun, near Stirling, has devoted much attention to this subject, and gone to great expense in order to efficiently carry out the many experiments he has instituted, while he has likewise afforded the author facilities for personally watching many of them, and furnished him with data as well as with specimens. When we consider that the ova of teleostean or bony fishes have, as a rule, to be fertilised by the milk of the males diffused in the surroundiag water, it is not difficult to believe that this fluid from the male of one genus might come into contact with the eggs from fish of another species, genus, or even family, and a hybrid offspring be thus occasioned. But the size of the micropyle of the ovum and that of the spermatozooid of the milt must be of conforming capacities, or fertilisation would be a physical impossibility. It would appear from the experiments made that the following conclusions may, with more or less probability, be drawn:—(1) Salmon and trout, trout and char, and different species of char, may interbreed and give rise to fertile hybrids. (2) Hybrids raised from Lochleven trout eggs fertilised by salmon milt breed in their fourth year, similar to young female salmon kept under the same conditions. (3) The anodromous instinct is not lost in these trout and salmon hybrids. (4) Judging from the period of breeding in the foregoing hybrids, the male element is prepotent. (5) In hybrids raised from Lochleven trout eggs fertilised by the milt of the American char, the male element would appear to be prepotent, if we judge simply by the colour of the offspring. (6) In hybrids raised from American char eggs fertilised by the milt of the Lochleven trout, the female element would appear to be prepotent, if we judge simply by the colour of the offspring. (7) In hybrids raised from American char eggs fertilised by the milt of the British char, the male element would appear to be prepotent, if we may judge simply by the colour of the offspring. (8) In all instances of hybridisation between different species, as between salmon and trout, or trout and char, numerous instances of malformation and great mortality occur among the offspring, but much less when two forms of char are intercrossed. (9) In intercrossing hybrids both the eggs and milt were found to be fertile, but the malformations and mortality very great. The parents, however, at Howietoun are not yet of sufficient age to admit any safe deductions on this head. (10) The age of the parent exercises great influence on the vitality of the offspring, for, when very young, we may expect a large percentage of malformations, as well as dropsy and other diseases of the offspring.

Chinese Insect White Wax, by A. Hosie.—The author began with a reference to the European and Chinese writers who mention Chinese insect white wax, and then proceeded to say that, although the province of Ssu-chuan, in Western China, where he has been stationed for the last three years, is the chief wax-insect and wax-producing country in the Empire, insects and wax are found in other provinces. Mr. Hosie was called upon by the Foreign Office to collect for Sir Joseph Hooker specimens connected with, and all possible information on, the subject of this industry, and he states that the present paper is a revision, with additions, of a Report already published in a Parliamentary paper in February last. He describes the insect-producing country, the tree on which the insects are propagated, the insects themselves, and their transit from the valley of Chien-chang, their breeding-ground, in the west of Ssu-chuan, across the mountains to Chia-ting Fu, the habitat of the wax tree. This tree is then described, and details are given of the treatment of the insects, their suspension on the trees, the depositing of the wax, and of a parasite on the insects. The method of removing the wax from the branches of the tree and of preparing it for market is then explained. The author then detailed the result of an examination of the insects after the wax has been fully deposited, finally passing to the annual quantity of insect white wax produced, its value, and uses.

On the Size of the Brain in Extinct Animals, by Prof. O. C. Marsh.—Prof. Marsh, of Yale College, said that for fifteen years he had directed his attention to the subject of the size of the brain in extinct animals. In every instance he found that the mammals from the lower Tertiary had very small brains. He carried out his investigation into the upper Tertiary, and found that the brain was much larger in the pliocene than in the miocene. All the tertiary mammals had small brains; there was a gradual increase in the size of the brain during this period; and this increase in the size was generally in the cerebral hemisphere or higher portions of the brain. In some groups the convolution of the brain had gradually become more complex. In some the cerebellum and the olfactory lobes had even diminished in size. There was now evidence that the same general law of brain growth holds good for birds and reptiles from the Jurassic period to the present time. The brain of an animal belonging to a vigorous race fitted for a long survival was larger than the average brain of that period in the same group, and the brain of a mammal of a declining race was smaller than the average brain of its contemporaries of the same group. The small animals now existing had proportionally larger brains than the larger animals, and young animals had proportionally larger brains than adult animals. They found some interesting examples which threw light on this question. For instance in the Eocene they had an animal, the oldest known ancestor of the rhinoceros, and it had an exceptionally large brain. Taking all the facts together it seemed as though this brain growth was an important element in the survival of animals. If the animal became large and unwieldly with a small brain, it would be liable to suffer from any change of climate. In other words, in early times the big brain conquered as it is the big brain that conquers in civilisation to-day. Prof. Flower said it was satisfactory to find a case where the facts worked out coincided with previously-formed theories, because that was not always the case, and sometimes the facts or the theories had to go to the wall. In this case they had no such difficulty; and they had to thank the American Government for the way in which it had taken up Prof. Marsh's work and were disseminating it.

On the Systematic Position of the Chamæleon and its Affinities with the Dinosauria, by D'Arcy W. Thompson, B.A. —The author believes that the great anatomical differences which separate the Chamæleon from all other Lacertilia are connected with marked resemblances to the Dinosauria, especially the group Sauropoda. The shoulder-girdle is quite identical with that of (*e.g.*) Brontosaurus, but differs wholly from that of the Lacertilia in the simple form of the scapula and coracoid, the absence of coraco-scapula fenestrations, of clavicle and interclavicle. Equally marked affinities with the Dinosauria may be traced in the carpus and tarsus, sternum, pelvis, and skull. While similarly the comparatively large size of the cerebellum, the absence of a urinary bladder, and the presence of pulmonary diverticula or rudimentary air-sacs, are all foreshadowings of ornithic structure.

The Origin of the Fishes of the Sea of Galilee, by Prof. Hull.—Of the abundant fishes of the Sea of Tiberias nearly one-half of the species are peculiar to the lake and its tributaries, while of the rest only one, *Blennius lupulus*, belongs to the ordinary Mediterranean fauna; two others are found in the Nile; seven other species occur in the rivers of South-Western Asia; and ten more are found in other parts of Syria. Tristram considered that this assemblage pointed to a close affinity of the fauna of the Jordanic basin with that of the rivers of tropical Africa; but what most struck the observer was perhaps the speciality of the species to Jordanic waters, sixteen out of a total of thirty-six species being peculiar. Assuming that the forms which are common to Jordanic and other waters had been distributed in a manner similar to that by which they had to account for the distribution of lacustrine forms in other parts of the world, they had yet to account for the presence of the forms which were special and peculiar. After referring to the formation of the Jordanic basin, Prof. Hull argued that by the subsidence of the floor of the sea along the line of the Jordan valley an inland lake was formed whose waters were first derived from those of the ocean itself, in which were enclosed the fishes, mollusks, and other forms which inhabited these waters themselves. The law of "descent with modification" would come into operation, and they might suppose that throughout the Miocene and Pliocene periods the process of modification in form, colour, and habit gradually proceeded. The fittest forms would survive, and differentiation between those of the outer and inner seas would result in an almost entire specific change. Prof. Hall also read a paper on the cause of the extreme dissimilarity between the faunas of the Red Sea and Mediterranean, notwithstanding their recent connection.

The St. Andrews Marine Laboratory.—Prof. M'Intosh stated briefly the structure and arrangement of the marine laboratory at St. Andrews, and made some general remarks on the work done during the last nine months there. A great many of our food fishes, he said, were carefully examined in regard to the development of the eggs and the growth of the young fishes. About twenty species were examined in this way. They experienced some difficulty with some of the forms, on account of their voracity, particularly with the cod. They found that a cod of five inches long would swallow a cod of three inches, and if it could not get it all down at once, it would keep it in its throat till the head part was digested, and then draw in the tail. Mollusca were studied chiefly in connection with the development of the mussel, but he might say that very hazy notions were held in regard to it. Some larger forms were also examined, including porpoises and sharks. One porpoise was extremely interesting. He had noticed it for some time in the bay, and that its motions were very peculiar. He could not make out what it was doing there so constantly in shallow water. But some days afterwards a large female was caught in the salmon nets, and they found that it was a female giving milk. Its milk was of a most interesting kind, and formed the subject of examination and analysis by Prof. Purdy. It was as dense as cream, and of a deep yellow colour.

On a Chemical Difference between Living and Dead Protoplasm, by Dr. Oscar Loew, of Munich.—Protoplasm, it was found, contains certain aldehyd groups, which account for the extreme mobility and readiness of change in living protoplasm. These aldehyd groups can be reduced by very dilute alkaline solutions of silver salts. *Spirogyra*, one of the lower *algæ*, acts on this solution in a peculiar way. Living protoplasm reduces the salt, while dead protoplasm does not. The specific gravity of the protoplasm of *Spirogyra* was increased, and was found to contain silver deposited in its interior. Argyria, or the effect of nitrate of silver on the human subject in certain diseases, was found in these *algæ*. Thus was shown a specific chemical difference between living and dead protoplasm. Ordinary poisons, such as prussic acid and strychnine, have no such striking effect on lower organisms, but a poison to all protoplasm is hydroxylamyl. Prof. Burdon-Sanderson said that this investigation had more importance than might at first appear, for it had arisen out of the epoch-making paper of Pflüger. Pflüger concluded that there must be a chemical change in the transition from living to dead protoplasm, and Dr. Loew took up the question as to what exactly this change was. His investigations are an important step in deciding this most important question. Prof. Stirling said this gave us a new test for living protoplasm. The chief thing to settle was what exactly causes reduction of the silver.

Digestion of Proteids in Plants, by Sidney Martin, M.D. (Lond.), B.Sc., M.R.C.P.—Of proteolytic ferments occurring in plants two kinds have been described—one acting like animal pepsin, and occurring in carnivorous plants, in the seeds of vetches, hemp, flax, barley, and malt, and the fruit of the fig, *Ficus cerica*; the other acting like animal trypsin (pancreatin) and occurring in the juice of the green fruit of *Carica papaya* (the papaw tree). The use of these ferments in the plant economy has only been surmised by testing their action on animal proteid, from which they form peptones. It is a question whether they form peptones from the proteid occurring in the individual, and from two considerations. It is doubtful whether a true peptone exists in plants—by which I mean a proteid soluble in water, and not precipitated by boiling, nitric acid, or acetic acid and potassic ferrocyanide. Vines (*Journal of Physiology*, vol. iii.) concludes that the body called vegetable peptone is hemialbumose (Meissner's α-peptone). It is also evident that the action of these ferments on the proteids will be slow in comparison to the action of animal proteolytic ferments; thus there might appear the proteids intermediate between albumen and peptone, which Kühne and Chittenden call *albumoses* (*Zeitschrift f. Biologie*, Bd. xx.). These questions I attempted to settle in the case of the papaw juice. I first of all extracted the proteids, which consisted of a ***globulin***, corresponding to animal paraglobulin; two albumoses, which I propose to call ***α- and β-phytalbumose***. The β form is precipitated; the α form is not thrown down by boiling; a vegetable ***albumen*** corresponding to egg-albumen. The effect of pure papain (the proteolytic ferment of the papaw juice) was tested on each of these bodies, but from none of them was a true peptone formed; only a body corresponding to Meissner's b-peptone. The very slow proteolysis explains the limitation of the formation of the final products of proteid change. Leucin and tyroin were formed. Full details of methods and results will be found in the forthcoming *Journal of Physiology*, September 14, 1885.

On the Application of the Anatomical Method to the Determination of the Materials of the Linnean and old Herbaria, by Prof. L. Radlkofer.—Prof. Radlkofer spoke generally of the anatomical method of botanical study, and dwelt on the results that had already been accomplished by it. With the aid of the anatomical system he advocated an extensive review of the herbaria of the country with reference to the writings of their former possessors. These herbaria should henceforth not merely be preserved; there should be the diffusion of new light on their contents so as to become useful to every one in a scientific sense, even to those who are unable to look through them. At some length he demonstrated the value of anatomical characters in systematic botany, and concluded with an appeal to all English botanists to direct their attention and their influence to the accomplishment of the work. In the accomplishment of this the British Association might, perhaps, give substantial assistance.

Notes on Experiments as to the Formation of Starch in Plants under the Influence of the Electric Light, by Mr. M. Ward, of the Owens College, Manchester.—The experiments, Mr. Ward said, were made not so much to determine a point already determined generally—that plants can be grown under the influence of the electric light—as to discover how far the electric light can be used for teaching purposes and investigations in the laboratory so to speak as an artificial sunlight. It would obviously be of enormous advantage to the vegetable physiologist if experiments could be easily performed under the influence of electric light. He explained the experiments he had made in the laboratories at the Owens College, Manchester, and at the residence of Mr. W. Crossley, of Bowden (who kindly placed a powerful arc lamp at his disposal), on this interesting subject, and described the means that had been employed in devising and conducting the experiments. Under a powerful arc light the results had been fruitful; but small clusters of Swan lamps had yielded no satisfactory results, at any rate at low temperatures. The subject requires still further examination, however, and Mr. Marshall Ward intimated that he intended to carry on the experiments, so that at a future date he might be able to convey more detailed information than could be given in a paper of a preliminary character. The plants employed were hyacinth potato, Algæ, *Faba*, *Phaseolus*, *Dicentra*, and the vine, and some interesting remarks on methods, &c., were made in the discussion which followed.

On the Coloration of the Anterior Segments of the Maldanidæ, by Allen Harker, F.L.S., Professor of Natural History, Royal Agricultural College, Cirencester.—The author, while studying the circulation and respiration of annelids at the zoological station at Naples, had been specially interested in the Maldanidæ, from their partially tubiculous habit and the brilliant coloration of their anterior segments. The bands of colour usually ornament the anterior segments, beginning with the second or third, and continuing to the ninth; but the distribution of the coloured bands differs widely in the different species. The colour in living or freshly-killed specimens is of a rich rose madder colour, shading off in each segment to a brighter rose-pink hue. Quatrefages attributed a physiological value to these coloured bands, describing them as being connected with the respiratory function. In connection with the whole subject of cutaneous respiration in annelids, it appeared important to settle this question, and the author made sections of the anterior segments in the Maldanidæ, and finds the colour to be due to a special pigment, whose behaviour under various reagents he described. On the other hand the author has studied the blood-vessels and their distribution in the living chætopod, and is satisfied that it extends equally in those portions of the cuticle which are uncoloured as in those which are. The coloured bands do not appear, therefore, to be in any way connected with the function of respiration.

SECTION E—GEOGRAPHY

The Indian Forest School, by Major F. Bailey, F.R.G.S., Royal Engineers, Director of the School.—It is only within the last twenty-five years that a special State department has administered the Indian forests. The staff was at first composed of men who had received no professional education, but they were able to do all that was then needed, and they accomplished work of great value. But as a result of their work the State became possessed of large forest areas, from which a permanent supply of produce had to be secured, and which had therefore to be managed systematically. At this time nothing was known of systematic forestry in England or in India, and an arrangement was made in 1866 under which candidates for the Indian Forest Service were trained on the Continent. The arrangement with the French Government is still in force, but it has now been decided to undertake the instruction in England. Great progress has been made in Indian forestry, which is mainly due to the professionally-trained men with whom the Forest Department has been recruited, but up to 1869 nothing bad been done towards the education of the subordinate ranks. As work requiring professional skill became necessary over large areas, it was found that the "divisions" must be broken up into a number of smaller executive charges under natives of the country, and that they must receive a professional education. In 1869 Mr. Brandis made proposals to organise the subordinate grades and to train men at the Civil Engineering Colleges, and several other attempts were made in the same direction, but without marked success. In 1878 Mr. Brandis proposed to establish a Central Forest School, and his proposals were accepted by Government. The chief object of the School was then to prepare natives of India for the executive charge of forest ranges, and to qualify them for promotion to the superior staff, but it was hoped that the school might ultimately be used to train candidates for the controlling branch. The chief forest officers of provinces were to select candidates and send them to be trained at the School. None but natives of India were to be admitted. A number of forests near Dehre Dun were grouped together as a training ground and placed under a separate conservator, who was also appointed director of the school. A board of inspection was appointed. The first theoretical course was held in 1881, and they have been held every year since then. The present system is that the candidates, who must be in robust health, are selected by conservators of the forest or by the director of the school. They must serve in the forests for at least twelve months before entering the School. Candidates for the ranger's certificate must have passed the entrance examination of an Indian University on the English side; candidates for the forester's certificate pass a lower examination. The course of training for these two classes extends over eighteen and twelve months respectively. Men who gain the certificates return to their provinces, and are employed there. The course of instruction for the ranger's class embraces vegetable physiology, the elements of physics and chemistry, mathematics, road making and building, surveying, sylviculture, working plans, forest utilisation, forest botany, the elements of mineralogy and geology, forest law, and the elements of forest etiology. The course for foresters is much more simple. The preparation of manuals is in progress, and a library, museum, chemical laboratory, observatory, and forest garden have been established. The period of probation in the forest before entry into the School has a twofold object: firstly, to enable the theoretical course to be understood; secondly, to eliminate men who are unsuited to a forest life before time and money have been spent on their training. As a rule, the students are *employés* of the Forest Department, and they draw their salaries and maintain themselves while at the School. No instruction fees are charged. It would not at present be possible to get condidates whose maintenance and education are entirely paid for by their friends. Nine men who have left the School have appointments of from 125*l.* to 200*l.* a year, and this ought to draw eligible candidates. Conservators of forests say that the men trained at the School are markedly superior to their untrained comrades. The area of reserved forests has largely increased of late, and the prospects of the students are very good. During the session of 1884 there were forty-six students of all classes at the School, of whom eight were from Madras, and seven from native States, the chiefs of which have been induced by the establishment of the school to take measures for the protection of their forests. The School has now been made an imperial institution, and this is a great advantage in every way. The expenses of the School in 1884 are said to have been 1911*l.*

On Journeyings in South-Western China, by A. Hosie.—In the autumn of 1881 Mr. Hosie was appointed Her Majesty's Agent in Western China, and reached Ch'ung-ch'ing, in the province of Ssŭ-ch'uan, in January, 1882. From this point he made three journeys in South-Western China. In the spring of 1882 he proceeded through Southern Ssŭ-ch'uan and Northern Kuei-chou, the Chinese "Switzerland," to Kuei-yang Fu, the capital of the latter province, whence he journeyed westward in the footsteps of Margary to the capital of Yünnan. From Yünnan Fu he struck north-east through Northern Yünnan, following for days here and there the routes of Garnier and the Grosvenor Mission. At last he descended the Nan-kuang River and reached the right bank of the Great River, the local name of the Upper Zangtsze, at a point below Hsü-chou Fu, an important city at the junction of the Min River and the Chin-sha Chiang, or River of Golden Sand. Here he took boat and descended the Great River to Ch'ung-ch'ing, his starting-point. In February, 1883, Mr. Hosie again left Ch'ung-ch'ing, and proceeded north-west to Ch'êng-tu, the capital of the province of Ssŭ-ch'uan, by way of the brine and petroleum wells of Tzŭ-liu-ching. From Ch'êng-tu he journeyed west and southwest through the country of the Lolos, skirting the western boundary of Independent Lolodom. From Ning-yüan, locally called Chien-ch'ang, and lying in a valley famous, among other things, as the habitat of the white-wax insect, he passed southwest through the mountainous Cain-du of Marco Polo, inhabited in great part by Mantzŭ tribes, and struck the left bank of the Chin-sha Chiang two months after leaving Ch'ung-ch'ing. From this point Ta-li Fu, in Western Yünnan, was easily reached. From Ta-li Fu Mr. Hosie jurneyed eastward to Yünnan Fu, which he had visited the year before, and then struck north-east through Western Kuei-chou to the Yung-ning River, which he descended to the Great River. Lu Chou, an important city at the junction of this river with the T'o River, was soon reached, and the Great River was again descended to Ch'ung-ch'ing. This journey occupied four months. In June, 1884, Mr. Hosie again left Ch'ung-ch'ing, and from Ho Chou, a three days' journey to the north of that city, he struck westward through a beautifully cultivated and fertile country to Chia-ting Fu, on the right bank of the Min at its junction with the T'ung River. Chia-ting is famous as the great centre of sericulture in Ssŭ-ch'uan, and as the chief insect wax-producing country in the Empire. A day's journey west of Chia-ting is the famous Mount O-mei, rising 11,100 feet above the level of the sea. This mountain, which is sacred to the worship of Buddha, Mr. Hosie ascended in company with crowds of pilgrims. He then proceeded south, skirting the eastern boundary of Independent Lolodom, to the River of Golden Sand, the left bank of which was struck at the town of Man-i-ssŭ, between forty and fifty miles above P'ing-shan Hsien—the highest point reached by the Upper Yangtsze Expedition in 1861. From Man-i-ssŭ Mr. Hosie descended the Chin-sha Chiang and the Great River to Ch'ung-ch'ing.

Antarctic Discovery, by Admiral Sir Erasmus Ommanney, C.B., F.R.S.—The object of this paper is to draw attention to the neglect of the Antarctic region as a field for exploration. The author gives a summary of the work which has already been done by Cork, Bellingshausen, Weddell, Biscoe, Balleny, Wilkes, Dumont d'Urville, James Ross, and Nares (in the *Challenger*). The author refers to a paper by Dr. Neumayer on the subject, the substance of which was reproduced in NATURE (vol. vii. p. 21). The author concludes as follows:—I have thus laid before you but a very imperfect description of these voyages; to give the details of the scientific results would occupy a separate paper. But I have endeavoured to demonstrate how large a field remains open for discovery. I think, from all we now know, we may infer that the South Pole is capped by an eternal glacier; and, from the nature of the soundings obtained by Ross, it would appear that the great ice-wall along which the ships navigated was the termination of the glacier—the source from which the inexhaustible supply of icebergs and ice-islands are launched into the Southern Ocean, many of which drift to the low latitude of 42°. The fact of finding the volcanoes of equal proportions to Etna or Mont Blanc creates a zest for further research regarding that awful region on which neither man nor quadruped ever existed. No man has ever wintered in the Antarctic zone. The great desideratum now before us requires that an expedition should pass a winter there, in order to compare the conditions and phenomena with our Arctic knowledge. The observations and data to be collected there throughout one year could not fail to produce matter of the deepest importance to all branches of science. I believe that such an achievement can be accomplished in these days with ships properly designed and fitted with the means of steam propulsion; nor is it chimerical to conceive a sledge party travelling over the glacier of Victoria Land towards the South Pole, after the example of Nordenskjöld in Greenland. Another interesting matter requires investigation, from the fact that all the thermometers supplied for deep-sea temperatures to Ross were faulty in construction, as they were then not adapted to register accurately beneath the weighty oceanic pressure. Moreover, another magnetic survey is most desirable in order to determine what secular change has been made in the elements of terrestrial magnetism after an interval of forty years and more, when taken by Ross. In fact, there exists a wide field open for investigation in the unknown South Polar Sea. This paper will, I trust, be the prelude for others to follow in arousing geographers and this powerful Association in promoting further research by despatching another South Polar expedition, having for its object to secure a wintering station. No other nation is so capable of providing and carrying it out. Even in the Australian colonies there exists the spirit and the means for such a noble enterprise.

Projected Restoration of the Reian Mœris, and the Province, Lake, and Canals ascribed to the Patriarch Joseph, by Cope Whitehouse, M.A., F.A.G.S.—The Berlin Geographical Society has published, in its *Zeitschrift* for May, 1885 (No. 116), the latest map of Egypt, from the Fayoum to Behnesa, and from the Nile to the Little Oasis. The text by Dr. Ascherson gives credit for a considerable area to the topographical observations presented to this society at Montreal. So much of the Reian basin as lies between the Quasr Qerūn and the Quasr Reian has not been visited by any European except the author of this paper (1882, 1883). It is now an accepted fact that there is a depression south of the Fayoum, not less than 150 feet below the level of the Mediterranean, with a superficial area at the level of high Nile of several hundred square miles. It is irregular in shape, curving like a horn from a point near Behnesa to the ridge which separates it from the Fayoum. In the southern part are two, and perhaps three, patches of vegetation, wild palm-trees, and ruins of Roman and early Christian date. This part was visited by Belzoni, May 22, 1819; Caillaud, November 24, 1819; Pacho and Müller, 1823-24; Sir G. Wilkinson, 1825; Mason Bey, 1870; and Ascherson, March 27, 1876. Dr. Ascherson determined by aneroid observations that his camp was 29 metres below the sea. Caillaud found ruins about +38m., or about the level of high Nile in the valley on the same latitude. The aneroid, theodolite, and other observations of March 6 and April 4, 1882, and April, 1883, by the author of this paper, established a depth of −175 to −180 English feet. The greatest depth is probably under the western cliffs south of the Haram Medhūret el-Berl. No previous explorer had conceived it possible that this might have been a lake within historic times. The level of the ruins, as determined by Caillaud, shows that the ancient station of Ptolemais might have been, as represented in the text and maps of Claudius Ptolemy, on a horn-shaped lake about 35 miles long and 15 wide, with a maximum depth of 300 feet, fed by a canal, partly subterranean, from Behnesa, as well as by a branch of the present Bahr Jūsuf communicating with it through the Fayoum. The lower plain of the Fayoum had been, at that time, fully redeemed, and the present Lake of the Horn reduced to such insignificant dimensions as to be unnoticed. The restoration of the Reian basin of Lake Mœris and the drainage by evaporation of the Birket el-Querūn would be a repetition in modern times of the best results reached in the Greco-Roman period, perhaps 3000 years after the first effort to utilise these two unique basins for storage and drainage.

On Batho-hypsographical Maps, with Special Reference to a Combination of the Ordnance and Admiralty Surveys, by E. G. Ravenstein.—The batho-hypsographical map, which exhibits the vertical configuration of the solid surface of the earth, above as well as below the ocean levels, is a product of modern times. It was Gerard Mercator who first inserted soundings upon a chart in 1585, but nearly two centuries passed away before Cruquins, in 1728, introduced the fathom-lines with which we are all familiar. Buache, and after him Ducarla, first suggested the introduction of contours upon maps, and their idea was realised in 1791 by Dupain-Triel on a map of France. The combination of these two descriptions of contoured maps we owe to modern German geographers, and more especially to Berghans, Von Sydow, and Ziegler. Cartographers, in effecting this combination, had hitherto quite lost sight of the fact that the heights on maps are referred to high or mean water, whilst the depths on charts represent soundings reduced to low water. This rough method gave satisfactory results when dealing with maps on a small scale, but a more rigid method would have to be applied when it was desired to combine accurate surveys like those made by the Ordnance and Admiralty Departments. The so-called mean level of the sea was not a suitable datum level, and it would be necessary to carry on tidal and other scientific observations on a far more comprehensive plan than had been done hitherto if a really satisfactory batho-hypsographical map of the British Islands were to become attainable. These various supplementary surveys, tidal observations, &c., it was to be hoped, would expand into a comprehensive scientific survey of the British seas.

What has been done for the Geography of Scotland, and what remains to be done, by H. A. Webster.—After remarking on the unsatisfactory state of the Ordnance Maps, Mr. Webster said that in regard to the depth of our lakes and rivers—and the submerged portion of a valley is geographically as interesting as the sub-aërial portion—absolutely no data are supplied by the Ordnance Survey. Nor, with a few individual exceptions, do they exist in an accurate and trustworthy form anywhere else. It was an open secret that, when this omission was pointed out to the Government by the Royal Societies of London and Edinburgh, the Lords of the Treasury refused, and again refused, to authorise a bathymetric lake and river survey being carried out, either by the officers of the Ordnance Survey or by those of the Hydrographic Department. Such a refusal could not be permanently accepted. It was to be hoped that when the Government was next urged to move in the matter they would be asked for more, and not for less. We required not only a hydrographic survey done once and for all (though that was worth the doing); we required a systematic registration of hydrographic facts throughout the country, in order that the true *régime* both of lakes and rivers may be known in detail and with scientific precision. The ignorant niggardliness of the British Government was in striking contrast to the conduct of those of some foreign countries. In Switzerland, for instance, there was a regular system of inland hydrographic observations, by which the *régime* of all the principal rivers was annually recorded and rendered easily intelligible by a series of graphic bulletins. In regard to a Swiss river we could tell the volume at any period of the year at several important points, and could compare the facts of 1884, for instance, with those of any year in the last two decades. Every one knew what a vast body of interesting data had for generations been accumulating about such rivers as the Po and the Rhone, and many had no doubt heard of the system of hydrographic stations recently established by the Italian Government in the basin of the Tiber. Why should we not endeavour to learn something definite and precise about the character of our own rivers? The investigation was only the natural complement, on the one hand, of the physical structure of the country, and, on the other hand, of its meteorology. Our Scottish Meteorological Society had now succeeded in establishing meteorological stations throughout the country; let hydrographic stations bear them company along our principal rivers. Rainfall and river discharge were mutually illustrative.

On Overland Expeditions to the Arctic Coast of America, by John Rae, M.D., F.R.S.—The following table shows the approximate amount of geographical work done by the expeditions under—

A Word or Two on the Best and Safest Route by which to attain a High Northern Latitude, by John Rae, M.D., LL.D., F.R.S., F.R.G.S., &c.—The plan proposed is that the route by the west shore of Spitzbergen should be taken by one, or perhaps two, steamers similar to the fine vessels used in sealing and whaling at the present time. That after forcing the ice "pack" at the north-west end of Spitzbergen, a north-east course towards Franz-Josef Land should be followed. That a depôt of coals should be placed at a convenient harbour in North Spitzbergen. Extracts are given from Parry's "Narrative," 1827, pp. 101 and 148, showing how open and small the ice was in latitude 82° 45′ N. The southern drift of the ice that so obstructed the advance of Parry's boats will be no great impediment to a powerful steamer, whilst if she gets helplessly fixed in the pack she will drift homewards with it. No well-equipped and powerful steamer has tried this route.

JAPANESE TATTOOING

THE last number (Heft 32, May, 1885) of the *Mittheilungen der deutschen Gesellschaft für Natur- und Völkerkunde Ostasiens* is almost wholly occupied by a paper of a most exhaustive character by Dr. Baelz, a physician in the service of the Japanese Government, on the physical qualities of the Japanese. A previous paper by the same writer gave the results of his investigations into Japanese skeletons. For the purposes of the present paper he obtained numerous anthropometrical measurements—about 2500—based on a scheme which included seventy-nine measurements in the case of each individual. It is noticeable that Broca confined himself to little more than a third of this number, Virchow's scheme contemplated thirteen, and at the most thirty-eight, Weissbach sixty-seven, and Quetelet, in his anthropometry, gives eighty-two measurements. The skeleton plan of the paper is as follows: 1. Skin and hair: the colour of the skin and its cause, artificial colouring, including tattooing, the characteristics and nature of the hair; 2. The *physique* in general, including the carriage and gait of both sexes, weight, size, and growth; 3. Measurements of the body and limbs. In the discussion of the results set forth in this section the author expresses the opinion, based on his own investigations, that in general the value of these anthropometrical measurements is much exaggerated by anthropologists and ethnographers.

The tattooing of the skin by Japanese, generally those of the lower classes, has attracted much observation from Europeans, due partly to the extraordinary elaboration and artistic skill displayed, partly to the fact that the occupations and customs of the class in which tattooing is most practised are such as to render it necessary frequently to wear none but the most indispensable garments. This subject has never, so far as we are aware, been examined with so much thoroughness and care as by Dr. Baelz. He says that among the various peoples which have, in the course of centuries, reached a high standard of culture the Japanese are probably the only race which have retained generally the practice of tattooing and have brought it to a state of highly artistic development. Up to a few years ago the practice was so widespread that in Tokio alone there are estimated to have been, possibly still are, 30,000 men who were tattooed. This decoration is not confined, as in Western countries, to a small part of the body, but it covers the whole back and a considerable part of the limbs. The head, neck, hands, and feet are never tattooed, a circumstance of importance in explaining the practice. It was confined to the lower classes; amongst the better classes it was considered unworthy to disfigure the body in this way. It was widely spread amongst the workmen in great towns and coolies, and even to-day it is exceptional to find an old man of either of these occupations who is not tattooed. The objects illustrated were various: amongst the most common were large dragons, lions, battle scenes, beautiful women, historical occurrences, flowers, &c. Dr. Baelz states that he never saw obscene pictures tattooed. The colours employed are black, which appear blue, and various shades of red. The first is obtained from Indian ink, the usual Japanese writing material, the red from cinnabar. When a man wishes to undergo the process he looks out in a popular picture-book some illustration which takes his fancy, or he evolves something from his own imagination, and goes with it to the artist. The latter makes his arrangements, and sketches the picture on the skin. If he is skillful at his calling he sketches the merest outline, and straightway introduces all the details; but if he is not so confident in himself he first draws the whole picture on the skin. There is no special ceremony attending the work as in some of the South Sea Islands, nor is there any religious signification whatever in the process. The artist uses for the purpose exceedingly fine, sharp sewing needles, fixed firmly, four, eight, twelve, twenty, or forty together, in a piece of wood. They are arranged in several rows; when there are forty they stand in four rows of ten each. The points are quite even, except when it is desired to produce a light or dark shading, when the needles are arranged in corresponding lengths. This combination is said to be especially painful. The skin, at the place where the puncturing is going on, is stretched between the thumb and first finger of the operator, who holds between the third and fourth fingers of the same hand a writing brush with ink or cinnabar, as may be required, on it. He holds the wood containing the needles in his right hand, and, having put the colour on them, he rests the hand on the thumb of his left hand, and then proceeds with extraordinary rapidity to puncture the skin, stopping every now and again to put on the fluid anew. Dr. Baelz counted on one occasion ten punctures per second, and as there were ten needles the person being tattooed received one hundred punctures per second. The wonder is that with such speed excellent pictures, with various degrees of shading, can be produced, but such is the fact. A skillful operator can in this way puncture the back or breast and stomach of a grown man in a day. A few hundred thousand punctures are necessary for this purpose. The patient, if he may be so styled, does not suffer so much pain as might be expected. The punctures are not very painful, they tickle rather than hurt. No blood is drawn; a circumstance which shows that the needles do not reach the cuticle, and which also explains the slight pain of the operation, and the possibility of enduring it. This, however, is not the case always, for in many parts of the body where the skin is tender, or where a deeper shade is required, some clammy blood comes slowly to the surface, and the operation becomes painful. This occurs most frequently at the knees and elbows. To be well tattooed, therefore, is taken as a sign of manly vigour and endurance. As soon as the sitting is over the punctured parts are bathed with warm water, which produces a slight pain. The colour then comes out more clearly than before, and the patient can do as he likes. No special diet is ordered. A few hours after the operation he often has a slight feverish feeling, but this soon leaves him. After about three days the skin scales off like bran, but the tattooed parts are never irritable or sensitive, and the man goes about his work as usual. There are cases in which women have been tattooed, but these are very rare. The women are mostly dissolute who allow this to be done; but it is said that the colours come out with great clearness and beauty on the comparatively fair skins of women. Recently tattooing has been prohibited by law under the impression

[1] Actually two expeditions—one east, the other west.

[2] Dease and Simpson had to pass over about 500 miles of previously traced coast before getting to new ground, but Franklin and Richardson were on new ground at once on reaching the coast.

[3] Of the coast, &c., traced by Rae, 1123 miles were done by sledging, believed to be the most laborious of Arctic work.

that it is a barbarous custom unworthy of a civilised people. But Japanese tattooing is so superior to that of all other nations that European sailors are said to look forward to it as the principal advantage in a visit to the land of the Rising Sun.

This being the method in which the practice is carried out, Dr. Baelz comes to discuss its origin and meaning. The oldest reference we have to tattooing in Eastern Asia states that a Chinese prince, about three thousand years ago, who was nominated heir to the throne against his will, had himself tattooed in order to render his succession impossible. But at the present day the practice in China and Korea has fallen into desuetude, while in Burmah it still appears to be in vogue. In 1872, a man was exhibited in Europe who had been a prisoner amongst the Burmese, and who was tattooed from the crown of the head to the sole of the foot. The practice is still prevalent amongst the South Sea Islanders and the American Indians. In his work on the origin of writing, Wuttke seeks to show that tattooing is a kind of writing; but however correct this theory may be in the case of the tattooed peoples known to him, it certainly does not hold good in the case of the Japanese. The signification of the practice, says Dr. Baelz, amongst the latter is quite distinct from that which it has amongst other peoples. In the first place, amongst the South Sea Islanders and the Indians, tattooing has a religious, a symbolical meaning; it is a ceremonial, frequently a sacred process. There is nothing of this in Japan—neither ceremony, nor other peculiar meaning; it is done for cosmetic purposes and for no other. Again, amongst other peoples tattooing was a species of distinction; it marked the heroes, leaders, chiefs, of the tribe. In Japan it marks a man of the lower classes. Elsewhere, also, the uncovered parts of the body, such as the face, neck, hands, &c., are the favourite spots for tattooing; in Japan it is only the portions usually clothed which are tattooed. It is noticeable that amongst the Ainos the tattooing takes place on the exposed parts of the body, and that it is largely practised by women, two circumstances which distinguish it from the practice amongst the Japanese, and in which the Ainos resemble other northern peoples such as the Esquimaux, the Ostiaks, and others. In answer to the question, What meaning has the practice amongst the Japanese, as distinct from other races? the author replies that in Japan tattooing is a garment, a decoration. Various proofs of this statement are advanced, amongst them being the following: only those parts of the body are tattooed which are usually covered; all workmen do not tattoo themselves, but exclusively those whose work causes excessive perspiration, and who can, therefore, work best in a semi-nude state, such as runners, grooms, bearers, &c., and amongst these the practice prevails only with those who have connection with large towns, where nudity would be objectionable. Their garments are tattooed on their bodies, and they appear clothed without clothes before the public. The peasants are never tattooed. Again, the colours of the tattooing corresponds with that of the dress; it is the same dirty, dark blue. This theory never suggested itself to the Japanese: they thought that it must have come from China, and that it was a species of punishment. It was, it is true, at one time the custom to tattoo marks into criminals, but this was confined to a ring on the elbow. It would not explain the spread of the practice amongst certain classes in certain directions. Dr. Baelz's theory that it is merely a substitute for dress, and as the wearing of clothes is now compulsory, tattooing has lost its meaning. As for its origin, the peoples around the Japanese, the Ainos and the Loochooans, have practised it; and the Japanese navigators who travelled far and wide in the Eastern seas in the sixteenth century might well have seen it elsewhere. The Japanese discovered, says Dr. Baelz, that man can paint a figure on his skin which the rain cannot wash away, the sun wither, or even all-devouring Time destroy, and with their instinctive artistic skill they gradually developed and perfected the original rude figures in idea and execution. At first few only wore this blue skin-dress, but these few appeared to their companions decorated and clothed (a tattooed person does not appear actually naked), and as such a garment was cheap and lasting, and every man could have it according to his own fancy, tattooing became the fashion.

It may be added here that among the Igorrotos of the mountanious districts in the north of Luzon tattooing is also exceedingly elaborate, although it consists rather of a series of lines, curves, &c., than of one large, elaborate picture. Dr. Meier, in a paper read not long since before the Anthropological Society of Berlin, described the Igorrotos as tattooing the hands, arms, breast, and also part of the legs. The back is untouched except by one tribe. A picture of the sun, as a number of concentric circles on the back of the hand, is the commonest object represented. The process takes place at puberty, and is a long one, as the punctures (which are made with a three-pointed instrument which is clumsy in comparison with the Japanese needles) become inflamed and take a long time to heal. The tattooing of the Buriks, a tribe of Igorrotos, takes three or four months to complete.

It may not be out of place here to refer to Dr. Baelz's aocount of the Japanese use of moxa, which, like tattooing, comes into his section dealing with the skin. On the bodies of almost every Japanese, and sometimes on every part of the body, one sees round white spots. These are the moxa spots, produced by burning the flesh with a species of plant, with the object of curing some affection. This is a universal popular specific in Japan, which is its home, although moxa is to be found used elsewhere. It was introduced from Japan to Europe by the Portuguese and Spaniards, and the name is Japanese. In May the leaves of the *Artemisia Chinensis* are powdered and dried, and the mass cut into small blocks or pieces. One of these is laid on the body and set on fire, burning slowly away. At first it naturally produces a sore, more or less deep, according to the intensity of the heat; soon this heals, leaving the scar for ever. The belief in the efficacy of this process is universal, and, Dr. Baelz thinks, not altogether misplaced, for the moxa acts much as our blisters do. Moreover, from the accounts of those who have gone through the cure, it is by no means so painful as one would anticipate from the heroic nature of the remedy.

SCIENTIFIC SERIALS

American Journal of Science, August.—Origin of coral reefs and islands, by James D. Dana. The arguments recently raised by Dr. A. Geikie against Darwin's theory of subsidence as an explanation of the formation of *atolls*, or barrier reefs inclosing a lagoon, are discussed and shown to be largely based on misunderstandings of the facts. It is pointed out that local elevations within the sinking area are not evidence against a general subsidence, such local disturbances and faults being almost necessary concomitants of subsidence. The conclusions as to changes of level in the large Pacific groups south of the equator agree mainly with Darwin's views, and the subsidence indicated, according to him, by *atolls*, is shown to be real, not an apparent sinking due to change of water-level.—On the meteorite of Tomatlán, Jalisco, Mexico, by Charles Upham Shepard. The striking peculiarity of this stone, which fell in August 1879, is the prevalence everywhere of octahedral crystals of nickeliferous iron. The specific gravity of the two fragments examined was 3·47—4.43.—On the widespread occurrence of allanite as an accessory constituent of many rocks, by Joseph P. Iddings and Whitman Cross. From its mode of occurrence and association the authors conclude that allanite must now be added to the group of primary, accessory rock constituents, similar to zircon, sphene, and apatite, though much rarer than any of these. In some regions it appears to be quite uniformly distributed through certain types of rock, such as the porphyrites and allied porphyries of the Ten Mile District, Colorado.—Crystals of analcite from the Phœnix Mine, Lake Superior Copper Region, by Samuel L. Penfield. These crystals, which occur thickly grouped together on calcite and native copper associated with tabular crystals of apophyllite, are of all sizes from minute particles up to one centimetre in diameter. The small ones are simply tetragonal trisoctahedrons of the form (211), 2 - 2; the larger ones are of the same form, but with the planes differently arranged.—On a differential resistance-thermometer, by T. C. Mendenhall. This instrument has been devised and constructed for the study of certain problems connected with meteorology, especially the observation of soil and earth temperature, and the use of which would not demand greater skill than that of the ordinary meteorological observer. It consists essentially of a mercurial thermometer, not unlike ordinary forms, except that the bulb is greatly enlarged, so that the stem may have a diameter of about a millimetre, still leaving the scale tolerably open. By its means observations may be taken in less than a minute, no time being consumed in the preparation of liquids of known temperature at the observing station, as in the use of the thermo-junction on the resistance coil.—Impact friction and faulting, by George F. Becker. The author discusses the phenomenon of "step faults," as described in Mr. Geikie's "Text-Book of Geology," p. 532, which he concludes to be not merely local, but of general occurrence.—A standard of light, by John Trowbridge. Objections are raised to the standard adopted at the Paris Conference of 1881–4—that is, the light emitted by a surface of platinum at the point of solidification. A more satisfactory standard might be an incandescent strip of platinum radiating a definite amount of energy, this energy being measured at a fixed distance, which will best agree numerically with the absolute system of measures now universally adopted in heat and electricity.—On hanksite, a new anhydrous sulphato-carbonate of sodium from San Bernardino county, California, by W. Earl Hidden. This new Californian mineral has a density of 2·562, hardness 3·—3·5, and is readily soluble in water, yielding an abundant precipitate of barium sulphate when barium chloride is added to the solution. The author names it "hanksite," after Prof. Henry G. Hanks, whose name is so intimately associated with the mineralogy of the Pacific coast.—Mineralogical notes, by Edward S. Dana and Samuel L. Penfield. The chief subjects of this paper are the analysis of a large crystal of hanksite from California and an artificial crystallised lead silicate from the Desloge Lead Company, St. François County, Missouri.—On the amount of moisture which sulphuric acid leaves in a gas, by Edward W. Morley.—Local deflections of the Drift Scratches in Maine, by G. H. Stone. Traces of these indications of secondary glaciation have been observed, especially in the Sebasticook Valley, the Belfast and St. George River districts.—Successional relations of the species in the French Old Tertiary, by Otto Meyer. In these, as well as in the corresponding American formations, many animal and vegetable species can be traced along through the succeeding strata, the latter being apparently connected by descent with the earlier forms. The paper is accompanied by a comparative table of Lower, Middle, and Upper Eocene and Oligocene forms illustrating this principle.

The American Naturalist for August contains notices of some human remains found near the City of Mexico, by Mariano de la Barcena.—Evolution in the vegetable kingdom, by L. F. Ward.—The relations of mind and matter, by Charles Morris.—Affinities of Annelids to Vertebrates, by E. A. Andrews.—The use of copper by the Delaware Indians, by J. C. Abbott.—Notes of recent literature, &c.

Bulletin de l'Académie Royale de Belgique, June.—Note on some derivatives of tetrabromuretted hydrocamphene, by M. De la Royère.—On certain developments of algebraic series; the general formulas of these developments and their application to special cases, by M. J. Deruyts.—Researches on the action of a beam fixed at both ends and subjected to a movable overcharge, by M. G. Leman.—Questions of indeterminate analysis, by M. E. Catalan.—Note on the motions of the human brain, by M. Léon Frédéricq.—A new process of vivisection for the physiological study of the thoracic organs, by the same author.—On the optical properties of Ludwigite ($R_4FeB_2O_{10}$), by M. A. F. Renard.—Determination of the coefficient of compressibility for some fluids and of the variations of this quantity under different temperatures, by M. P. De Heen.

Rendiconti del Reale Istituto Lombardo, July 23.—On the causes and treatment of certain ophthalmic affections (preliminary note), by Dr. R. Rampoldi.—An exposition of the third paragraph of Riemann's memoir on the theory of the Abelian functions, by Prof. Giulio Ascoli.—Further researches on the neutralising agents of the tubercular virus, by Prof. G. Sormani and Dr. E. Brugnatelli.—Toxico-chemical affinities and differences of gelseminina and strychnine, by Dr. C. Raimondi.—On the phenomenon of etherification by double decomposition, by Prof. G. Bertoni.—The mental infirmities and last days of Torquato Tasso, by Prof. A. Corradi.—Note on an artistic palimpsest of the fourteenth century, by Prof. G. Mongeri.—Meteorological observations made in the Brera Observatory, Milan, for the month of July.

Rivista Scientifico-Industriale, July.—On the solar spots, their origin, nature, and harmless character, by Prof. Annibale Ricco.—Application of the telephone to the study of vibrating columns of gas, by Prof. Fossati.—A contribution to the study of etherification by double decomposition, by Prof. Giacomo Bertoni.—Geological constitution of Mount Vincigliata in the Fiesoli range, by C. del Lungo and R. Cocchi.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, September 28.—M. Bouley, President, in the chair.—Equilibrium of the moon, by M. F. Tisserand. In this paper calculations are submitted in support of M. Ch. Simon's theory, supplemented by M. Poisson, that, neglecting the excentricity of the lunar orbit, the axis of rotation is displaced in the interior of the moon in such a way as constantly to oscillate in the plane perpendicular to the main axis directed towards the earth.—Note on earthquakes, by M. A. d'Abbadie. The author gives an account of the seismic movements observed by him last winter in Egypt, where the seismograph was exceptionally active. He urges a systematic study of these phenomena in France, such as has already been commenced by M. E. de Rossi in Italy, and by Mr. Milne in Japan.—Researches on the nitric cellulose substances (gun cotton, &c.), by M. Ch. Er. Guignet. The constituents and properties are described of the four distinct nitric cellulose bodies hitherto determined, all of which may be regarded as derivatives of the cellulose $C_{48}H_{40}O_{40}$, where 4eq., 6eq., 8eq., or 10eq. of water are replaced by the same number of equivalents of hydrated nitric acid.—Memoir on the treatment of phylloxera by means of the organic sulphurs and the polysulphides of ammonium obtained by dissolving powdered sulphur in the night-soil of cesspools, by M. J. Jullien. This treatment is described as inexpensive, thoroughly efficient, and applicable to every description of soil.—Note on an unpublished document by Sergio Venturi, dated February 26, 1610, on the invention and the theory of the telescope, recently edited by M. G. Govi. This letter, addressed by the writer to the Marquis John Baptist Manso at Naples, is specially interesting as being anterior to the earliest publications of Galileo on the telescope which had just been invented by Lippersheim in Holland.—Note on the separation of liquefied atmospheric air into two distinct fluids, by M. S. Wroblewski.—Description of two new types of condensing hygrometers, by M. Georges Sire. The essential character of these hygrometers is that the moisture is precipitated on a bright metallic surface without solution of continuity. Perfect equality of temperature is secured in both instruments by the agitation of the volatile fluid and the thinness of the walls of the cylindric tube.—Genesis of the crystals of sulphur in square tables (five illustrations), by M. Ch. Brame. The author's experiments on the genesis of the square tables of sulphur show the direct passage from the curve to the straight line in the development of these crystals.—Morphology of the mandibule of the hymenoptera, by M. Joannès Chatin. This organ of the hymenopteræ is shown to be perfectly analogous in all its parts to that of the grinding insects.—Note on the application of thermo-chemistry to the explanation of geological phenomena, continued; iron ores, by M. Dieulafait.

COMPARATIVE ANATOMY AND PHYSIOLOGY

Comparative Anatomy and Physiology. By F. Jeffrey Bell, M.A., Professor of Comparative Anatomy at King's College, London. (London: Cassell and Co., Limited, 1885.)

THIS work is one of a series of "Manuals for Students of Medicine," each of which is to be "compact and authoritative"—"embodying the most recent discoveries," and also to "contain all the information required for the medical examinations of the various colleges, halls, and universities in the United Kingdom and the Colonies."

On behalf of those of our readers who may be unfamiliar with the demands of certain of the examining bodies referred to above, it may be well to state that nothing but a *résumé* of all that is known in the subject could meet the requirements of the case. That which the publishers demand, and which the public therefore has a right to expect under the conditions laid down, is an ultra-condensed digest of all authoritative work in zoology and physiology. Incredible though this may appear to any one acquainted with the bibliography of the subject, Prof. Bell's manual is so far satisfactory that we cannot but congratulate the publishers upon their choice of an author, whose work in connection with the *Journal of the Royal Microscopical Society* and the *Zoological Record* render him *par excellence* the man for this *opus mirabilis*. When it is stated that there are but 548 pp. to the book it will be clear that it must be a vast collection of facts, little being left as to style or originality for that criticism which the author invites. The method of treatment, however, is somewhat novel, and in our opinion open to comment.

The author divides his work into fourteen chapters. Of these the first is introductory; the second is devoted to the Amœba as a physiological study; the third to "the general structure of animals," that is, to a consideration of the "broader characteristics of the groups into which the animal kingdom has been divided." Those which remain are devoted, each to one of the great systems of organs and to development.

In estimating the value of this volume, it must be clearly borne in mind that it is a book intended for beginners. Chapter II. is written for biological babes, and it will be clear to any one who reads the volume that the author would have the student familiarise himself with the facts in the order in which they are presented to him. This being so, it is a pity that Chap. I. should have been so largely devoted to the subtle details of cell-structure; the beginner is lost in descriptions of the "cytod" and the "cell," for each of which broad differences are dogmatically formulated, such as would tend to bias the mind of the average student. Draw hard lines by all means for the beginner, but not in such delicate matters as these. Only by working from the known to the unknown, can the student of science ever hope for success; the order of his elementary studies must be a recapitulation of that in which the science itself has advanced—he must here begin with gross anatomy, and we believe that to treat first of the subtle details of cell structure is to do violence to the cause of inductive science. A somewhat similar comment may be offered upon the manner in which the great phyla are dealt with in Chap. III. Having devoted nearly half the chapter to defining these, the author proceeds (pp. 58, 59) to deal with types of each. He prefers to commence with the Echinodermata, dealing thus "first of all" with the "most aberrant" phylum. If the Echinoderms are dismissed as a stumbling block, why not the Brachiopods, the Polyzoa, and certain other creatures well known to zoologists? These are all wisely relegated to the end of the chapter, as "groups of animals which in the present state of our knowledge cannot be satisfactorily placed with any of the great phyla" (p. 100). Just so, but why not put the Echinoderms there also If the student is to be allowed the exercise of any judgment in the matter, he cannot be expected to deal with the aberrant before he is familiar with the normal, and more stereotyped grades of organisation.

Although the work is professedly a text-book of comparative anatomy and physiology, the latter branch has suffered much in the process of condensing, necessary we presume in order to keep the book within the prescribed limits. At the commencement of each chapter a concise definition of that system of organs to be dealt with comparatively is given, together with a brief description of their functional activity; but the field of comparative histology is sorely neglected. The author neither furnishes the required information on this subject, nor does he take for granted that his readers have worked through even the broad principles of it. The student is occasionally referred (*Ex.* pp. 368 and 372) to Klein's "Manual of Histology"—a fellow volume to the one now before us; but as that work deals with the subject altogether from a special human-anatomist's point of view, the reader is at a loss to make much of the subtle differences in the comparative anatomy of, say, shells and teeth, until he knows more precisely than he is here informed what is involved in an exoskeleton and a tooth. Similarly, the statements made (p. 258) concerning the vertebrate excretory system are altogether too brief and dogmatic. The student is merely informed that *Meso* and *Metanephros* exist; of their adult structure he learns little or nothing, and in the face of such descriptions of the essential structure of an excretory organ as are given, he would be at a loss to make much of that of the vertebrate at any rate for himself.

Chapters V. and VI. are also at a disadvantage from this curtailing of the histological portion of the subject. The definition of the blood given (p. 181) would not convey to the beginner's mind a notion of its real complex nature; he would rather infer that it is merely "the result of the process of digestion," in function "respiratory as well as nutrient." Least successful of all the definitions given of great systems is that (pp. 393-94) of the nervous system, and it is exceedingly unfortunate that (p. 411) the nerves should be described as bringing or carrying "messages." A fascinating conception of the nervous activity this may be, but it is a commonplace one, well known to every teacher of physiology; the mischief attendant upon its use is patent, and it is highly desirable that special efforts should be made to secure its abolition. Its adoption in this work is therefore greatly to be regretted.

Prof. Bell's book is fully up to the date of writing, and the subject-matter is for the most part judiciously selected and arranged; but in a volume where so much of fundamental importance to the student is recorded, we could wish to see more discretion used in the transcription of certain hypotheses. We frequently find the most elementary facts set down side by side with the most daring generalisations. Nowhere is this more conspicuous than on p. 85, where Hubrecht's well-known Nemertean-Vertebrate hypothesis is referred to. The author mentions this with a caution it is true, but its introduction in the manner adopted, and with the illustrations given, is out of place. Again, a teacher is not justified in telling a novice as a *procès verbal* in an elementary text-book that "the Echinodermata, the Arthropoda, and the Mollusca form (p. 84) three very distinct branches or phyla, the common ancestor of which is to be sought for only in a simple worm." Neither is he justified in asserting (p. 403) without further qualification than is here given, that "with the exception, then, that in Peripatus and Proneomenia, the anterior end of the nerve-cords is enlarged into a cerebral mass, we should appear to be able to see no essential difference between them and a Craspedote Medusa, save in fact that the Medusa has a complete nerve ring." Statements such as the above may prove in the long run to be expressive of the truth, but if introduced into a text-book, efforts should be made to convey to the mind of the student some notion of what they involve. The beginner is too ready to rely upon his teacher and his text-book at all times, and the admixture of elementary facts with startling hypotheses is—in a work of this order—directly opposed to the true scientific principle. The natural tendency to generalise prematurely needs to be checked rather than otherwise, and if countenanced by a teacher, it must lead to fallacies greater and more mischievous, than were those of the catastrophic school.

There is a dangerous sketchiness about certain portions of this work. For example, on pp. 185 to 193 there is instituted a brief comparison of the great blood-vessels in the leading groups of animals. The descriptions given would lead one to infer that the antennary, hepatic, and sternal arteries of the Crustacean, and the auricles of Mollusca, are serial homologues of the circular commissures of a worm (here called "transverse"); this is in fact stated (pp. 186, 189) to be the case. The argument used above applies equally well here, and we are at a loss to imagine the state of him who, with the aid of this book, shall try to ascertain the actual condition of these vessels in the admittedly all-important worm.

When we reflect upon the advisability of placing this work in the hands of the average medical student, it must be admitted that it is not calculated to be of much service to him during his ordinary student life, except as a cram-book for the examination-room. The author has, by the terms of his agreement, pledged himself to produce a *précis* of all that is of first importance on the subject. The work will be very valuable as a remembrancer and book of reference to those who already know something definite of the broad principles of the science, and we conceive of it as calculated to be of especial service to geologists and others, whose work among the "dry bones" occasionally needs the light from within. So far as the medical student is concerned, it must be admitted that he is overtaught, and it is monstrous to reflect that there exist systems of medical education, such as have necessitated the production of this book as a "Manual for Students of Medicine." The days for "signing up" attendances on long courses of lectures upon zoology and botany are—or ought to be—numbered; and if, as is most desirable, the biological leaven is to be introduced into the medical curriculum, it can only be done to good purpose along lines such as have been successfully laid down, mainly by Prof. Huxley.

There is undoubtedly a need of a sound elementary book, which shall be up to date, on "the general structure of animals," and Chap. III. of this volume supplies the want in a measure. The paucity of certain parts of this, however, is a serious obstacle to its adoption, for diagnoses such as are given for the Scaphopoda (p. 82), for the Copepoda (p. 68), and for the Siphonophora, are of little avail.

Taking the book as a whole, the success with which the author has performed his task will be obvious to any one cognisant of the immensity of the field. Small errors cannot well be excluded from a work of this kind, but the volume contains some which ought to be rectified as soon as possible. For instance, there is no good ground for stating (p. 359) that the sesamoids are "no doubt to be explained by a reference to the primitively multiradiate condition of the vertebrate limb," and there is something akin to a contradiction in the assertion (p. 140) that the teeth are "developed from cells of epiblastic origin," and that there is "a community of origin between what have been well called dermal denticles and what we call teeth." One remarkable instance of the manner in which errors of observation may be spread and distorted in the process of abstracting, is to be found on pp. 301 and 377, where we read that the telson "sometimes, though very rarely (Scyllarus), *bears minute appendages.*" We mention this as the author lays stress upon it, and unless we are mistaken in the identity of the paper from which the above idea has been culled,[1] an attempt was merely made to show —and that unconclusively—that "the telson is a true body segment with lateral appendages, which are modified by cohesion and adhesion." He who abstracts cannot be expected to verify the accuracy of every statement he reproduces—life is too short for that—but a matter such as the above should not have been allowed to pass. In defining the Arachnida (p. 72) it is stated that "the mouth is never placed so far back that any of the appendages become antennary organs." This is but one view of a complicated and deeply involved question, and, even should it chance to be true in the end, it is but a deduction at the most, and its use here as a definition is unwarrantable. This same deduction underlies the statements made on p. 303 under a similar head, and also the insertion of the foot-note uncalled for to p. 224. The first mention of the "transverse processes" of the vertebra (p. 314) as "given off" from the centrum is to be regretted, as it leads up to a complete misunderstanding of the nature of the component parts of the adult vertebra; and, passing (pp. 324-25) from a somewhat jerky description of the vertebral column, it is doubtful how far it is wise to usher in so complex a subject as that of the skull, by a direct appeal to embryology. The statement (p. 325) that the trabeculæ "never form more than an

[1] Garrod, *Journal of Anatomy and Physiology*, May 1871.

imperfect roof" in the region of the fore-brain, hardly accords either with fact or with the characters delineated in Fig. 138. In dealing with another complex matter—the origin of the fœtal membranes—the student's attention is abruptly transferred (p. 509) from the vitelline membrane to the amnion, and that in such a manner that he would scarcely follow what is really meant. Closely allied is the description of the germinal layers, and we doubt if the bare statement (p. 34) that "the outer and inner layers undertake the functions which their position entails on them" is justifiable.

The work is got up in good style. The technical terms are printed in large type, but the choice of these is not always happy; on p. 5, for instance, in describing the movements of living protoplasm, we find the words "stream" and "gliding" set up in large letters; while, on p. 12, where the time-honoured terms "ontogeny" and "phylogeny" cannot well be dispensed with, neither they nor equivalents are employed—in fact, but for the aphorisms quoted on p. 13, the arguments used under the head of "development" would hardly carry conviction. Considering the nature of the book there are very few typographical errors. The more important are: p. 49, the description of Aspidogaster as "*ecto*parasitic;" p. 138, the "*anterior posterior* of the digestive tract;" and, p. 501, "the *cephalous* Mollusca, such as the mussel," &c. The illustrations are, for the most part, fairly good. Fig. 11, representing, as it does, only one-half of an anemone, is not easily intelligible to the reader, and the student should be informed what the right half of Fig. 22 is intended to illustrate. Fig. 66 illustrates but feebly part of an important subject—Mammalian odontology—which is poorly dealt with. Figs. 36, 42, 81, 82, 101, 170, and 192, are all out of place in a work of this kind. They convey little or no impression to the mind of the student, and are bare schemes such as an observer might construct for use in his own private notebook *side by side with actual drawings of the facts observed.* Diagrams such as Fig. 101 should never be shaded up, as if indicative of actual appearances.

To sum up. The author has successfully produced, at immense labour, a volume, of service to those who already possess a practical knowledge of the broad principles of the subject. A "Manual for Students of Medicine" it emphatically is not, except under that atrocious and misdirected *régime* of parrot-work not yet extinct. For this the system, and not the author, is to blame; he has performed a good service, the return for which will but ill repay him. G. B. H.

BRITISH DAIRY FARMING

British Dairy Farming. By James Long. (London: Chapman and Hall, 1885.)

THIS very readable volume is from the pen of one who evidently understands the highly technical subject to which he has devoted himself. Writing upon agriculture has too often been attempted by mere theorists, and as an inevitable consequence practical men have been contented to cursorily scan and forthwith consign both book and author to oblivion. In this department more than in many others those who know are not book-writers and those who are book-writers do not know. Mr. Long is happily able to exercise the discernment which comes of knowledge in the marshalling of his facts and the quality of his suggestions. In his introductory chapter he gives solid statistical reasons why we should as a community endeavour to "produce more and import less," and the subsequent chapters are devoted to a review and comparison of our dairy system and those of our Continental neighbours, much to the advantage of the latter. The genius of the English farmer does not appear to have as yet shone into his dairy. His fields, his machines, his cattle stalls, his animals, have each and all been the admiration and the model of Europe and America. But he pauses on the threshold of his dairy and, we may add, his hen-house. These are, he thinks, the proper domain of the dairy-maid or the housewife, and the farmer is done with the milk when he has set it down at his dairy door.

It is a case parallel with that of our *cuisine.* We produce the finest beef and mutton, but we are only too constantly reminded of the forcible old proverb that while God sends meat the Devil sends cooks. There is some ground for hope that we shall, if only by force of competition, be compelled to further elaborate our products. English cheese is excellent, but it is lamentably wanting in variety, and certainly is much too apt to be regarded as one of the necessaries rather than as one of the amenities of our daily fare. Butter-making offers fewer facilities for innovation, but much requires to be done before we can successfully compete with the butter-makers of Denmark, Normandy, and Brittany. It is to cheese-making that Mr. Long devotes the largest share of his space. In England the principal cheeses may be almost told off upon the digits of one hand: they are "Stilton, Cheshire, Cheddar, Gloucester, Derby, and Leicester." The two last are, however, a little less definite than the first four, and we do not quite see their right to continue a list so well begun. Derby and Leicester are, no doubt, very good cheeses, but if they are to be admitted to stand in the same relation to English dairying as Stilton and Cheddar, we think Mr. Long might well have increased his list by adding Cutherston, Dorset-blue, North Wilts, and other cheeses well known to thousands of admirers. The principal English cheeses are, however, undoubtedly the first four mentioned in Mr. Long's list, and, with the exception of the Stilton, none of them can compare, in the estimation of an epicure, *connoisseur*, or *gourmand*, with the soft, rich, palatable cheeses imported to this country under a puzzling variety of appellations.

The chief interest of Mr. Long's book consists in his minute workable descriptions of the manufacture of a large number of cheeses, which indeed appear to be as numerous and various as are different sorts of wines. The book is well illustrated, and the "plant" required for carrying on the manufacture of some of the cheeses is complicated and expensive. Still, there appears to be no reason why similar cheeses should not be successfully made in England, and it is not improbable that the processes would be further improved in English hands were the matter once taken up.

Take, for example, Camembert:—

"The rennet is added to the milk at a temperature similar to that at which it is drawn from the cow: it is heated in a tub, and a portion of the morning's milk is added to the milk of the previous evening. . . . When the rennet is added the milk is gently stirred with a long spoon for two or three minutes; a wooden cover is then placed on each pan, and it is left for five or six hours. . . . The curd is then taken out by spoonfuls and put into cylindrical white metal moulds which cost about 4*s.* 6*d.* a dozen, and which are open at both ends. These are previously placed upon rush mats upon slightly inclined tables, and which have on the lower extremity a small gutter which carries off the whey into a receptacle beneath. . . . When the curd has remained two days in moulds the cheese possesses consistency enough to enable it to be moved with ease. Then the left hand is placed beneath it, and, assisted by the right hand, cheese and mould are turned, so that the top face is placed at the bottom, in contact with the mat. At the end of thirty-six to forty-eight hours from filling, the cheeses are taken out of the moulds and salted. . . . When salted, they are placed upon the wooden shelves above the draining tables, and here they are left for two or three days until they are ready to be sent to the *hâloir*."

We have quoted the foregoing passage in order to show that there is nothing more complicated in the making of a French Camembert cheese, nor yet so complicated, as in the making of an English Cheddar. Whether by following Mr. Long's directions an English dairyman could produce the correct type and flavour can only be demonstrated by trial, but probably a cheese would be produced suitable to English methods which would add to the variety of our dairy products and find a ready market. Mr. Long also describes the manufacture of various other cheeses, among which are Pont l'Evêque, Livarot, Mignot, Boudon, Brie, Géromé, Coulommiers, Mont d'Or, Void, Suisse, St. Remy, Gervais, St. Marcellin, Jour iac, Gex, and a large number of others, the mere mention of which would occupy more space than we can spare.

Mr. Long has certainly contributed a handy text-book which it is hoped will find its way among and be studied by dairy farmers.

JOHN WRIGHTSON

OUR BOOK SHELF

Chain Cables and Chains. By Thomas W. Traill, C.E., R.N., the Engineer-Surveyor to the Board of Trade. (London: Crosby Lockwood, and Co., 1885.)

IN the volume before us we find the business of chain cable-making in its several branches well explained and illustrated; nor does the aim of the author end here. There is information given which is most useful to surveyors and inspectors, and we recommend all who have to deal either with the manufacture, inspection, or testing of chain cables to study the work. The volume contains many well-executed plates, showing good, bad, and indifferently-formed links, &c., for various kinds of cables, also tables of the best dimensions of each part of each link and shackle used in cables from 7-16th to 2½ inches, the dimensions being given in decimals to two places, and also calculated to thirty-second parts of an inch. We find also exact copies of certificates given by the several public proving establishments, seven plates in all, more than one example being quite unnecessary, varying as they do only in colour and the name of the town in which the establishment happens to be.

After a few pages giving an outline of the general manufacture and the methods of welding the links, we have a long historical chapter of the early uses of metallic chains, in which we are told that their uses date back to the time of Pharaoh and King Solomon; but it was not until 1808 that chain cables were used on board ship; at this time a chain cable was used in a vessel called the *Ann and Isabella*, of 221 tons, built at Berwick, and owned by Joshua Donkin. This cable was made by Robert Flinn, in North Shields, perhaps the first artificer in chain cables. In the year 1833 the first machine for testing iron cables in a Government yard was put down at Woolwich, and in 1834, although chain cables were almost in general use, the rules of Lloyd's Registry only specified the length, and it was not until twelve years afterwards it was part of the surveyor's duty to see that they had been properly tested. The author gives a very interesting account of the progress of manufacture and general adoption of iron cables. We then find the various Acts of Parliament pertaining to their use given in full. All public proving establishments are now under the management of Lloyd's Committee.

The method of proving chain cables is as follows:—From every length of 15 fathoms of the cable to be proved a piece consisting of three links is taken and subjected to an appropriate breaking-strain. If the piece so selected fail to withstand such a breaking-strain, another piece of three links is taken from the same 15-fathom length and tested in a like manner. If the first or second of such pieces withstand the breaking-strain, the remaining portion of the 15 fathoms of cable is then subjected to the tensile strain. If it is found that after the application of the tensile strain the cable is without defects or flaws, it is then stamped as proved with the distinguishing marks of the proving establishment; on the other hand, should the cable fail to stand the appropriate tests, it is rejected. Mr. Traill condemns the overtesting of cables, considering that the material is injured by so doing, and we agree with him in saying:—"A moderate test is all that is not detrimental. Proving the iron from which the cable is made, and breaking a sufficient number of samples, is what can and should be done to prove the actual quality and reliability of a chain."

The volume does great credit to the publishers, being well printed on good paper. We can safely recommend this work to all in any way connected with the manufacture of chain cables and chains as a very good book.

United States Coast and Geodetic Survey. Determination of Gravity at Stations in Pennsylvania, 1879-1880. *Appendix No.* 19. *Report for* 1883.

THIS appendix is a portion of the Annual Report of the U.S. Survey, and contains the pendulum observations made in 1879-1880 by Mr. C. S. Peirce at three stations in Pennsylvania—namely, at the Alleghany Observatory, at Ebensburg, and at York. The observations form part of a series undertaken in connection with the Geodetic Survey of the United States. A Repsold reversible pendulum was used and oscillated *in vacuo*, using various kinds of supports. At York a series of experiments were made to determine the effect of the flexure of the support. It appears from a previous report (Appendix No. 14 of 1881) that Mr. C. S. Peirce maintained against MM. Plantamour and Hirsch in Switzerland, that the oscillations of the support have a marked effect on the time of oscillation of the pendulum, and he accordingly undertook an exhaustive series of experiments to prove his point, and to measure the allowance to be made. The experiments given in Appendix No. 19 are only a small portion, and are in fact re-published from Appendix No. 14, with some few corrections. The question was disposed of in Appendix No. 14, and it was clearly shown that the flexure of the support ought to be taken into account, and it is evident, therefore, that the stiffness of the support is of vital importance. Experiments were also made at York to determine the relative value of the method of transits and a method of eye and ear coincidences invented by Mr. Farquhar; the method is not described, but appears to be far less accurate than the method of transits. The effect of substituting steel cylinders for the usual knives was also tried, and every care taken to prevent the inclusion of dust, but the results were very unsatisfactory.

The results obtained are as follows:—

Length of second's pendulum reduced to sea-level at the equator.

	Metre.
Alleghany Observatory	0·9909384
Ebensburg	0·9910672
York	0·991015

At Alleghany, the effect of a valley was not taken into account, as there was no topographical survey available; the necessary correction will slightly increase the above value.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Presence of the Remains of Dicynodon in the Triassic Sandstone of Elgin

In my address to the Geological Section of the British Association I was fortunately able to announce a discovery which is of the very greatest interest both to geologists and biologists. As this discovery was made only a few days before the commencement of the meeting at Aberdeen, and after the draft of the address was in type, it does not appear in your columns; I will therefore ask you to insert this note upon the subject. Visiting the "Cutties Hillock" quarry near Elgin early in September, I found that the workmen had recently obtained a new specimen of a reptile, in which the head was preserved. On examining this I found that there were clear indications of two large canine teeth in the upper jaw with permanent pulp cavities. These characters and the general form of the skull left scarcely the smallest doubt in my mind that the remains must belong to a reptile closely allied to *Dicynodon*. From the examination of a photograph which I submitted to him, my friend Dr. Traquair was able to fully confirm this conclusion, and to lay a preliminary note on the specimen before the Geological Section at Aberdeen. I hope that ere long he will be able to give a complete description of it.

As Dicynodonts have hitherto been only found in South Africa, in India, and in the Ural Mountains, this discovery is an exceedingly important one. Seeing that doubts have been expressed concerning the Triassic age of the South African deposits, the occurrence of the very characteristic African form in the Trias of Western Europe is an important link in the chain of evidence by which these beds have been correlated. It is interesting, too, to be able to point out that the sandstones of Elgin, concerning the age of which such a great amount of controversy has taken place, have now yielded reptiles belonging to no less than *four* orders—namely, the Lacertilia, the Crocodilia, the Dinosauria, and the Dicynodontia. J. W. Judd

An Earthquake Invention

While on a visit to the Melbourne Observatory I saw Nature of July 2 containing two letters from Prof. Piazzi Smyth, intended to expose a piratical attempt on the part of a "B.A. man" to adopt an idea of Mr. David Stevenson with regard to the construction of houses to withstand earthquake motion. The publication of the first of these letters is at the request of Mr. D. A. Stevenson. The piracy referred to by Prof. Smyth is a brief note in a paper written by myself. My name is at the head of it (see *Report* to the B.A. 1814). Prof. Smyth complains that I have not taken notice of a paper written some twenty years ago by Mr. D. Stevenson. I regret to say that I am not acquainted with that paper, and how Prof. Smyth expects that I should be when living 10,000 miles away from collections of European books, I fail to see. I am, however, acquainted with very much relating to aseismic or aseismatic tables, and if I made reference to the work of Mr. David Stevenson, I must necessarily have referred to the work of others. As every report which I have hitherto written for the British Association has been in the form of notes which have subsequently been expanded in special papers, an historical account of aseismic tables would have been out of place. Prof. Smyth is apparently only acquainted with the work of Mr. D. Stevenson. Under the head of aseismic tables I include ball and plate seismographs, the lamp tables in certain Japanese lighthouses, two model houses which I constructed in Japan, together with the model lighthouse spoken of by Prof. Smyth, and my own dwelling house. *All of these involve the same principles, and they only differ in their dimensions.*

(1) *Ball and Plate Seismographs.*—Of these seismographs I have constructed *several* types. At the time of an earthquake, in consequence of acquiring a surging movement, they fail to give reliable records. They have been *independently* invented and described as original by many. Mr. Briggs, of Launceston, Tasmania; Dr. Verbeck, of Tokio, Japan; Mr. T. Gray, of Glasgow; Mr. D. A. Stevenson, of Edinburgh, &c., have all been authors of such instruments.

Mr. D. A. Stevenson recently figured and described his form of seismograph in the pages of Nature. If we overlook certain mechanical defects in this instrument, as, for instance, attaching a recording index to the edge of the "steady plate" rather than at its centre of inertia, the resemblance of Mr. Stevenson's contrivance is strikingly like a seismograph the photographs and descriptions of which existed in several societies and libraries in Britain prior to the appearance of Mr. Stevenson's invention. After reading Mr. Stevenson's description I did not ask for the publication of an "interesting" and "well-put" letter, accusing Mr. Stevenson of having appropriated the ideas of others, but I furnished him with copies and references to papers in the *Transactions* of the Seismological Society and other periodicals where mention was made of this type of instrument.

(2) *Lamp Tables.*—As I have been an officer in the Public Works Department of Japan for the last ten years, where I have every facility of knowing what the performance of the lamp tables at the lighthouses has been at the time of severe earthquakes, I trust that some credence may be given to what I may say on this subject. When I last made inquiries about these tables, I found that they were all regarded as failures and one and all had been clamped. If Mr. Stevenson would like to have details respecting these failures I shall, on my return to Japan, have great pleasure in making them public.

Mr. Mallet, in his "Palmieri's Vesuvius," very distinctly states that he was consulted by Mr. Stevenson respecting the Japanese structures, and that the principles indicated by him (Mallet) were followed out in their construction.

As Mr. Mallet is dead, perhaps Mr. Stevenson or Prof. Smyth will kindly enlighten us as to the meaning of this passage. Although I have made seismology a speciality for some years, I must confess that I am as yet in the dark as to who was the first inventor of the aseismic joint. To me it appears that there have been many inventors.

(3) *Models.*—My first model was about as large as a good-sized dog kennel. For a *short*-period oscillatory movement the house resting on its rollers remained at rest. Prof. Smyth speaks of Mr. Stevenson having imitated earthquake motion by the blows of a sledge-hammer. Although Prof. Smyth regards the blows of a sledge-hammer as an admirable illustration of earthquake motion, any one acquainted with the true nature of earthquake motion would decline to recognise Mr. Stevenson's test as any test whatever.

(4) *Building.*—The only *building* placed on free foundations with which I am acquainted is the one I have erected in Tokio. At first it rested on balls, and, like Mr. Stevenson's lamp tables, it was for certain reasons a failure. Now it rests on spherical grains of cast-iron sand. It is now astatic, and I regard it as a success. At the time of an earthquake the motion outside the house is usually about six times what it is inside. A description of it will be found in the *Reports* of the British Association for 1885.

From what I have now said it will be clear that I have no desire to claim the authorship of the aseismatic joint. Detailed reference to the obscure and manifold authorship of what has hitherto proved a failure would certainly have been out of place in the report to which Prof. Smyth has referred.

Had Messrs. Stevenson and Smyth been acquainted with the nature of earthquake motion, a few of the more important facts in the history of the ball and plate joint, and the details of the failure of the tables in the Japanese light-houses, I feel sure that much of the objectionable innuendo to which I have been subjected would never have been penned. JOHN MILNE

s.s. *Waihora*, Hobart, Tasmania

P.S.—The above has been written whilst at sea, and I have neither had opportunity to refer to books or papers. On my return to Japan I shall be glad to continue the history of the ball and plate joints, should it be required.

Tremble-terre du 26 Septembre, 1885

UNE seule secousse a été constatée le 26 Septembre à 0h. 58m. du matin ; elle a été composée de 2 à 3 oscillations, de direction variable suivant les localités. Le centre de la secousse a été dans le milieu du Valais, où son intensité a été appréciée comme très-forte, mais où il n'y a cependant pas eu de dégâts matériels ; il faut lui attribuer le No. VI. de l'échelle qui évalue en dix degrés l'intensité des tremblements de terre.

La secousse s'est étendue vers le nord jusqu'à Schwenden et Zweisimmen dans le Simmenthal, à Château d'Oex, Aigle et Yvorne ; dans les Alpes vaudoises elle a été fort bien sentie dans les vallées de l'Avençon, de la Gryonne, de la Grande-eau, et de la Savine. Dans tout le reste du canton de Vaud le tremble-terre semble avoir passé inaperçu, tandis qu'il nous est signalé de deux localités fort distantes, Genève et Nidau ; il est cependant probable que la secousse de Nidau a précédé de quelques minutes la grande secousse du Valais; d'après un observateur très précis la secousse de Nidau a eu lieu à 0h. 53m.

En même temps que le sol de la Suisse était ainsi ébranlé, les appareils très délicats de l'observatoire sismique de Rome, qu' avaient été en repos les jours précédents, ont signalé des vibrations du sol vers 1 heure du matin ; et dans le même nuit un violent tremblement de terre ravageait la ville de Nicolosi près de Catane en Sicile. Morges, 8 Octobre

Larvæ of Cerura vinula

LAST year I was rearing up some larvæ of *Cerura vinula*, the Puss Moth, from the egg, and I determined, while I had the chance, to write a life-history of them.

On examining the egg closely I found a small hole in the apex of each, and I thought at the time that this was probably caused by ichneumons, and therefore I laid the eggs by in a small box that I might capture the ichneumons when they made their appearance. Great was my surprise, then, when I found that the young larvæ came out as usual.

I therefore determined to get some more eggs and to find out whether this hole in the apex was caused by the mandibles of the larva inside, but I found that the larva did not emerge by this hole, but by a fresh one made in the side of the egg. And I find that all Puss Moth eggs have this hole in the apex.

I am now hoping to get some eggs of moths belonging to the same family (*e.g. Cerura furcula* and *bifida*) to see if they also are perforated in this way. I should be much obliged if any one who has got any of these eggs would kindly let me know whether this is the case.

This hole reaches through the shell of the egg, but is covered, on the inside (of the egg) with a thin tissue, like that which is found in birds' eggs.

I have carefully examined several scientific books, but have been unable to find this fact mentioned ; therefore I should be much obliged if any one could throw a light on this mysterious fact.

I unfortunately have none of these eggs to forward as examples ; but, as they are pretty common in May and June on poplar trees, I have no doubt that such of your readers as are interested in the subject will be able to examine them for themselves. CYRIL B. HOLMAN HUNT

Draycott Lodge, Fulham, October 9

Pulsation in the Veins

I AM quite satisfied that the pulsatory movement in the veins, to which my former communication referred, is not in any way *abnormal*, as suggested by Mr. Williams (p. 466). In all cases, without exception—and they have been a good many—in which I have had opportunity for the observation, the minute *visible* evidence of the pulsatory action has been present, and I have invariably been able to count the pulse of the individuals, as in the experiment detailed in my former letter.

The mirror experiment was tried on my own hand. And a medical friend who applied the sphygmograph in the usual way informed me that my pulse was free from any abnormality.

It is to be borne in mind that the pulsatory indications with which my paper is concerned are exceedingly minute and would escape the perception of nine persons out of ten—requiring an eye educated to appreciate very minute differences of shade and colour. I do not think that the bristles or sealing-wax thread which a correspondent (p. 437) kindly suggests, or even the orthodox sphygmograph would have a chance of effectually exhibiting them. I say shade *and colour*: for when a vein free from turgidity, and not sensibly altering the smooth surface of the skin, is seen only by its blue track, a modification of the *tint* is perceptible (to an educated eye) ; and the blue varies in intensity with the pulsatory action, sufficiently for the success of the pulse-counting experiment. Stoneaston Park, October 4

Stonehenge

IN NATURE, vol. xxxii. p. 436, R. Edmonds associates Stonehenge with the metonic cycle, and quotes from Diodorus Siculus, whom he says flourished about 44 B.C. Would not the latter part of the first century A.D. be more accurate? He gives in his extract from Diodorus Siculus a quotation from Hecatæus, whom he confuses with Hecatæus of Miletus, when it was Hecatæus of Abdera to whom Diodorus referred. Hecatæus of Miletus flourished about 500 B.C., and Hecatæus of Abdera about 300. Mr. Charles Elton, M.P., in his "Origins of English History," gives the very same extract, and says that "We cannot admit that the work of Hecatæus is on the subject of Ancient Britain," and estimates its value in the following extract from the works of an eminent Polish scholar (Lélewel, Pythéas, 45): "Hécatée a publié un fameux ouvrage dont le titre décèle une vieille idée poétique rajeunie sous sa plume. Elle devait s'allier aux nouvelles découvertes et y prendre une place éminente au détriment de la science et du bon sens. Hécatée, énumerant tous les êtres mystérieux de la géographie septentrionale, enrichit leur nomenclature d'une rivière Scythique récemment trouvée en Orient par le conquérant, qu'il a appelée Parapamisos ; et plus encore des promontoires et des îles Celtiques, qu'il a probablement puisées dans les rélations véridiques de Pythéas pour les entrelacer dans les plages superboréennes."

The quotation from Diodorus is from his second book, but the whole of this second book is dedicated solely to a description of Asia ; and it is not until the fifth book is reached that he describes the British Isles, and with a very considerable degree of accuracy. (See Fergusson's "Rude Stone Monuments," p. 8).

I do not think, either, that "Nine Maidens" is simply an abbreviation of "Nineteen Maidens," for, like "Nine Ladies" of Stanton Moor, in Derbyshire, it is a memorial circle.

Stone Henge, moreover, is much more probably a memorial circle, as its original name implies—"Stan Hengis"; and commemorates the massacre of Vortigern's chiefs by Hengist in 462 A.D. The Rollright circle probably commemorates the victory of Rollo over Eadward, circ. 913, whilst Avebury and Hakpen (520), Kit's Coty House (455), Long Meg and her Daughters (508–520), Stanton Drew (508–520), Arthur's Table, Arbor Lowe, Cumrew, Salkeld and Mayborough commemorate some of the victories of Arthur. That this is reasonable may be mentioned the facts that coins of Claudius Gothicus (270 A.D.), Constantine the Great, Constantine junior, and Valentinian have been found at one or other.

Milverton, Leamington SAND. S. STANLEY

The Forecasting of Barometric Variations

IN a paper published in the *Journal* of the Royal Meteorological Society, vol. x., p. 219, 1884, I pointed out that during a series of years the barometric variations in Western India had presented certain features which, had they been known at the beginning of 1876, and, indeed, at the beginning of 1872, would have made it possible to have calculated with a considerable degree of precision and reliability the general course of the barometric variations from 1872 up to 1883, in some cases three months, and in some cases even twelve months beforehand. The facts brought forward in that paper were of such a nature that, as will be readily understood, I wished very much they could be found to occur generally. But it was undoubtedly better to restrict their application to the area and period dealt with in the paper. It having been shown, however, that at one period and over a certain area quantitative relations had existed between previous and subsequent barometric variations, it is natural to suppose that quantitative relations may be found to exist at other periods and over other areas also. The question arises, Can the facts brought forward in the above-mentioned paper serve as a guide to future investigation? I think to a certain extent they can.

The paper pointed out that there was a remarkable approach to an annual symmetry in the abnormal variations of the barometer in Western India during many of the years under observation. It supposed that this symmetry would have occurred every year during that period had it not been masked by larger variations of another character; and it was mainly by acting on this supposition and noting the departure from symmetry in any given year, and by considering that departure as being an index of the variation that was about to come, that the position of the barometer in the subsequent year was calculated. The paper attempted to explain the occurrence of this annual symmetry in two ways: (1) By supposing it to be a constant phenomenon connected with the annual double oscillation known to be present in the normal barometric curve; and (2) by supposing it to be a chance phenomenon, characterising a phase in the march of barometric variations, and persistent during the period dealt with, but not necessarily to be found in any other period. After further reflection I am inclined to believe that the latter is the correct explanation.

And here I think may be a guide to future investigation. It seems very likely that barometric variations may always be passing through phases which are persistent for several years. And, during the continuance of each phase the abnormal barometric curve will necessarily approach more or less to a certain annual type. In the cases dealt with in my paper that type chanced to be of a symmetrical form, sufficiently remarkable to strike the eye at once. The regularity of its form made it comparatively easy to be dealt with. An irregular type would of course be less easy to recognise and less easy to be dealt with. But it is obvious that if such types do exist and persist for several years in succession, then, by catching the type as the barometric phase comes in and by noting the departures from it each year, in a manner similar to that adopted with the symmetrical type I had to deal with, these departures may serve also in a similar manner as indices of the coming variations. Of course the methods of calculation would have to be purely arbitrary and specially devised for each barometric phase. If barometrical curves would yield to strictly mathematical methods, the problem of season-forecasting could be regarded as in a fair way of being solved. But it has never yet been found possible to resolve them entirely into regular periodical oscillations; and I believe they will always have to be arbitrarily dealt with.

Melbourne, July 21 A. N. PEARSON

Transmission of Sound

IN connection with the subject of mechanical telephones, which has been occupying public attention lately, there is a note by Mr. Miller in a recent number of NATURE, regarding certain experiments made in 1878 on the propagation of sound. With reference to this, Prof. Wernhold, of Chemnitz, writes to me, saying that as early as 1870 he had shown that human speech could be transmitted very distinctly through stretched wires or threads, and mentions that the results of his researches were published in an article on "The Transmission of Human Speech through an Iron Wire," in Carl's "Repertorium für Experimental Physik," Band vi., Serie 168. As your correspondent will probably like to refer to this, may I ask you to kindly publish this letter? W. E. AYRTON

Central Institution, Exhibition Road, London, October 12

Are there Rabbits in the Western Islands?

PROF. THOROLD ROGERS in his interesting book on "Work and Wages" mentions the relatively high value of rabbits in the thirteenth century, and suggests that they were then a recent introduction to England. It is well known that several islands on the west coast of Scotland have no rabbits upon them—for instance, Kerrera, which seems to point to the same conclusion. It would be interesting to know whether this is really the fact or not? HERBERT ELLIS

112, Regent Road, Leicester, October 4

THE HELL-GATE EXPLOSION

PROBABLY the largest chemical mechanical experiment ever thought of was successfully performed last week in New York Harbour by the removal of the obstruction known as Hell Gate, or Flood Rock, a considerable-sized island, as stated by the papers, about nine acres in extent, in Long Island Sound. The agent employed for this immense engineering work is a preparation or preparations of nitro-glycerine, and there is no doubt that this is the only explosive compound which could have been used for the purpose on account of the very enormous quantity required and the peculiar nature of the explosion of this substance. All the compounds or preparations of nitro-glycerine produce by explosion what are known as local effects only, as distinguished from gunpowder, the effects of which are much more gradually developed on ignition, but extend, owing to the slower and larger wave of disturbance, to a much greater distance. The legitimate use of nitro-glycerine is for purposes such as this, where a disruptive action is required.

The operations leading up to the final explosion have been some years in progress. They have consisted in forming a system of tunnels at a considerable depth under low-water level in the solid rock, and the charging of these tunnels with dynamite and mixtures known as rackarock, of nitro-glycerine with compressed gun-cotton. Twenty-four galleries were driven through this island, some of them 1200 feet long, and these were intersected by some forty-six others. These tunnels were about 10 feet high and 8 feet wide, and the roof of rock above them varied from 10 to 25 feet in thickness. The quantity of rock to be removed by the explosive was about 275,000 cubic yards, the quantity removed by tunnelling being about 80,000 cubic yards. A good deal of trouble has been occasioned during the course of the mining work by fissures, which have had to be stopped by wooden plugs in most instances. The explosive was charged into holes drilled into the roof and supporting walls and pillars at different angles, with a view to disrupt the strata of rock as much as possible.

The holes to be charged were about 9 feet in length and $2\frac{1}{2}$ inches in diameter. The holes were charged first with the blasting gelatine or rackarock and filled to the ends with a dynamite cartridge, to which the detonator and electric wire were attached. In all fourteen thousand cartridges of a total weight of fourteen tons were employed. Near observers describe the explosion as being accompanied by a dull roar, but with only the slightest shaking of the ground, even at a moderate distance. An immense quantity of water was bodily raised up to heights estimated variously at 150 to 200 feet.

The results, as far as can be ascertained, are very satisfactory, the rock having been very thoroughly broken up, so that it can easily be dredged away.

After the example of an experiment on this scale, carried out without the least accident, perhaps it may occur to those in authority that we have on our own coasts dangerous rocks, not of the extent of Flood Rock, which might with immense advantage be similarly "chemically" removed.

Had gunpowder been the only explosive available, at least five times the quantity by weight of the nitro-glycerine preparations used in this experiment, would have been necessary and the results would not have been by any means so local or perhaps so satisfactory.

After this the engineer may find it to his advantage to cultivate more the acquaintance of the chemist and his products than has been hitherto the case.

SUBMARINE DISTURBANCE

THE following is an extract from the Meteorological log kept by Capt. R. J. Balderston on board the ship *Belfast*:—

"On December 22, 1884, at about ten minutes to 3 a.m., local ship's time, or 21d. 19h. 6m. Greenwich mean time, the ship *Belfast*, of Liverpool, was shaken by an earthquake which lasted from about 75 to 90 seconds. The vessel at the time was in latitude 34° 34′ north and longitude 19° 19′ west, the island of Madeira bearing true S.E., distant 145 miles.

"The shaking of the ship was accompanied by a loud rumbling noise, which, as heard from the cabin, resembled the sound which would be made by the rolling of large, empty, iron tanks about the decks, but which, as heard from the upper deck and in the open air, was as that of not very distant thunder, and it appeared to fill the whole of the air.

"I did not hear the commencement of the thunderous sound, and cannot say on what compass-bearing of the visible sky it commenced, but it travelled rapidly through the air and towards the S.W.

"The vibration of the vessel and the noise were greatest during the first 50 or 60 seconds; the former then died gradually away and ended in the very faintest tremor, while the latter, as it travelled south-westward through the atmosphere, died out with a low roar as it appeared to sink beyond the horizon.

"The helmsman found the steering-wheel much shaken as he held it, and in the cabins and cook-house, tin ware, crockery ware, and other light articles were rattled about.

"This little earthquake occurred three days prior to the commencement of the earthquake which caused so much loss of life and property in Spain.

"Meteorological Office, October 9"

THE BOTANICAL GARDENS IN JAVA

DURING the last few years so many useful and important improvements have been made in the botanical gardens at Buitenzorg and Tsi-Bodas that it might not be amiss if the attention of the readers of NATURE were again drawn to these valuable seats of systematic and philosophical research.

On entering the gardens at Buitenzorg the stranger is at once struck with the wealth and luxuriance of the vegetation he sees, the great height of the trees whose trunks and branches are in many cases covered with heavy creepers, the dense copses of the different species of bamboo, the eccentric-looking screw-pines and the handsome palm trees; but the scientific observer is also struck with the care that has been taken to arrange all these many varieties of tropical plant life in, as far as possible, their systematic order, and that each specimen has its scientific, and in many cases its Malay name also, clearly and distinctly printed on a little board by its side.

It is not difficult for any one to find his way about the garden, and in a very short time he can discover the particular family or group of plants which he may desire to study. Many families have probably more representatives in these gardens than in any in the world. The Sapataceæ, for instance, so rarely seen in Europe, are here represented by a great variety of genera and species, and the Palmaceæ, the Rubiaceæ, the Burseraceæ, the Orchidaceæ, and other families have now a large number of rare and interesting representatives.

The herbarium which is attached to the garden contains a large collection of dried plants and seeds collected together from the many expeditions into the little or unknown parts of the archipelago and from other sources. Attached to the herbarium there is a comfortable and convenient little library which contains most of the mportant botanical books and journals.

The laboratory, which, thanks to the energy of Dr. Treub, the director, is now completed, is a large, lofty and, for these climes, particularly cool room, and is well fitted out with reagents and apparatus for carrying on botanical research. The generous invitation which Dr. Treub has issued to naturalists and to which the attention of the readers of NATURE has already been directed has attracted several scientific men of different nationalities, and some excellent research has already been made in this laboratory.

When I arrived in Buitenzorg Dr. Treub was at Tsi-Bodas; so, after spending a few days in study in the gardens, I made the journey across the mountains to pay him a visit. The road from Buitenzorg to Tsi-Bodas crosses the Poenchuk Pass and is full of interest and beauty. On the way the traveller passes quite close to the Talaga Werner, the crater of an extinct volcano which is now filled with water, and forms a most beautiful little lake hidden in the dense foliage of the mountain slopes. The path from the road to the lake is through a dense wood of fine forest trees, and amongst the undergrowth is found many fine shrubs and plants which are not found in the low-lying country beneath.

The gardens at Tsi-Bodas are situated on the slopes of the Gedeh Mountains, at an altitude of 5000 feet, and here I found Dr. Treub at work in the comfortable little house which is attached to the gardens.

From this spot a very wide range of vegetation may be studied, from the rich and varied vegetation of the plains to the interesting vegetation of the Gedeh and Pangeranso peaks, at an elevation of 10,000 feet. In the gardens themselves a very fine collection of Coniferæ from America, China, Australia, and other parts of the world has been got together, and spaces have been cleared for the growth of the various species of Eucalyptus, Cinchona, and other plants. Year by year the surrounding forest is being encroached upon by these gardens to make room for new importations. I was extremely sorry that I could not prolong my stay at Tsi Bodas, but I had to return to Batavia to catch the Molucca boat. I saw, however, enough to convince me of the great importance of these gardens for the advancement of our botanical knowledge and the great opportunities they afford for research into all branches of the science.

I need hardly say that the climate in this region is extremely pleasant and invigorating, and the neighbouring village of Sindanlaya is much resorted to by Europeans and others whose health has suffered on the coasts or low-lying districts of the Archipelago. At Buitenzorg the climate is by no means unpleasant or unhealthy, but as it lies a few thousand feet lower than Tsi-Bodas, it is naturally a good deal warmer; but I am assured that several Europeans have worked there for several years without feeling their health the least bit affected.

It is hardly necessary to add that every one who has come over to Java to work in these gardens has been amply repaid for the time spent in the long journey over the sea, for the insight which can be gained here into what tropical botany really is is one which can be gained nowhere else in the world so well, and leaves an impression which is not likely to be forgotten in a lifetime.

Batavia, July SYDNEY J. HICKSON

ON CERTAIN NEW TERMS OR TERMS USED IN A NEW OR UNUSUAL SENSE IN ELEMENTARY UNIVERSAL GEOMETRY.

Point, Line, Plane, Space, Extension

A LINE may as usual be understood to mean a right line unless the contrary is stated.

Representable extension will comprise the concepts corresponding to the first four terms above written. So understood, the term *a space* is susceptible of a more precise meaning than is usually attributed to it: its *intrinsic* equation is given by Cayley's theorem of squared distances. It is a homaloid or flat of the 3rd as a plane is such of the 2nd, a line of the 1st, and a point of the *zero*th order.

The phrase *space of the 4th order* ought accordingly to be superseded if we would avoid using the same word in two different senses—*i.e.* in a wider and narrower sense. *Extension of the 4th* order is the proper expression to take its place, and so in general we ought to speak of *extension* of any given order n, and drop the phrase *space* of n-dimensions.

Figure, Plasm, Enclosure

A figure may exist in extension of any order. When pervasively limited by homaloids, simple and closed, I had proposed to give to it the *provisional* name of *plasm*, but Dr. Ingleby has supplied me with the more appropriate, or at least more simple, term, *enclosure*.

On the number and nature of simple regular enclosures in extension of any order, consult a remarkable memoir by Prof. Stringham * of the University of California (formerly of the Johns Hopkins University), in the third volume of the *American Journal of Mathematics*.

Homaloid, Flat, Niveau, Absolute Measure of Distance

Homaloid, the term long ago introduced by the writer of this note, *flat*, suggested by the late lamented Clifford, are now well understood, and need no new explanation; but it is well to bear in mind the *intrinsic equation* which serves to define them *to wit*

A homaloid in *extension of the nth order* is definable by means of an equation of the second order (naturally expressible in the language of determinants), in which $(n+1)$ points are the standards of reference, and the squared distances from these of any other point in the homaloid are the coordinates.

Observe that the squared length is the absolute measure of distance *between* two points. The distances of each *from* the other are not equal but opposite quantities differing in algebraical sign.

A *niveau* is a very convenient term to signify the *homaloid* of the *lowest* order that can be drawn through a given point-group and is always *unique;* the order of the homaloid which is the *niveau* to a group of n points cannot exceed $n - 1$.

Curves, surfaces, &c., of the 1st, 2nd, and nth *kind.*

A plane (or simple) curve is of the first kind; "a twisted curve," "courbe gauche," or a curve in extension of the 3rd order, of the second kind, and in general a curve in extension of the nth order is a curve of the $(n-1)$th kind.

Similarly we may define a simple surface as one of the first kind, and a surface in extension of the nth order as one of the $(n-2)$th kind; and so in general a figure of *variety* i † (i being 1 for a curve, 2 for a surface), in extension of the order n, is one of the $(n-i)$th kind.‡

Curve, Locus, Assembly, Envelop, Environment

A *curve* is that which is common to a locus of points and an assemblage of tangents; the locus is the *envelop* of the assembly, and the assemblage the *environment* of the locus.

Lines and Points

A line may be used in the double sense of a locus or direction. In the latter signification an Euclidian or objective line is the union of two lines running in contrary directions and an analytical line is a half-line, a "semi-droite," meaning, of course, a half-Euclidian line.

So a point may mean either a position or an infinite assembly of lines (containing or) contained in it; used in the latter sense, it might temporarily be termed a *pencil-point.*

There are half or split points, as there are half or split lines. Thus the infinite extremities of the asymptotes to a hyperbola are half-points, the union of two of them being the correspondent to a single point in any ellipse of which the hyperbola is a perspective image.

Coordinates, *Homogeneous and Correlated*

Homogeneous systems of coordinates may be distinguished into *absolute* and *proportional.*

In the former the absolute magnitudes of each are material, in the latter their ratios only.

Also into *direct* and *inverse.*

Direct coordinates are measured by given multiples of the distances of a variable point from fixed homaloids; inverse by given multiples of the distances of a variable line, plane, &c., from fixed points.

Correlated systems of direct and inverse coordinates are those in which my "universal mixed concomitant" (Clebsch's *connex*) $\xi x + \eta y + \zeta z$ (for greater clearness I confine myself for the moment to a particular diagrammatic case) equalled to zero expresses a line whose inverse coordinates are ξ, η, ζ, when these are made constant and a point (pencil-point) whose direct coordinates (when it is regarded as denoting position) are x, y, z when these in their turn are made constant.

If the distances of a point from the sides of the triangle of reference are l, m, n, and of a line from the angles of the *same triangle* λ, μ, ν, and if the direct coordinates being cl, dm, en, and the inverse ones $\gamma\lambda, \delta\mu, \epsilon\nu$, and the distances of the angles from the sides p, q, r—

$$c\gamma p = d\delta q = e\epsilon r.$$

l, m, n; λ, μ, ν are *correlated* systems.

If $l'\ m'\ n'\ p'$; l, m, n, p the direct coordinates of two corresponding points in a homography are connected by the Matrix M and $\lambda'\ \mu'\ \nu'\ \pi'$; λ, μ, ν, π (the inverse coordinates of two corresponding planes of the same homography) by the Matrix M', then if the two systems of coordinates are correlated, M and M' will be *opposite* matrices.*

Of course the like will be true in extension of all orders: thus *ex. gr.* in the case of a plane if for a given homography

$$\begin{aligned} & l' : al + bm + cn \\ :: \ & m' : dl + em + fn \\ :: \ & n' : gl + hm + kn \end{aligned}$$

Then

$$\begin{aligned} & \lambda' : (ek - fh)\lambda + (fg - dk)\mu + (dh - eg)\nu \\ :: \ & \mu' : (ch - bk)\lambda + (ak - cg)\mu + (bg - ah)\nu \\ :: \ & \nu' : (bf - ce)\lambda + (ed - af)\mu + (ae - bd)\nu \end{aligned}$$

* Mr. Stringham, a native of "the bloody land" of Kansas, studied mathematics and fine art under Peirce and Norton, at Harvard, obtained a fellowship at the Johns Hopkins University, and completed his studies under Klein in Leipsic. In his memoir he has given perspective drawings of the bounding solids about a vertex of the regular figures in quaternary extension, such solids being supposed to be previously rotated round the vertex into the same *space*, which of course may be done just as the bounding planes about a vertex of a regular figure in ternary extension may be rotated round that point into the same *plane*.

† A curve may be called a one-dimensional, a surface a two-dimensional, a solid a three-dimensional *continuum* and, and so on. Thus a *solid* is to a space what a *surface* is to a plane and a *curve* to a right line.

‡ The ordinary systems of geometry, whether Euclidian or Non-Euclidian (Ultra-Euclidian would be the more correct term), contemplate figures as contained in homaloids of some order or another; but this limitation has an empirical origin, and is not an essential ingredient of the pure theory of form; for instance, a curve, *i.e.* a *unidimensional continuum*, may, and in general will, be such as cannot be contained in a homaloid of any number of dimensions whatever; it might be said that the order of its *niveau* in such case is infinite; but this would be a mere verbal quibble—the right view being that it is *sans niveau*. The radical distinction therefore is not between the common Euclidian geometry and its generalisation (the so-called Non-Euclidian) but between the Homaloidal and the Anhomaloidal geometries.

* In other words, for two point line, point-volume, &c., schemes homographically related, employing *correlated* systems of *proportional* coordinates, the matrix which serves to express the relation between the direct coordinates of the first scheme and those of the second may be taken the transverse of the matrix which does the same between the inverse coordinates of the second and those of the first. This is an important and as far as I am aware a new *theorem*.

provided that l, m, n; λ, μ, ν are *correlated* systems of coordinates.

Images: Reciprocals or Polar Reciprocals

It is very convenient to speak of any function which equated to zero expresses a figure as an *image** of such figure; thus *ex. gr.* $\xi x + \eta y + \zeta z$ may be spoken of as an image of the line ξ, η, ζ and of the point x, y, z.

A curve being the concept common to a locus and an assembly (the common ground, so to say, of the existence of each of them), will be capable of being imaged in terms of either direct or inverse coordinates. If the two coordinate systems are supposed to be correlated (as they ought always to be) then any two homogeneous functions which are reciprocal, or, let us say, conjugate to one another (each in common parlance the *polar reciprocal* of the other) will be images—the one of the curve under its aspect as a *locus*, the other of the very same curve under its aspect as an *assemblage*.

Reduced Perpendicular Distances

An extremely convenient system of homogeneous coordinates of a point is where each coordinate is the distance from one of the boundaries of the fundamental enclosure divided by the distance of that boundary from the opposite angle. Such coordinates may be termed coordinates of reduced distance or reduced coordinates; they are analytically defined by their sum being unity. If a, b be the two vertices which correspond to the coordinates of reduced distances, the squared distance of any two points, $x, y, z, \ldots$; $x', y', z', \ldots$ in extension of any order is capable of being expressed by the formula $\Sigma(ab)^2 (x - x')(y' - y)$, which, as far as I have been able to ascertain, is nowhere stated in the books, except for the case of trilinear coordinates.

Exchangeable Figures

Two figures indistinguishable from each other by any of their internal properties, but incapable of occupying the same place (such as the left- and right-hand glove or shoe) have received the very awkward and misleading name of *symmetrical* figures; I propose to call them exchangeable figures, inasmuch as in the nature of things, as they are in themselves (without regard to the limitation of the human faculties), they may be made to pass into each other's places by a semi-revolution about a suitable homaloidal axis.

The Point-Pair at Infinity, Lines and Planes of Null

It has been already shown in these columns that the "absolute" in a plane has full right to be called the *point-pair* at infinity, in analogy with the received expression of the *line* at infinity, and those who have considered what has been here stated under the head of *reciprocity* will see good grounds for admitting that the line at infinity ought to be regarded as a complete line, *i.e.* as made up of two analytical "semi-droites."

Every line through either half of the absolute besides the property of being infinitely distant from any point in the finite region may be termed a *line of null*, in the sense that the distance between any two points in such line is zero.

In like manner any plane *touching* the absolute in extension of the 3rd order, besides being infinitely distant from the finite region, is in the same sense a *plane of null*; in it, form is divorced from content, for a figure of any shape being described upon such plane, its content will be *nil*.

Pluri-duality: Containing and Contained

In extension of i dimensions each continuum of λ dimensions stands in a relation of reciprocity to one of $i - \lambda - 1$ dimensions, the total number of these "dualities" being $\frac{i+1}{2}$ when i is odd and $\frac{i}{2}$ when i is even (in the former case the continuum of $\frac{i-1}{2}$ dimensions being its own reciprocal). It is very convenient in connecting reciprocal geometrical statements to ignore the difference between (and to regard as exchangeable and equivalent) the terms *containing* and *contained in* as applied to heterogeneous continua; indeed the ordinary distinctive use of these words suggests an erroneous conception; as *ex. gr.* of a line being *made up* of points or a plane of lines. A point may be said to contain every line or plane which passes through it, and a line every point which lies on it, and every plane which passes through it: as an example of this extended locution the order, rank, and class of a surface may be defined as follows—viz. the order and class as the number of its point and plane elements respectively contained in any given line; the rank as the number of its line elements contained in common by any given point and plane which contain one another.

A plane-section of a surface is the totality of its point- or line-elements contained in a plane and similarly a point-section (an enveloping cone), the totality of its plane- or line-elements contained in a point: hence indifferently the class of any plane-section or the order of any point-section of a surface is its rank.*

J. J. SYLVESTER

* When an *image* is given, its *object* is absolutely determined, but not *vice versâ*, since an image may be magnified or diminished at will by the introduction of a constant factor.

* The word *spread*, to signify an unlimited expanse of discontinuous points and so used by Dr. Henrici, is, I am informed, originally due to the late Prof. Clifford. In ignorance of this fact, on hearing that Henrici had been attacked for his use of the word, I stated my belief that it must have been borrowed from my use of it to signify a limited portion of a tissue of equi-spaced points, such as that which is turned to so profitable account in my *constructive theory of partitions* in the *American Journal of Mathematics*.

I did not know at the time that Clifford had used the word, nor that Dr. Henrici's treatise preceded by several years the publication of my memoir above referred to. This erroneous oral statement seems to have found its way by some more or less circuitous channel to the columns of the *Saturday Review* in a notice of a criticism, by Mr. Dodgson, of Dr. Henrici's geometrical manual in the Scientific Series. Dr. Ferrers (the Master of Caius College, Cambridge) was the first to apply a spread to demonstrate intuitively a celebrated arithmetical theorem of reciprocity due to Euler. Mr. Durfee a quarter of a century later led the way to a further and more pregnant use of the same by showing how to trisect a symmetrical spread bounded by two right lines and a broken line into a regular square and two quasi-triangular appendages, to which I superadded the notion of multisecting it into a succession of angles. Another pupil of mine at the Johns Hopkins University (Mr. Ely) has laid the foundation of a new theory of partitions, by studying the various modes of decomposing a *solid* spread of discontinuous points; his memoir on the subject is to be found in a recent volume of the *American Mathematical Journal*.

By means of the trisection method I obtained *inter alia* a new expansion of $(1 - xz)(1 - x^2z) \ldots (1 - x^2z)$, which, on making z unity and n infinite leads immediately to Euler's celebrated pentagonal-power series, and other results of a totally novel kind by the multisection method: so that a *spread* may justly be regarded as a potent instrument or magical mirror for extending old and bringing to view new truths in the *wonderland* of partition and elliptic-function series.

NOTES

ALL the five French academies will celebrate by a banquet the ninetieth anniversary of the foundation of the Institut, which was established on October 25, 1795, by the Conseil Législatif and Directoire Executif of the French Republic. The actual organisation is not quite the same as the original, great alterations having been made in 1814, and only partially abolished on subsequent occasions.

THE death took place last month of General J. J. Baeyer, President of the Central Bureau for European Triangulation and of the Royal Prussian Geodetic Institute. General Baeyer had reached the age of ninety-one years. A biography of some length will be found in the *Astronomische Nachrichten*, No. 2687.

M. ROBIN, a member of the Paris Academy of Sciences and of the French Senate, died last week. He had devoted his exertions to microscopy, and was professor to the School of Medicine.

By invitation of the Lieutenant-Governor of the Isle of Man Prof. Boyd Dawkins recently visited that island in order to report on its antiquities and the best means of preserving them. The result is given in a short communication to the Lieutenant-Governor, in which Prof. Dawkins indicates the present condition of the various classes of remains. He points out what should be done for their preservation, and advises that the island Legislature should pass an Act similar to the "Ancient Monuments Act" of the "neighbouring islands" of Great Britain and Ireland. The advice given by Prof. Dawkins is sound, and it is creditable to the Lieutenant-Governor that he has shown so much intelligent zeal in the matter. We are glad to note that he intends to follow up his action by introducing a bill into the Council with a view to carrying out Prof. Dawkins's recommendations.

The last publication of the Japanese Meteorological Observatory which has reached us contains the monthly summaries and monthly means for 1884, and is accompanied by forty-one maps, showing the isobars, isotherms, and prevailing winds. These volumes must demand unusual care on the part of the compiler, for they are printed in Japanese as well as English, and contain a mass of meteorological data of all sorts. We observe that three new stations have been added during the year, one in the north of Yezo, and the other, which should prove a valuable station, is at Fusan, the port of Corea recently opened to Japanese trade. This constant annexation of new territory by the Tokio Meteorological Bureau is to be highly commended.

A recent issue of *Cosmos* contains an account of the Jesuit establishments at Zikawei near Shanghai, the meteorological publications of which have frequently been noticed in Nature. The central establishment of the Jesuits in China is at Funkadoo in Shanghai, but about six miles away at Zikawei (Siccawei) they have a large adjunct, containing their schools, an orphanage, and a college. In the course of its existence the place has been twice sacked, but it was again rebuilt. In 1870 the fathers began with the rudiments of a meteorological observatory, of which Father Dechevrens was the founder, and has been to the present moment the director. Gradually, by purchase and by presentations from various Governments, the observatory became tolerably well equipped, and it is now a magnetic and meteorological station of the first order, making with excellent instruments observations on atmospheric pressure, temperature, humidity, evaporation, rain, winds, solar radiation, terrestrial magnetism in its various manifestations, &c. It issues a monthly *Bulletin* containing the observations, and a *résumé* and discussion of the meteorological events of the month. Thanks of the numerous missionaries scattered over the neighbouring provinces, who correspond with the director, the peculiar atmospheric movements in the China seas are beginning to be understood. Quite recently (as mentioned at the time in Nature) he has taken advantage, with the assistance of Sir Robert Hart, of the Telegraphs, to establish a regular daily weather service, for the benefit of mariners. The observatory is situated in a vast plain, where the horizon alone stops the view, and where atmospheric movements are not complicated by ranges of hills. A tower 33 metres in height has been erected, and the Beckley anemometer, constructed in 1884 by Munro, of London, is placed on a platform 7 metres higher. The observatory has gone on developing year by year, and there is little doubt that it will soon include in its field astronomical observations. The *Bulletins* are printed at the mission printing-press, which is included in the establishments at Zikawei, the printers being young Chinese. The monthly *Bulletins* form a considerable volume at the end of the year, and that for 1884, which has lately been issued, is the tenth in the series.

With regard to the new star in Andromeda Dr. Sophus Tromholt relates the following curious story in a Norwegian journal:—"When the interesting discovery had been made in 1877 that Mars was accompanied by two moons, it was shortly afterwards pointed out that Swift, in 'Gulliver's Travels,' relates that the Liliputian astronomers had discovered the two satellites (Voltaire, too, in a work in which he describes the experiences of two terrestrial beings on Mars, says that they saw the two moons unknown to mundane astronomers, but he has probably borrowed the idea from Swift). A similar remarkable proof that poets may also be prophets in astronomy has just come to light with regard to the new star in Andromeda. In the Hungarian periodical *Losonczi Phönix* for 1851 is a story by Maurus Jókai, the celebrated author, in which he refers to this star. Jókai makes an old Malay (?) relate that the Evil Spirit, Asafiel, revealed to King Saul and his sons the star in the nebula, and predicted that those who could not see it should perish in the impending battle. The Malay also reveals the star to his listeners and describes its position so accurately that there cannot be any doubt of the Andromeda nebula being the one referred to, although it is not named. The story, according to Jókai, rests on a biblical or Jewish legend. On the writer of these lines asking one of the greatest living authorities on biblical research whether the bible contains any reference to the point, he is informed that there is absolutely no such reference in that book, and that it is hardly possible that the nebula is mentioned in any Jewish legend. It is first mentioned by a Persian astronomer of the tenth century, and was first discovered in Europe in 1612. It would be exceedingly interesting to ascertain whether any Jewish tradition has preserved the mention of a star in the Andromeda nebula, as from this might be concluded that the new star is a variable one with a long period. I intend to inquire of Jókai whether his story is founded on any tradition or only an outcome of the author's imagination, but even should the latter be the case the story is a very curious one."

Algology is becoming a favourite science with some Russian botanists. After the valuable researches of Dr. Gobi on the algæ of the Gulf of Finland, several memoirs have been published by MM. Reinhardt and Rishavi on those of the Black Sea, and we find now in the last issue of the *Memoirs* of the Novorossian Society of Naturalists (ix. 2) an elaborate paper, by M. Reinhardt, being contributions to the morphology and classification of the Black Sea algæ. The paper is the first of a series. Following Bornet and Thuret's example given in their "Notes Algologiques," the author publishes his observations on separate species, without awaiting the time when he will be enabled to publish a more complete work. In the morphological part of his paper, M. Reinhardt discusses the development of a few Chlorophylleæ, and enters into more details with regard to some of the Cyanophyceæ, and especially the Phæosporeæ (the conjugation of *Ectocarpus siliculosus* and the growth of *Sphacelaria*). As to the Rhodophyceæ, only short remarks, especially as to pores in their external covering, are given. The chief attention has been devoted, however, to the Bacillariaceæ, and the paper contains a good deal of new observations on the structure of gelatinous colonies, the structure of the cell and its protoplasmatic parts, and the auxospores. The systematical part will appear in a next issue. The paper is accompanied by eleven tables engraved in Germany.

The same volume contains a very interesting paper on the development of Rotifers, by the Director of the Sebastopol Zoological Station, Miss Pereyaslavtseff. This subject has been rather neglected until now, and M. Zaleski's paper on the history of the development of the *Brachionus urceolaris* could not be considered as a complete solution of the question. Miss

Pereyaslavtseff's method differs from most of those hitherto recorded: she does not select one or another phase of development as being the most important, but, placing several Rotifers and Lepadellæ under the object-glass of a microscope, she waited until one of them would lay an egg, and the development taking about three days from the beginning of the segmentation until the issue of the new animal from the egg, she observed it continually throughout the first thirty to thirty-five hours, with only short interruptions of two to three hours in the observation of subsequent phases. This method has of course its inconvenience by preventing sleep for two nights. It cannot be applied also to those Rotifers which live an errant life. These last do not survive confinement, and must be kept in watch-glasses until they lay their eggs, which last are then brought under microscopic investigation. Ten different species were studied in this way, and proved to undergo the same development, so that *Rotifer inflata* has been given as a type of the development of the egg. The stages are all figured in forty-eight drawings on a plate accompanying the memoir.

THE same volume contains, moreover, three papers on geology: one by M. Sintsoff, on Tertiary fossils from Novorossia, being a description of the following new species: *Anodonta unioides*, *Scrobicularia tellinoides*, *Ervilia minuta*, *Neritina pseudo-Grateloupana*, and several others formerly described; it also contains a list of the fauna of the intermediate Ponto-Sarmatian deposits of the region. Another, by M. Miklashevsky, gives some information on the Government of Tchernigoff; and a third, by M. Andrusoff, deals at length with the geology of the Kertch peninsula, and throws some new light on the confused geology of the Crimea. It appears from the author's researches that the Tertiary deposits of the Crimea may be subdivided into the following: (*a*) the true *Congeriæ* deposits (Pontri), consisting of iron-bearing clays, equivalent in West Europe to the deposits of Hidas and Arpad, and of limestones, sandstones, and marls equivalent to the *Dreissena triangularis* deposits of the Vienna basin, the *D. rostriformis* deposits of Ploeshti and the upper Siebenbürgen deposits; (*b*) the Ponto-Sarmatian intermediate group of the Kertch limestone, equivalent to the lower Siebenbürgen deposits; (*c*) the Sarmatian group, equivalent to the same of Roumania, Turkey, and Austria-Hungary; and (*d*) the Upper Mediterranean, equivalent to the *Leythakalk*, the *Badner Tegel*, &c. It would result from the above, and from what is known about South Russia and the Crimea, that during the older Miocene period both were a continent. Later on they were invaded by a sea penetrating from the west, and a narrow gulf limited in the south by the Yaiba hills, extended towards the East. During the Sarmatian epoch the subsidence continued, followed soon by an upheaval towards the end of that period, which upheaval led to the formation of narrow, less settled bays, like those we see now on the Kuban, at the place formerly occupied by the Sarmatian Gulf.

The Garner and Science Recorder's Journal is the title of a new scientific monthly, edited by Mr. A. Ramsay, and published by W. E. Bowers, Walworth.

A SOCIETY for the Advancement of Science has been formed in Bergen, numbering about a hundred members, the President being Dr. Danielsen.

MR. ARTHUR S. PENNINGTON'S Manual of British Zoophytes, to be published immediately by Messrs. L. Reeve and Co., will include not only the Hydroida but also the Actinozoa and Polyzoa found in Great Britain, Ireland, and the Channel Islands. The same publishers announce an illustrative volume of "Collections and Recollections of Natural History and Sport," by the Rev. G. C. Green.

WE have received the sixteenth annual Report of the Norfolk and Norwich Naturalists' Society, forming part 1, vol. iv. of the *Transactions*. Amongst the published papers is a presidential address by Mr. Francis Sutton, F.C.S., on the nitrification of soils by means of minute living organisms; and the same gentleman also contributes a most valuable paper on the varieties of sugar, natural and artificial; Mr. Horace B. Woodward, F.G.S., gives a paper on the earthquake of April, 1884, which made itself so severely felt in the counties of Norfolk and Suffolk; Mr. F. D. Power, who visited the Norfolk coast during the period of the autumnal migration, in his "Ornithological Notes from Cley and Blakeney," shows the wonderful influx of birds, some of which are generally supposed to be of the greatest rarity, which takes place on the eastern coast at that period; amongst Mr. Power's list of rarities occurs the blue-throated warbler, of which he says he must have seen from eighty to one hundred individuals, and the barred and ictarine warblers. Mr. J. H. Gurney, jun., also contributes some valuable facts bearing upon the vexed question of migration, for the observance of which the Norfolk coast is so favourably situated. Mr. Southwold furnishes his usual review of the herring fishery from the ports of Yarmouth and Lowestoft, from which it appears that the enormous number of 505,005,600 fish were taken by the fishermen using those two ports; the same gentleman also contributes a paper on the white-beaked dolphin, a Cetacean which has been procured on several occasions on the east coast. The "Ornithological Notes" of Mr. Hy. Stevenson, F.L.S., are in continuation of a series extending back for many years; and a most interesting memoir of John Scales is contributed by Prof. Newton, forming one of a series of memoirs of naturalists of whom the county of Norfolk has since the commencement of the present century produced so many notable examples.

AN experiment has recently been tried at the Inventions Exhibition Aquarium by Mr. W. August Carter with a view to discovering how far fish are prone to sleep. After close examination he found that amongst freshwater fishes the roach, dace, gudgeon, carp, tench, minnow, and catfish sleep periodically in common with terrestrial animals. The same instincts were found to actuate marine fish, of which the following were observed to be equally influenced by somnolence—viz. the wrasse, conger eel, dory, dogfish, wrasse bass, and all species of flat fish. Mr. Carter states that, so far as he can discover, the goldfish, pike, and angler fish never sleep, but rest periodically. Desire for sleep amongst fish varies according to meteorological conditions. Fish do not necessarily select night-time for repose.

THE specimens of fish collected for the International Ichthyological Museum, which is being formed by the National Fish Culture Association, now number about 500. They include many rare fish as well as those of extraordinary growth and formation. Many of the specimens are the finest to be seen in London, having been specially caught for the Association by qualified ichthyologists and agents. The work of setting the fish out in glass jars is now being commenced, and it is hoped to be able to exhibit them to the public shortly.

WE have received the third and concluding part of Dr. Hann's paper before the Berlin Academy of Sciences on the temperature of the Austrian Alps. The tables contain monthly and yearly averages of temperature for 382 stations in the Austrian Alps and the neighbourhood reduced to the true (24-hour) average, and to a thirty-year period (1851–80). Of the stations 277 were below 1000 metres, 88 lay between 1000 and 2000, while 17 were over 2000 metres in height. The data obtained at all these stations over a period of years are here worked up and arranged. The present part contains over 160 pages, so that the whole paper would make a considerable volume dealing with temperatures in the Alpine regions of Austria.

M. D'ABBADIE begs us to state that the earth-tremors observed in his apparatus (NATURE, vol. xxxii. p. 568) about two miles north of the Spanish frontier coincided with the many earthquakes in the south of Spain. There were no such phenomena in Egypt.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus* ♂) from India, presented by Mr. L. C. Phillips; a Ring-tailed Coati (*Nasua rufa* ♂) from South America, presented by Lieut. W. F. Tunnard, R.N.; a Black Wallaby (*Halmaturus ualabatus* ♂) from South Australia, presented by Mr. R. E. Wootton Isaacson; a Javan Cat (*Felis javanensis*) from Java, presented by Capt. T. H. Franks; a Puma (*Felis concolor* ♂) from South America, presented by M. Rodolfo Aranz; two West Indian Rails (*Aramides cayennensis*) from Brazil, presented by Mr. J. C. Fraser; a Levaillant's Amazon (*Chrysotis levaillanti*) from Mexico, presented by Mr. H. D. Astley, F.Z.S.; a Silver Pheasant (*Euplocamus nycthemerus*) from China, presented by Mrs. James; three Robben Island Snakes (*Coronella phocarum*), a Hoary Snake (*Coronella cana*), a —— Elaps (*Elaps hygiæ*), a Reddish Pentonyx (*Pelomedusa subrufa*) from South Africa, seven Geometrical Tortoises (*Testudo geometrica*) from the Orange River, South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; a Rose-crested Cockatoo (*Cacatua moluccensis*) from Moluccas, deposited; a Blue and Yellow Macaw (*Ara ararauna*) from Trinidad, received in exchange; eight Summer Ducks (*Œx sponsa*, 4 ♂ 4 ♀) from North America, purchased; a Bennett's Wallaby (*Halmaturus bennetti* ♀), born in the Gardens.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, OCTOBER 18-24

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on October 18

Sun rises, 6h. 31m.; souths, 11h. 45m. 9·9s.; sets, 16h. 59m.; decl. on meridian, 9° 47′ S.: Sidereal Time at Sunset, 18h. 48m.

Moon (two days after First Quarter) rises, 14h. 51m.; souths, 20h. 0m.; sets, 1h. 17m.*; decl. on meridian, 10° 27′ S.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	6 37	11 51	17 5	9 43 S.
Venus	10 37	14 30	18 23	23 26 S.
Mars	0 6	7 38	15 10	16 38 N.
Jupiter	3 35	9 54	16 13	3 5 N.
Saturn	20 41*	4 49	12 57	22 17 N.

* Indicates that the rising is that of the preceding and the setting that of the following day.

The Phenomena of Jupiter's Satellites are such as are visible at Greenwich.

Oct.	h.	
20	0	Saturn at least distance from the Sun.
20	13	Saturn stationary.

GEOGRAPHICAL NOTES

THE work done by Lieut. Wissmann in his exploration of the Kassai River, the great southern tributary of the Congo, is second in importance only to the discovery of the Congo itself. It will seriously modify the conjectural geography of that part of Africa. He found the river to be of immense volume, and navigable from its junction with the Lulua. He found the Sankuru and the Lubilash to be one river, which, instead of flowing northwards to the Congo, turns westwards, and join the Kassai. As it approaches the Congo Kassai receives the great Koango, and enters the main river by the Kwamouth, after receiving the water of Lake Leopold. Thus the river which on Stanley's last map joins the Congo west of Stanley Falls cannot be the Lubilash, and, moreover, must be of no great length. This discovery of Lieut. Wissmann, along with that of the Mobangi by Mr. Grenfell, greatly increases the navigable waterway of the Congo system.

THE September number of *Petermann's Mittheilungen* has for its principal article the first part of an account of Paulitschke and Hardegger's journey to Harar, by Dr. Paulitschke. It is accompanied by a map of the districts traversed. The present instalment describes the circumstances under which the journey was undertaken, the preparations at Zeila, where the English consul was able to put the travellers in friendly communication with Abu Bakr, the Governor of Zeila, who gave them the most important help, and the details of the journey as far as Bussa, on the frontier of the Northern Gallas country. Dr. Schinz asks the question whether Namaqua-Land or Nama-Land is correct, and decides in favour of the latter. "Namaqua" is a Dutch corruption; the term "Nama" is applied to Hottentots in general, without any distinction of sex; "namaqua" is properly "namagu" or "namaga," the nominative and dative plural of "nama"; "qua" is therefore doubly wrong as a suffix, and Namaland is the proper term. M. Rabot writes on the Stor Börgefjeld in Nordland in Norway, and the usual literary and geographical news brings the number to a conclusion.

THE last number (Band xxviii. No. 29) of the *Mittheilungen* of the Geographical Society of Vienna contains a paper on the ethnic members of the western Somali and north-eastern Galla tribes, by Dr. Paulitschke, accompanied by a map; six letters from Dr. Lenz on his Congo expedition, and the first part of a paper by Herr Jülg on the erosive action of the sea on coasts; the bibliography of Africa for the last half year, and the usual notices of geographical works conclude the number.

M. BRAN DE SAINT POL-LIAS, who was sent on a scientific mission to Tonquin and Java, returned to France towards the close of September. He brought back with him numerous specimens of the flora and fauna of the districts through which he travelled.

THE chief geographical societies in Germany have resolved to erect a monument to the late Dr. Nachtigal on Cape Palmas, where he lies buried. It is intended to have it so large that it will serve as a landmark to seamen.

THE Godeffroy Museum at Hamburg, illustrative of the natural history of the South Sea Islands, has been sold to the Ethnographical Museum of Leipsic.

THE GREAT OCEAN BASINS[1]

I.

THE ancients, down to the time of Aristotle—and most of them for a long time afterwards—regarded the earth as a great plain surrounded on all sides by the mighty, deep, gently-flowing stream of the ocean.

In the geography of the Homeric age there was not supposed to be any communication between the Mediterranean and this all-encircling ocean river. When, in consequence of the excursions of the Phœnicians, the communication through the Pillars of Hercules became known, ideas respecting the outer sea gradually changed. At first, curiously enough, the Atlantic Ocean was regarded as muddy, shallow, and little agitated by the winds—a belief apparently associated with the supposed subsidence of the legendary island of Atlantis. The world, as known to the ancients down to about 300 years before Christ, is represented in this map of Hecatæus.

There seems to be no doubt that the spherical form of the earth was known to some philosophers even before the time of Aristotle—the proof that the earth is a sphere being indeed easy to minds that had received a mathematical training—but these have been few in all ages, and an idea so directly opposed to the apparent evidence of the senses could only be expected to win its way with difficulty. Indeed, at the present day the majority of even educated people are unable to give any reason for their belief that the earth is a sphere, other than that navigators are now in the habit of sailing around it.

[1] Lecture delivered at the Aberdeen meeting of the British Association by Mr. John Murray, Director of the *Challenger* Reports.

However, we find that Erathosthenes, Posidonius, and other learned Greeks, who flourished between one and two centuries before our era, were in possession of ideas concerning the figure and position of the terrestrial globe which do not differ materially from those of the modern geographer. They had considerable knowledge of the great wide sea, a clear perception of the diurnal recurrence of the tides, of their monthly cycles of variation, and correctly ascribed these changes to the influence of the moon. They speculated on the circumnavigation of the globe, and thus anticipated by many centuries the project of Columbus of sailing direct from Spain to the Indies.

During the century immediately preceding the Christian era, and during the dark and middle ages, there was a large acquisition of information with respect to the superficial extent of the ocean. But, when we look back on the history of knowledge concerning our planet, there is to be found no parallel to the impression produced in men's minds and conceptions by the discovery of America, and the circumnavigation of the world, a few years later, by Magellan and Drake. The influence of these events and the great ideas associated with them, can be traced throughout the literature of the Elizabethan period; Shakespeare appears to have had the mental picture of the great, solid, floating globe continually before him. His spirit seemed

> ". . . . blown with restless violence round about
> The pendant world."

To the great mass of people the circumnavigation of the globe was the practical demonstration that the earth was swung in space, supported alone by some unseen power; it was the conclusive proof of its globular form—a fact which must be regarded as the fundamental principle of all scientific geography.

The rage for geographical exploration which set in after the discovery of America brought the phenomena of the ocean into greater prominence, but the science of the sea can hardly be said to have commenced till the seventeenth century, when Hooke and Boyle undertook their experiments as to the depth of the sea and the composition of ocean water; and several naturalists gave descriptions of the animals and plants inhabiting the shallow waters surrounding the land. During the eighteenth century there was again a large acquisition of knowledge concerning the ocean, for the navigator was busy with the study of the winds, currents, and tides; while the two Rosses with other explorers and scientific men made most praiseworthy endeavours to investigate the greater depths of the sea during the first half of the present century.

The vast abysmal regions of the great ocean basins, however, lay all scientifically unexplored, when about twenty years ago their systematic examination was undertaken by expeditions sent forth by our own country and by the Governments of the United States, Germany, Italy, France, and Norway.

It is not easy to estimate the relative importance of the events of one's own time, yet in all probability the historians of the reign of Victoria will point to the recent discoveries in the great oceans as the most important events of the century with respect to the acquisition of natural knowledge, as among the most brilliant conquests of man in his struggle with nature, and doubtless they will be able to trace the effect of these discoveries on the literature and on the philosophic conceptions of our age. A mantle of mystery and ignorance has been cleared away from the eleven-sixteenths of the earth's surface covered by the ocean, and in its place we have much definite and accurate knowledge of the depths of the sea. The last of the great outlines showing the surface features of our globe have been boldly sketched; the foundations of a more complete and scientific physiography of the earth's surface have been firmly laid down.

This evening we will endeavour to pass in review some of the chief phenomena of the great ocean basins, and attempt to bring before you some of the more important results arrived at by the many distinguished men who have been engaged in oceanographical researches during recent years.

If it be remembered that the greatest depth of the ocean is only about five miles, and that the height of the highest mountain is likewise about five miles above the level of the sea, while the globe itself has a diameter of 8000 miles, the comparative insignificance of all the surface inequalities of the earth is at once forced on our attention. A circle 66 feet in diameter having on its surface a depression of one inch; or a globe one foot in diameter, with a groove on its surface one-sixtieth of an inch in depth, would represent on a true scale the greatest inequality, of mountain height and ocean deep, on the surface of the earth. Misconceptions often arise, and erroneous conclusions are frequently arrived at when these proportions are not rigidly borne in mind. But, unimportant as these surface features may appear when viewed with reference to the diameter of the earth, or to the superficial area of an ocean several thousand miles in extent, still to the geologist and physical geographer the elevations and depressions, foldings and dislocations, vertical and lateral, which form these inequalities are truly gigantic, immense, profound; and the more they are studied the more do they appear to be the result of changes taking place in a very definite and orderly manner in the course of the earth's developmental history.

Allow me to direct your attention to the maps representing hemispheres of the earth drawn in equal surface projection. The continental land of the world is coloured black, the abyssmal regions are coloured red, and between these two there is a border or transitional area which is uncoloured.

You will observe that the dark-coloured masses of continental land are, at some one point, more or less closely connected with similar masses; there is usually a place where adjacent masses are not separated by oceans of very great depth. A traveller might almost journey from any one point in these regions to any other without once losing sight of land. If an exception must be made to this statement it is in the case of New Zealand and the Antarctic Continent, for the *Challenger's* dredgings, which brought up masses of schist, gneiss, granite, sandstone, and compact limestone along the borders of the ice-barrier, show beyond all doubt that there is a mass of continental land at the south pole, but, since it is buried beneath perpetual snow, its exact extent is a matter of conjecture.

The surfaces of the continents are everywhere cut into cliff and gorge, mountain and valley, and are continually undergoing a process of disintegration. Water, frost, ice, sudden changes of temperature, are ever tearing the solid rocks to pieces, rivers are transporting the fragments down to the ocean, or carrying away the solid earth in solution; the bulk of this material is deposited in the areas bordering the continents—the uncoloured areas on the maps—there to form rocks which may once again become dry land. Sooner or later the whole of the continents would in this way be reduced below the level of the waves, were not other forces at work producing elevation. Such forces there are, and they are probably more potent than the disintegrating and transporting forces, since there are many reasons for believing that there is now more dry land than at any other period of the earth's history.

The continents have an average height of about 900 feet above the level of the sea; they may be regarded as elevated plateaus occupying five-sixteenths of the earth's surface.

The abysmal regions of the earth, represented by the red colour on the maps, occupy eight-sixteenths, or one-half of the earth's surface, and have an average depth of three miles beneath the surface of the waves. The greatest depths in the Pacific are to the south and east of Japan, where there are abysses of over five miles; and in the Atlantic the greatest depth is to the north of the Virgin Islands, where there is a depression of a little over four miles.

From all we yet know of these abysmal areas they have not a diversity of peak, gorge, mountain, and valley comparable to those which are met with on land; they are fundamentally areas of deposition. It is true that the close soundings of telegraph engineers appear to show that in some cases there may be steep cliffs in the shallower depths of the ocean in volcanic areas; yet the general aspect of the abysmal regions must be that of vast undulating plains, interrupted here and there by huge volcanic cones, with slopes at a very low angle. When these cones rise above the surface they form volcanic oceanic islands. When they rise nearly to the surface they are, in the tropics, often capped by coral atolls; but many of them are far beneath the waves and are covered by a white mantle of carbonate of lime—the dead shells and skeletons of pelagic and deep-sea organisms.

The land of the oceanic islands is of small extent and differs widely in the nature of the rocks, as well as in the character of the terrestrial and marine fauna and flora, from the continents and continental islands. There has not been found in the abysmal areas any land made up of gneisses, schists, sandstones, or compact limestones; nor have fragments of these sedimentary formations been found in the erupted rocks of the volcanic islands, though they are frequent in the volcanic eruptions on the continental areas.

We may, indeed, compare the oceanic islands to the fresh and salt water lakes scattered over the surface of the continents and cut off from direct communication with the ocean. These lakes differ as much from the waters of the ocean as do the oceanic islands from the land of the continents.

The surface of the earth may then be divided into three great regions—the abysmal area, occupying, so to speak, the bottom of the basins, covering one-half of the earth's surface; a border region occupying, so to speak, the sides of the basins, covering three-sixteenths of the earth's surface; and lastly, the continents which cover five-sixteenths of the earth's surface. The average height of the elevated plateaux of the continents above the submerged plains forming the abyssmal regions is fully three miles.

When we pass to a consideration of the water of the ocean, which fills these great hollows of the earth, it is essential to take account of the superincumbent atmospheric ocean, which everywhere rests on its surface, for the composition of the ocean water, the currents, the distribution of salinity, density, temperature, and even that of deep-sea deposits, are largely determined by the movements of the atmosphere.

One of the most important parts played by the ocean in the economy of the globe is to bring about a more equable distribution of temperature by the winds which blow from it over the land and by means of the oceanic currents that are originated and maintained by the winds.

From the smallness of the *daily* variation of the temperature of the surface of the sea, which are shown by the *Challenger* observations, as discussed by Mr. Buchan, not to exceed 1° F., as compared with the large daily variation on land, there result directly the land and sea breezes with all their beneficial consequences. Similarly from the small *yearly* variation of the temperature of the sea, as compared with the very large variation of the temperature of the land surfaces of the globe, result those great annual changes of the prevailing winds—the most important of which, with respect to widespread climatic effects, is the summer monsoon of the Europeo-Asiatic continent.

But the most important, as well as the most direct, effect of the unequal distribution of temperature over the surfaces of the oceans and continents, is an unequal distribution of atmospheric pressure varying more or less with season. On the one hand, in a particular season we see a portion of the earth's surface with atmospheric pressure much less than in surrounding regions, and as long as the low pressure is maintained the winds from the regions all around continue to blow inwards upon it, bearing with them the temperatures and humidities of the regions from which they have come. On the other hand there are other parts of the earth's surface with atmospheric pressure much higher than in adjoining regions, and, as this state of things continues with little variation throughout the year, the winds blow out in all directions towards surrounding regions. Of this two illustrations may be given.

During winter months atmospheric pressure is much less in the North Atlantic about Iceland than it is all round, and towards this area of low pressure the winds from the surrounding continents blow vorticosely, thus determining the winter climates of the more important countries of the world. Over Canada and the United States the winds are north and north-westerly, by which the rigours of winter are intensified; but in Western Europe the prevailing winds are south-westerly, and, as these winds bring with them the warmth and moisture of the Atlantic, the winter climates of Western Europe contrast strongly, latitude for latitude, with those of the eastern states of America.

Again, pressure is higher in the Atlantic between the north of Africa and America than it is all round, and out of this anticyclonic area of high pressure observations show that the winds blow in all directions towards surrounding regions where pressure is less. To the westward of North Africa the prevailing winds are northerly and north-westerly, but on the south side of this anticyclonic region the winds are easterly, and on the west the winds are southerly.

Owing to these very different winds, and the oceanic currents to which they give rise, the temperature of the sea is much higher off the coasts of Florida than it is off the coasts of Africa in the same latitudes. The effect of these differences is recognisable in the distribution of marine life and coral reefs, and, consequently, of the deposits at the bottom of the sea.

Since over this anticyclonic area, and similar ones in the South Atlantic, North Pacific, and in a less marked degree in the South Pacific, atmospheric pressure remains high throughout the year, notwithstanding the outflow of wind all around from them, it follows that aërial upper currents must flow towards these high pressure regions accompanied by a slow downward movement of the air through their central portions. Now, as observations show that in such circumstances the sky is clear, the air dry, the rainfall small, and the evaporation large, it follows that over these parts of the great oceans, where atmospheric pressure is higher than all around, the rainfall is very far from being sufficient in amount to make good the loss arising from evaporation—a consideration which has important bearings on the difficult question of oceanic circulation.

As in these anticyclonic regions in the great oceans there is opened up a direct communication between the upper regions of the atmosphere and the surface of the sea, by means of the descending aërial currents, it is interesting to ask whether this fact may not have some connection with the volcanic and cosmic dust found in the same regions in the deep-sea deposits; especially is this interesting in connection with recent speculations as to the presence of these substances in the higher regions of the atmosphere.

In thus indicating the positions of the high-pressure areas, and of the winds that blow out from and around them over the great oceans, we have at the same time traced the courses of the great oceanic currents and the positions of the Sargasso seas, for the winds everywhere determine and control the movements of the surface waters.

The moisture taken up from the sea surface by the winds—leaving the water salter than before—is borne to the land and condensed on the mountain-slopes. Eventually this water gathers off the land, passes by rivulet, stream, and river down again to the ocean, bearing along with it a burden of earthy matters in solution. In this manner the ocean has most probably become salt in the course of ages. The water of the ocean now contains, it is almost certain, a portion of every element in solution. Many of these are present in exceedingly minute traces. They are detected either in the sea water or the evaporated-down residue by spectrum analysis; in the copper of ships' bottoms, which have withdrawn them by chemical decomposition; or, again, in the ashes of sea-weeds and marine animals, which, during life, exert a selective influence upon the surrounding water.

(A diagram was exhibited showing the average composition of sea salt.) The individual salts present in sea water are, of course, constantly interchanging their metals and acid radicals, so that it is impossible to say authoritatively what is the precise amount of the respective chlorides and sulphates of sodium, potassium, calcium, and magnesium actually present. But it has been shown by hundreds of laborious and most delicate experiments that the actual ratio of acids and bases in sea salts—that is, the ratio of the constituents of sea salts—*is constant* in waters from all depths, with one very significant exception—that of lime—which is present in slightly greater proportion in deep water.

The total amount of dissolved salts in the ocean would, it is calculated, if extracted, form a pavement 170 feet thick over the entire sea-bed, and of this amount 1¼ inches would be composed of pure carbon, chiefly present as carbonic acid in the carbonates.

On account of the constancy in its composition the determination of any one of the constituents of sea salt—chlorine, for instance—gives the datum for calculating the salinity—that is, the proportion of total salts to the water in which they are dissolved; though determinations of this nature are more conveniently made by observations of density by means of the hydrometer. (A map was exhibited on which Mr. Buchanan has shown the results of his laborious investigations in this direction.) An examination of this shows that the surface water of the ocean is freshest—that is, contains the least salt—at the poles and in the equatorial belt of calms. In the east of the Indian Ocean a change of the monsoons brings about a great change in the salinity of the surface water. The centres of the great systems of oceanic currents produced by the trade winds are the areas of highest salinity in the open ocean; yet here the water is not so salt as in some enclosed seas situated in areas of great evaporation, as the Mediterranean, and especially the Red Sea and Persian Gulf, where the saltest water is found and where a regular circulation is kept up by the outward flow of the denser water. The salinity of the deeper waters is considerably below the average at the surface in the open ocean, especially in the Atlantic.

In the equatorial regions the surface water of the ocean has occasionally a temperature of 85° or 86° F., and the normal temperature in tropical and sub-tropical regions ranges from 60° to 80°. This warm water is, however, a relatively thin stratum on the surface, the great mass of the ocean consisting of cold water—water of 45°, 40°, and of even a much lower temperature. At a little over half a mile of depth in the tropics the water has a temperature of 40°, and at the bottom it is still colder—ice-cold indeed. The ooze which is dredged from the bottom beneath the burning sun of the equator is so cold that the hand cannot be held in it for any time without great discomfort.

In the open ocean the temperature usually decreases with the depth, the coldest water being found at the bottom; but sometimes there are limited areas where the temperature remains uniform for a mile or half a mile above the bottom. This has been shown to depend on the existence of barriers to free circulation, which exist on the floor of the ocean, and cause in a measure a resemblance to the conditions which are so marked in many partially enclosed seas, shut off by submarine barriers from general oceanic circulation, where the temperature is uniform, it may be, from a few fathoms below the surface to the bottom—for instance, in the Mediterranean and Seas of the Malayan Archipelago.

The low temperature of deep ocean water was acquired at the surface in high latitudes, chiefly in the high latitudes of the southern hemisphere. The salt warm water of the tropical regions, which is driven in relatively rapid currents along the eastern shores of South America, Africa, and Australia by the action of the prevailing winds, on reaching a southern latitude of 50° or 55° sinks on being cooled, and spreads over the floor of the ocean. A similar circulation takes place in the northern hemisphere, though modified in many ways by the peculiar configuration of the land: for instance, it is almost certain that the cold water at a temperature of 30° F., which occupies the deeper part of the Norwegian Sea beyond the Wyville-Thomson Ridge, is the dense surface water of the Atlantic, which becomes cold and sinks as it passes northward in the extension of the Gulf Stream. Again, the relatively low temperature found on the eastern coasts of Africa and America seems largely due to the cold deep water which is drawn up to supply the place of the warm surface water driven forward by the trade winds.

While surface currents, both warm and cold, have at times considerable velocities, there is no evidence that rapid currents exist anywhere in the great deeps, on the contrary, the movements must be extremely slow and massive in character; the only exception seems to be on the crests of some ridges at moderate depths between volcanic islands or other similarly situated places.

Through the constant circulation in the ocean the gases of the atmosphere, which are everywhere absorbed at the surface of the sea according to the known laws of gas absorption, are borne down and thus enable myriads of living organisms to carry on their existence at all depths. The nitrogen remains at all times and places nearly constant, but frequently the proportion of oxygen is much reduced in deep water, owing to the processes of oxidation and respiration which are there going on.

The absorbed carbonic acid plays a most important and intricate *rôle* in the economy of the ocean, owing to its tendency to reduce normal carbonate of lime and magnesia to solution in the form of bicarbonate; and to the rapid interchanges to which it is subject in consequence of vital processes. It probably receives large additions from the bottom of the ocean, as an after-product of volcanic eruptions, and through the respiration of animals.

It is often supposed that hydrochemical actions go on with much greater activity in the deep sea where there may be a pressure of four or five tons on the square inch, but, while it would be convenient to assume it, there is no sufficient evidence that such is the case. The disintegrations, decompositions, and depositions which take place in the deposits are all similar to those which take place in shallow water or on land, and any chemical peculiarities occurring in inorganic or organic substances in great depths are probably due chiefly to the low temperature, almost perfect stillness, and the absence of light: for, although it may be admitted that some rays descend to much greater depths in the sea than is usually supposed, yet we must at present believe that none of them reach the greatest depths. The absorbed gases are probably but little affected by the great pressure of the superincumbent water, for in this connection it should be remembered that water is but little compressible; any substance which will sink to the bottom of a tumbler of water will in time sink to the bottom of the deepest ocean; this is true at least for all substances which are more compressible than water itself. The compressibility of water cannot, however, be neglected in oceanographical questions. In very great depths the lower layers are considerably compressed; for instance, in an ocean five miles deep, were the action of gravity suddenly to cease, the water would rise about 500 feet above its present level from expansion, a height sufficient to submerge nearly all the habitable land of the globe.

It remains to mention the investigations, which have recently been made, as to the change of level of the ocean, owing to the attraction of the masses of continental or other land—such, for instance, as that of the Himalayas for the water of the ocean to the south, by which the level of the Southern Indian Ocean is lowered some hundred feet; the bearing of this on the apparent elevation or submergence of land along coast-lines is evident, for the level of the sea, to which we refer all heights and depths, cannot be regarded as much more stable than the solid land itself.

(*To be continued.*)

NEW PROCESS OF LIQUEFYING OXYGEN[1]

LIQUID ethylene, the preparation and use of which I have already explained, shows, at its boiling point under the pressure of the atmosphere, a temperature of at least −103° C., only some 10° from the critical temperature of oxygen (−113° C.). It is understood how in the expansion of compressed and cooled

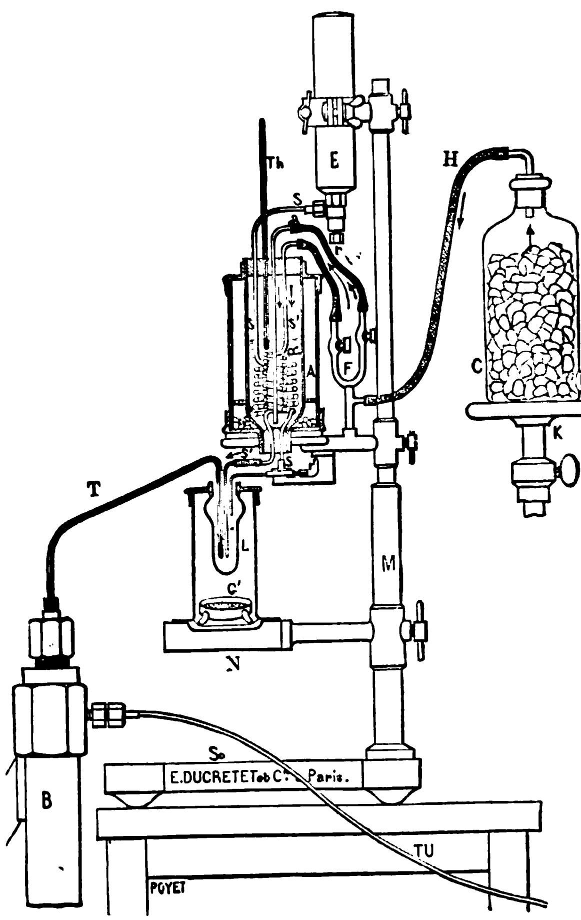

FIG. 1.

oxygen in the boiling ethylene the lowering of the temperature resulting from the expansion enabled me to establish "a tumultuous ebullition continuing an appreciable time." In

[1] From the *Journal de Physique*. By M. L. Cailletet. The illustrations have been kindly lent by MM. Ducretet et Cie, the manufacturers of M. Cailletet's apparatus.

regulating the expansion so as to maintain a certain pressure in the tube, the oxygen is seen for some time completely liquefied.

When by means of the air-pump the evaporation of liquid ethylene is accelerated, as was done by Faraday with protoxide of nitrogen and carbonic acid, its temperature is reduced much below the critical point of oxygen.

With a view to avoiding the inconveniences and complications involved in the necessity of working *in vacuo*, I indicated liquid *formène*, which with the greatest ease achieves the liquefaction of oxygen and nitrogen. Notwithstanding these advantages, in consequence of the perfection to which I have recently brought the preparation and management of ethylene, it has seemed to me that this substance should be preferred to formene, and so, by means of boiling ethylene in open vessels, I have succeeded in obtaining a temperature sufficiently low for the complete liquefaction of oxygen.

The preparation of ethylene by means of sulphuric acid and alcohol is frequently impeded by the frothing of the material, terminating the experiment before the gas has been completely liberated. The admixture of sand, recommended by Wöhler, does not always serve to counteract this frothing, but I have found the addition of a small quantity of vaseline efficacious in this respect.

The material I work with consists of 400 grammes of alcohol, 2000 grammes of sulphuric acid, and 15 to 20 grammes of vaseline. This is warmed in a glass globe, of 5 or 6 litres capacity, over a burner in the usual way. The gas is washed in two large flasks of caustic soda, and then collected in a water gasholder. By means of a mercury pump the ethylene is dried by passing through a flask of sulphuric acid and condensed in steel bottles having a screw tap.

Fig. 1 represents the apparatus I made use of to liquefy oxygen by the rapid evaporation of ethylene by means of a current of air or of refrigerated hydrogen. The liquid ethylene is inclosed in the bottle E, which is fixed to a vertical support, with its mouth directed downwards, and is in communication with a copper worm, S S, of 3 mm. to 4 mm. in diameter, closed at its lower extremity by a screw cock, *r'*. After the worm has been cooled to – 70° by means of chloride of methylene in the manner I shall explain further on, the ethylene there accumulating possesses at this temperature but a weak tension, and it may therefore be run without sensible loss into the test-tube, L, when the cock, *r'*, is opened. This new arrangement I have adopted for ethylene and formene allows the liquefied gas to be cooled as well as though the whole reservoir containing it were of the same temperature as the worm.

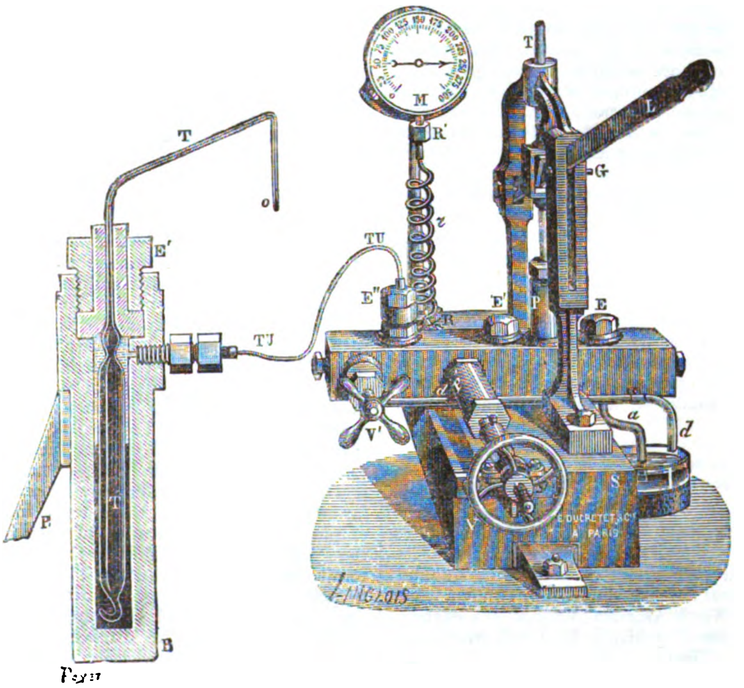

FIG. 2.

The glass test-tube L is arranged in a vessel containing, air dried by means of pumice and sulphuric G', and in this way hoar-frost is prevented from being deposited on the refrigerated sides.

When the ethylene has been received in the test-tube L, its evaporation is accelerated by passing through it a current of air, or, still better, of hydrogen dried by its passage in the vessel C, containing chloride of calcium, and cooled in the worm S'.

The two worms in which the air and the ethylene circulate are plunged into chloride of methylene which is rapidly evaporated by means of dry and cool air, and in this way a temperature of – 70° is obtained.

Fig. 2 shows the arrangement of the oxygen apparatus and the compression pump. When the tube T*o* is plunged into the ethylene, the evaporation of the latter is accelerated by gently opening the cock F, and blowing on to it the air or hydrogen cooled in the worm S'.

The pump is then brought into action, and the oxygen resolves into a colourless, transparent liquid, separated from the gas surmounting it by a perfectly sharp meniscus.

By means of a hydrogen thermometer, the construction of which I shall shortly explain, I have measured the temperature of the ethylene, which in one of my experiments was found to be – 123° C. By dint of certain modifications effected in the apparatus I am in hopes of achieving a still lower temperature.

Altogether, I have proved that by quickening the evaporation of the ethylene by means of a current of air or hydrogen cooled to a low degree, its temperature is lowered much under that of the critical point of oxygen, and that in such a medium the oxygen liquefies most easilyr[1]

This experiment is so easy of accomplishment, that the practice of it may be commenced at once in laboratories, and be repeated in public lectures.

The apparatus I have described has been constructed with great care by M. Ducretet, and I have to thank M. Jamin for kindly permitting me to perform the expeiiments in the Physical Laboratory of the Sorbonne.

[1] M. E. Sainte-Claire Deville, engineer to the Gas Company of Paris, and son of my illustrious master, has now for some time, by my advice, been studying the problem of lowering the temperature by means of the rapid evaporation of chloride of methylene, and has established that, by sufficiently cooling the injected air, temperatures varying from –23° C., to –72° C. may be maintained nearly constant for several hours.

NOTES FROM THE OTAGO UNIVERSITY MUSEUM

V. *On an "Index-Collection" for small Zoological Museums in the Form of a Genealogical Tree of the Animal Kingdom*

EVEN in the smallest museums it is for many reasons difficult, and often impossible, to arrange the representatives of the various groups of animals in such a way as to bring out clearly their mutual relations. Hence arises the need of an "index-collection" in which each group is represented by one or more specimens so arranged as to indicate as accurately and clearly as possible the affinities of the groups they typify. The form which naturally suggests itself as the most suitable for a small type-collection of the kind indicated is that of a solid phylogenetic diagram or "genealogical tree."

An excellent form of "diagram in three dimensions" for lecture purposes has been devised by Haddon; the model I have recently had constructed appears to me to be more suitable for permanent use in a museum.[1]

It consists of a vertical wooden rod about 3 feet 6 inches in height, representing the main line of descent from Protozoa to Vertebrata; from this spring, at various levels, branches representing types which lie off the direct line; these have in most cases an upward direction, but are directed downwards from their point of origin in the case of degenerate groups. At appropriate points on this framework are placed either actual specimens or models of one or more examples of each group.

As the Vertebrata inevitably take up the largest share of space in a museum as well as of public attention, each of the classes of that group is represented on the model, while in the case of Invertebrata one or two examples only are given to each type or sub-kingdom.

For each group—type or class, as the case may be—a label is provided, giving (*a*) the name of the group, (*b*) the name of the specimen or model serving as an example of it, and (*c*) the place in the Museum where representatives of the group are to be found.

A more correct mode of construction for a model of this kind would be to make the branches of such a length as to bring the ends of all of them, and consequently the specimens they support, to one level; advance of organisation would thus be indicated, not by height above the ground, but by distance from a centre. But such a model would be far less convenient than the form I have adopted.

VI. *On the Size and the External Sexual Characters of the New Zealand Octopus* (*O. maorum*, Hutton)

In his work on the octopus,[2] as well as in his more recent pamphlet, "Sea-Monsters Unmasked,"[3] Mr. Henry Lee states that the largest British specimen he had examined had arms 2½ feet long; that examples with arms of about 4½ feet had been found in the Mediterranean; but that the largest specimens known were those found on the coast of North America (Vancouver's Island), one of which had been measured by Mr. J. K. Lord, who found the length of one arm to be 5 feet.

From this it would seem not to be generally known, even by naturalists, that a species of octopus is very common on some parts of the coast of New Zealand, and notably in Dunedin Harbour, the average size of which is fully equal to, while it occasionally exceeds, that of the specimen from Vancouver's Island just referred to.

I have recently had mounted for this Museum a female *Octopus maorum*, the longest arm of which is 4 feet 3¼ inches, but larger specimens have been frequently seen by my assistants and myself. The following are the dimensions of the largest individual—a male—which we have actually measured:—

		Feet	Inches
Length of body and head		1	1
Diameter of body		0	8
Length of arms—			
1st pair	Left	5	5
	Right	5	3
2nd ,,	Left	4	10
	Right	5	2
3rd pair	Left	4	7
	Right (hectocotylised)	2	11
4th ,,	Left	4	3
	Right	4	8
Diameter of largest suckers (on 1st or "dorsal" arms)		0	1¾

[1] The model referred to was exhibited and described in detail at a meeting of the Otago Institute on June 9.

[2] "The Octopus; or, the 'Devil-Fish' of Fiction and of Fact." (Chapman and Hall, 1875.)

[3] One of the "Handbooks" of the Fisheries Exhibition, 1883.

Besides the hectocotylisation of the third right arm, there is a striking difference between the two series which I have not seen mentioned. In the male the suckers simply undergo a gradual diminution in size in passing from the prominal to the distal end of the arm; they retain their characteristic form, and are easily counted up to about half an inch of the tip. In the female, on the other hand, the suckers become quite indistinct for several inches, and in some cases for fully a foot, from the extremity of the arm, taking on the form of small tubercle-like elevations. As an instance of this difference I may mention that in a male specimen with the first left arm 4 feet 2½ inches in length, from 292 to 319 suckers could be readily counted on each arm; while in a female with the corresponding arm of the same length, only 90 to 115 could be counted on each arm, the distal portions bearing tubercles so crowded as to make it practically impossible to count them.

T. JEFFERY PARKER

Dunedin, N.Z., June 19

THE BRITISH ASSOCIATION

SECTION H—ANTHROPOLOGY

Prof. W. Turner read a paper on *The Index of the Pelvic Brim as a Basis of Classification.*—That the inlet to the human pelvis presented variations in outline and in the proportions of its conjugate and transverse diameters has been recognised since the publication by Vrolik in 1826, and by M. T. Weber in 1830, of their important memoirs on the pelvis in certain races of men. In 1866 Zaaijer, of Leyden, in his study of the pelvis in women of Java, recognised differences in form in women of the same race, and he expressed these differences numerically, taking the transverse diameter as = 100, and then multiplying the conjugate diameter by 100, and dividing by the transverse; the numeral so obtained is the index of the pelvic brim, or "pelvic index." By applying this method to the pelvis in different races of man, a classification of races based on the index of the brim may be framed. In carrying out this method the male pelvis should especially be studied, as in women the pelvis, for sexual reasons, does not present such wide divergences in the form of its inlet as in men. To give precision to the classification, it will be advisable to employ special terms, and in order as far as possible to bring these terms into accordance with those employed in the classification of crania based on differences in the relations of the length to the breadth of the skull, Greek terms will be employed. Thus dolichopellic will signify a pelvis the conjugate diameter of which is longer than the transverse, or closely approaching to it; platypellic, a pelvis in which the transverse diameter greatly exceeds the conjugate; and mesatipellic, a pelvis in which the transverse diameter is not so greatly in excess of the conjugate. Owing to the comparatively limited number of pelves in the different races of men which have been measured, either it may not be possible to fix definitely at present the numerical limits of each of these groups; but the following were adopted provisionally by the author:—dolichopellic, a pelvis with brim index above 95; platypellic, one with brim index below 90; and mesatipellic, a pelvis with a brim index between 90 and 95, both inclusive. The number of pelvic measurements from which the author drew his conclusions were comparatively few, but from these it would seem that the dolichopellic division contains Australians, Bushmen, Hottentots, Kaffirs, and Andamanese; whilst Negroes, Tasmanians, and New Caledonians are mesatipellic, and Europeans, Chinese, and probably American Indians belong to the platypellic group. When a pelvis has dolichopellic characters it approximates in the relations of its transverse and conjugate diameters to the form of the pelvic brim met with in mammals lower than man; and in the dolichopellic Australians, Bushmen, Kaffirs, and Andamanese, the length of the sacrum is on the average greater than the breadth, and this also is an animal character.

Mr. W. F. Stanley exhibited a portable scale of proportions of the human body. The instrument is a small thin scale or rule of ivory, about three inches in length, and divided on each edge of the two faces by lines which represent the proportions of the human body, the male on the one side, and the female on the other. The opposite edge to that on which the proportions are shown is divided into 100 parts in the same space as the height of the body. The object aimed at by the use of this scale is to compare any person, or statue, or photograph with the model of perfect human form given by John Marshall, or to determine the parts of the body in proportional decimals of the whole, to facilitate description.

Mr. J. Theodore Bent read a paper on *Insular Greek Customs* as seen in the islands of the Ægean Sea. He proceeded to notice the modern Greek customs concerning birth and childhood, comparing them with ancient ones, among the customs described being that of fate-telling, and the notions regarding the deleterious influence of Nereids on children. The customs connected with death and burials were next described, and shown to be the same as those of the Greeks 2000 years ago. Some instances were given of the poetry of death-wails, and it was shown that the belief in Charon and Hades existed still in the islands of the Ægean Sea. Among the other customs described in the paper were feasts for the dead, which could be traced to a remote antiquity, and the ancient belief in vampires still survived. Instances were also given from agricultural life of the identity between ancient and modern customs, including the ceremony gone through before sowing of seed, the use of skins for grain, the granaries in the ground, in the kind of agricultural implements used, and also in the names used for animals.

Gen. Pitt-Rivers explained the provisions of the Act of Parliament relating to the preservation of ancient monuments. The Act scheduled the most important and best-known ancient monuments in the country, and provided that these should be registered. and after their registration, although they remained the property of the owner of the land on which they were situated, and might be sold along with the land, could not be destroyed by the owners. There were also a vast number of minor monuments of great interest and value well worthy of being preserved. It was not proposed that the Government should meddle with these minor monuments. What he (Gen. Pitt-Rivers) had done with regard to these minor monuments was to endeavour to see all the principal gentlemen most interested in local archæology, and ask them to let him know when any injury was done to monuments in their district. In the Island of Lewis the agent of Lady Matheson had promised to assist him in every way he possibly could; and Dr. Aitken, Inverness, had promised to him to do the same thing; and he had received promises of a like kind from a number of other gentlemen. In his wanderings throughout the country in connection with the working of this Act of Parliament, he had found no owner of the monuments scheduled in the Act unwilling to put his monument under the Act because he wished to destroy it. The feeling of those who were unwilling to put their monuments under the Act had rather been that they considered they were quite as able and willing as the Government to preserve the monuments. What the State desired was to preserve the monuments in the hands of any owners into whose hands they might fall. In these days there was no knowing to whom land might belong now that the gospel of plunder was proclaimed, and it was desirable that there should be some sort of security that the monuments might be preserved hereafter. As the result of his wanderings in order to work this Act in England and Wales, about half of the owners of the scheduled monuments had voluntarily placed them under the protection of the Act. In certain cases the monuments were leased, and the proprietors refused to place them under the Act without compensation, which the Government could not give.

Miss A. W. Buckland read a paper on *American Shell-Work and its Affinities*. In this paper the attention of anthropologists was called to some remarkable works in shell recently discovered in mounds in various States of North America, as described by Mr. W. H. Holmes in a valuable contribution to the *Proceedings* of the Bureau of Ethnology, Washington. These shell-works consist not only of beads of various shapes and sizes, but also of celts, fish-hooks, chips, and other implements of war and the chase, bracelets, pins, crosses of various forms, and more particularly of masks and elaborately engraved gorgets, the ornamentation upon which seems to bear some religious or astronomical signification. From the fact that implements and ornaments of the same form are found in the islands of the Pacific, and that some of the peculiar symbols engraved upon the ancient American gorgets reappear slightly altered on shell gorgets in the Solomon and Admiralty Islands, and also on the great Japanese drum exhibited this year at the Inventions Exhibition, the author inferred that a commerce existed between the islands of the Pacific and the American continent prior to the Spanish conquest.

Mr. E. F. im Thurn read a paper giving an account of the red men about Roraima, in British Guiana. In the paper an interesting account was given of the journey to Roraima, the scenery being described, as well as the manners and customs of the natives. In some of the villages visited the natives had never previously seen white men, and the utmost excitement was caused by the arrival of Mr. im Thurn. The natives of the villages visited were repulsively ugly, and it was almost impossible to distinguish men from women by their dress. The native tribes lived in remarkable isolation from each other, and even the different families in the same village lived in remarkable isolation from each other. There were traces of the Stone Age to be found of high interest. Stones were shaped into adzes and wedges, and they were often made into forms of animals, or of whistles, and models of bottles, which the natives had seen. There was among these tribes a revival of the ancient art of making stone implements, though these implements were simply regarded as ornaments. The natives also made drawings of rocks, which were used as ornaments, and which were evidently imitations of the drawings seen on the actual rocks. Mr. im Thurn closed his paper with an account of a number of some very remarkable games played by the tribes for the amusement of the visitors, in which the movements of animals were imitated in dances.

Mr. J. W. Crombie read a paper entitled *A Game with a History*, which was really an exposition of the antiquity, universality, and signification of the well-known game of "Hop-Scotch," a term which is probably a corruption of "hop-score." The author commenced by pointing out that as children in their play generally imitate something they have observed to be done by their elders, and a game once introduced is handed down from generation to generation of children long after its original has ceased to exist, many innocent-looking children's games conceal strange records of past ages and pagan times; hence the importance of the study of this apparently frivolous subject is now fully recognised by anthropologists. The game of "Hop-Scotch" is one of great antiquity, having been known in England for more than two centuries, and it is played all over Europe under different names. Signor Pitré's solar explanation of its origin appears improbable, for, not only is the evidence in its favour extremely weak, but it would require the original number of divisions in the figure to have been twelve instead of seven, which is the number indicated by a considerable body of evidence. It would seem more probable that the game at one time represented the progress of the soul from earth to heaven through various intermediate states, the name given to the last court being most frequently Paradise or an equivalent, such as Crown or Glory, while the names of the other courts correspond with the eschatological ideas prevalent in the early days of Christianity. Some such game existed prior to Christianity, and the author considers that it has been derived from several ancient games; possibly the strange myths of the labyrinths may have had something to do with "Hop-Scotch," and a variety of the game played in England under the name of "Round Hop-Scotch" is almost identical with a game described by Pliny as being played by the boys of his day. The author believes that the early Christians adopted the general idea of the ancient game, but they not only converted it into an allegory of heaven, with Christian beliefs and Christian names, they Christianised the figure also; abandoning the heathen labyrinth, they replaced it by the form of the Basilicon, the early Christian church, dividing it into seven parts, as they believed heaven to be divided, and placing Paradise, the inner sanctum of heaven, in the position of the altar, the inner sanctum of their earthly church.

Mr. George Campbell, M.P., read a paper entitled *The Rule of the Road from an Anthropological Point of View*, in which he maintained that for all right-handed people the rule of going to the left hand in passing people was the most scientific and the most convenient. There was nothing, he maintained, to be said in favour of going to the right, and he held that the British rule should be maintained both for roads and for footpaths, and that we should give in to no right-handed innovation.

Miss Jeanie M. Laing read a paper on *The Modes of Grinding and Drying Corn in Old Times*. In some parts of Aberdeenshire are found the remains of the straw kilns that were used for drying corn before sending it to the mill. The kiln was conical in shape, joists called cabers were laid across, some distance from the ground, and above these were roughly-hewn sapplings called simmers; on the top of these was spread straw, and on the straw was laid the corn. A fire was kindled on the ground, and the heat therefrom dried the corn. A stone called a sparker was placed above the fire to catch the sparks, but in spite of this precaution the kiln sometimes took fire. At an early period corn was ground between two millstones, with an iron rod by way of a handle; this primitive mill was called a quern, and was generally turned by two women, as in Eastern lands. In later times querns were used for grinding malt.

Mr. A. J. Evans contributed a paper on *The Flint-Knappers' Art in Albania*, and exhibited some beautifully-worked gun-flints and strike-a-lights, partially cased in ornamented lead sheaths studded with glass gems.

Mr. W. M. Flinders Petrie read a paper on *The Discovery of Naukratis*, the remains of which city had been brought to light during the work of the Egypt Evploration Fund in the first half of this year.

Mr. Thomas Wilson read a paper on *A New Man of Mentone*, in which he described the discovery, in March, 1884, in one of the famous caverns at Mentone, of a skeleton, believed to belong to the Palæolithic age. The excavations were made during the winter of 1883-4 by M. Louis Julien, of Marseilles, and at his expense, aided by the advice of M. Bonfils, Curator of the Museum at Mentone. This cavern had been searched many times before, and about 9 or 10 feet in depth had been removed from the original surface, which, however, was plainly marked by a large piece of *brèche* which still adhered to the perpendicular side wall. The formation of the floor of the cavern and the process of its filling up presented all the usual evidences of human occupation and industry: charcoal, burnt earth and ashes, hearthstones, split and broken bones of animals (estimated to the number of 15,000 pieces), flint instruments, chips, nuclei, &c., &c., were found in sufficient number, quantity, and distribution to indicate an indefinitely long occupation. No morsel of pottery was found, nor were any of the stone implements polished. At the depth (from the original surface) of 8 metres 40 centimetres was found the skeleton of this "new man of Mentone." He was laid on his back with his limbs extended, and had for funeral equipments three large chips of flint (*éclats de silex*), 6 or 7 inches long and 2½ inches broad, in the form of the largest scrapers, placed one on each shoulder like epaulettes, and one on the brow. It was evidently an interment. This became more evident when it was found that the body was placed in a sort of natural vault or tomb, formed on one side by the wall of the cavern, and on the other by an immense block of stone with an overhanging edge, which reached to a line perpendicularly over the centre of the skeleton. This placing of the body required an excavation between these rocks of 3 or 4 feet in depth. The skull was broken into sixty fragments by the pick of the workman; it was carefully taken up and put together by M. Bonfils, and is now exposed in the Museum at Mentone. This was a fortunate accident, for while the rest of the skeleton was being exhumed a quarrel broke out as to ownership, which ended in the theft and utter destruction of all that remained. Mr. Wilson maintained that the new discovery of the skeleton dissipated all idea of disturbance, for while disturbance might exist for one or two, or even five or six feet, to the depth of twenty or thirty feet it would be impossible. It must be conceded that the human industry as manifested by the objects found in these caverns, indicated their occupation during the palæolithic age, for of the thousands found, all bear the impress of that age, while none denote particularly the age of polished stone. Mr. Pengelly said that he had visited the cavern where M. Rivière's new man of Mentone was found, and he was of opinion that the man found by M. Rivière had not been interred at all, but had died where the body was found, and had been buried by the sand blown into the cavern, and the waste of the walls of the cavern. He had measured the place himself where the body was found, and found that it was only eight feet below the surface. The skull of the man was so good that he should have been glad to have possessed such a skull. It was a large skull, and the measurements he made of the bone showed that the man must have been of great stature. The bones of animals found in the cavern were partly those of animals now extinct, and partly those of existing species. With reference to the age in which the man found by Rivière lived, his impression was that it was the palæolithic age. He would not say so positively, however, and from the information they possessed he did not think that the man would be of any value whatever for or against the doctrine of human antiquity.

Dr. R. Munro read a paper on *The Archæological Importance of Ancient British Lake-Dwellings and their Relation to Analogous Remains in Europe*. Dr. Munro commenced by giving a short introductory notice of the discovery and investigation of the crannogs of Ireland and the lake-dwellings of Central Europe. He then gave a *résumé* of the more recent explorations made among the crannogs of Scotland and the remarkable objects recovered from them. From a comparative examination of these relics with other collateral antiquities of the Celts, he arrived at the conclusion that the lake-dwellings of Scotland were essentially the product of Celtic genius, that they were constructed for defensive purposes, and that those in the south-west parts of the country attained their greatest development in post-Roman times, after Roman protection was withdrawn from the provincial inhabitants, and they were left single-handed to contend against the Angles on the east and the Picts and Scots on the north. Having established the Celtic origin of the crannogs of Ireland and Scotland, Dr. Munro proceeded to inquire if there is any ancestral relationship between them and the lake-dwellings of Central Europe. Taking into account the recent discovery of lacustrine abodes in the Holderness and the few previous records of their existence in Wales and other parts of England, together with the statement of Cæsar that the Britons were in the habit of making use of wooden piles and marshes in their defensive works, he thought that such indications are not merely solitary instances, but the outliers of a widely distributed custom which prevailed in the southern parts of Britain at an earlier date than that assigned to the crannogs of Scotland. Hence he suggested the theory that the British Celts were an offshoot of the founders of the Swiss lake-dwellings, who emigrated into Britain when these lacustrine abodes were in full vogue, and so retained a knowledge of the custom long after it had fallen into desuetude in Europe. On this hypothesis it would follow that subsequent immigrants into Britain, such as the Belgæ, Angles, &c., being no longer acquainted with the subject, would cultivate new and perhaps improved methods of defensive warfare; whilst the first Celtic invaders, still retaining their primary notions of civilisation, when obliged to act on the defensive would naturally have recourse to their inherited system of protection. In support of this hypothesis the author pointed out that the geographical distribution of lake-dwellings, so far as they are known in Europe, closely corresponds with the area formerly occupied by the Celts; that no lake-dwellings have been yet found either in the northern or southern parts of Europe, though the topographical and hydrographical conditions of these regions are not unfavourable for such structures; that the *fascine* dwellings in Europe were identical in structure with the crannogs; and that, though the pile-dwellings were not largely used in the British Isles, the principles on which they were built were not unknown, their disuse being due to topographical and other considerations. Finally, he argued that the wideness in the chronological gap which is supposed to separate the crannogs from the lake-dwellings of Europe is more apparent than real, as the latter existed during the Roman occupation of Gaul, and in one instance at least the custom survived to about the tenth century.

Prof. D. J. Cunningham exhibited a large coloured plate of sections of a young chimpanzee, illustrative of some important points of comparison between the chimpanzee and man. Prof. Cunningham said that he had purchased a male chimpanzee, which was said to have died in the process of second dentition, and which he believed to be about six years of age. The body of the chimpanzee was frozen for two days, and he now exhibited the sections of the chimpanzee for the purpose of showing one or two points of comparison between the chimpanzee and man. Any one looking at the plate would be attracted to the region of the face, where the protrusion was shown which was so well seen in the living animal. If they compared it with the corresponding section of man they would find brought out very forcibly the elongated brute-like tongue of the chimpanzee. An anatomist looking at the section now exhibited would fix his attention at once upon the spine. In man the spinal form was beautifully curved. It showed an alternation of curves in the different regions of the body, and to these curves in the spine of man in a great measure was due in his erect attitude. It was remarkable that the chimpanzee even at six years of age there was a very manifest lumbar curve. In the Biological Section that day there had been described the spine of a child six years of age, and it was remarkable that the lumbar curve in this chimpanzee of a corresponding age was very much more marked than in the child. At six years the chimpanzee was much more advanced in life than a child six years old, and therefore his lumbar curve was correspondingly greater. If they wished to get at the distinction between the spine of man and the chimpanzee they must look lower down at the sacrum. After noticing one or two other points, Dr. Cunningham drew the conclusion that the human child occupied an intermediate position between the chimpanzee and the human adult. In the plate he now exhibited they would see compared the skull of the chimpanzee with that of man, bringing out that the cerebral or larger brain in man extended a good deal further back than in the chimpanzee; and there was not much difference between the New World ape and the chimpanzee in that respect.

Dr. J. G. Garson, one of the secretaries of the Section, read a paper on *Abnormal and Arrested Development as an Induction of Evolutionary History*. Dr. Garson began by stating that, perhaps, the most fertile source of information regarding the history of man's evolution was derived from a study of his embryological development. Another source from which much valuable information regarding the early history of our own specialisation, and that of other animals, might be gleaned, was Teratology, which had for its domain the consideration of abnormal conditions of development. Many of the conditions included under this branch were of a pathological nature, and due to the effects of disease; others, however, were not—such, for example, as an abnormal and an unusual production of normal structures and cases of arrested development. It was to a consideration of some conditions occurring under one or other of these categories that he ventured now to call attention. The examples which he had selected had come more especially under his own observation. Persons were occasionally found with abnormal development of hair on their bodies. The type of mammal was an animal whose body was covered with hair. Under certain circumstances the hair might more or less disappear, according to the conditions under which the animal lived. In man it was only feebly developed, except on the head; and in the cetacea or whales it had entirely disappeared, with the exception of a very few bristles near the mouth. Dr. Garson proceeded to explain how excessive development of hair takes place in man. In ordinary cases the hair-growing apparatus in the embryo remained stationary, instead of keeping pace with the growth and development of the other organs of the body, with the result that no hairy covering such as was found in other mammals was present, but only short rudimentary hairs appeared at intervals. But in some exceptional cases this stationary condition of the hair follicles did not occur, and they went on actively developing with the rest of the body, with the result that a hairy covering was produced over the body. The hairless condition now normal in man had evidently been gradually acquired through a long period of time, as such a change could not take place rapidly and become such a stable condition as it was found to be otherwise. Abnormal development of fingers occurred sometimes in man, but must be classed entirely apart from such forms of abnormality as had been considered in the hair-growth. In arrested development the abnormal organ or portion of the body, instead of going through the various stages it usually does till it arrives at the condition it normally assumed in the group of animals in which it occurs, stops short at one or other stages. The stage at which it stops may correspond to that which is normal in a lower grade of animal life, and so gives direct evidence that the higher forms of animal life, such as man, pass through and beyond the stages at which the lower stop. It must not be forgotten also that in some respects an animal of a lower grade may possess specialisations in some structures or organs of a higher ground than animals much higher in the scale of life.

Dr. Robert Laws, from Livingstonia, Lake Nyassa, East Central Africa, read a long and interesting paper descriptive of the manners and customs of the Bantu tribes living around Lake Nyassa in Eastern Central Africa. In the outset of his paper Dr. Laws said that Lake Nyassa was 350 miles long, and varied from 16 to 60 miles broad, and around that vast inland sea they knew of fifteen different tribes, speaking so many different languages, besides dialects of these languages. Though these tribes had much in common, they differed among themselves in many of their habits, customs, and religious beliefs. He proceeded to notice the names and residences of the leading tribes, and gave a brief summary of what was known of their history. As a rule, he said, the people of all these tribes were physically developed, but their vigour and general healthy condition differed considerably, depending chiefly on the climate, soil, and food. Where maize and mapira were the staple foods, the natives were strong and hardy. Where cassava root was their chief food, and especially if along with that there was a state of actual or dreaded warfare, the people were weak and sickly. On the hills the people were hardier and more vigorous than on the lake-shores and on the river-banks. Mental energy was greater on the hills than at the lake-side, and at places where there was most radiated heat this was less than where the breezes played freely. Keenness of vision and acuteness of hearing were spoken of as being remarkable in civilised tribes, and among the lake tribes these faculties attracted the attention of travellers, but Dr. Laws was inclined to attribute these characteristics to training and exercise in given directions rather than to any radical superiority in the organs of sight and hearing among the tribes. All the tribes depended principally on agriculture for their support, and the only appearance of a rudimental division of labour was to be found in the classes of fishermen and blacksmiths. No traces of a Stone age had been found among these tribes. Yet in certain districts they were to be found cultivating their gardens with tools of hard wood instead of iron, distance from markets being the cause of their use. At the east side of Nyassa many lake-dwellings were found in 1875, and often on war being threatened the inhabitants of the lake shore took refuge by living in such constructions. Iron mines had been found, and copper had been found in one of those near the Livingstone range. The iron of the mines was usually near the surface. Charcoal was used for smelting. Dr. Laws went on to describe the manner in which the tribes made their canoes, their nets, and their huts. Fire was procured among them by the rapid rotation of rods of wood between the hands, the spark being caught in cloth and kindled into a flame. The natives exhibited great surprise when they saw the traveller strike a lucifer match, and that was regarded by them as an unquestionable proof of his superior knowledge. The natives indicated time by pointing to the position of the sun. They named Sunday as the day of God, Monday as the day for beginning work, Saturday as the day for stopping work. The intermediate days were indicated by numbers. The eclipse of the moon was described as the moon put in a bag, and comets as stars with tails. Slavery was common in all the tribes, and half of its horrors had not been told. Infanticide was not practised, but infant mortality was very high, and cases had been found of children labouring under a lingering disease having been buried alive. Polygamy was common, and the number of a man's wives taken as an index of his wealth. One chief told him he had a hundred wives, and he (Dr. Laws) believed he was rather under-estimating than over-estimating the number. The early marriage of girls was the rule, and in one tribe a girl was often betrothed before she was born. In buying land they had to buy it first from the chief and then buy the tenant-right from the cultivators. After describing the customs of the tribes relating to the punishment of crime, Dr. Laws concluded his paper by noting the leading peculiarities of the language of the tribes, directing especial attention to the complications in the forms of speech, and especially to the extraordinary number of variations in the verbs.

Mr. E. H. Man contributed a paper on *The Nicobar Islanders*. —In the interior of Great Nicobar there is a wild race, styling themselves "Shab Dawá," of whom as yet little information has been obtainable; they are distinct from the inhabitants of the other islands and of the villages on their own seaboard, who are of Malay origin, and by whom they are called "Shom Peñ" ("Shom" denoting tribe," and "Peñ" being the tribal designation). It appears certain that they are the descendants of a very ancient aboriginal population of Mongolian origin. The first mention that we find of them is from the pen of pastor Rosen, a Danish missionary, who, while resident at the Nicobar Islands between the years 1831–34, spoke of them, from hearsay, as in much the same degraded condition as we find them at the present day. He said that "they wear no clothes, possess no houses, live like animals in the depths of the forest, and shun the sight of men, never leaving their lairs except to search for food, which they sometimes steal from such of the coast huts as are temporarily vacated or occupied only by a few aged or infirm folk whom they are able to surprise or overpower." In 1876 and 1881 a few members of this tribe living near the north-east of Great Nicobar were seen by the late Mr. de Röepstorff, who was accompanied in the latter year by Col. T. Cadell, V.C., Chief Commissioner of the Andamans and Nicobars. During the last eighteen months Mr. E. H. Man, while in charge of the Nicobar Islands, has paid six visits to Great Nicobar, on four of which he succeeded in seeing and photograhing parties of this tribe, both near Ganges Harbour and on the west coast. On the first of these occasions (viz. February 1884) two youths, aged about eighteen and fourteen years respectively, were persuaded to leave their friends for seven days, at the end of which they were conveyed back from Nancowry in the settlement steamer. During their visit to Mr. Man they proved themselves tractable and timid, and submitted with a good grace to ablutions which were found very necessary. Although this is the first recorded instance of a Peñ having ventured from his savage haunts, these lads exhibited the Oriental characteristic absence of wonderment at all the novel surroundings and tokens of civilisation in the Government settlement. They were fair specimens of their race, the members of which are found to be usually well nourished, of good physique, and, while young, favoured with pleasant features. The height of the males appears to range between 5 feet 2 inches and 5 feet 8 inches; their skin is fairer than that of the generality of the coast people, who, on their part, are less dark than the Malay; the hands and feet seem to be decidedly large, and bear evidence of the rough work of their daily lives; the hair, which is straight, is commonly worn uncut and unkempt, and, as habits of cleanliness are manifestly foreign to their nature, its condition can better be imagined than described. As a result of their friendly intercourse in recent years with the coast people, they have acquired the habit, so universally practised among the latter, of chewing the betel-nut (*Chavica betle*) with or without quicklime, and are consequently beginning to be similarly disfigured with black teeth, though not yet to the hideous extent common among their more civilised, or, rather, less savage, neighbours. They likewise now imitate the latter in respect to clothing, the men adopting the narrow loin-cloth and the women a small cloth skirt. Their dwellings are small, and cannot compare with those of the coast people, and are indeed but little, if at all, superior to those of the Negritos in Little Andaman, but they more nearly assimilate the former in design as well as mode of construction, for they are erected on posts; the floors being raised 6 or 7 feet above the ground necessitate the use of ladders. It is impossible, within the limits of this abstract, to make further mention of the dwellings, or to describe the peculiar sack-like cooking-vessels of this strange race. Mr. Man hopes before long to be able to supplement in many particulars the rudimentary information which has hitherto been obtainable regarding the Peñ, but the task is one of considerable difficulty, for, apart from the dread entertained by this tribe towards aliens, their frequent feuds place from time to time a temporary barrier to all intercourse between them and our friends on the coast, through whom at present all our communications have to be conducted. The nearest portion of Great Nicobar Island is, moreover, about 60 miles distant from the Government settlement at Nancowry.

SCIENCE IN RUSSIA

THE Kazan Society of Naturalists continued last year its valuable explorations of Eastern Russia, and we have before us several new fascicules of its *Memoirs* and *Proceedings*.[1] M. Ivanitsky publishes a list of plants of the Government of Vologda, which contains 804 Spermatophytæ, Gymnospermæ, and Sporophytæ. As to these last, only 6 Equisetaceæ, 5 Licopodiaceæ, and 20 ferns being given, the list obviously will be much extended by subsequent research. The flora of Vologda, which is situated on the limits of the middle and Arctic Russian floras, offers a certain special interest, and M. Ivanitsky has not neglected to mention the wild and cultivated plants which find their northern limits within the province. It consists chiefly of Compositeæ (107 species), 49 Cyperaceæ, 48 Gramineæ, 41 to 34 each of Ranunculaceæ, Caryophylleæ, Rosaceæ, and Cruciæeræ, 27 to 22 Papilionaceæ, Scrophulariæ, Labiatæ, Salicineæ, and Polygonaceæ, and 21 to 19 Umbelliferæ, Filices, and Orchideæ. The list of plants is prefaced by a masterly sketch of the physical conditions of separate parts of the province. The same volume contains a paper by. M Mislavsky on the irritability of the nervous-muscular system, being an inquiry into the causes of the well-known differences of the effects of electrical irritation on the frog, when measured by the methods of Dubois-Reymond. All causes which may depend upon the conditions of the experiments themselves having been eliminated, there still remain notable differences which must be ascribed to the state of the system altogether. A paper, by Th. Tsomakion, on the laws of transmission of electricity through gases, embodies the results of several new experiments in this field. In a former inquiry the author, by introducing into the chain of condensation a discharger where the discharge could take place only at close contact of the two electrodes, had experimentally proved the law, already deduced by Forselman and Heer, that the whole amount of heat produced at the discharge of the condensator does not depend upon the composition of the chain. But as soon as he introduced a layer of gas between the electrodes, he found that his results widely differed from all previously obtained by other students; he undertook a series of experiments for discovering the sources of that discrepancy of results, and he has arrived at a long series of conclusions which are of great interest, but ought to be submitted to a closer inquiry. This last is continued.—To the same vol. xiii. M. Zaitseff contributes a paper on the petrography of the crystalline rocks in the neighbourhood of Krasnovodsk, on the eastern shore of the Caspian. The chief rock in the Shakh-Adam Mountains, which reach about 600 feet above the sea, is a massive, unstratified quartz-dioritic porphyrite (according to the classification of Herr Rosenbusch). Between the bays of Muravioff and Soymonoff the rocks are closely akin to the above, and might be described as a quartz-mica-diorite. The former extends also for some miles east of Krasnovodsk, and is intersected by veins of a muscovite-granite (according to Herr Rosenbusch's classification) and quartz porphyry of rare occurrence, its magnesial mica being replaced by a potassium mica.—The same author contributes two papers on the petrography of the Soymonoff valley in the south-east part of the district of Ekaterinburg, which incloses the 3200 feet high Yurma summit and several high ridges of mountains. The author makes a detailed inquiry into the structure of the crystalline rocks of this locality (granites, gneisses, and various schists), and is inclined to admit that at least one part of the olivine-bearing serpentines endow their origin to the metamorphism of the actinolite schists. The iron ores and gold-bearing deposits are also described, the age of these last being undoubtedly settled as Post-Pliocene, as they contain numerous remains of Mammoth, *Bos primigenius*, *Cervus tarandus*, and *Cervus alces*. We may remark that the very high position of several gold-bearing deposits on the slopes of the valleys and their structure is one testimony more in favour of their glacial origin, but the author does not touch this interesting question. He mentions also—a fact which has often been doubted, but is now confirmed more and more—that the gold of these deposits is derived from the decomposition of the chloritic slates. The papers are accompanied by a geological map. In the same volume (fasc. 4) we find a preliminary report, by S. Korzinsky, on a botanical excursion into the delta of the Volga. The list of plants is not yet given by the author, and he publishes only a valuable sketch of the general characters of the delta, distinguishing in it two different regions: the delta proper, which consists of fluviatile deposits; and the Steppe region, covered with the so-called *bougry*, or a kind of *kames*, first described by Karl Bear and still bearing his name, about which *bougry* the author holds a different opinion as to their origin, denying—with full right, we suppose—their origin from the retreat of the Caspian.

As to the *Proceedings* of the Kazan Society, we are glad to learn from them that three new meteorological stations (at Sarapul, Tcherdyn, and Debessy) have been added to those already organised by the Society. There was a great want of meteorological observations precisely for that part of North-East Russia. Several shorter papers are embodied in the *Proceedings*:—On the geology of the Vetluga region, by P. Krotoff (a polemic concerning the Permian and Trias, as also the southern limit of the boulders).—On the fauna of Kazan (between the Kama and Vyatka), by N. Varpakhovsky. The author gives the lists of fishes found in the lakes and rivers, and lists also of serpents and amphibians of the region.—On the preparation

[1] *Trudy Obschestua Estestvoispytatelei pri Kazanskom Universitete*, vol. xii. fasc. 5 and 6; vol. xiii. fasc. 1 to 4.—*Protokoly* (*Proceedings*) of the same for the years 1883 and 1884.

of tripsine, by V. Nikolsky.—On the *bougry* of the Caspian, by A. Zaitseff. They do *not* have the uniformity of structure supposed by Baer; they often cross one another at angles of 20° to 30°, and some of them follow a north-eastern direction, while others, close by, run west and east; and they contain not only broken mussels, as affirmed by Baer, but also plenty of quite full mussels of *Cardium trigonoides*, *Dreissena polymorpha*, *rostriformis*, and *caspia*. The theory of Baer altogether is based on an insufficient supply of data, and the structure of the *bougry* ought to be better explored before pronouncing as to their origin.—On the sulphur ores at Tetushi, on the Volga, by G. Wilenius.

The fourth volume of the "Collection of Materials for the Description of Caucasus,"[1] published by the schoolmasters of Caucasus, contains, as usual, much valuable information, especially of historical and ethnographical character. M. Hahn contributes a most valuable paper of 250 pages, in which he has compiled all information on the Caucasus he was able to discover in authors since Homer up to the fifth century of our era. The information gathered from Byzantine writers who have much more written about the Caucasus, will be embodied in a second part of the work. The importance of this very careful work, where textual translations are given of passages dealing with the Caucasus and its inhabitants from no less than eighty Greek and Latin authors, will be fully appreciated by all those who have to deal with the geography of the country. A complete index will much facilitate the research. M. Eivazoff gives a description of the Aisores of Koilasar, of their manner of life and customs, followed by an Aisor alphabet; and M. Arkannikoff contributes a detailed description of the town Temruk and of the Temruk mouth of the Kuban River. In the second part of the same collection we find a series of interesting notes on the Tchokh village in Daghestan, on Daghestan legends, and on the life of Abkhazes; a collection of Little Russian songs from Kuban; and two lectures on the beautiful seven-centuries-old Georgian poem of Shota Rustaveli.

SCIENTIFIC SERIALS

THE *Journal of Physiology* for July contains:—Note on the cause of the first sound of the heart, by G. F. Yeo and J. Barrett.—An experimental investigation to ascertain the action of veratria on a cardiac contraction, by S. Ringer (plate 2).—Concerning the action of small quantities of calcium, sodium, and potassium salts upon the vitality and function of contractile tissue and the cuticular cells of fishes, by S. Ringer and D. W. Burton.—A study of the action of the depressor nerve, and a consideration of the effect of blood-pressure upon the heart regarded as a sensory organ, by H. Sewall and D. W. Steiner (plate 3).—On secondary and tertiary degenerations in the spinal cord of the dog, by C. S. Sherrington (plates 4 and 5).—On the structure and rhythm of the heart in fishes, with especial reference to the heart of the eel, by S. A. M'William (plate 6).—The innervation of the heart of the Slider terrapin (*Pseudemys rugosa*), by J. Wesley Mills.—Note on the sound accompanying the single contraction of skeletal muscle, by E. F. Herroun and G. F. Yeo.

The Journal of Anatomy and Physiology for July contains: Account of some recent experiments on the effects of very low temperatures on the putrefactive process and some vital phenomena, by J. J. Coleman and J. G. McKendrick, M.D.—Accessory lobe to the left lung, by L. Humphry, M.B. (plate 17).—Case of abnormal development of the reproductive organs of the frog, by A. F. S. Kent (plate 18).—Rotation and circumduction, by Thomas Dwight, M.D.—Movements of the ulna in pronation and supination, by C. W. Cathcart, M.B.—Anatomy of a hydro-monocephalous brain, by A. Hill, M.D.—Corpus callosum in the adult human brain, by Dr. J. Hamilton, (plates 21 and 22).—Tumours in animals, by J. B. Sutton (plate 23).—Hyomandibular clefts and pseudobranchs of Lepidosteus and Amia, by R. Ramsay Wright (plate 24).—Anatomy of *Spinal bifida*, by Prof. Humphry.—Notes on some variations of the shoulder muscles, by W. B. Ransom.—Tarsus and Carpus, by Prof. K. Bardeleben.

The Quarterly Journal of Microscopical Science for July contains:—On spermatogenesis in the rat, by Herbert H. Brown (plates 22 and 23).—A simplified view of the histology of the striped muscular fibre, by B. Melland (plate 24).—On the development of a freshwater macrurous crustacean (*Atyephora compressa*), by C. Ishikawa (plates 25–28).—On the supposed communication of the vascular system with the exterior in Pleurobranchus, by A. G. Bourne, D.Sc. (plate 29).—Observations on the nervous system of Apus, by P. Pelseneer (plate 30).—Note on the chemical composition of the zoocytium of *Ophrydium versatile*, by W. D. Halliburton, M.D.—The development of *Peripatus capensis*, by A. Sedgwick, M.A. (plates 31 and 32).

The Journal of the Royal Microscopical Society for August contains:—The pathogenic history and the history under cultivation of a new bacillus (*B. alvi*), the cause of a disease of the hive bee hitherto known as foul brood, by F. R. Cheshire and W. Watson Cheyne, M.D. (plates 10 and 11).—Experiments on feeding some insects with the curved or "comma" bacillus, and also with another bacillus (*B. subtilis?*), by R. L. Maddox, M.D.—On four new species of the genus Floscularia and on five other new species of Rotifera, by C. T. Hudson, LL.D. (plate 12), with the usual summary of current researches.

The American Naturalist for September contains the reputation of the Lantern fly (*Fulgoræ lanternaria*), by John C. Brauner. To the bibliographical references made in an editorial note to this paper may be added the spirited discussion on the whole subject in the *Entomological Magazine* of 1836.—The age of forest trees, by J. T. Campbell.—The relations of mind and matter, by C. Morris.—The exhalation of ozone by odorous plants, by J. M. Anders and G. B. M. Miller.—Glacial origin of Presque Isle, Lake Erie, by J. D. Ingersoll.—Recent literature and general notes.

The Proceedings of the Linnean Society of New South Wales, vol. x. Part 1 (June 4).—The papers in this part are of great interest, and worthily sustain the credit of this most active and energetic Society. *Zoology* — Dr. R. von Lindenfeld, On Australian sponges, part iv. The Myxospongiæ, with 5 plates. On *Amœba parasitica*, a new protozoon infesting sheep. On the Phoriospongiæ.—William Macleay, On a new snake from the Barrow Ranges, and On some reptiles from Herbert River.—A. S. Oliff, On some Ceylonese Coleoptera.—J. Brazier, Synonymy of some shells described by Dr. Gray.—W. A. Hasnell, On some Australian Amphipods, with 9 plates.—Captain Hutton, Revision of the Toxoglossate mollusca of New Zealand.—J. Douglas Ogilby, Some rare Port Jackson fishes. *Botany*—Dr. W. Wools, Australian Proteaceæ. *Palæontology*—F. Rattle, On a Devonian Australian fossil allied to Worthenia, with a plate; also on the Glacial period in Australia; and on the meteorology of Mount Koskiusko, by Dr. von Lindenfeld, with two plates.

Morphologisches Jahrbuch, Band 11, Heft 1, contains:—Contribution to a knowledge of the renal organ of the Prosobranchia, by Dr. B. Haller (plates 1–4).—On the morphological significance of the nucleus, by Dr. W. Pfitzner (plate 5).—Short contributions to a knowledge of some marine Rhizopods, by O. Bütschli (plates 6 and 7).—On the significance of the *Linea semicircularis Douglassii*, by Bernhard Solger.—Notes on Apseudes, by J. E. V. Boas.—Short Notes.

Zeitschrift für wissenschaftliche Zoologie, Band 42, Heft 1, July 24, contains:—A biographical sketch of Carl Theodor Ernst von Siebold, one of the founders of the *Zeitschrift*, by Ehlers (with a photograph).—On the significance of the nucleus from the point of view of evolution, by Prof. A. Kölliker.—Researches on some Flagellates and kindred organisms, by Dr. C. Fisch (plates 1 to 4).—On the anatomy of the Amphisbœna, by Dr. Carl Smalian (plates 5 and 6).

Band 42, Heft 2, August 18, contains:—An essay on the history of German slugs, and on their European allies, by Dr. H. Simroth. This monograph is illustrated by five plates, that of the species being coloured.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, October 5.—M. Bouley, President, in the chair.—Spectral analysis of the elements of the terrestrial atmosphere, by M. J. Janssen. The author describes the special arrangements that have been made at the Meudon

Observatory for the study of the hydrogen, oxygen, and other substances present in the terrestrial atmosphere. Four tubes, one 60 metres long, have already been fitted up in a chamber in which solar, electric and other lights can be employed under favourable conditions.—Thermic studies of the aromatic series: the phenols of complex function, by M. Berthelot. New characters derived from thermo-chemistry have been determined for the purpose of distinguishing the various isomerous groups of the aromatic series and disclosing the phenolic function belonging more particularly to some of these groups. In order to establish the general character and importance of this new instrument of research, the author continues his experiments with the compounds derived from the oxybenzoic acids, to which the synthesis of vanilline and the allied substances has given so much interest. The results already obtained establish a perfect agreement between the thermic indications and the chemical theories respecting the complex phenolic functions.—The treatment of mildew and rot with a mixture of lime and sulphate of copper, by M. A. Millardet. During the present season M. Nathaniel Johnston has applied this new process to 50,000 vines in the Médoc district with complete success. The plants so treated are in a perfectly healthy state, while those not treated are in a wretched condition.—On the destruction of mildew by the sulphate of copper, by M. A. Perrey. A solution of 5 per cent. of sulphate of crystallised copper has this year been successfully and economically applied to vineyards in Burgundy hitherto unsuccessfully treated with sulphur.—Ravages of mildew in the northern districts of Touraine during the present year, by M. Larreguy de Civrieux. The disease broke out suddenly a few days after a violent storm in July, attacking several varieties of the vine and the oak trees of the surrounding plantations to the exclusion of all other plants.—Note on the quadratic forms in the theory of the linear differential equations, by M. Halphen.—On the physiologic action of the salts of rubidium, by M. Ch. Richet. Subcutaneous and intra-venous injections of the chloride of rubidium applied to frogs, fishes, rabbits, guinea-pigs, and pigeons, show that this metal has the same toxic effect as potassium, but somewhat less virulent.—On the internal phenomena of muscular contraction in the striated primitive fasces in *Corethra plumicornis* and the frog, by M. F. Laulanié.—Line of development followed by the inoculated virus of tuberculosis in man, the rabbit, and guinea-pig: application to the study of inoculation and re-inoculation for tuberculosis, by M. S. Arloing.—A remarkable vegetable centre in the peninsula of Brittany, by M. L. Crié. Of this vegetable zone the characteristic species appear to be *Narcissus reflexus*, Lois.; *Eryngium viviparum*, Gay; *Omphalodes littoralis*, Leh.; and *Linaria arenaria*, D. C.—Application of thermo-chemistry to the explanation of geological phenomena; general principles; ores of manganese, by M. Dieulafait. The principle is laid down that of all the natural combinations of each metal, that which developes the greatest heat in its formation occurs most extensively in nature, and must be regarded as its principal ore. Applying this principle to the study of manganese, the author finds that the ores of this metal exist in nature in the relative proportions and under the conditions anticipated by the laws of thermo-chemistry.—On the whirlwinds observed by aëronauts, by M. Diamilla-Müller. These whirlwinds are attributed to the collision of two atmospheric currents coming from opposite directions, and are compared with the eddies produced in streams by analogous causes.—Note on a meteor observed at Saigon, Cochin-China, on August 22, 1885, by M. Réveillère.—Kinematics of the locomotion of quadrupeds: trajectories and comparative velocities of the pastern and hoof of the horse at the different phases of its motion.

Stockholm

Academy of Sciences, September 16.—The following paper was presented and accepted for publication in the *Proceedings*:—"Nouvelles Observations sur les Traces d'Animaux et d'autres Phénomènes, d'Origine purement mécanique, décrits comme Algues fossiles," by Prof. A. G. Nathorst.—Experiments to determine with the galvanometer the limits of elasticity and the absolute tension of iron wire of different thickness and with varying contents of carbon, by Dr. P. Isberg.—Researches on the influence of temperature on the electromotoric force of certain electric pile combinations, by Dr. F. Kahlmeter, both the latter papers being presented and explained by Prof. Edlund.—Prof. Wittrock referred to a report left by the late Dr. Lönnroth on his botanical journey to Gothland and Östergötland, chiefly to study the Hieracia, at the expense of the Academy, and to a paper presented at a previous meeting and prepared in the Botanical Section of the Natural History Museum by Herr R. Boldt.—Contributions to our knowledge of the chlorophyllophyceæ of Siberia. He further presented and explained the two following papers, viz.:—Contributions to our knowledge of the development of the physiological tissue of some algæ, by Herr N. Wille, and contributions to the flora of the American Desmidicæ, by Herr G. Lagerheim.—Prof. Chr. Aurivillius presented a paper, "Conspectus Generum et Specierum Microceridarum," and gave a review of the same. He further exhibited living specimens of the slave-keeping ant, *Polyergus rufescens*, recently found by him near Stockholm.—Prof. Nilsson presented a paper prepared by himself and Prof. O. Petterson, "Nouvelle méthode pour déterminer la densité de vapeur des corps volatisables en même temps que la température y appliquée," and gave a review of its contents.—The Secretary (Prof. Lindhagen) presented the following papers, containing the results of researches made at the Upsala Chemical Laboratory:—On the production and nitrification of kumenylacryl acid; on the ortoderivates of kumenylacryl acid and the new indigo and chinolin-derivates obtained from the same; on the meta-derivates of kumenylacryl acid, and on derivates of kumenylacryl acid formed through substitution in the group of the acryl acid: all four by Dr. O. Widman.—Researches on the dependence of galvanic resistance in certain alloys of tin and bismuth on time, by Dr. G. Bäcklin.—On capacity of saturation and atomic weight, by Dr. J. R. Rydberg.—On Polyarsenite, a new mineral from the mine Sjögrufvan, in the province of Örebro, by Herr L. J. Igelström.—Remarks on the genus Cysteosoma, Guérin-Méneville, by Dr. C. Bovallius.—On the Lake Wettern and the formation of Visingsö, an island, by Dr. G. Holm.

AMERICAN ANTHROPOLOGY

Reizen en Onderzoekingen in Noord-Amerika. Van Dr. H. F. C. Ten Kate, Jun. (Leyden: Brill, 1885.)

Prehistoric America. By the Marquis de Nadaillac. Translated by N. D'Anvers. Edited by W. H. Dall. (London: Murray, 1885.)

The Lenape Stone; or, the Indian and the Mammoth. By H. C. Mercer. (New York: Putnam, 1885.)

DR. TEN KATE (son of the celebrated Dutch painter) has published the account of his late anthropological journey in the regions about Arizona and New Mexico. His exploration was supported by the Government of Holland, for whose Rijks Museum at Leyden he brought home a collection illustrating the peculiar civilisation of the Pueblo Indians and their wilder neighbours of the plains; also by several scientific bodies, among them the Anthropological Society of Paris, for which he took body-measurements of the various tribes he met with. Belonging to the school of observers who depend on the measurement of skulls as a means of classing the natives of America into stocks of the general Mongoloid race to which they primarily belong (p. 432), he has to deal with the interesting problem, what relation the ruder and fiercer tribes bear to the comparatively cultured and peaceable dwellers in the pueblos. This, however, is confused by the fact that among neither is the type uniform. Dr. Ten Kate (p. 173) recognises among the Apaches two or three varieties, one more Mongolian and especially seen among the women, the others more of the bold-featured Redskin-type. The brachycephalic and occipitally flattened skull which he considers especially characteristic of the Pueblo Indians, enables him to contradict (p. 155) the opinion that the handsome Pimas belong to these. But then he finds it necessary to divide the Pueblos into much the same Mongolian and Redskin types (see his remarks on the Moquis, p. 253). On the whole his observations do not seem incompatible with the view that the difference between the roving Indians of the skin tents and the tillers of the fields around the towns of mud-brick houses depends less on race than on difference of stage of civilisation, itself due in great measure to the respective circumstances of a wild life of war and plunder or a tame life of peace and industry. That the neighbourhood of the nations of Old Mexico may have influenced the civilisation of the Pueblo tribes is likely enough, but Dr. Ten Kate argues on grounds both of skull-measure and language (pp. 265, 221) against any identification of Zuñis or Moquis with Aztecs. Indeed, it is the general experience of anthropologists, in spite of resemblances in such matters as the step-pattern on the pottery, that the language, customs, and religion which the natives of Zuñi or Tehua have preserved since the Spanish Conquest, show original and peculiar types which are not to be accounted for as borrowed from Mexico. Thus the designs on the earthen water-vessels, when explained, prove not to be copies of Mexican ornaments, but mostly direct symbolic pictures, a spiral for the whirlwind, a semicircle with descending lines for a rain-cloud, &c. This even affects the argument that the celebrated "cliff-dwellings" of the district were the strongholds of the ancestors of tribes such as the Moquis, who claim to continue and interpret the designs on their pottery (p. 265). Dr. Ten Kate had the good fortune of visiting Hualpé with Major Powell and seeing the Moqui snake dance (p. 242). He was allowed to go down the *estufa* to see the paraphernalia of the dancers and the vessel of drink taken as prophylactic against rattlesnake-bites, and his account of the dance itself, particularly as to the way in which the rattlesnakes are carried in the mouths of one set of dancers while another set by tickling them with feathers prevents their striking, is much in the same terms as that given by Capt. Bourke (see NATURE, vol. xxxi. p. 429). Mr. Cushing was still at the pueblo of Zuñi under his Indian name of Ténatsali or "Medicine Flower," and with his guidance Dr. Ten Kate had opportunities of studying the social life of the interesting matriarchal community. The main features of the family system are now clear, as to the young man being chosen by the young woman as "hers to be" (*yiluk'ianiha*) and his being taken by her father into the house as pupil (*talahi*); thus he passes into the position of a husband who can be sent back to his home, and the father of children who belong to their mother and inherit only from her. But in this and other accounts there are indications of what is evident to every traveller who has visited a Zuñi home—that the father after all has real power even in that matriarchal household. It is to be hoped that Mr. Cushing, when he gives the world his long-expected treatise on Zuñi language, manners, and religion, will be able to make the practical working of the matriarchal life more perfectly intelligible to the prejudiced patriarchal mind of the white man. Dr. Ten Kate inspected characteristic tribes throughout the New Mexican district, from these comparatively high Zuñis down to the low Utes, noting details of customs and other anthropological material which at times illustrate the effects of intercourse through a yet wider range of culture. Thus the wooden plough and creaking ox-cart of ancient Rome, introduced into America by the Spanish conquerors, are to be seen at work in the fields around the pueblos; and white men passing near an Indian cairn still throw each a stone upon it for luck (p. 271).

The well-known questions as to America before the time of Columbus may be counted on more than ever to arouse the interest of even the "general reader"—whether and how the natives came across from Asia, whether they made or imported the peculiar civilisations of Mexico and Peru, and so on. Thus it was quite worth while to translate the Marquis de Nadaillac's "Amérique Préhistorique," with its summaries of information and illustrations borrowed from the best sources. The work has been improved by being edited by Mr. W. H. Dall, whose own researches in the Aleutian region form one of the most interesting chapters in the anthropology of America. In the first place, the interesting though as yet hardly clear evidence is fairly given as to man's existence in America before the recent geological period. One of its most curious details is the description by Ameghino the geologist (p. 29) of his finding human remains on the banks of the Rio Frias, some twenty leagues from Buenos Ayres, associated with charcoal, potsherds, and stone arrow-heads, near the carapaces of gigantic extinct armadillos (Glyptodon) which had served as ready-made roofs to the pits in the ground which formed the dwellings of the ancient savages of the Pampas. It seems that, though the relater was a well-known geological explorer, his account was received with such incredulity, even in the district, that the Argentine Scientific Society refused to allow a paper to be read before them. The present volume, however (p. 477), contains particulars of a further discovery of the same kind, a human skull and most part of the skeleton having been found below an inverted Glyptodon carapace. This is not indeed conclusive, on account of the frequent displacement of the Pampas soil by floods, and even were the contemporaneity of man and Glyptodon made out, the upper bed containing the remains of this huge edentate may be more recent than the quaternary date. But no doubt there will be more finds, and it may help the discussion to point out that there seems nothing improbable in a man's living under a Glyptodon shell four or five feet long, inasmuch as there is classical authority for such habitations in the Old World. The natives of Ceylon, according to Ælian, could live under their great turtle-shells as roofs; so Pliny mentions the Chelonophagi of the Persian Gulf covering their huts with the shells of turtles and living on the meat. It is to be feared that the late Dr. Lund's researches in the limestone caves of Brazil, claimed as proving that the American man was a contemporary of the extinct megatherium and horse, were not made accurately enough to be relied on now, but it is well to keep them in view to encourage similar research. On the northern continent, Dr. Abbott's rude implements of argillite trap are the most remarkable objects claimed as the work of Glacial man, and they have proper description and drawing here, while every other discovery worthy of any consideration receives it. As is usual in French works, proofs of the high geological age of man are received somewhat more readily than in our more sceptical English literature. An unusually full account is given of the shell-heaps which fringe the coasts of both Americas, sometimes fifty feet thick and more, so as even to be valuable for the supply of lime to the builders of neighbouring towns. The high age of some of these rubbish-heaps is shown by elevation of the ground having lifted them high above the sea-level where the shell-fish were doubtless cooked and eaten, while the cannibal habits of the rude savages of the shores are shown by the usual evidence of human bones split for the marrow. Probably the more recent heaps are those characterised by tobacco-pipes, and stone pestles and mortars like those in which the modern Indians bruise seeds. This seems at least a reasonable opinion notwithstanding that such stone pestles and mortars have been put forward as evidence of man inhabiting California far back in the Tertiary period. M. de Nadaillac's chapters on the mound-builders and cliff-dwellers, and the nations of Mexico and Peru, give much popular information. The original French work discussed at some length the native American legends of deluges and other catastrophes, commemorating the mythic forefathers of nations and introducers of religious laws, and arts; but the American editor, with better judgment of the historical value of these tales, has pared them down, leaving the reader to form his judgments on more solid matters. Should a new edition of "Prehistoric America" be demanded, it will be well to have the press more carefully corrected. So well-known a living authority as Prof. Marsh figures as "March," and it is with an effort that one recognises the ancient Chinese emperor "Fo-hi" under the designation of "Fo-Fli." At p. 271, M. de Nadaillac yields to the common temptation of finding the name of the *Nahua* nation in the name of the country *Anahuac*, as if it meant "the country of the Nahuas by the water;" but this is grammatically impossible, and indeed the etymology of *A-nahuac*, meaning simply "near the water," is quite indisputable.

The interest felt by Americans in the antiquity of man on their continent is shown by the appearance of forged relics. The so-called "Lenape Stone" is one of the flat perforated stones known as gorgets, common in Indian graves, but on it is scratched a rude representation of hunters attacking a mammoth. When it was produced, Mr. Carvill Lewis at once called attention to the obvious point, that the mammoth is a palpable imitation of that of the cave of La Madeleine, whereas the hunters are imitated from the childish modern American Indian pictures on bark or deerskin. The artistic power of the men of the mammoth-period is shown by its being unconsciously conveyed through the hand of so stupid a copyist.

E. B. TYLOR

PHYSIOLOGICAL PLANT ANATOMY

Physiologische Pflanzenanatomie im Grundriss dargestellt. Von Dr. G. Haberlandt. (Leipzig: Wilhelm Engelmann, 1884.)

WHEN one recognises the immense importance of continually keeping before the student, the fact that from whatever standpoint the plant is viewed, physiological considerations must never be lost sight of, one cannot but welcome the appearance of Dr. Haberlandt's text-book on physiological plant anatomy, and one is disposed to do so with more than ordinary favour, recalling those chapters on physiological organography which appeared some three years ago in Prof. Sachs's "Vorlesungen." The subject is one to which Dr. Haberlandt has specially devoted himself, the present volume being in fact the most recent of a series of detailed publications. On this account it is not surprising to find that much of the subject-matter is not new, and that of the twelve sections into which the book is divided five have already appeared in the article in Schenk's handbook entitled "Die physiologischen Leistungen der Pflanzengewebes." Dr. Haberlandt's aim on the present occasion is to publish as complete an account as may be, of the present history of the subject, and the great point upon which he insists, is that the whole anatomical structure and the mode of arrangement of the various tissues composing the plant, are simply so many illustrations of the phenomenon of adaptation to physiological needs.

The first two sections are devoted to the consideration of the cell and the formation of tissues. The third treats of the tegumentary system, and as far as regards the epidermis special stress is laid upon Westermaier's discovery that the epidermal cells serve for the storage of water, in addition to their well-known protective function.

The important influence of cuticular wax and epidermal hairs upon transpiration is also discussed.

In Section IV. the mechanical system is considered. With much of the subject-matter of this section we have been acquainted since the appearance of Schwendener's classic "Das mechanische Princip;" but it is of interest to note that in the fungi, *e.g.* *Usnea barbata*, evidence exists of a mechanical tissue which in the higher plants takes the form of sclerenchyma, collenchyma, and bast. The absorptive system includes roots, rhizoids, and like structures; attention being also drawn to the absorptive tissue of the scutellum. This organ in *Briza minor* is peculiar on account of the pronounced development of the absorptive cells, and their striking resemblance to root hairs.

Section VII. deals with the assimilative system, and one is much struck by the marked manner in which the whole structure of the leaf illustrates the principles of which Dr. Haberlandt is the exponent. The pallisade layers are naturally regarded as being the chief seat of assimilative activity, and it is pointed out that the cells below these layers, which are of the nature of spongy parenchyma, and contain comparatively few chlorophyll grains, are distinguished by the remarkable manner in which they abut on to the pallisade cells. Their special function appears to be to conduct or absorb the products of assimilation, and to be the means of conveying them to other parts of the plant. They are in consequence designated as receptive or conducting cells (Aufnahme oder Sammelzellen). The infoldings which occur in numerous pallisade cells and are so well developed in the leaf of the various species of Pinus, have for their object the increasing of surface-area, and consequently also the number of chlorophyll grains in the cell.

Some space is devoted to the consideration of the conducting system, which includes the parenchyma of the cortex and pith, the medullary ray parenchyma, &c., the vascular bundles and laticiferous tissue.

Dealing with the vascular bundles from the point of view of physiological anatomy, a special terminology has been adopted. The whole bundle is known as the Mestom, the xylem as the Hadrom, and the phlœm as the Leptom. The idea of Mestom includes purely vascular tissue, and excludes the mechanical sclerenchymatous and fibrous tissue (stereom), consisting usually of prosenchymatous cells (sterëides), such as occur accompanying the bundles of most monocotyledons. Dr. Haberlandt's experiments demonstrate that in the moss stem the central strand of tissue is to be regarded as consisting of rudimentary hadrom, having for its function the conduction of water. To the layer surrounding the vascular bundle in roots, &c. (endodermis of De Bary) is applied the term "protective sheath," or "protective layer," on account of its function with relation to the bundle.

For a more complete understanding of the nature of laticiferous tissue we are again indebted to Dr. Haberlandt, whose observations upon this point appear to be of extreme importance. These observations demonstrate that in many of the thick-leaved Euphorbias, those portions of the laticiferous cells which enter the leaf become repeatedly branched in the leaf-tissue, and in such a manner that the extremities or blind ends of these branches abut directly on to the pallisade parenchyma cells, and are thus brought into the closest possible relation with the seat of greatest assimilative activity. The natural inference as to the function of laticiferous tissue has consequently everything to be said in its favour.

In Section IX. the intercellular space system is dealt with, and the various forms of stomata and their mechanism described. Much importance must necessarily be attached to this system when one bears in mind the relation of transpiration and gaseous diffusion to plant-life. The remaining sections are devoted to the secretory and excretory organs, and to the phenomena attending the normal and abnormal mode of increase in thickness of the stem and root.

The few remarks that have already been made are sufficient to show that the book contains numerous points of much interest. It is, moreover, carefully written, and furnished with a copious bibliography.

We cannot conclude this review without pointing out as Dr. Haberlandt has so fitly done, the importance of recognising that in every system there is not only the chief, but also the subsidiary, function, and that in considering any one of them which is especially significant, the less pronounced but still existing functions must be kept in mind. By such means alone will the true advance of physiological anatomy be maintained.

W. G.

WILLIAM HEDLEY

William Hedley, the Inventor of Railway Locomotion on the Present Principle. By M. Archer. Third Edition. (London: Crosby Lockwood and Co., 1885.)

IN this little book the author endeavours to place on record more exact facts with regard to the invention of the locomotive, and to give prominence to the name of the man who first made the locomotive a practical and financial success.

Richard Trevithick is perhaps the only man, before Hedley's time, who narrowly missed the fame now accredited to Stephenson and Hedley. In 1808 Trevithick constructed a circular railway in a field, now forming the southern half of Euston Square. On this railway he placed a locomotive of his own construction, having flanged wheels, a tubular boiler, and a vertical cylinder, driving by means of a cross head the hinder pair of wheels. This engine was attached to a coach, and the few people who would venture in it were taken round the railway at so much per head. After running for a few weeks, a rail broke, causing the engine to leave the rails, and turn over on its side. At this time Trevithick had expended all his means, and was compelled to give up his endeavours to convince the public of the many advantages to be obtained from the use of the locomotive; had he been backed up by influential men, no doubt he would now be known to fame as its inventor.

Many men before Hedley's time had tried their utmost to make a workable locomotive, such as would supersede horses on a colliery railway. Trevithick, Blenkinsop, and Chapman all exercised great ingenuity in their designs, but success was as far off as ever, owing to the general idea prevailing that some mechanical connection must exist between the engine and the railway, believing that the mere adhesion between the smooth wheels and smooth rails was completely insufficient to prevent slipping.

In the year 1812 William Hedley was viewer at the Wylam Colliery, and in order to reduce the working expenses he endeavoured to construct an engine to haul the coal waggons from the colliery to the river, and to do it cheaper than by horse haulage. At this time he had a knowledge of what others had done in this direction, but was forcibly impressed with the idea that the weight of an engine was sufficient for the purpose of enabling it to draw a train of loaded waggons. After having made successful experiments to prove the idea correct, he set to work and constructed his first engine, which, when completed, did not prove a success owing to shortness of steam, and a second one was made. The second one, the well-known "Puffing Billy," was put to work in May, 1813, and was a complete success. This may be safely called the first practical and efficient locomotive ever constructed. It had a return-tube boiler of wrought iron, vertical cylinders, and was placed on four wheels. Very soon after the engine commenced to work the exhaust steam was turned into the chimney to create a blast on the fire. This engine worked nearly continuously until 1862, when it was bought, and has now found an honourable resting-place in South Kensington Museum.

Puffing Billy was put to work in 1813, nearly a year before Stephenson's first engine was tried at Killingworth in 1814, thus proving without doubt that William Hedley was the first man to construct the first practically successful locomotive engine, and the first economical substitute for animal power.

It should not be thought that our author claims for Hedley the fame of being the first to develop the railways. Puffing Billy was at work sixteen years before the celebrated Rainhill contest took place, and ten years before locomotives were allowed to work the goods traffic on the Stockton and Darlington Railway.

Stephenson's success may be dated from the Rainhill contest in 1829; and he was one of the first men to bring the present railway system forward and develop it. At the same time William James must not be forgotten; he surveyed the Manchester and Liverpool Railway before Stephenson was placed in charge of the Railway Works, and had it not been for a difference of opinion on certain technical points, William James would have been the engineer of the line until open for traffic. Again, William James went to see Stephenson's engine, before Stephenson came to Liverpool, finding him an intelligent working man and the engine a success, he brought Stephenson to Liverpool, where he eventually commenced his successful career.

The author is to be congratulated on having proved his case, and in the preface he truly says: "Without William Hedley, George Stephenson might have lived in vain. It was William Hedley who gave the locomotive its life and power, and made the work of other men possible."

The book is very interesting, and is useful as a book of reference, the appendix containing extracts from the opinions of many writers, and letters from men able to give information on the subject. This little book will prove useful to all who wish to know the facts concerning William Hedley and his inventions. N. J. L.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Shotfiring in Mines

For some time past I have been conducting a series of shot-firing experiments at Dowlais and elsewhere on behalf of the Royal Commission on Accidents in Mines. Towards the end of August last Prof. C. G. Kreischer, of Freiberg in Saxony, visited me at Cardiff for the purpose of conferring with me on the coal-dust question. The experiments at Dowlais have a direct bearing on that subject, so, after pointing out to Prof. Kreischer the perfectly private nature of the investigation and the delicate position in which I would be placed were the results allowed to transpire through any channel other than the Royal Commission, and having received his assurance that such a contingency was impossible as far as he was concerned, I asked him to accompany me to Dowlais, so that he might witness some of the experiments on August 28 and September 1.

On the second (?) day Prof. Kreischer asked my permission to write to his friends in Germany, suggesting that they might make a few similar experiments privately in an apparatus that had been set up at Zwickau, at the expense of the Saxon Government, for the purpose of conducting a series of experiments with coal-dust. He again assured me that no publication of results would take place until after those obtained here were made known, and offered, if I had the least doubt as to the integrity of his friends, not to put it in their power to anticipate our results by not writing to them at all.

I did not feel justified in resisting such an appeal to my trustfulness, and agreed to his proposal.

A few days ago I received the following letter, which I shall be glad if you will kindly publish, along with my answer.

Sir F. A. Abel is the inventor of the dynamite water-cartridge, and not myself, as might be inferred from the article in *Glückauf*. W. Galloway

Freiburg, October 2, 1885

Hochgeehrter Freund.—Es war mir unmöglich wieder nach Cardiff zurückzukehren da wir uns zu lange im Durhamreviere aufgehalten hatten und die Zeit meiner zulässigen Bleibens in England sich allzusehr dem Ende zuneigte. Leider bin ich dadurch um das Vergnügen gekommen noch einmal mit Ihnen persönlich verkehren zu können, doch hoffe ich, dass wir uns bald einmal wieder sehen, vielleicht in Zwickau.

Die Schiessversuche mit Wasserbesatz und Pulver———der Versuchsstrecke haben sowohl in Zwickau als auch in Neunkirchen zu guten Resultaten in so fern geführt als die Gasen nicht entzündet wurden. Versuche mit Pulver und Wasserbesatz in der Plauitzer Kohle ergeben aber in so fern keine guten Resultate, als die Schüsse nicht werfen.

Leider hat Assesser Nonne, welcher den Versuchen beiwohnte, ganz gegen unsere Verabredung sogleich die Resultate; dieser ersten Versuche in einer kurzen Notiz im *Glückauf* veröffentlicht, jedoch ohne ihre Priorität zu nah zu treten, da Sie besonders darin erwähnt sind. Ich hatte ausdrücklich vor jeder Publication gewarnt ehe die Ihrige nicht erschienen sei, ein ordinärer Character kümmert sich aber um so etwas nicht.

Bei späterer Veröffentlichung der Zwickauer Versuche kann eventuel darauf Bezug genommen werden.

Nochmals für alle Liebe und Freundschaft, die sie mir so vielfältig erwiesen haben bestens dankend,

Verbleibe ich mit herzlichem Glückauf,

Ihr,

Ergebenster,

C. G. Kreischer

Herrn Bergingenieur Galloway, Cardiff

Cardiff, October 9, 1885

Dear Professor Kreischer,—I have received your letter of the 2nd inst. I observe that the friends to whom you sent a description of the shot-firing experiments have violated the conditions under which I gave you permission to make your communication to them by already publishing their results, as if they were in some sort original. You mention as a kind of palliative that, although my priority is not distinctly admitted, my name is mentioned in a prominent manner.

Personally I consider this a very small affair. Long experience of having my name mentioned in a similar manner, or mixed up with the names of others, or altogether omitted in connection with certain coal-dust matters in which I have undeniable priority, has hardened me; and I confess that this part of your letter gave me no concern. But although I could afford to pass it over in this way as far as I am myself concerned, I cannot adopt the same course when the interests of some of the members of the Royal Commission on Accidents in Mines are also at stake.

I must therefore ask you to give me a token of your good faith by restraining your friends from publishing anything further until the English Royal Commissioners shall have seen fit to make known the results obtained here. At the same time also I would suggest it as a simple matter of duty on your part to take immediate steps to let it be known to those before whom your friends' communications have appeared that the credit, if any, of the original investigations in this case rests with Sir Frederick Abel and Mr. W. Thomas Lewis quite as much as with me. Believe me yours very faithfully,

W. GALLOWAY

Herr Bergrath Kreischer, Professor der Bergbaukunde, Freiberg, Sachsen

The Resting Position of Oysters

IN books on Conchology, such as Woodward's "Manual of the Mollusca" and Jeffrey's "British Conchology," it is stated that the oyster rests in the natural state on its left valve, which is the larger and more convex. In this respect it is pointed out the oyster differs from the animals belonging to the genera Pecten and Anomia, which rest on the right valve, the Anomias being firmly attached by muscle with the flat right valve applied closely to the surface of attachment. In his lecture on oysters at the Royal Institution, which was published in Nos. 1 and 2 of the *English Illustrated Magazine*, Prof. Huxley also states that oysters rest on the left or convex valve, the flat right valve acting as a kind of operculum. Examination of oysters from the Firth of Forth has convinced me that this statement is erroneous. I do not know on what evidence the current belief of conchologists is founded. The evidence which appears to me conclusive is that the right flat valve is always quite clean, while the convex valve is covered with worm tubes, *Styela grossularia*, and Hydroids. The latter are in this connection the most important; it would be impossible for specimens of Sertularia and Thuiaria 4 or 5 inches long to grow, as I have found them on almost every oyster, in the central part of the left valve, if that valve were the lower in position. On examining Pectens I found that they resembled the oyster in the contrast between the surfaces of the two valves, the upper convex one being covered with Balanus and other fixed animals, the lower being almost clean. It is generally stated that the Pecten lies on its right valve; if this statement rests on the evidence afforded by the condition of the surface of the valves the same criterion applied to the oyster leads to the same conclusion, that the right valve is the lower. I have never seen a young oyster in the attached condition: Huxley states that it is the left valve which is fixed; in papers on the embryology of the oyster I have not yet been able to find any definite information on the point. Whether it is the right or left valve that becomes attached when the larva assumes the sessile condition I cannot therefore say of my own knowledge, but with regard to the adult oyster it seems to me certain that the current belief is caused by the repetition of an error. My attention was first called to this point by my assistant, Mr. John Walker, who tells me that the opinion of the fishermen at Newhaven is divided on the point, some saying that the convex valve, others that the flat valve, is the lower.

Scottish Marine Station, Granton, October 14

Two Generalisations

Two generalisations seem to have been staring us in the face for some time, and yet I have seen no one give them a look of recognition; they may be phantasms, but they seem solid enough:—

(1) That the number of elements is infinite; the most readily-formed types of ethereal vortices being the commonest, but our knowledge of them being only limited by the scarceness of the more complex forms, and not by any limit to the infinite varieties of complexity that may exist. Their relative commonness being analogous to the relative sizes of the bodies of the solar system; a few large, and always recognisable, and a greater number of examples as we descend in size to mere meteors. We already see that there are far more rare elements known than common ones.

(2) That the reduction of an electric current to heat in an imperfect conductor is solely due to the independent heat-motions of the molecules, which check and divert more and more of the current as their motions are larger; if there were no pre-existing heat-motions there would be nothing to resist a complete transmission of the current motion, and hence there would be no limit to conduction at the zero of temperature except the cohesion of the material.

Bromley, Kent W. M. FLINDERS PETRIE

Meteors

ON the morning of October 13, at 2h. 26m., I saw a fine meteor giving a bright flash at the end point and leaving a streak for about 12 seconds. It shot from the Lynx towards the pointers in Ursa Major, and while carefully fixing its direction relatively to the stars near, another conspicuous meteor, about as bright as Jupiter, crossed the lingering streak in a path but slightly inclined to it and of nearly similar length. I have never before observed two large meteors almost simultaneous and with paths so nearly identical.

I subjoin the observed paths of these meteors, also of five other bolides recently noted here during the progress of my habitual watches for shooting stars:—

1885	G.M.T. h. m.	Mag.	Path From ° °	To ° °	Length °	Radiant ° °
Sept. 9	15 48	♃	149 +82	152 +64	18	335+71
,, 15	15 11	♃	37 + 6½	26½+ 7	10½	70+ 4
Oct. 7	10 51	♃	51½+22	71½+24	18	31+18
,, 8	15 9	♃	155 +53	162½+46½	8	42+55
,, 12	14 26	♀	119 +51	151 +60½	20	88+18
,, 12	14 26	♃	119½+50	143 +60½	16½	103+33
,, 16	16 35	♃	213 +47½	226 +41	11	143+49

The radiant points are derived in each case by combination with many other meteors registered on about the same nights. I have seen 357 meteors since early in September, and those selected in the above table comprise all the brighter specimens estimated to equal Jupiter. W. F. DENNING

Bristol, October 17

Statigrams

THE increasing use of graphic representations of statistics by means of lines, areas, &c., seems to render it convenient to have some word which would specially designate diagrams exhibiting the progress and tendencies of the numerous tables of figures which do not pretend to strict scientific accuracy. The word *diagram* is used in most elastic senses and by all sorts and conditions of men.

May I suggest the word *statigraph* as a definite and convenient one for adoption? This might be sometimes shortened to *graph*; whereas *statigram*, if preferred, would not admit of this abbreviation. Most, if not all, graphic results of statists, economists, anthropologists, &c., might thus be termed *graphs*, whilst mathematicians and the experimental men of science would be left with the use of their own words, such as *curves*, *indicator diagrams*, &c. Each class would possess its own degree and limits of accuracy: mathematical precision and the doctrine of energy would apply to the latter, but *graphs* would be understood to involve human elements with intricate factors whose recognition or relationships the statistics are intended to elucidate and compare rather than to define and measure.

12, Merton St., Oxford J. F. HEYES

THE GEOLOGICAL SURVEY OF BELGIUM

PROBABLY no country of Europe has had its geology more attentively studied and mapped than Belgium. From the early labours of the veteran and pioneer

D'Omalius down to those of Dumont and his contemporaries, the structure of this country has engaged the attention of many able observers, and in its broad features is now well known. The map of Dumont, on the scale of 1-160,000, is one of the most excellent geological representations of any part of the European continent. But a good many years have passed away since its publication, and though it remains essentially accurate, it is now capable of improvement as regards details. Accordingly, after many discussions of the subject, a Commission was appointed to undertake a more detailed and exhaustive geological investigation of the country. This Commission consists of five members of European reputation, viz., M. Brialmont, Inspector-General of Engineers, one of the most distinguished engineer officers in Europe; M. Maus, Honorary Director-General of Bridges, Roads, and Mines, who made the preliminary plans for the piercing of the Mont Cenis Tunnel; M. Stas, the well-known chemist; M. Liagre, Perpetual Secretary of the Royal Academy of Belgium, who measured the geodetic base-line of Belgium; and M. Houzeau, Director of the Royal Observatory, whose writings on geological geography are widely appreciated. These able and thoroughly representative men of science were constituted as a Board of Control by which the operations of the Survey were to be governed, the practical carrying out of the work being placed in the hands of M. Dupont, Director of the Royal Museum of Brussels—a geologist of established reputation.

The work was begun in 1878 with the topographical map of the Engineer Department on the scale of 1-20,000th, or, roughly, about 3 inches to the British statute mile. It was estimated that the survey of the whole of Belgium on this scale would be completed in seventeen years from that date. This detailed map is divided into 430, or, excluding the frontier sheets, 369 sheets. Each of these is oblong in form, comprising an area of 10 × 8 kilometres, or 8000 hectares, or nearly 20,000 English acres. To produce upon this larger scale a map which should be only an enlargement and rectification of that of Dumont was very far from the object of the Commission. It was determined to adopt a monographic method of surveying. Each important geological system or group of formations has been entrusted to one or more specialists, who have given particular attention to its investigation, and who have been charged with the duty of tracing the same system or group completely across the country. Each geologist is furnished with two assistants who detach rock-specimens, collect fossils, make borings, and in other ways save the time and labour of the officer under whom they serve. Every actual outcrop of rock is marked on the map, and where the rock is fossiliferous the fossils are noted and the various palæontological subdivisions of the strata are traced, the collector being afterwards sent back where more ample collections are thought necessary.

It was from the first determined that the detailed geological map should be not merely a scientific undertaking, but a work of as much practical utility as possible. Special attention was accordingly given to the soils and subsoils, and care was taken to express upon the map the variations in the agricultural character of the ground. For greater exactness in this respect a system of boring was adopted. A stout auger was constructed which could be thrust a yard or so into the ground and bring up samples of the soil and subsoil. This instrument is made use of at intervals of 100 metres along the lines of traverse, so that the variations in the superficial layers can be accurately noted.

To secure harmony in the work, each officer entrusted with the survey of a particular series of strata from time to time confers with his colleagues who are engaged on contiguous bands, and thus the general geological structure of the country is worked out on a uniform plan.

Up to the present time thirteen sheets have been printed off, and many more are in various stages of engraving and preparation. It is believed that one-third of the entire work of the survey has been completed. The ordinary topographical maps of the État-major are printed from zinc plates, and with their crowded contour-lines and rather blurred printing are but ill adapted for the insertion of further geological details and the reception of colour. The Commission of the Geological Map accordingly decided to engrave this map on copper, adding new roads and other features, but leaving out all non-essential topographical details. By this means an admirably clear base has been secured for the delineation of the geological structure, while at the same time copper-plate engraving has been introduced as a new industry into Belgium. Comparing the ordinary sheets with their geological equivalents we are struck with the great beauty and clearness of the latter. Even for every day topographical use they are immeasurably superior.

One of the great problems of geological cartography is how best to pourtray at once the superficial accumulations and the solid rocks that lie underneath these. In this country it has been found practicable on the detailed six-inch maps of the Geological Survey to represent the surface-deposits by various kinds of stippling on the copper plates, the alluvia and the solid rocks being expressed by tints of colour. On the one-inch maps, however, which show the surface features by shading, this method cannot be employed. It has accordingly been necessary to issue two versions of each sheet of the one-inch map—one showing the solid rocks, the other representing the distribution of the various drifts and other detrital accumulations. These maps are coloured by hand, and are often of great beauty, but of course are somewhat expensive, more especially as two editions are needed to complete the representation of each district. M. Dupont deserves the admiration of geologists for having solved this difficult problem in an altogether novel way, and for having produced a series of maps which will probably inaugurate a new departure in geological cartography. His principle is to represent all the geological formations of a district, ancient as well as modern, upon the same sheet. As the superficial accumulations extend across much the largest area of ground, they are shown by various broad washes of colour over the tracts which they respectively cover. These colours, though they necessarily spread over most of each sheet, are kept so subdued in tone that they do not interfere with the easy legibility of the stronger tints employed to denote the underlying solid rocks. Every actual outcrop of these rocks is marked by a patch of the colour chosen for the particular formation. We thus note at a glance the localities where the rocks of that formation can be seen at the surface. At these outcrops, signs are inserted to mark the dip, and any lithological or palæontological subdivisions which have been noticed, and regarding which a detailed legend on the sides and bottom of the map gives ample explanation. So far the map is merely a transcript of what is observed in nature. But it is of course necessary to express the limits of the several rock-groups. And it is here that M. Dumont's ingenuity is most remarkable. He shows these limits by dotted lines, the dots varying in strength according to the importance of the limit which they define, and by strips of colour. Each stage has its margin defined by a shaded strip of its characteristic colour where the actual boundary is concealed, while where the junction of two stages or sub-stages is actually seen on the ground, the colours are not shaded, but of the full strength. The eye can thus easily follow the windings of such sub-division across the map, and can at a glance mark where the actual exposures are to be observed on the ground.

As the maps are chromo-lithographed it is quite simple to secure harmony of tone and great clearness and accuracy. We at once perceive what is actual observation and what is inference. One is put in possession of the data on which the geological boundaries have been traced, and can thus judge where and how far these are conjectural. We are not aware of any other published maps where this confession has been so frankly made.

The pale yellows and greys adopted for the superficial deposits cover so much of each sheet as to show at once how large a part of the ground is occupied by them. The detrital material is traced up to its source upon the table-lands, and being of poor agricultural value its colour on the map shows where farming operations are least likely to be successful. Where observations by boring or otherwise have been made on the nature of the soil and subsoil these are marked on the spot by the requisite sign, and as the borings are numerous these indications abound all over the map.

During the progress of the work improvements have been made in the methods of surveying and also in the modes of expressing geological details on the maps. In the Brussels area, for example, besides the ordinary borings into the soil and subsoil, deeper borings have been made to ascertain the nature and succession of the strata underlying the uppermost deposits. Messrs. Rutot and Van den Broeck, two of the staff, have invented an ingenious instrument with which they can ascertain the nature of the formations down to a depth of even 10 metres. By its means they have pierced below the sub-soil in all directions, and have accurately traced out the areas of the younger deposits around Brussels. The results obtained by them at each boring are clearly engraved on the map; so that at numerous points all over the district the farmer, the water-engineer, the railway-contractor, the quarryman, and others can learn precisely through what layers they must pass in any cutting or excavation beneath the surface. By another ingenious device, the section of each artesian well at Brussels is represented on the map beside the position of the well, and so clearly that the succession of rocks bored through may be taken in by the eye at once.

Each sheet of this detailed survey is so crowded with information that to those who have been accustomed only to the ordinary style of geological map-making it may at first seem a little confused. But if any one will take the least trouble he will soon find that the confusion is only in appearance. No maps have yet been published in any country giving so large an amount of accurate information with such clearness and precision, and where the actual facts are kept so clearly apart from inference. These sheets are not wall-maps to be looked at from a distance, but detailed maps to be closely studied in the hand. And they will well repay an attentive study. There is probably no national Geological Survey in any part of the world which may not find in them some useful hint or suggestion for its own improvement.

On completion of the detailed survey it is part of the original plan to prepare a smaller or wall-map like that of Dumont. But such a map is hardly needed; at least its preparation can well stand over until the whole country has been surveyed in detail by the methods so well conceived by M. Dupont. But besides the maps, the work of the Belgian Survey has included the preparation of ample explanations illustrative of the maps. Each sheet is intended to be accompanied with an "Explication" giving the detailed structure of the ground, descriptions of the rocks, natural sections, lists of fossils, and all the information required as supplementary to the geological maps. A number of these memoirs have already been printed. Each of them contains fundamentally three sections running N. and S. across the formations, which in Belgium have a general E. and W. strike. These sections are described in detail, and full local references are given. The books are well printed, and the coloured plates of sections are excellent, while a novel attraction is given by the insertion into the text of coloured engraved sections of special localities.

None of the maps or explanations, though they have been ready for some time, have yet been published. They are to be seen, however, in some of the public libraries and museums in Europe. Belgium has every reason to be proud of them, and we trust that the delay in their publication will speedily be followed by the issue of the whole series now ready and by the completion of those in progress. It is impossible to over-estimate the practical utility of such a detailed survey in a country like Belgium. No time should be lost in pushing on and bringing to a conclusion a work which has been so admirably begun.

ARCH. GEIKIE

THE THIRD INTERNATIONAL GEOLOGICAL CONGRESS

THE third International Congress of Geologists, postponed last year on account of the spread of cholera in southern Europe, has just been held at Berlin. Each successive gathering has far surpassed its predecessors in numbers and in the representative character of its members, the numbers attending the meeting at Berlin being no fewer than 255. Of these of course the large majority were Germans, who mustered in all 163. Italy, however, furnished 18 representatives; Austria, 16; Great Britain, 11; France, 10; United States, 9; Belgium and Russia, 6 each; Sweden and Switzerland, 3 each; Norway and Holland, 2 each; Spain, 1; Brazil, 1; India, 1; Japan, 1; Portugal, 1; Roumania, 1. The meetings were held in the buildings of the Reichsrath, or Parliament, the large room set apart for the deliberations of the Congress being that of the Lower House of Representatives, and no little interest was taken by the foreign geologists in the names of the Members of Parliament inscribed on the backs of the seats. The door also was pointed out from which the great Chancellor emerges to launch his philippics against the contumacious opposition. But the *genius loci* inspired no flights of eloquence nor much disputatiousness among the geologists. The use of French as the language of discussion was no doubt one effective cause of silence on the part of many members who would otherwise only too readily have made themselves heard. Under such circumstances the Latin races have of course a considerable advantage over the Teutonic. One of the Berlin papers gave articulate expression to the complaint that in an audience nearly two-thirds of which were Germans, French should have been chosen, and great was the delight expressed by the German element in the Congress, when the Minister of Public Instruction, who officially welcomed the assembly, gave his eloquent and appropriate address in German. But by common consent, and with much good humour, though often with a disregard for the claims of grammar, idiom, and pronunciation that must have been infinitely ludicrous to the French-speaking members, the international official language was used throughout the proceedings.

The ostensible work of the Congress, which lasted nearly a week, may be divided into five parts. Of these the first in order of treatment and also of importance was the report of the Commission entrusted at the previous (Bologna) meeting with the preparation of a geological map of Europe. During the four years that have elapsed since the Congress determined to undertake this work, satisfactory progress with it has been made. The topographical outlines of the map have been completed and engraved, and the Commission were able to show upon the wall a mounted copy of the outline map. The materials necessary for filling in the geology have already been supplied for a large part of Europe, and it is expected that in the course of next year the work will be so far advanced that proofs in colour of many of the sheets of the map will be ready. There can be no doubt that the preparation of this great map is the most important and useful undertaking of the Congress. It is an eminently practical piece of work, with an attainable aim which unites the geologists of all European States in a common definite labour. The engraving and colouring of the map are carried on in Berlin. Judging from the present state of the engraving and from the scheme of colours adopted, we may confidently anticipate that the completed map will be a singularly clear and beautiful specimen of cartography, and will form a noble monument of international co-operation.

The second subject, to which the Congress devoted most of its time, was the unification of geological nomenclature. Reports had been received from different countries as to the names and classification of the various subdivisions of the geological record. But the wide differences of opinion expressed in these reports showed how little prospect there was that anything approaching to unanimity on such a subject would be reached by the Congress. It is to be feared, indeed, that the endeavour to unify stratigraphical nomenclature all over the world is more Utopian than practical. Nature is not everywhere uniform, and it seems almost puerile to strive after a uniformity of classification and terminology which has no counterpart among the rocks themselves. The Congress itself appeared to realise this, for it wisely postponed the consideration of all questions about which there could be any serious differences of opinion, and adopted only those propositions which nobody would controvert, and which hardly required an international congress to settle. Thus it was agreed that the Archæan rocks should be divided into sections according merely to petrographical characters and without expressing any opinion as to their relative age. The vexed question of the Cambrian and Silurian classification was postponed until the next Congress three years hence. A day was spent in discussing the position of the Permian system, with the result of leaving it for the present where it is usually placed. The subdivisions of the Mesozoic and Tertiary rocks were rapidly enumerated, but no discussion of them was possible in the time. In truth, it is difficult to see how any real effective discussion of these subjects can be attempted at the ordinary meetings of the Congress. The assembly is so large that probably only a fraction of the audience is really competent to express an opinion on the particular subject under debate. Some of the members who might contribute most valuable suggestions are deterred from so doing by their timidity in the use of the French language. To count the heads of so miscellaneous an audience and say that such and such are the decisions which it has voted can really carry little weight with the geologists of the world at large. Such at least was the opinion freely expressed among the members at Berlin. There was a very general feeling that the less the Congress attempts in the way of authoritative decision or legislation the more likely is it to carry on effectively other functions which are of far more general importance and usefulness.

Thirdly, the reading of communications on geological questions of general interest. Several good papers were read, but the thinned audience showed that this part of the programme was not very popular. There seemed to be no careful selection of papers, for some of those that were read hardly deserved a hearing before an international gathering of geologists. If this section of the proceedings is retained, it might be well to invite beforehand a few men of acknowledged reputation to give discourses, each on his own subject. There would be a strong desire to hear the masters of the science, and if three or four of them of different nationalities could be induced to accede to this proposal, there would be no need for catering among the rank and file of the assembly for papers to fill up the time.

Fourthly, an exhibition of geological maps, sections, specimens, and models. This collection was arranged in the room of the Bergakademie, and proved a source of much interest and instruction. The series of national geological surveys represented on the walls embraced a large part of Europe, and included some admirable examples of cartography. Among the specimens special attention was given to those exhibited by Mr. Reusch, showing Silurian fossils in the crystalline schists of Norway, those of Dr. Lehmann illustrating his work on metamorphism, the wonderful group of amphibian remains shown by Prof. Credner, the series of fossils brought by Dr. Torell from the Primordial and Lower Silurian rocks of Sweden, various collections from different localities among the Cretaceous rocks of Germany, and a remarkable assemblage of specimens of northern rocks and fossils from the drift of North Germany, exhibited by Dr. A. Remelé.

Fifthly, excursions to places of geological interest. At the close of the Congress a large number of the members proceeded in a special train to Potsdam, and spent a day seeing the sights of that royal demesne. Next morning they started for Thale in the Harz, whence, under the able guidance of Prof. Lossen, they were enabled to see some of the more interesting features connected with the protrusion of the granite and the metamorphism of the surrounding rocks, likewise the succession of stratified rocks up to the Chalk, thrown against the flanks of the Harz. From Thale the party travelled to Stassfurt, and descended into the salt mines, which were illuminated in its honour; thence to Leipzig, where Prof. Credner acted the part of host and guide, and from which an interesting excursion was made into the Saxon granulite region.

But it is not by its formal and ostensible proceedings that the usefulness of the Congress is to be measured. There was a widespread feeling which constantly found audible expression, that the opportunities it afforded for personal intercourse and exchange of views were amply sufficient to justify its existence and to give assurance that it would long continue. The discussions among the animated groups in the corridors and ante-rooms were much more vivacious and probably quite as conclusive as those held in the large room. But most useful and enjoyable of all was the nightly *Kneipe* held in some beer-saloon. There in a thick and pungent atmosphere of tobacco-smoke, amid the clattering of beer-jugs and shoutings for the *Kellner*, many of the foremost geologists of the Congress gathered together — stratigraphists, petrographers, palæontologists, mineralogists — full of scientific enthusiasm and good fellowship. Loud and long were the debates in these dim retreats. Tongues that had been shackled by French articulation now shook themselves free in the unrestrained vernacular of the country. There were no reporters of course, and no record remains of the discussions. But the recollection of these evenings will not soon pass away from the memory of those who took part in them. Men from distant parts of the world who had only known each other's writings, or at most had exchanged letters, were here brought face to face, and the foundations of many a pleasant and profitable friendship were doubtless laid.

Great praise is due to the organising Committee at Berlin, and especially to its indefatigable General Secretary, Herr Hauchcorne, for the arrangements made for the business of the Congress and the comfort of the visitors. Every detail seemed to have been carefully planned, and the result was evident in the smooth working of the whole machine. It was a great gratification to see the venerable Dr. Von Dechen presiding over such an assembly of geologists, and to hear his reminiscences of the early days of European geology. The *bonhommie* of the President, Prof. Beyrich, put everybody in good humour, and the active guidance of the former President, Prof. Capellini, contributed largely to the success of the Congress.

The next session of the Congress is to meet in London between August 15 and September 15, 1888, and Messrs. Blanford, Geikie, Hughes, and Topley have been nominated a committee to make the necessary arrangements.

BOTANICAL EXPLORATION OF THE CHILIAN ANDES

WE are indebted to the Kew authorities for the accompanying extract from a letter dated August 21, 1885, addressed to Sir Joseph Hooker by Dr. R. A. Philippi, the Professor of Botany at Santiago:—

"My son made in the summer during 110 days a voyage from Copiapo to the River Camarones, the actual boundary between Chili and Peru. He went first from Copiapo to Antofagasta de la Sierra (26° 5′ lat., 27° 20′ long., 3570 metres above the sea), where about 60 to 100 people are living, and thence (nearly always on the high table-land of the desert at an elevation of 3500 to 4200 metres) to Huasco de Tarapacá, from whence he descended to the tamarugal. The voyage extended over 8 degrees of latitude. This high table-land is nearly a single bed of trachytic lava, on which are scattered a number of extinct volcanoes, three of which are higher than Chimborazo—viz. the Llullaillaco, 6600 metres (I was, twenty-one years ago, at its west foot); the Tumiza, 6540; and the Pular, 6500 metres. There are many large salt lakes, several entirely dry. The vegetation in this easterly part of the desert is not so scanty as in the westerly, visited formerly by me, perhaps owing to a slight influence of the trade wind; and the water-places are more numerous and nearer one to the other.

"The number of species of plants brought home exceeds 400, of which half are not described. Amongst them is one *Polylepis* (without flowers), found only in one quebrada, and *Pilostyles Berterii*, a parasitic plant belonging to the same family as *Rafflesia*, found at the height of 3700 m.!—of course on an *Adesmia*. The three species of ferns are: *Pellæa ternifolia*, *Cheilanthes micropterus*, and a beautiful *Cincinnalis* which seems to be new. The most numerous family is, of course, Synanthereæ, with 94 sp.; Gramineæ has 42 (among them a new species of *Munroa*); Leguminosæ, 28-29; Verbenaceæ, 15; Solanaceæ, 28; Chenopodiaceæ, 15. Amongst these plants nine or ten must form, in my opinion, new genera. Some are very curious, as a Verbenacea, which grows in small hemispherical tufts and has the aspect of a Synantherea, with sessile flowers and pappus. This pappus proved to be a deeply-divided calyx with long cilia. There is another genus which I took at first sight for a *Tribulus*. I hope that my age, my health, my eyes, and my time will allow me to draw up the generic diagnosis, at least, of these plants."

KRAKATÃO

THE publication of the first part of Verbeek's "Krakatão," which chiefly contained the *history* of the great eruption of 1883, had raised many expectations regarding the promised description and discussion of the *phenomena* then observed. In his completed work, which contains 25 coloured drawings and 43 large and small maps, those expectations are fully realised. Immediately after the great outburst of August, 1883, the Dutch Indian Government sent him to visit Krakatão and to investigate the causes and effects of this awful catastrophe, more sudden and destructive than the famous eruption of Vesuvius. The great facilities they placed at his disposal enabled him to do this in the most satisfactory manner, and the really beautiful character of his completed work reflects the greatest credit not only on the learned author, but on the zeal and public spirit of the Dutch-Indian Government, who have aided him in making so valuable a contribution to scientific knowledge. So much interest has been taken by the general public, as well as by men of science, in this remarkable eruption, that we feel certain they also will welcome this volume, since it is lucid in style and profusely illustrated. With an expression of his gratitude to various institutions and individuals who have rendered him valuable assistance, the author gives in the preface a list of the weights and measures, together with a summary of the most recent ideas that geological science has received from the Krakatão eruption.

Krakatão itself lies on the point of intersection of three fissures or cracks in the earth's crust, and from this position is naturally exposed to volcanic disturbances. The earthquake of September 1, 1880, which damaged the lighthouse on Java's First Point, probably affected the Sunda fissure and facilitated the entrance of greater quantities of water into the volcanic furnace underlying the Straits of Sunda. Accepting the theory that volcanic eruptions are caused by steam at high pressure, we have thus the probable explanation of the terrible outburst of 1883. From the observations of earthquakes in the Indian archipelago during the year 1883, it appears that the eruption was neither preceded nor accompanied by heavy shocks. It is even far from certain that any trembling of the surface took place at the time, since the vibration of the air caused by the explosion was sufficient to shake houses and crack walls, and thus might easily have been mistaken for earthquakes. The author further treats of the ejected materials; their thickness, which, on some parts of Krakatão, amount to 60 metres; their size, varying from bodies of one cubic metre to the finest dust; the velocity with which they were thrown out, which must have been considerably greater than that of projectiles from the heaviest rifled ordnance; the elevation which they reached has been calculated at 50 kilometres, or nearly six times the height of Mount Everest, the highest mountain of the world, and the ashes have fallen over an immense area. From investigations made at fifty different places regarding the thickness of the fallen ashes and also the change in the depth of the sea around Krakatão, M. Verbeek has calculated that at least 18 cubic kilometres of matter must have been ejected. To give an illustration: imagine a box of ashes as large as Hyde Park and as high as the dome of St. Paul's, a hundred such boxes will give an idea of the mass of matter thrown out by Krakatão in 1883.

For three days after the eruption various ships to the westward found ashes falling on their decks; the names of these ships are given, as well as a map showing their exact position at the time. Mr. Verbeek believes that the finest particles, forced by the steam into the upper air, did not descend, but were carried westward by strong east winds, making twice the circuit of the earth and causing the phenomena observed at various places of a blue and green sun and moon. The passage of this cloud has been reported from islands and ships in the Pacific Ocean and its velocity must have been as great as that of a hurricane. After the steam and dust-cloud were dispersed over a wider area the beautiful red sunsets occurred, which were owing to the presence of such a large volume of aqueous vapour, while the blue and green colours of the celestial bodies were caused by the solid particles in the air.

The author goes on to elucidate the geology of Krakatão by two maps and four very instructive sections, showing its development during that number of periods. The first period was marked by the destruction of the great cone, probably 2000 metres high; during the second period the peak Rakata was formed by a lateral eruption, while in the third period two parasitic cones, Danau and Perbvewatan, were added, and these, by their successive eruptions, built up the island of Krakatão. In the fourth period two of these cones have been destroyed by the terrible eruption of 1883. As our authentic records of Java only date back 300 years, we have absolutely no data respecting anything that occurred in the first three of these periods. We have accounts of an eruption of the Perbvewatan in the year 1680 from two travellers—Vogel and Hesse—to which I drew attention in the *Algemeen Dagblad van Ned. Indie* of May 23, 1884; but they say nothing as to whether that crater was formed at that time or had been already active. After a rest of 203 years the Perbvewatan became again active in May, 1883, and the Danau joined it in activity during the following June, forming the principal crater in the centre of the old volcano. In August, at the great eruption of the 27th, this part of the volcano was again destroyed; the Perbvewatan and the Danau, with the northern half of Rakata Peak, disappeared, and the site of the old crater is now covered by the sea between the islands Lang, Verlaten, and Krakatão.

If the volcano resumes its activity, which is to be expected since the island lies on such a favourable point for eruptions, then small islands will appear between the three already mentioned. Krakatão has been at rest since 1883, although it has erroneously been reported to be active. The roll of thunder and the flashing of lightning over the ruins of the crater wall have been mistaken for the action of subterranean forces, while the volcanic dust swept off from the crumbling summit by the wind appears at a distance like smoke.

A very curious and interesting feature of the recent eruption of Krakatão was the ejection of fragments of underlying sedimentary rocks. The base of the Krakatão volcano, and in general the entire bottom of the Straits of Sunda, consists of eruptive rocks of the miocene period covered with horizontal layers of diluvial and recent marine deposits, the materials of which have been derived from the various volcanoes in the vicinity.

The first volume of Verbeek contained a valuable report from his colleague, Mr. J. A. Schuurman, on the phenomena of the eruption of May, 1883, as observed by himself, and the second volume has a lengthy and minute description by the mining engineer, Mr. J. W. Retgers, of his microscopical examination of the ash which fell at Buitenzorg, and of the various substances thrown out by the eruption of 1883, as well as of the older rocks.

A portion of the pumice which covered the sea after the eruption was carried westward by winds and currents and driven on the shores of various islands, even so far as the east coast of Africa. Another portion, which floated in the bays of Semangka and Lampong for several months, being driven in the beginning of 1884 by westerly winds along the coast of Java toward the Moluccas and Australia, is at present encountered in the Pacific Ocean between the Caroline and Marshall Islands. The author has calculated that this pumice will arrive on the west coast of America at Panama early in 1886.

With regard to the spherical bodies of a calcareous and clayey nature, called "Krakatão marbles," found lying loosely on the surface, Mr. Verbeek at first supposed them to have been formed by the rotary motion of particles ejected from the volcano, but as they were afterwards found imbedded in ejected fragments of claystone and marls, this theory must be given up; he considers it possible that there may have been concretions in the tufa, although their presence in rock sometimes quite destitute of lime is certainly surprising, and this form of concretions has not been observed hitherto.

The chemical analyses of the rocks of Krakatão can be fully relied upon, as they have been made by Dr. Cl. Winkler, Professor of Chemistry in the well-known Mining School of Freiberg, in Saxony. Dr. P. J. van der Stok, Director of the Meteorological Observatory at Batavia, proves that the disturbance in the position of the magnetic needle observed during the falling of volcanic dust was due, not to the eruption, but to the presence of magnetite therein, since the disturbance only lasted during the shower of ashes.

The low temperature observed at that time at Batavia, Buitenzorg, Kroë, Moeara-Doea, Bandar, and elsewhere was not due, according to hygrometrical observations, to the evaporation of the humidity of the ash; near the volcano and on ships in the vicinity it was oppressively hot, but the ashes thrown into the icy regions of the upper air and falling at a distance from the volcano had become cooled in their passage. Heavy electrical discharges occurred continually in the ash cloud around Krakatão. On Java's First Point and at Flat Point the lighthouses were struck by lightning.

On Sunday, May 20, 1883, all Batavia was in great commotion as to the cause of the mysterious sounds and detonations which apparently came from the west and in fact did come from Krakatão. At Serang and Anjer, which are situated much nearer to the volcano, no sounds had been heard. Again at Batavia on the morning of Monday, August 27, after the tremendous detonation at 8h. 26m., the eruption seemed to have ceased; they heard nothing at all of another enormous explosion which took place between 11 and 12, as reported from Middle and East Java. The explanation of this curious phenomenon is that earlier in the morning an ash cloud like a gigantic lamp-shade settled over the volcano, extending as far as Bandong, and that the quantity of these ash particles floating in the air prevented the transmission of sounds. Above the ash cloud the detonations were transmitted in all directions, but naturally were most distinctly heard to the windward. The farthest points where the sounds have been heard are Doreh, in New Guinea, some points of Central Australia, among others the telegraph stations of Daly Waters and Alice Springs, the islands of Rodriguez and Ceylon. Accounting for the difference in time and taking the rate of transmission of sounds, the author has calculated for different places which grand detonation in particular has been heard. The detonation of Monday morning, 5h. 30m., has been heard in Australia; that of 10h. 2m. a.m. has been heard at Banca, Billiton, the west coast of Borneo, the southern and eastern divisions of Borneo, Bawean and Banda; that of 10h. 52m. a.m. at Riouw, Middle and East Java, Bali, &c.; the last two detonations have not been noticed at Batavia and Buitenrorg. The area within which the explosions have been heard is represented on a map; it amounts to one-fourteenth of the whole surface of the globe—a quite extraordinary transmission of sound over so large a space. From the vibration of the air caused by the heavy detonations houses, doors, windows, clocks which hung against the walls, objects which stood on cabinets or were suspended from the ceiling were set trembling; but the swinging movements given to hanging objects by earthquakes have nowhere been observed. That some walls have been cracked, and houses been damaged so as to be no longer habitable, can be accounted for, according to the author, by the probability that they were already weak, and thus had an opportunity of showing it.

The greatest air-disturbance caused by the eruption has transmitted itself as a regularly moving atmospheric wave, with Krakatão as centre, over the whole earth; and to the discussion of this entirely new phenomenon the author has devoted about seventy pages. With the assistance of very accurate barograms from Sydney, N.S.W., he calculated the heaviest explosion and fixed it at 10h. 2m. a.m. Krakatão time. The same result has been arrived at by another calculation based on the markings of the indicator of the gasworks at Batavia. That indicator marked fifteen oscillations, corresponding with as many explosions, of which the four severest occurred in the forenoon of Monday, August 27, at 5h. 30m., 6h. 44m., 10h. 2m., and 10h. 52m., Krakatão time. Of these four, that of 10h. 2m. a.m. was by far the greatest, and it is probable that the air-wave then formed made the tour around the world. Forty places in Europe, America, and Australia are named where the disturbance of the air has been indicated by barometers, and with the help of these data the author has been able to calculate the velocity of the air movement, which has been found to be considerably less than the velocity of sound at 0° C.; consequently the movements took place at a great height and in cold-air strata.

According to the author's calculation this air-wave required 35½ hours to make the circuit of the earth; it would have been of great interest to know just when the wave returned to Batavia, but, unfortunately, the diagrams of the indicator at the gasworks that might have marked such a return have been lost.

Part of Chapter V. treats of changes in the sea-bottom. The sea now covers to a depth of 200 to 300 metres what was formerly the northern part of Krakatão, and the small island called Polish Hat has also disappeared. Between the remaining islands, which are fragments of the old crater ring, an area has subsided of at least 41 square kilometres, or about 10,000 acres. Outside these islands, within a triangular space of 34 square kilometres, the sea is also deeper than formerly, so that altogether a surface of 75 square kilometres has subsided, which is clearly shown on maps 1, 2, and 4.

The part of the Peak which has disappeared must have been 1 cubic kilometre in size, and the fall of such a mass into the sea is quite sufficient to cause the great sea-wave which swept away thousands of human beings. Nowhere is there the slightest vestige of any upheaval, from which we may be certain that no seismic movement of the sea-bed has occurred. In Bantam and in the Lampong districts, after the disaster, the remains of the macadamised roads along the coast were everywhere as high above the sea as before, and soundings in Sunda Straits showed that no change of sea-bottom has taken place there. The shallower depth in the immediate vicinity of Krakatão, and between Krakatão and Sebesi, has probably been the result of fallen materials, to which also the islands Steers and Calmeyer, which have since disappeared, for the greater part, no doubt owed their existence.

As the last of the phenomena which accompanied the eruption of 1883, the movements of the sea are discussed, as shown by the destructive waves which have made this catastrophe so terrible. It is certain that the greatest wave of all started from Krakatão at 10 a.m., and that wave completed the destruction of Telok Betong, Anjer, and Tjiringin. This great wave had been preceded by small waves on Sunday afternoon at 6, and Monday morning at 6h. 30m., by which these places were already partly submerged and destroyed; but the really very remarkable phenomenon was observed that not every wave reached all the places situated along the coasts of the Straits of Sunda. For example: the wave which destroyed on Monday morning, at 6, a part of Anjer, and at 6h. 30m. the lower part of Telok Betong, has not been noticed at Tjiringin. The author explains this by the supposition that the preceding waves were not caused by the falling in of parts of the volcano, but by the enormous quantities of ejected matter that splashed into the sea. Suppose on Sunday evening during the eruption of 5h. 7m. a large quantity was thrown out on the spot where Calmeyer lies, the wave thus formed was noticed everywhere around —at Merak, Anjer, Tjiringin, Beneawang, Telok Betong, and Ketimbang. If, during the eruption on Monday morning (5h. 30m.), the matter was thrown down on the spot where Steers lies, then the wave would be obstructed in a south-easterly direction by Calmeyer, and Tjiringin, lying behind it, be protected, whilst the wave would roll to Anjer, where it must have arrived a little after 6 a.m. In like manner, at the explosion of Monday morning (6h. 44m.), Anjer and Tjiringin were protected by Krakatão, and Telok Betong by Lagoendie, whilst Beneawang in the Bay of Semangka was nearly destroyed; but the wave of 10 o'clock being of such enormous magnitude, swept over all obstacles.

Most careful calculations fix the time of the formation of the great wave at 10 a.m., the same hour at which the heaviest detonation was heard, so that the ejection of a stupendous quantity of ashes, pumice, and mud, the rushing in of the sea upon the mass of glowing lava, and the falling in of half the mountain, must have taken place almost simultaneously. From the height registered by the tide-gauges at Tandjong-Priok on Monday at 7h. 30m. p.m. it is evident that Batavia narrowly escaped a second inundation. The data collected from all parts of the world regarding an extraordinary movement of the sea soon after the eruption, made it possible to compute the velocity of the great wave, and this velocity enabled the author to calculate the average depth of the sea along the path the wave travelled. In this way he has ascertained that the depth of the sea between Krakatão and South Africa must amount to 4200 metres; between Krakatão and Rodriguez, 4560; and between Krakatão and South Georgia, 6340 metres; which shows that west and south-west of Australia there must be a deep-sea basin, the existence of which has not yet been revealed by soundings. Mr. Verbeek considers that, if the irregularities of the tide noticed at Aspinwall happened at the hour reported, they were not caused by the Krakatão wave, but by volcanic activity in the Antilles; that wave, however, was observed on the coast of France, at San Francisco, and even in Alaska. Its velocity was so great that it reached Aden in twelve hours, a distance of 3800 nautical miles, usually traversed by a good steamer in twelve days.

It is greatly to be regretted that our knowledge of this phenomenon beyond the Indian Ocean remains incomplete, on account of the small number of tide-gauges on the Atlantic and Pacific coasts; the author suggests that this want shall be promptly supplied, so that in future no important movement of the sea shall escape notice.

Chapter VI. is devoted to a consideration of the volcanic phenomena which have been observed during the eruption of Krakatão at other places within or beyond the Indian Archipelago. Simultaneously the volcano Gœnong Api, on the island of Great Sangi, the Merapi on Java, the Merapi on Sumatra, and also, it is supposed, a volcano in the Moluccas were in activity. A seismic movement of the sea-bottom occurred in the whole region of the Moluccas, which could not have been due to Krakatão, and this movement has been noted by three tide gauges in the Straits of Madura. Over a large part of Australia, from August 27 to 29, more or less serious earthquakes were felt—a phenomenon the more remarkable because Australia suffers very seldom from any shaking of the earth. It is probable that sudden displacements of steam—perhaps of lava—occurred in the subterranean cavities, caused by a change of pressure through the great discharge of lava and steam at Krakatão. We must therefore conclude that the underground recesses between Krakatão and Australia are in some way connected, so that any change of pressure in one cavity causes a change of pressure in the other.

Even at points in the neighbourhood of the antipodes of Krakatão shocks and volcanic effects were noticed, and if, as is probable, some point in the Antilles was in activity, then evidently the whole surface of the earth during the terrible discharge of Krakatão was agitated, and apparently the crust of our earth is not so solid as many of its inhabitants fondly imagine.

The author maintains the doctrine that part of our globe remains still in a molten state, and he disputes the theory, which has been advanced, that the heat of the volcanic furnaces is entirely due to local chemical action. He, however, acknowledges that it is very difficult to explain why, during the Krakatão outburst, the antipodes was more favourably situated for an eruption than the other volcanic regions of the earth. A similar tendency during former eruptions has not been recorded, and we must wait until another great outburst enables us to decide whether it is of any importance.

The coloured drawings, twenty-five in number, are all by Mr. Schreuders, who accompanied Mr. Verbeek in October 1883, and give a faithful picture of the devastated regions as they appeared two months after the eruption. The most striking picture is that of the stupendous wall, 832 metres high, which was laid bare by the destruction of the northern part of the peak. No one who has gazed upon this grandest of nature's ruins can forget its solemn desolation.

The careful typographical execution of the work reflects great credit on the Director of the Government Printing Office at Batavia. We can heartily congratulate the learned author on the successful completion of his most valuable and exhaustive work, interesting alike to the scientific and general reader.

ON THE COLOUR-SENSE

THERE is an interesting paper in the *Nineteenth Century*[1] for February last in which the colour-nomenclature in the Homeric poems and that of the modern Hindústání language are compared with modern English usage. The writer traverses to a great extent Mr. Gladstone's suggestion[2] that the ancient Greeks were deficient in colour-sense (*i.e.* compared with modern Englishmen), and propounds the idea that the natives of India have a keen colour-sense.

It will be shown below that the use of colour terms in modern English is not only loose, but even incongruous. Illustrations will be taken from both the papers referred to, with additions from the author's experience in India.

Natural Objects.—Uniformity might surely be expected in the use of colour terms with bright-coloured natural objects. There is, however, no uniformity in their use, even when intended to be real colour designations; and opposite and sometimes unnatural colours are—in a figurative sense—ascribed to a single object.

Thus the colour of fresh blood and the tint arising therefrom in the healthy cheek and also in the blushing cheek (of a fair person) are probably among the most well-marked, definite, natural colours. Yet the blood itself is styled *blood-red*, *gory*, *crimson*, *red*, *scarlet*, whilst the healthy cheek is described as *carnation*, *vermeil*, *red*, *ruddy*, *rosy*, and *pink*, and the blushing cheek as *scarlet*, *crimson*, *red*, *aflame* (perhaps rather a heat than a colour term). These terms, though used as real colour designations, are by no means synonymous, whilst in a figurative sense quite different and even unnatural colours are ascribed. Thus *blue blood* is used of aristocratic descent, *black blood* and *white* or *pale blood* of descent from dark or fair races.

Again, healthy bile is bright yellow, and a yellowish tinge in the "white" of the eye is often called a *bilious* colour; yet in the figurative sense black is ascribed to the condition known as *melancholy*, *atrabiliousness*, *black bile*.

The colour of good milk is so characteristic as to give rise to the term *milk white*, whilst skim-milk or poor milk which has merely a blueish tinge is styled *sky-blue*.

Again, the parts of the human eye and of a bird's egg styled from their characteristic tint the *white* of the eye and the *white* of an egg, always bear the *name* of *white*, although occasionally of a decidedly blueish tinge, stronger than that of skim-milk.

Colour is usually ascribed to the human eye from the tint of the iris, probably as being the part most subject to colour-variation—*e.g.* *black*, *dark*, *pink*, *brown*, *hazel*, *green*, *blue*, *gray*, *light*. Of these, *black* is loosely applied (*e.g.* in the phrase *black-eyed*) in the case of any dark-coloured iris, whilst *green* and *blue* are used in the case of a mere tinge of green or blue.

On the other hand the phrase *red eyes* indicates either redness of the eyes (as from weeping) or a bloodshot state of the "whites," whilst a *black eye* implies only a dark-coloured bruise of the skin near the eye; *green in the eye* is a figurative expression implying freshness or ignorance, and *green-eyed* is a condition ascribed to jealousy.

The colour of sea-water varies from greenish (aquamarine) to a deep blue (ultramarine); but a wide range of colour-names is applied to various seas—*e.g.* the *Black Sea*, *Red Sea*, *Yellow Sea*, *White Sea*, and this in many languages.

The colour of river-water varies from turbid yellow to blueish and colourless; but in this case there is an equally wide range of colour-name—*e.g.* *Blackadder R.*, *Blackwater R.*, *Red R.*, *Orange R.*, *Green R.*, *Blue R.*, *Blue Nile*, *Grey R.*, *White R.*, *White Nile*, *Whiteadder R.*

Human Colouring.—Colour-terms, applied to races of men, or to the complexion or hair, are loosely used to cover a wide range of colour. Thus *black*, *dark*, *dusky*, *swarthy*, and *nigger* (*lit.* black), are applied to any merely dark skins; *red* and *coppery* to the whole of the North American (so-called) Indians; *white* and *pale* to any fair skin. The terms *dark* and *fair* (shade- rather than colour-names) are loosely applied both to the complexion and to personal description. Thus any complexion darker than the average in a fair race, or fairer than the average in a dark race, is called *dark* or *fair* respectively; the two terms being merely *relative* in this usage.

Also among a fair race, a person with dark eyes and dark hair is called *dark*, and one with light eyes and fair hair is called *fair*, without reference to complexion. Again, the terms *red*, *carroty*, *fiery* are often applied to hair which has merely a reddish tinge.

Among races of different complexion in the same country curious figurative usages of the racial colour-terms arise. Thus *nigger* (*lit.* black), *black*, *dark*, *redskin* are sometimes used by a (ruling) fair race to denote inferiority, and this usage is sometimes adopted even by the (ruled) dark race—*e.g.* occasionally by both negroes and natives of India. There is a curious restricted use of the phrase *gorá log* (*lit.* fair people) in India to denote the British soldiery, but not the higher classes of English.

Animal Colours.—Colour terms applied to animals have sometimes a technical meaning quite different to the fundamental colour. Thus *bay* and *strawberry*, as applied to horses, are very different colours from those of the bay-leaf and strawberry; thus also the Hindústání term *sabz*, usually meaning green, denotes *gray* when applied to animals. Again, *red* is applied to animals—*e.g.* cows, deer, foxes, squirrels, &c., whose coats are any sort of reddish-brown. A similar usage occurs in the Homeric poems—(*e.g.* φοινιξ and its derivatives), and in the Hindústání word *lál* (*lit.* ruby).

Colour-terms are sometimes applied to animals, plants, &c., even when only slightly affected with the named colour, to indicate a particular variety of the object in question. Thus a *blue* pigeon, fox, or rabbit, is only slaty blue; a *white* elephant is only spotted with white pink patches; a *blood* orange may be only speckled with blood-markings; a *black lion* and *black* leopard are only dark with black markings. Colours differing from nature are also ascribed to animals on signboards—*e.g.* *black*, *red*, *blue*, *white* lion; *blue* bear, &c.; thus also *green* man; also (in cookery) a *green* goose.

Artificial Objects.—Among artificial objects, even of strongly-marked hue, colour-terms are often strangely mis-

1 "Light from the East on the Colour Question," by W. J. Furrell, p. 321 of *Nineteenth Century* for February, 1885.

2 "The Colour Sense," by the Right Honourable W. E. Gladstone, M.P., p. 366 of *Nineteenth Century* for October, 1877.

applied (sometimes apparently by contrast with the characteristic colour). Thus all wines which are not of some red tint are loosely styled *white wines*, though their real colours are various shades of yellow, golden, and orange. Again, light-coloured hats, usually light gray, drab, or brown, are often styled *white* hats, probably in contrast with the black chimney-pot hat so common in England. The colour-term *green* with the figurative sense of "fresh," is applied to unseasoned timber and to freshly-quarried stone.

Metals.—Whilst some few metals have a sufficiently striking colour to give rise to a special colour-name—*e.g.*, *coppery*, *bronze*, *brazen*, *golden*, *aureine*, *steel-blue*, *leaden*, *iron-grey*, *argent*, *silvery*, the most of them have a general similarity of tint, and are loosely called *white* (probably in contrast to the coloured metals), whilst a mere tinge of blue in some of them leads to their being called *blue* (*e.g.*, lead, zinc, steel).

Curious applications occur in trade names: thus, *white metal* is used of any cheap alloy resembling silver in appearance; *white brass* is a whitish alloy of copper and zinc; *gray iron* and *white iron* are cast iron whose fracture is grey or white; whilst *white lead*, *zinc white*, *white arsenic* are the white oxides of the metals in question; *red lead* is the red oxide of lead, and *black lead* is really plumbago (which resembles lead only in its property of marking paper); *white*, *yellow*, *orange*, and *red*, when applied to gold, denote alloys of gold in which the golden colour is modified *slightly* in the directions indicated; *red-short* is an epithet descriptive of malleable metals which are brittle when hot.

Blue and Black.—There is a curious confusion between *dark blue* and *black* in both English and Hindústání. Thus, in English there are *blue-black*, *invisible blue* (both used of a very deep blue almost black), *black and blue* (applied to a bruise), *black as ink* and *inky black* (although most inks are nowadays blueish) often applied to rain-clouds (nimbus) and to the deep indigo blue of the deep sea, quite like the Hindústání phrase *kálá páni* (*lit.* black water) used of the sea. Dark blue cloth is by some (even by ladies) habitually called *black;* the writer has also known *black*berries miscalled *blae*berries (by a Scotch-woman), although *blae* is literally blue; this is quite like the Hindústání word *kálá*, which is used for both *black* and *dark blue*, especially in cloth. This confusion is curious in English, wherein the terms *jet-black*, *jetty*, *coal-black*, exist for a true black. In the melody, "The Coal-black Rose," the colour is attributed really to a person of the name of Rose.

Physical States.—Colour-terms are applied to physical states, sometimes in an exaggerated sense (the name of a bright colour being ascribed to any faint tint of the same), and sometimes in a special and almost inexplicable sense.

Thus we speak of *the black death*, *as black as death*, *black looks*, *looking as black as thunder*, *scarlet fever*, *yellow fever*, *jaundice*, *turning green with sickness*, *being beaten black and blue*, *blue with cold*, *a fit of blue devils*, *pale* or *white with illness* or *with loss of blood.*

Mental, &c., States.—The connection of colour terms with mental and moral emotions, conditions, and actions, is curious and often inexplicable.

Thus *black* is associated with the idea of evil—*e.g.* the *blackest of lies*, *black as sin*, *blackened with crime*, *as black as the devil;* and also with degradation in both English and Hindústání—*e.g.* to *blacken one's face* (Hind. *munh kálá karná*) implies disgrace in both languages. Again *black*, *purple*, *crimson*, *red*, *scarlet*, *pink*, *livid*, *pallid*, and *white* are all ascribed to rage; whilst *crimson*, *red*, and *scarlet* are also ascribed to shame, in both cases doubtless from their effect on the hue of the cheek. Further *crimson*, *red*, and *scarlet* are associated with crime (probably from their connection with blood), and also with sin generally—*e.g. red-handed*, *sins as scarlet*, the *scarlet woman*, &c. Next *black*, *yellow*, and *blue* are all used of depression of spirits—*e.g.* in the words *melancholy*, *atrabilious*, *jaundiced*, a *fit of the blues.* Again, *green* and *verdant* are used of the freshness of youth and of the state of a novice, and in this use both these colour-terms are oddly attributed to the eye; whilst *green* is also applied to (unusual) freshness in old age. The terms *green*, *blue* (*e.g.* a blue funk), *pale*, *pallid*, *livid*, *ashy*, *gray*, and *white* are all used as descriptive of fear; similarly the words χλωρος (commonly translated *green*) in Homer and *zard* (commonly translated *yellow*) in Hindústání are used of fear.

Again, *blue* is sometimes associated with religious feeling, and also with literary or scientific pursuits among women, *e.g.*, *blue-stocking.* Lastly, *white* is associated with the idea of good (perhaps in contrast to black, which goes with evil), *e.g. white lie* (*i.e.* a slight or venial lie), to be *whitewashed* (*i.e.* freed from debt), and extreme *whiteness* is associated with purity (probably from the pure whiteness of snow) *e.g. sins shall be as white as snow*, *white-robed angels*, &c.

Summary.—With such a looseness in the use of colour-terms in modern English and Hindústání as exemplified above, it seems (to the writer) that it is hardly possible to draw inferences as to the strength of the colour-sense in either the past or present from the (supposed) correct or incorrect application of colour-terms by other nations. Paucity of colour-terms is probably fair evidence of a poor colour-sense, whilst an abundance of the same is probably good evidence of a fine colour-sense. Viewed by this test, the colour-sense evidenced in the Homeric poems is certainly poor, and that of the natives of India is also poor compared with that of modern western nations; as to the latter, it may be said that a great development of colour-sense is now going on, and much more rapidly than in the past, judging from the frequent additions to the stock of dyes and pigments of late years, especially since the discovery of aniline and its derivatives.

Natives of India.—The author of "Light from the East on the Colour Question" considers that there is a "highly-developed colour-sense among the natives of India," and adduces the Indian coloured textile fabrics and works of art as evidence of this. This does not agree with the present writer's experience from a residence extending over twenty-three years in North India. The textile fabrics have certainly a good blending of colours; the cloth dyes and colours laid on pottery and other art-productions are also often beautiful. But the cloth-workers, dyers, potters, and other artisans in colours, and the educated classes, are the few among whom the colour-sense is well developed, and they are few among the 250,000,000 of India. The colour-terminology of Hindústání is poor, especially out of the classes above-named. Moreover, in the writer's experience the eyesight of the uneducated masses in India is defective in every way. They have great difficulty in threading a needle, in reading small type or small MS., also in reading at all except in a strong light, in discriminating colours, and (strangest of all) in making anything out of a picture, engraving, or photograph. This last defect is at first sight most surprising to an Englishman: it would seem as if a certain "picture-education" were necessary to develop a "picture-sense." A villager in India, or a quite uneducated servant, will sometimes examine a picture sideways, or even upside down, and will hazard the most incongruous ideas as to the subject, even when it is that of an object quite familiar to him.

ALLAN CUNNINGHAM

ENSILAGE

WE have observed with satisfaction, if we may be allowed to say so, the increasing attention which is being devoted to the subject of ensilage in this country, not only in view of the importance of this method of storing fodder as an auxiliary to the farmer, but because it evokes discussions which tend to the diffusion of the teachings of biologic science, and to widen the search after natural knowledge. The harvesting of ripe crops has become stereotyped by custom reaching back into the dim past; the practice of ensilage, on the other hand, involves a view of plant life which is not only foreign to our agricultural traditions, but is based upon less obvious teachings of nature, and it therefore demands a more intelligent cooperation of human industry. Notwithstanding these features, which make it a serious innovation, the unprejudiced acceptance of the system and the impartial spirit in which it is being practically investigated, testify to the growth of scientific culture amongst our agriculturists and to the general interest taken by them in the more recondite discussions of natural science which cannot fail to be widened by the study of the profound problems presented by the subject of ensilage. In contributing to the study of these we shall do so rather as observer than investigator, and as the text of our discussion we shall take Mr. Fry's excellent little work on "Sweet Ensilage." Whatever the fate of the theory of the silo expounded by the author—and it is certainly a bold excursion into the *terra incognita*—he furnishes us with a good and clearly expressed working hypothesis for the regulation of the system to the production of "sweet" ensilage, to which his efforts as an agriculturist have converged, he has sought a warrant in the teachings of vegetable physiology, and the theoretical account of the silo which has resulted may be stated in broad outlines as follows:—The crop to be ensiled is cut in the full vigour of the growth of the plant; the tissues of the plant do not die, but continue to exercise their organic functions for some time after being deposited in the silo. The rise of temperature which ensues in the silo is due to what the author terms "intercellular oxidation," or, from what we gather from the context, to the oxygen respiration of the cells.

In consequence of this increased temperature and its maintenance for a sufficient time, the cells of the plant are deprived of organic activity. The life of the plant under the restricting conditions of ensilation, induces an "intercellular fermentation," which manifests itself in one direction by the trans-generation of sugar into alcohol, the sugar being derived from the starch of the plant by hydrolysis. In regard to this function the author goes so far as to say: "When these transgenerations in the silo have been performed, the functions of the vegetable cells are at an end and they become inert and moribund." The formation of acetic acid in the silo, as also of lactic and other acids, are referred to ferment actions. The parasitic organisms present in the original mass are reduced to inertness by exposure to the elevated temperature produced in the silo, provided this is sufficiently high; nor can they resume their functions when the temperature falls to within the limits favourable to life. The ensiled matter, therefore, having attained and maintained for a sufficient time this suicidal temperature, is thenceforward without the pale of organic change. If, however, from any cause—the author gives prominence to two: viz. insufficient robustness of the cells and too large a proportion of water, which conditions, *e.g.*, are correlated in an immature growth—this critical temperature (at or about 50° C.) should not be reached, then the contents of the silo will, on cooling, become the prey of the bacterial life which has survived, and is ready to avail itself of favourable conditions for active development. The latter conditions determine the production of "sour" silage, the former of "sweet." In the chapter on the chemical composition of silage, in which analyses of various products are given, special attention is directed to the relatively high proportion of albuminoid to amide nitrogen in those which may be ranged in the latter class, as indicating their superior feeding value.

As a necessary preliminary to our discussion of the phenomena of the silo, in which we shall follow the lines thus laid down by Mr. Fry, we will review a few of the more prominent features of the chemistry of plant life, which no writer on this subject can afford to leave out of consideration.

That they have been considered, to some extent, in the account of the silo above detailed, is evidently due to Mr. Fry's position as an agriculturist writing for agriculturists. The practical purpose of his investigation and description of ensilage was only attainable by aiming at *a* probable truth to the exclusion of the whole truth. Our attempt will be to do justice to such an aim and its results, at the same time to aid in maintaining the scientific perspective of the question.

Many fruitless definitions of the supposed ultimate distinctions between a plant and an animal have from time to time been advanced; and while the controversies to which they have given rise have but little interest to those who take the broader view of classification, still there are certain very marked distinctions between the vegetable and animal worlds, considered each as a whole, which are independent of all views as to their abstract import and of all attempts to reduce them to a typical expression. First, in regard to synthetical activity and the power of appropriating carbon and nitrogen—the characteristic elements of living matter—the position of the vegetable world is anterior to that of the animal; or, to attempt a definition, the synthetical work of plants is ultimate, that of animals proximate. Secondly, nitrogenous or proteid substances are not essential constituents of the more prominent structures, *i.e.* the fibrous skeleton of a living plant, whereas the tissues of the animal are largely composed of such compounds. With regard to the functions of the protoplasm of the vegetable as compared with those of the animal organism, we may quote Michael Foster ("Physiology," 2nd ed., 343):—"It is not unreasonable to suppose that the animal is as constructive as the vegetable protoplasm, the difference between the two being that the former, unlike the latter, is as destructive as it is constructive." Thirdly, the synthetic activity of plants does not cease with the cessation of life, but persists in some measure in the substances which it has built up. We use the term "synthetic" here in a wider sense. The vast aggregations of the vegetable life of past ages with which we are so familiar in so many forms sufficiently illustrate our meaning; and the study of the everyday work of the redistributing agencies of Nature upon moribund vegetable matter, will prove the same refractory relationship—the possession of a power of resisting change under their influence not possessed by animal matter. Resolution takes place to a certain extent, in degree depending upon the circumstances of its deposition, and the surrounding physical conditions, but there is always to be observed the tendency to *accumulate* the characteristic element carbon, at the expense of the oxygen and hydrogen; we have every reason to regard the processes by which this result is attained as a self-contained re-arrangement of the matter and energy, localised in and by the plant during its life, and as the result, therefore, of the same activity. The life-history of a perennial plant also points to a high endowment of the molecules which are built up into its permanent parts; for these are not, as in the animal, subject to perpetual removal and renewal, but fixed and permanently localised. At the same time they run a long course of adaptation to the ever-changing condition of the structure which they compose, for which the necessary energy must be either concurrently or aboriginally supplied, or, as is probably true, both conditions of supply obtain. The study of the chemistry of liquification, and of the fate of moribund vegetable matter, therefore proves the possession of a high degree of intrinsic energy by plant substances, and the tendency to retain this energy in the form of derived compounds in which the carbon is proportionately accumulated.

Let us consider this endowment of energy of plants from a point of view more nearly that of the subject of these remarks—viz. the formation of the seed in an annual. We take it that every cell is impressed with the striving, so to speak, to bring about this result. In regard to the energy necessary, again we may conceive a storing up in the earlier processes of elaboration, together with a continuous supply from the external world. Supposing, now, the organic existence of the plant arrested by cutting during the period of inflorescence; the one supply is cut off, but what becomes of the other, the intrinsic energy and tendency of the organised matter in this direction? Analogy leads us to conclude that it flows on, expending itself on an unattainable end, until it fails from failure of the co-operative supply.

Now if this account of the relationship of the matter and energy of plants is generally true, we think they demand first consideration at the hands of investigators of ensilage. Mr. Fry attributes the rise of temperature in the silo to "intercellular oxidation." We think the term a good one, as it points to intrinsic oxygen exchanges. But we gather from the context that the oxydation referred to is at the expense of atmospheric oxygen. We think this qualification weakens the value of the term in diverting attention to a cause inadequate to produce the result. How much oxygen is contained or is supplied to the silo? Supposing it completely burned to carbonic anhydride and all the resulting heat effective in raising 100 times its weight of water 30° C. in temperature, is this sufficient on the most favourable calculation to raise the whole mass to 60°–70° C., the temperature which usually obtains? Why does the temperature continue to rise for some weeks after the crop has been ensiled, when from all causes the supply of oxygen must continually diminish? Apart from these considerations the conditions of the matter in the pit are surely unfavourable to oxidation by atmospheric oxygen, chiefly in the impediments to gaseous circulation and the absence of light. As we wish to confine ourselves to suggestions and to avoid statements of opinion, we do not hazard any conclusions on this point, but we ask for a comparison of the considerations drawn from the study of the intrinsic energy of plants with those from their relationships to the external world, in regard to this first phenomenon of the silo.

In regard to Mr. Fry's theory of "intercellular fermentation," we again think the term conveys a wider truth than his exposition. As an agriculturist he recognises two main kinds of ensilage products—sweet and sour—and we have already alluded to his account of their production.

Now, on what does this terminology turn, in as far as it is correlated with the chemical composition of the silage? Upon quantities of certain constituents which are a small fraction of the whole. It is, on the other hand, an axiom with the chemist, in his study of reactions, not to be led away by issues which are obviously subordinate. From a number of considerations which follow directly from the previous discussion, the cellulose fabric of the plant studied comparatively with the changes which it undergoes in the silo, is best calculated to throw light on the general nature and tendency of these changes. These changes involve a commerce of molecules, if we may use the expression, of which the appearance of small quantities more or less of particular acids or other compounds are minor results. We prefer the term "intercellular *commerce*" as less specialised than "fermentation"; and and in so far as the problems involved are essentially chemical, we think a study of the matter changes from this point of view in the order pointed out by relative quantity and permanence of relationship to the plant structure, is better calculated to elucidate the nature of these transformations.

In regard to sour ensilage, and the view of it as resulting from bacterial fermentation, we have little to say. The study of the life of such organisms under the very peculiar circumstances of the silo has been thus far very slender. From the later researches of Nägeli and others, which have considerably modified the theory of anærobic fermentation as propounded by Pasteur, we are inclined to attach less weight to this probable factor of the changes in the silo than Mr. Fry.

Generally speaking, and as he admits, the whole subject needs a very exhaustive investigation, and as we would point out, on the widest basis, and altogether independently of its special bearings upon agriculture The scientific method must be followed, even though in particular experiments the silage were rendered unfit for food. The factors of the result must be caused to vary artificially that their influence may be severally measured. The silo may be heated in any suitable way, the organic matter may be sterilised as regards parasitic germs, substances may be added to modify the reactions, and many other and similar self-suggestive means employed to test particular issues. In conclusion we revert to our original text, and we congratulate Mr. Fry on having laboured well in a good cause. As an agriculturist he has exceeded in his investigations what was to be expected; but in his endeavour to give a scientific account of the silo simultaneously with the agricultural, we think he has disposed of the complications of the subject by repressing their consideration. It is to the somewhat thankless task of reproducing certain of these that we have addressed ourselves, with the view, as already stated, of aiding to keep the subject in its true perspective.

NOTES

Thomas Davidson, LL.D., F.R.S., of Muirhouse, Midlothian, died, from an attack of lung disease, at West Brighton, on the 16th inst., in his sixty-ninth year. Dr. Davidson, who was so well known in the scientific world, more especially for his work on the "Fossil Brachiopoda," was a Fellow of the Royal, the Geological, and many other learned Societies, foreign as well as British. In 1851 he began his description of the "British Fossil Brachiopoda," which has been published from year to year by the Palæontological Society, the concluding supplements having appeared in the last volume of that Society in December 1884. Numerous memoirs on similar subjects have been published in the *Transactions* of several scientific Societies. Recently Dr. Davidson prepared a "Report on the Brachiopoda dredged by H.M.S. *Challenger* during the Years 1873–76." At the time of his death he was engaged upon a further monograph on recent Brachiopoda, the first part of which is now appearing in the *Transactions* of the Linnean Society. Dr. Davidson latterly resided at Brighton, and notwithstanding his other scientific avocations he devoted a considerable portion of his time to the perfecting of the town museum.

President Cleveland's invitation to Prof. Agassiz to assume the direction of the United States Coast Survey has been hailed in America as an assurance that the new administration will encourage scientific work, and is not indifferent to survey, but is desirous of placing it under a head whose name and character would be a guarantee of success. The health of the Professor precluded his acceptance of the post; but beyond this he is of opinion that the guidance of the Coast Survey requires an expert. The problems to be decided, the methods to be employed, the men to be engaged, should, he thinks, be determined by one who knows the business. Any other person would be in danger of failure. In concluding an article on the subject *Science* says:—"The correspondence of Secretary Man-ning and Prof. Agassiz is to us an assurance that science will not be retarded, and that scientific men will not be slighted by any act of President Cleveland."

Science comments in a recent issue on an extraordinary statement published in certain New York and Boston journals to the effect that a committee which had been appointed to investigate the geological survey of the United States had found that illegal practices prevailed in the work of that department. It appears that no such committee ever sat; the whole was pure fiction. There was no report, no illegal proceedings, no examination. The officer to whom it was said the committee made this report has no authority to appoint or superintend such a committee, and the whole story had its origin in the fertile brain of an imaginative newspaper correspondent. It is well that this should be understood in this country, in case the baseless statements referred to should have made their way here.

THE Annual Meeting of the London Mathematical Society will be held on Thursday evening, November 12, and will be made special for the purpose of considering alterations in the rules, which will be proposed by the Council. At the same meeting it will be proposed to elect Mr. C. Leudesdorf and Capt. P. A. Macmahon, R. A., as new members of the Council in the place of Dr. Hirst, F.R.S., and Mr. R. F. Scott, who retire.

THE following are the conclusions of the Scientific Commission appointed by the Spanish Government to examine Dr. Ferran's method of treating cholera patients. They are abbreviated by the special correspondent of the *Times* in the cholera districts of Spain, writing from Valencia on October 12: (1) Dr. Ferran's inoculations cannot be considered inoffensive. (2) The attenuation of the comma bacillus has not been demonstrated. (3) The prophylactic measures conceived by Dr. Ferran are empiric, for they are in no wise governed by scientific rules or laws. (4) By means of the vaccination the epidemic is propagated. (5) It is not demonstrated by the results ascertained that the inoculations secure immunity from cholera. (6) The individual during the first days following his inoculation is rendered more susceptible to contract any other form of disease. (7) This is due to the fact that the inoculation disturbs more or less profoundly the physiological equilibrium which it is so necessary to maintain during a period of epidemics. (8) The results as seen by the Commission do not prove immunity from cholera. Neither is it possible to obtain conclusions from statistics relating to inoculations, because general laws cannot be deduced from isolated facts.

DR. QUAIN delivered the Harveian oration on Monday afternoon before the Royal College of Physicians. He set himself to answer two questions: first, why it is that among a vast number of persons, alike in ancient and in modern times, medicine has not enjoyed that high estimate of its value, as an art and as a science, to which it is justly entitled; and, secondly, whether we have any grounds for anticipating a more satisfactory future for medicine, either in the security of the foundations on which it is laid, or in the consequent appreciation of it by the public. In the course of the oration Dr. Quain spoke of the progress of medical science before the foundation of the College of Physicians; the advances made in our knowledge of etiology, especially in the practice of arresting the diffusion of disease by limiting the spread of contagion, and of improvements in our knowledge of pathology. Having pointed out the progress which science and art have made in every direction, Dr. Quain produced statistical evidence that the improvement has been productive of substantial results. In answer to the second question he quoted the words of "one of the most eminent of our statesmen," to the effect that in a generation or two the medical profession would be far in advance of the other arned professions."

WE lately quoted in NATURE, with a comment on the exceedingly unusual character of such an announcement from America, a statement to the effect that the Astronomical Observatory of Beloit College was being closed on account of want of funds. We are very pleased to learn from *Science* that this statement is quite erroneous. On the contrary, Prof. Bacon, the Director of the Observatory, states that new arrangements have been made for carrying on additional observations in meteorology, and that especial attention will be paid to solar and spectroscopic work with greater facilities than before. This, we may observe, is happily by no means a surprising or novel announcement from across the Atlantic.

THE new School of Metallurgy which has recently been added to the Birmingham and Midland Institute, was formally opened on September 24, when Prof. Chandler Roberts, F.R.S., delivered a lecture on the Development of Technical Instruction in Metallurgy. Prof. Roberts pointed out how very recent has been the introduction into this country of systematic instruction in metallurgy. After referring to the important share which Dr. Percy has had in the development of metallurgical work in England, and to the steps taken by the Committee of Council on Education for its practical working, Prof. Roberts insisted on the importance of combining theory and practice, and referred at length to the methods adopted in the School of Mines. A full report of Prof. Roberts' lecture will be found in the *Chemical News* of October 9.

THE increasing efficiency with which electric lighting can be applied has recently been shown by Messrs. Woodhouse and Rawson, who, at a *soirée* at Guy's Hospital, lit up the building with their incandescent lamps, worked off Faure Sellon accumulators, which were only delivered on the morning of the *soirée*. Equally efficient was the lighting supplied by the same firm at the Leicester Exhibition of the Sanitary Institute of Great Britain. It is certainly a great convenience that such temporary illuminations can be effected under almost any conditions.

IN an article on the use of the French Academy, *Science* says:—"But, aside from all personal considerations, there remains a question whether an organisation like the French Academy may not perform an important service to the country by giving its collective authority to the encouragement of excellence in the use of language. May not its criticism of its own members, its judgment of works presented to it, its bestowal of academic honours, its election of associates, its public discourses, and its serious scrutiny of the vocabulary and phraseology of the language in their combined influence, be a very powerful agency in the promotion of literary excellence? May it not become a sort of schoolmaster to the nation, incapable of making good writers out of bad, but helpful in discipline? Who can tell what has been the net gain to France from such a society? Is the clearness, the precision, the symmetry, the finish of a good French style worth having? What would the German language be to the world if there had been a German academy at work for 250 years smoothing its roughness and insisting upon clear, unencumbered, and pleasing forms of expression?"

THE Calendar of the University College of North Wales, at Bangor, has just been published. Besides the usual information, examination papers and lists, it contains a brief sketch of the establishment of this college, which now enters its second year, and which promises to have a success worthy of the efforts by which it was founded. The thirst of the Welsh people for knowledge and for the education of their children is well known, and the introduction to the "Calendar" states that never before in so short a period have so many persons, either in England or in Wales, subscribed towards a movement for the promotion of higher education. In twelve months the list rose to upwards of 30,000*l.*, and by the end of 1884 it had exceeded 37,000*l.*

WE have received Prof. Rockwood's account of the progress in vulcanology and seismology in the years 1883, 1884, from the Smithsonian Report for 1884. Under Vulcanology he treats of the volcanic eruptions during the two years (dealing mainly with the Krakatoa eruption), and of the investigations of former volcanic activity. In seismology he divides his subject into earthquake lists of 1882 and 1883, special earthquakes of 1883 and 1884, lists of former earthquakes, and theories of earthquakes. In seismometry Prof. Rockwood deals with instruments and their records. The pamphlet, which should be a *vade mecum* for all engaged in investigating seismic phenomena, concludes with a bibliographical list of all the books and papers relating to the subject, which appeared during the two years under review. This list is surprising for its length and variety.

VUIBERT'S *Journal de Mathématiques Élémentaires*, which has had an existence of nine years in a lithographed form, commences its tenth year in print. It may be called the French schoolboys' mathematical journal, for it is addressed specially to them, and all the solutions are contributed by them. It appears fortnightly from October 1 to July 15, and the terms of subscription are very moderate. We have unfortunately in this country nothing to correspond to it, and it may therefore be useful to signalise its existence to mathematical masters.

AT a meeting of the Council of the National Fish Culture Association held on Friday last under the presidency of the Marquess of Exeter, it was resolved to take immediate steps to conduct a series of investigations and observations on the ocean in regard to its temperature at various depths; also as to the habits of fish, their spawning grounds, their enemies, and the cause of their erratic migrations. The Duke of Edinburgh, it was stated, had much interested himself in the subject, and had obtained the cooperation of the Admiralty and Trinity Board in aiding the Association to carry out the observations with the view of promoting marine fish culture and undertaking it on a thoroughly scientific basis.

THE Severn Fishery Board have made arrangements with the National Fish Culture Association to incubate salmon ova. When hatched out the fry will be placed in the waters under the control of the Board, which is doing its utmost to cultivate all species of Salmonidæ. The National Fish Culture Association will, it is understood, render similar service gratuitously to other Boards, in order to assist in developing the inland fisheries of the United Kingdom.

THE Institute of Chemistry has obtained a Royal Charter of Incorporation from the Privy Council, and it is intended to celebrate the occasion by a dinner on November 6.

THE following Penny Science Lectures will be given at the Royal Victoria Hall and Coffee Tavern, Waterloo Bridge Road, during the ensuing weeks.—On Tuesday, October 27, Mr. W. D. Halliburton will lecture on the "Circulation of the Blood"; on Tuesday, November 3, Sir John Lubbock will lecture on "Ants"; on Tuesday, November 10, Mr. W. Lant Carpenter will lecture on "Electrical Fire Alarms in America."

A SHOCK of earthquake was felt at half-past seven o'clock on the morning of the 13th in Granada and the surrounding country. The movement is described as a long trepidation, with a rumbling noise. At Palermo a shock occurred on the morning of the 15th. A house, three storeys high, fell in, and a number of persons were buried in the *débris.*

IN connection with the General Italian Exhibition held in Turin last year, the Italian Meteorological Society has just issued an interesting *brochure* on the present state of astronomical, physical, and meteorological studies in the peninsula. In these departments the show was thoroughly national, special prominence having been given to those branches which are at present most widely cultivated in Italy. Thus in terrestrial physics full scope was given to seismology, vulcanology, and geodynamics, all which studies, owing to the special local conditions, have here been associated with some of the most illustrious names in science. Meteorology was well represented by specimens of the best apparatus from the chief meteorological stations in the country, and in astronomy the progress of all the local observatories was fully illustrated. Amongst the objects on view were astronomical, physical, and meteorological apparatus; charts, maps, designs, photographs; printed and manuscript works on these subjects. Although still far behind some other countries in the production of scientific instruments, the display showed that in recent times Italy has made considerable progress in this branch of mechanics. To illustrate the history of these sciences the exhibition included some curious old instruments associated with the names of illustrious pioneers, who laboriously prepared the way now followed by their more fortunate successors living in better times and enjoying the advantage of more perfect appliances. The pamphlet contains a complete list of the ninety-one meteorological and geodynamic stations already established throughout the peninsula, as well as the names of exhibitors, to whom diplomas, gold and silver medals, and other distinctions were awarded.

MR. MELLARD READE'S presidential address to the Liverpool Geological Society was on "The North Atlantic as a Geological Basin." After discussing the form and nature of the ocean-bed so far as is disclosed by the latest soundings and dredgings, he pointed out that all along the coast of Spain and North Africa the bottom was exceedingly irregular, as proved by the soundings for the telegraph cables, consisting apparently of mountains and valleys. On the opposite coast of South America, and especially about the mouths of the Amazons, the soundings were comparatively shallow and of nearly uniform depth. Taken together with the known great depth of alluvial deposits at the mouths of all the great rivers where borings had been made, and the undoubted great age of the Amazons Basin, Mr. Reade arrives at the opinion that this plateau is a submarine extension of the delta proper, consisting of geologically modern sediment probably thousands of feet thick. The same reasoning, he points out, will apply to other great rivers and coasts where similar conditions exist.

FROM a series of experiments by Herr Graber, relating to the effects of odorous matters on invertebrate animals, it appears probable that in the case of many insects neither the antennæ nor the palpi can be absolutely pronounced the most sensitive organ of smell, inasmuch as the one organ is most sensitive for some odorous matters, and the other for others.

THE additions to the Zoological Society's Gardens during the past week include a Purple-faced Monkey (*Semnopithecus leucoprymnus* ♀) from Ceylon, presented by Major Norris; a Rhesus Monkey (*Macacus rhesus* ♀) from India, presented by Mr. J. H. Fielding; a Common Marmoset (*Hapale jacchus*), a Black-eared Marmoset (*Hapale penicillata*) from Brazil, presented by Miss Knowles; a Common Marmoset (*Hapale jacchus*) from Brazil, presented by Lady Cowley; a Common Hare (*Lepus europæus*), British, presented by Mr. F. J. Allpress; a Mexican Souslik (*Spermophilus mexicanus* ♂) from Mexico, presented by Dr. Stuart; a Herring Gull (*Larus argentatus*), British, presented by Mr. J. G. Taylor; a Macaque Monkey (*Macacus cynomolgus* ♂) from India, a Green Monkey (*Cercopithecus callitrichus* ♀) from West Africa, deposited; an Ariel Toucan (*Ramphastos ariel*) from Brazil, purchased; a Hoolock Gibbon (*Hylobates hoolock* ♀), received in exchange.

OUR ASTRONOMICAL COLUMN

The Variable-star V Cygni.—In Dr. Hartwig's ephemeris of the variable stars for the present year a maximum of V Cygni is doubtfully assigned to November 15. The change in the brightness of this strikingly red star was notified by the late Mr. Birmingham in May, 1881. The several determinations of the time of maximum in the following year were very discordant; thus, Dr. Lindemann (who made an interesting communication on this star to the St. Petersburg Academy in January 1884) fixed it on August 31 "auf wenige Tage sicher"; Schmidt gave July 17, while Prof. Safarik considered it was reached on June 17. This divergence induced Dr. Lindemann to commence regular observations of the star in August 1882, details of which will be found in his paper (*Bulletin de l'Academie Imperial des Sciences de St. Pétersburg*, t. xxix.). The variation appeared to be from 6·8 m. to below 10 m., and the period indicated by the observations of 1882 and 1883 was about a year, though a longer one is now assigned. Several of Dr. Lindemann's notes are worthy of attention. On July 19, 1881, the star had a nebulous cometary aspect, with sensible diameter. On August 13 in the following year it was more stellar, and had no longer the nebulous appearance it presented in 1881, though a month later this was again suspected. On May 13, 1883, we read: "V funkelt sehr stark, leuchtet momentan auf und verschwindet dazwischen beinahe," though a comparison star DM + 47°, 3162 showed a steady light. On July 27 it shone as steadily as the neighbouring stars, without any nebulous appearance. On October 8—"sehr verschwommen"; a week afterwards, this aspect was not remarked, though the images of surrounding stars were very indifferent. At the end of the same month V was again stellar. Variations in the intensity of the colour were also remarked.

The place of this star for 1885·0, according to meridian observation at Pulkowa is in R.A. 20h. 37m. 35·7s. Decl. + 47° 43′ 53″.

Occultation of Aldebaran on November 22.—The Greenwich mean times of disappearance and reappearance of this star and the corresponding angles from north point, in the occultation on the evening of November 22, may be pretty closely determined for any place in this country from the following formulæ:—

$$\text{Time of disap.} = 9^{h}\ 45^{m}{\cdot}7 + [0{\cdot}2259]\,L + [9{\cdot}3110]\,M$$
$$\text{,, reap.} = 10\ 56{\cdot}2 + [9{\cdot}8575]\,L + [9{\cdot}4779]\,M$$

$$\text{Angle at disap.} = 104^{\circ}{\cdot}1 + [0{\cdot}3581]\,L - [9{\cdot}307]\,M$$
$$\text{,, reap.} = 281{\cdot}6 - [0{\cdot}412]\,L + [9{\cdot}246]\,M$$

In which the latitude of the place is put = 50° + L, and M is the longitude in minutes of time counted positive towards the east. The quantities within brackets are logarithms.

The above equations are founded upon the following results of direct calculation:—

	Disappearance h. m. s.	Reappearance h. m. s.	Angles from N. Point °	°
Greenwich ...	9 48 9 ...	10 57 15 ...	108	278
Edinburgh ...	9 53 5 ...	10 56 39 ...	120	264
Dublin	9 46 10 ...	10 51 0 ...	117	268

Double-Stars.—Two important series of measures of double-stars have lately appeared in the *Astronomische Nachrichten*: the first in Nos. 2677-78, by Dr. R. Engelmann, of Leipsic, in continuation of a series previously published; the second by M. Perrotin, made at the Observatory of Nice, in Nos. 2684-85. According to the Leipsic observations of Σ 2173, for which Prof. Duner found a period of 45 years only, calculation is not yet so much in error, as for a first approximation, and so difficult a star, might well have been anticipated. Dr. Engelmann's mean result is, for 1883·88, position, 24°·8; distance, 0″·23; the orbit gives 34° and 0″·2. The Leipsic series contains measures of many of Mr. Otto Struve's and Mr. Burnham's stars.

ASTROPHYSICAL NOTES

Stars with Spectra of the Third Type.—Prof. Dunér has published an important catalogue of stars having banded spectra. Following Prof. Vogel's classification he prefers to regard the spectra with bands fading away towards the violet as a subdivision of the same type as those in which the bands fade away towards the red, rather than, with Secchi, to make them into a separate class. Dunér's type III. *a*, therefore, corresponds to Secchi's third type and his III. *b* to Secchi's fourth type. Prof. Dunér's purpose in forming this catalogue is to supply the means for future observers to detect changes in these spectra should any such occur, for, as he points out, these stars are probably in a very advanced state of development, and we may therefore, perhaps, hope to discover some day changes in their spectra which, carefully studied, may lead to important results as to the nature of suns. They are the more interesting, also, because variable stars of long period usually belong to this class.

With this view Prof. Dunér has carefully examined all the known objects of this type which are visible in his latitude, and for which the optical means at his command were sufficient, and he has catalogued 297 stars of type III. *a*, that is, with bands shading off towards the red, and 55 of type III. *b*, with bands shading off in the opposite direction. An important section follows giving a list of stars which different astronomers have regarded as belonging to the third class, but which Dunér cannot so classify. Only in a very few instances, however, is there any good reason to suspect a change in the spectrum. In the great majority Secchi, whose observations supply most of these cases of discrepancy, had himself at one time or another registered the star as being of the second type, *i.e.* without bands, or else had especially remarked on the extreme feebleness of the bands which he thought he saw. There are, however, three stars observed by D'Arrest for which the evidence of change seems stronger, viz. 24034 LL., D.M. + 60° 1461 and D.M. + 36° 2772. Prof. Dunér has also failed to find Schjellerup No. 249. which is, perhaps, a long period variable, and he draws special attention to R Andromedæ, a star the spectrum of which, though of type III. *a*, presents some very marked peculiarities. Great care has been taken in the determination of the positions of the bands in the different spectra. It is clear, as many spectroscopists have already observed, that the bands of type III. *a*, occupy the same positions in all the spectra of the type, and the same is true for the bands of type III. *b*. With regard to the former class, the sharp dark edges on the more refrangible sides of the bands generally coincide with strong metallic lines; thus one of the most prominent bands is terminated by the *b*-lines of magnesium. The nature of the connection between the bands and these metallic lines is not at all clear at present, the symmetrical arrangement of the bands seeming to suggest that they are due to some one substance rather than to several. The three principal bands of the spectra of the other type Prof. Dunér considers to be unmistakably those of a carbon compound, and to correspond to the bright bands so familiar in the spectra of comets. The determinations of the wave-lengths of the bands in spectra of this type are necessarily not quite so accurate as those of the bands in spectra of type III. *a*, but if Prof. Dunér's measures are accepted, this most important correspondence may be considered fully established. But, apart from the value of these measures, Prof. Dunér's catalogue, with the full and clear descriptions he has appended to every star, will be of the utmost service to future observers of these interesting and beautiful objects.

The Comet of 1866 and the Meteors of November 14.—Prof. D. Kirkwood has recently pointed out in a paper read before the American Philosophical Society, that there is distinct evidence that there are three meteoric swarms travelling in the orbit of Tempel's comet. Of these the principal group is the one which produced the great showers of 1833 and 1866, the period of which Prof. Adams showed to be about 33·25 years. In 1875 Prof. Kirkwood identified a second group from the dates of meteoric showers given by Humboldt and Quetelet, the period of which would be about 33·31 years. The next shower from this group will be due about November 13-15, 1887; but the display may perhaps commence in November 1886, or even in the present year. The third cluster has been less observed; its period is about 33·19 years, and its next return will be from 1912 to 1915. Prof. Kirkwood suggests that the very great diminution in brightness in Tempel's comet since 1366, the comet of that year being now generally regarded as one of its apparitions, may possibly be due to the separation of the first and largest swarm from the comet having taken place in that year, the meteoric shower of that year being nearly contemporaneous with the apparition of the comet.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, OCTOBER 25-31

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on October 25

Sun rises, 6h. 44m.; souths, 11h. 44m. 7·5s.; sets, 16h. 45m.; decl. on meridian, 12° 16′ S.: Sidereal Time at Sunset, 19h. 2m.

Moon (two days after Full) rises, 17h. 32m.*; souths, 0h. 46m.; sets, 8h. 11m.; decl. on meridian, 12° 52′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	7 18	12 7	16 56	14 22 S.
Venus	10 56	14 38	18 20	24 54 S.
Mars	0 1	7 26	14 51	15 30 N.
Jupiter	3 15	9 32	15 49	2 33 N.
Saturn	20 13*	4 21	12 29	22 17 N.

* Indicates that the rising is that of the preceding day.

GEOGRAPHICAL NOTES

A recent Blue-book (Siam, No. 1, 1885) contains a report by Mr. Archer, of the Consular service in Siam, on silk-culture in the province of Kabin, which lies on the eastern side of the Siamese delta, at the foot of the mountains separating the Meinam valley from that of the Meiking. In the course of his journey Mr. Archer came across certain Laos settlements, of which he gives an interesting account which is deserving of note, on account of the very little known of the Laos. He says the settlements in the provinces of Pachim and Nakon Nayok are, as it were, the south-western outposts of the Laos race, which forms the bulk of the population of Eastern and Northern Siam, but they are "phung khao," or "white-bellied," and therefore distinct from the "black-bellied," or inhabitants of the Chiengmai provinces. They are not, however, the original inhabitants of these provinces, but captives from Muang Kalassin, a province to the north east of Korat, formerly dependent on Wien Chan, who, after the war waged successfully by the Siamese against that ancient kingdom about sixty years ago, were transported to and allowed to settle in the country extending from the province of Nakon Nayok to that of Battambong. This country consists, for the most part, of a series of slight and gradual elevations and depressions, the dwellings, gardens, and any other plantations being generally situated on the former, whilst rice is cultivated in the latter. The population is sparse, and consequently the greater part of the country is covered with jungle. The inhabitants are exceedingly indolent, and appear unable to exert themselves to procure more than enough rice for their bare sustenance. Their mode of living is of the simplest description, and their country being far from any commercial centre and outside any trade route, hardly any foreign goods, with the exception of cotton, are to be found amongst them. All Laos tribes, however, are not characterised by such indolence. Those living in the provinces closer to Korat are much more active, and devote more attention to agriculture, especially to the rearing of silkworms. This is stated to be due to the latter having a poorer soil at a higher altitude, which compels the inhabitants to devote more attention to silk-producing as a means of livelihood.

Mr. Coutts Trotter read a paper at the Aberdeen Meeting of the British Association "On Recent Explorations in New Guinea," bringing up to date the information he laid before the Section two years ago. It deals with certain hydrographical and other physico-geographical questions on which light has been lately thrown by Mr. Chalmers's journey, and by the ascent of the Amberno River, and points to the conclusions to be drawn from certain temples, with a special priesthood and objects of worship lately discovered—implying an order of religious ideas quite foreign to the Papuan mind. As regards the natives of New Guinea, he believes the conflicting jurisdiction, and different views as to the mode of dealing with them, must be prejudicial to their interests.

The Arctic steamer *Alert* returned to Halifax on October 18 from Hudson Bay with the observation party who have spent fifteen months there testing the practicability of that route for navigation from the Canadian north-west to Europe. The result of the observations shows that the average temperature is not so low as was expected, nor so low as the average winter temperature in the North-West. The lowest monthly average was 30° below zero. The ice observations show that the Hudson Straits and Bay are navigable by properly built and equipped vessels for from three to four months—from July to October. While this report is somewhat favourable, doubts are expressed in Canada whether the Hudson Bay route can ever be made practicable.

THE GREAT OCEAN BASINS[1]

II.

The advances during recent years in the knowledge of the forms of life inhabiting the floor of the ocean surpass those in any other department of oceanic investigation. Thousands of new organisms have been discovered in all seas and at all depths in the ocean, and either have been, or are now being, described by specialists in all quarters of the world. There does not seem to be any part of the ocean bed so deep, so dark, so still, or where the pressure is so great as to have effectually raised a barrier to the invasion of life in some of its many forms. Even in the greater depths all the great divisions of the animal kingdom are represented.

As might have been expected, forms of life are most rich and varied in the shallow water surrounding the continents, where there is abundance of food, sunlight, and warmth; where there is motion, rapid change of water through currents, and other congenial conditions. At the depth of half a mile there are still numerous animals, though many of them differ from those of shallower depths, but plant-life seems to have wholly disappeared, if we except the diatoms and calcareous algæ, whose frustules and skeletons have fallen to the bottom from the surface, carrying with them some of their protoplasm and chlorophyll.

At the depth of one mile there are a few animals which are barely distinguishable from, if they be not identical with, shallow water forms; but the majority of the animals are specifically distinct from those found within the 100-fathom line, and many of them belong to species peculiar to the deep sea, and are universally distributed over the ocean bed in deep water.

As we descend into still deeper water, and proceed further seawards from the borders of the continents, species and the number of individuals become fewer and fewer, though they often present archaic or embryonic characters, till a minimum is reached in the greatest depths furthest from continental land. Distance from continental land is, indeed, a much more important factor in the distribution of deep-sea animals than actual depth.

If we neglect the Protozoa and compare the results of twelve of the *Challenger's* trawlings and dredgings in the central line of the Pacific, in depths greater than 2000 fathoms, on globigerina ooze, radiolarian ooze, and red clay, with twelve trawlings and dredgings taken under similar conditions and depths, but on the blue and green muds within 200 miles of the continents, we find that the Central Pacific stations have yielded 92 specimens of animals belonging to 52 species, all, with two doubtful exceptions, new to science, and among them 13 new genera; on the other hand, the stations near the continents have given over 1000 specimens belonging to 211 species, of which 145 are new species and 66 belong to species previously known from

[1] Lecture delivered at the Aberdeen meeting of the British Association by Mr. John Murray, Director of the *Challenger* Reports. Continued from p. 584.

shallower water. These numbers are not final, but the proportions are not likely to be greatly altered when the whole of the *Challenger* Reports are completed. These facts may be in part explained by the greater abundance of food present in the continental *débris* which forms the chief constituent of the terrigenous deposits; but it is probably more closely connected with the greater distance of the seaward stations from the original place of migration. We must suppose that all deep-sea animals have been derived originally from shallow water; those which descended first into deeper water have, generally speaking, been able to migrate to a greater distance seawards than those which set out later, and being derived from older stocks they have retained in the great deeps some of the characters which are now regarded as archaic and embryonic.

Although no new types of structure have been discovered in organisms from the deep sea, the peculiar modifications which animals have undergone to accommodate themselves to abysmal conditions are sufficiently interesting and remarkable; the eyes of some fish and crustaceans have become atrophied or have disappeared altogether, while in others they have become of exceedingly large size or have been so modified as to be scarcely recognisable as eyes: for instance, in the case of the scopelid fish *Ipnops*; fins and antennæ have become extraordinarily elongated and at times appear to simulate the alcyonarians of the deep sea. The higher crustacea and some families of fish have very few and very large eggs in the deep-sea species, while their shallow-water representatives have a very large number of very small eggs, showing apparently that the deep-sea species have relatively few enemies. While some groups, for instance the Pycnogonids, Tubularians, and Nudibranchs, have much more gigantic representatives in the deep sea than in shallow water, the representatives of the majority of groups, and especially the Gasteropods and Lamellibranchs, are much smaller, and generally speaking have a dwarfed and delicate appearance, the shells being poorly supplied with carbonate of lime. Indeed the solid tissues of most deep-sea animals are but feebly developed when compared with shallow-water forms. The experienced dredger has, as a rule, little difficulty in recognising a deep-sea species in a dredging from its general appearance. Many deep-sea animals emit, and some have special organs for the emission of, phosphorescent light, which appears to play a large *rôle* in the economy of deep-sea life.

One of the most striking facts with respect to deep-sea animals is their very wide distribution—the same species being found in all the great ocean basins. At the depth of half a mile identical species are dredged off the coast of Scotland and off the coast of Australia at the Antipodes; the nearly uniform conditions, existing everywhere at depths greater than half a mile, facilitates the wide distribution of species which have once accommodated themselves to a life at that depth. The same consideration probably explains the occurrence of some identical and nearly identical species in the shallow waters of the temperate and polar regions of both hemispheres.

Among the higher crustacea the Brachyurans, which are regarded as a modern group, are found in great numbers in shallow waters, but have very few representatives in deep waters, and appear to be quite absent from the abysmal regions. On the other hand, the representatives of the Schizopoda, Anomoura, and Macrura, which are regarded as older groups, are widely distributed in the deep sea; many similar instances of this kind could be given. The stalked Crinoids, the Elpidiidæ among the Holothurians, the Pourtalesiæ and Phormosomas among the Echinids, and other groups, have now no representatives in depths less than 100 fathoms, but are widely distributed in all greater depths; while many genera are confined to the abysmal regions. We are not as yet, however, in a position to fully discuss many curious points in distribution, even did time permit.

It may be urged that after all the few hundred scrapings of our small trawls and dredges can give but a very inadequate idea of the condition of things over the millions of square miles covered by the ocean, but against this it may be argued with great force that as the same animals and deposits occurred again and again with little variation, we doubtless have even now a tolerably complete knowledge of deep-sea life.

When we turn to the surface waters, one may exclaim: it is a dull and stupid soul that would not rejoice at the first acquaintance with the teeming pelagic life of the ocean, rich in bizarre forms and varied colours, or that would not be struck with wonder at the magnificent displays of phosphorescent light sent forth on a dark night from the surface of an equatorial ocean, like flashes of "spirits from the vasty deep."

> "Beyond the shadow of the ship
> I watched the water snakes;
> They moved in tracks of shining white,
> And when they reared the elfish light
> Fell off in hoary flakes.
>
> "Within the shadow of the ship
> I watched their rich attire;
> Blue, glossy green, and velvet black,
> They coiled and swam, and every track
> Was a flash of golden fire.
>
> "Oh, happy living things! No tongue
> Their beauty might declare.
> A spring of love gushed from my heart,
> And I blessed them unaware."

Experiments with tow-nets have shown that life exists in all the intermediate waters of the ocean, between the surface and the bottom, yet sparingly there when compared with what occurs just above the bottom, or more markedly when compared with the abundant and luxurious development of life in the surface and sub-surface waters.

In mid-ocean the majority of the organisms are quite distinct from those usually found along the coasts in bays and estuaries, though, like the deep-sea animals, they were, in all probability, originally derived from the shallow waters around the continents. There are species of diatoms, calcareous and other algæ, many foraminifera, siphonophora, a few annelids, many crustaceans, numerous pteropods, heteropods, and other molluscs, the pelagic tunicates, and many fishes whose home is in the great systems of oceanic currents. It is only occasionally, or in special localities, that some of the species are borne to continental shores, for the members of this oceanic pelagic fauna and flora appear to be killed off where the ocean is affected by the fresh waters from the land. In the equatorial regions the species and individuals are most abundant, and they vary with temperature, latitude, and the salinity of the water.

In the Antarctic or Southern Ocean diatoms abound at the surface, and in the same region the sea-floor is covered with their dead siliceous frustules, which form a *diatom ooze*. In the middle and western Pacific, where the surface water is less salt than in the Atlantic, the radiolarians, which likewise secrete silica from sea water, occur in vast numbers at the surface and in intermediate waters, and in these regions their dead shells and skeletons make up the chief part of the deep-sea deposits, known as *radiolarian ooze*.

But it is those species belonging to the varied pelagic oceanic organisms which secrete lime for their shells and skeletons that are principally forced on our attention, both from their prodigious numbers and the part played by their remains in the formation of deposits. These species flourish especially in the warmest and saltest waters. In a square mile of equatorial water 600 feet deep it is estimated that there are over 16 tons of carbonate of lime in the form of shells, which belong to about 30 species of calcareous Algæ, Foraminifera, Pteropods, and Heteropods. When these surface organisms die and fall to the bottom they form the deposits known as *pteropod* and *globigerina oozes*. In descending they, as well as other surface organisms, carry down with them some of the organic matter of their tissues, which, not decomposing rapidly in the cold deep water, forms the chief source of nourishment for deep-sea animals, and the chlorophyll which Prof. Hartley has discovered in some deep-sea deposits is probably derived from diatoms which have fallen to the bottom in this way.

It is, however, a very remarkable fact that the dead shells of these Foraminifera and Pteropods are not found on the bottom of the sea beneath all the regions where they flourish abundantly at the surface. They are found at greater depths beneath warm equatorial waters than elsewhere, but there is barely a trace of them in all the greatest depths, although in an adjacent area, where the surface and intermediate conditions are the same, but where the depth is less than three miles, they may make up 75 or even 90 per cent. of the deposit. It has been abundantly proved that when sea water, and especially sea water containing absorbed carbonic acid, passes over a dead shell or coral, the lime is gradually removed, being carried away by the water as bicarbonate in solution; and the shell or coral is removed more rapidly the more surface it presents to the water in proportion to the amount of carbonate of lime present in the shell. This is what happens to pelagic shells as they fall through the water to the bottom. Where the depth is not very great only the thinnest and most delicate shells are removed, and the others accumulate, forming vast deposits; with increasing depth other shells disappear, only the thicker ones reaching the bottom; but in the very greatest depth nearly every trace of these surface shells is removed, or we find them making up but 1 or 2 per cent. of the deposit. It is possible that this process of solution of the shells may be somewhat accelerated in the deepest layers of water by the great pressure.

In the deepest parts of the abysmal areas, where the carbonate of lime shells are either wholly or partially removed from the bottom, there are met with those peculiar deep-sea clays, the origin of which has been the subject of considerable discussion. They are principally made up of clayey matter resulting from the disintegration of volcanic rocks, and derived chiefly from floating pumice and showers of volcanic ashes. Mixed up with these clayey and volcanic materials are thousands of sharks' teeth, some of them of gigantic size, and evidently belonging to extinct species, also very many ear-bones, and a few of the other bones of whales, some of them also probably belonging to extinct species. These organic fragments are generally much decomposed and surrounded and infiltrated by depositions of peroxide of manganese, which is a secondary product arising from the decomposition of the volcanic material in the deposits. Again, we have in some places numerous zeolitic minerals and crystals formed in the clay, also as secondary products. Lastly, there are numerous minute spherules of native iron and other rare substances, covered with a black coating of oxide, which are referred with great certainty to a cosmic origin—probably the dust derived from meteoric stones as they pass through the higher regions of our atmosphere. Quartz, which is so abundant as a clastic element in deposits around the continents, is almost absent from the deposits of the abysmal regions.

In the abysmal regions, then, which cover one half of the earth's surface, which are undulating plains from two to five miles beneath the surface of the sea, we have a very uniform set of conditions: the temperature is near the freezing point of fresh water, and the range of temperature does not exceed 7°, and is constant all the year round in any one locality; sunlight and plant-life are absent, and although animals belonging to all the great types are present, there is no great variety of form nor abundance of individuals; change of any kind is exceedingly slow. In the more elevated portions of the regions the deposits consist principally of the dead shells and skeletons of surface animals, in the more depressed ones they consist of a red clay mixed with volcanic fragmental matter, the remains of pelagic vertebrates, cosmic dust, and manganese iron nodules and zeolitic crystals, the latter being secondary products arising from the decomposition of the minerals which have long remained exposed to the hydrochemical action of sea-water. The rate of accumulation is so slow in some of these clays that we find the remains of tertiary species lying on the bottom alongside the remains of those inhabiting the present seas. It has not yet been possible to recognise the analogues of any of the deposits now forming in the abysmal regions in the rocks making up the continents.

It is quite otherwise in the areas bordering the continents—the uncoloured areas on the maps. Almost all the matter brought down to the ocean in suspension is deposited in this region, which is that of variety and change with respect to light, temperature, motion, and biological relations. It extends from the sea-shore down, it may be, to a depth of three or four miles, and outwards horizontally from 60 to 300 miles, and includes all partially inclosed seas, such as the North Sea, Mediterranean, Caribbean, and many others. The upper or continental margin of the area is clearly defined by the coast line, which is continually changing from breaker action, elevation, and subsidence; the lower or abysmal margin of the region is less clearly marked out, passing insensibly into the abysmal regions and terminating where the mineral particles from the neighbouring continents disappear from the deposits. In the surface waters the temperature varies from over 80° in the equatorial to 28° in the Polar regions, and from the surface to the ice-cold water at the lower margins of the regions there is in the tropics an equally great range of temperature. Plants and animals flourish luxuriantly near the shore, and animals extend in relatively great abundance down to the lower limits of the region. Here we find now in process of formation deposits which will form rocks similar to those making up the great bulk of continental land, such as schists, shales, sandstones, marls, greensands, and chalks; the glauconitic grains of the green muds and phosphatic nodules can be traced in all stages of formation, and probably, though much less certainly, the initial stages in the formation of flint.

Throughout all geological time the deposits formed in this border or transitional area appear to have been pushed, forced, and folded up into dry land, through the secular cooling of the earth and the necessity of the outer crust to accommodate itself to the shrinking solid nucleus within. These depositions do not in themselves cause elevation or subsidence, but most probably the changes of pressure, resulting from them, tend to destroy the existing equilibrium and to produce lines of weakness along the borders of the continents and in the regions of enclosed and partially enclosed seas, with the result that the borders of continental land have been more frequently thrown into folds and have suffered greater lateral thrusts than any other regions on the surface of the earth.

On the other hand, while we know that there are vast deposits of carbonate of lime taking place over some portions of the abysmal regions, and that volcanic outbursts occur in others, still these are not comparable with the great changes which have taken place in the past, and are now taking place, on the continents and along their borders.

When the coral atolls and barrier reefs which are scattered over the tropical regions of the great oceans are examined in the light of recent discoveries, it is found that their peculiar form and structure can be accounted for by the truncation of some submarine cones through breaker action; by the upward growth of others through the accumulation of marine deposits; by the solution of dead coral through the action of sea-water; and lastly by a study of the source and direction from which the food supply reaches the reef-building animals. That this in all probability is the true history of the origin of these marvellous structures is further confirmed by the recent examination of the upraised coral atolls of the Pacific by Dr. Guppy, and the researches of Mr. Buchanan into the characters of oceanic banks and shoals. Coral atolls and barrier reefs, instead of pointing out great and general subsidences, must be regarded rather as indicating areas of great permanence and stability.

The results of many lines of investigation, then, seem to show that in the abysmal regions we have the most permanent areas of the earth's surface, and he is a bold man who still argues that in Tertiary times there was a large area of continental land in the Pacific, that there was once a Lemuria in the Indian Ocean, or a continental Atlantis in the Atlantic.

In this rapid review of recent oceanographical researches my chief object has been to show you the wide range of the observations, for every science has been enriched by a large store of new facts. It matters little whether the opinions which I have given as to the bearing of some of these be correct or not; for the observations are now or will soon be in the hands of scientific men, and errors in interpretation or deduction will soon be exposed. The great point is that there has been a vast addition to human knowledge, and it must be a matter of satisfaction that our own country has taken so large a share in these important investigations as to call forth the admiration of the scientific men of all countries. You have learnt from the President's address that there is usually not much to say in commendation of the Government for its liberality to science. But in the matter of deep-sea investigation, neglecting mere details, we can say that the successive Governments of the Queen during the past twenty years have, either from design or by accident, undertaken a work in the highest interests of the race, have carried it on in no mean or narrow patriotic spirit, and are likely to carry it to a termination in a manner worthy of a great, free, and prosperous people.

ON A SUPPOSED PERIODICITY OF THE CYCLONES OF THE INDIAN OCEAN SOUTH OF THE EQUATOR[1]

In papers printed in the *Reports* for 1872, 1873, 1874, and 1876, I endeavoured to show that there were grounds for supposing that the cyclones of the Indian Ocean south of the equator increased in number, extent, and intensity from a minimum in one year to a maximum in another, and then decreased to a minimum, the period or cycle apparently corresponding with the eleven-year period of solar activity.

From the data given in the last of these papers (*Report* for

[1] Paper by Mr. Charles Meldrum, F.R.S., read at the British Association.

1876, p. 267), it would appear that from 1856 to 1875 the years of minimum cyclone activity were 1856 and 1867, and the years of maximum activity 1861 and 1872, but that the results for each of those years did not differ much from the results for the year immediately preceding or following it, the variation near the turning-points being small.

Before giving a brief outline of the results which have been obtained since 1875, it may be well to mention that the sources of information were the same as in former years. Two clerks were constantly occupied in tabulating the meteorological observations contained in the log-books of vessels that arrived in the harbour of Port Louis from different places. The number of days' observations tabulated in each year—that is, observations extending over twenty-four hours and made in different parts of the ocean—was as follows:—

Years	Days' Observations	Years	Days' Observations
1876	... 17,017	1881	... 16,473
1877	... 17,005	1882	... 15,089
1878	... 17,050	1883	... 16,930
1879	... 15,889	1884	... 16,700
1880	... 17,306		

The tables give an average of 46 observations of 24 hours each for every day of the nine years over the frequented parts of the ocean.

All details and reports respecting hurricanes, storms, or gales were recorded in separate registers.

For each day on which there was a gale in any part of the ocean between the equator and the parallel of 34° S. a chart was prepared, showing as nearly as possible the positions of the vessels the direction and force of the wind, &c., at a certain hour, namely, noon on the meridian of 60° E.

From these synoptic charts the details given from hour to hour in the log-books, and all the information obtained from other sources, the position of the centres of cyclones at noon on each day were determined, and the tracks laid down on separate charts.

Nine cyclone-track charts have thus been prepared, namely, one for each of the years 1876–84.

These track-charts, together with the twenty that had previously been prepared for the years 1856–75, show, as far as has yet been ascertained, the tracks of the cyclones of the Indian Ocean south of the equator in each of the years 1856–84, and the tracks for the years 1848–55 are nearly ready.

With respect to the period 1876–84, the *areas* of cyclones and the *distances* traversed have not yet been determined, but upon the whole the *number* and *duration* of the cyclones decreased to a minimum in 1880, and then increased till, in 1884, they were more than double of what they were in 1880.

From the accompanying track-charts for the eleven years 1856, 1857, 1860, 1861, 1867, 1868, 1871, 1872, 1879, 1880, and 1884, it will be seen that the number and duration of the cyclones of 1856 and 1857 were much less than those of the cyclones of 1860 and 1861; that the number and duration of the cyclones of 1867 and 1868 were much less than those of 1860 and 1861 on the one hand, and also than those of 1871 and 1872 on the other; and that the number and duration of the cyclones of 1879 and 1880 were much less than those of the cyclones of 1871, 1872, and 1884.

It would appear, however, that in 1884 there was less cyclone activity than in 1861 and 1872.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—The commencement of Michaelmas Term does not witness many changes in the *personnel* of scientific departments in Oxford. A lecturer in Human Anatomy has been appointed, and commences work this term. The opening of the new physiological laboratories at the back of the University Museum completes the scheme for physiological education which has been so strenuously opposed by the enemies of scientific research in the University.

One of the most noticeable changes in Oxford to outward view is the opening of the new buildings in Trinity College. The new block of buildings, designed by Mr. Jackson, stretches backward from Kettle Hall in Broad Street to the Bathurst building and college chapel, making a new quadrangle bounded on the south by Broad Street and Trinity Cottages (now thrown into the "quad"), on the west by Balliol, on the north by the chapel and Bathurst, and to the east by the new buildings. The new "quad" is only second in size to "Tom quad" in Christchurch.

With our respect and sorrow for Dr. Bulley, late President of Magdalen, who died during the vacation, is mingled a feeling of intense satisfaction and not a little surprise at the appointment of his successor.

In Mr. T. H. Warren, the new President, Magdalen has gained a man no less distinguished for his scholarship than for his liberal views on education. Under the virile direction of her new president, Magdalen, already prominent among our Colleges for her recognition of natural science, may well hope to extend her usefulness. In the liberal Oxford of to-day—in the teaching as opposed to the voting University—Mr. Warren's election has been received with enthusiasm.

The following courses of lectures and classes in Natural Science will be given during the ensuing term:—In the Physical Department of the Museum Prof. B. Price lectures on Hydro-Mechanics. Prof. Clifton lectures on Ohm's Law; Mr. Selby lectures on Electrostatics; and Mr. Walker on Elementary Mechanics. The laboratory is open for practical instruction daily.

At the University observatory Prof. Pritchard gives three courses. Firstly, on the Application of the Theory of Probabilities to Astronomical Observation; secondly, on Spherical Astronomy; thirdly, on the Astronomy referred to by Polybius and other classical writers.

At Christchurch Mr. Baynes lectures on Conduction of Heat, and has a class for practical Instruction in Electrical Measurements.

At Balliol Mr. Dixon lectures on Elementary Magnetism and Electricity.

In the Chemical Department Prof. Odling lectures on the Phenic Compounds; Dr. Watts gives a course on General Organic, and Mr. Fisher gives a course on General Inorganic Chemistry.

The laboratories are open daily for practical instruction.

At Christchurch Mr. Vernon Harcourt has a class for Quantitative Analysis.

In the Biological Departments Prof. Moseley lectures on the Comparative Anatomy of the Vertebrata; Mr. Spencer lectures on Elementary Animal Morphology.

Prof. Burdon-Sanderson lectures on the Physiology of Motion, Mr. Dixey lectures on Histology, and Mr. Thomson on Human Anatomy.

The Morphological and Physiological Laboratories are open daily for practical instruction.

Mr. Jackson lectures on Parthenogenesis, Mr. Thompson on Osteology, and Mr. Poulton on the Distribution of Animals.

Prof. Westwood lectures on the Orders of Winged Arthropoda. Prof. Prestwich lectures on Geology: Physical Questions, Volcanic Action, &c.

At the Botanic Garden Prof. Gilbert lectures on the Results of Field Experiments, and Prof. Balfour gives practical instruction in Vegetable Morphology and Physiology.

Dr. Tylor lectures at the Museum on Social and Religious Systems.

SCIENTIFIC SERIALS

THE only structural paper in the August and September numbers of the *Journal of Botany* is by Mr. Thomas Hick, on the caulotaxis of British Fumariaceæ. "Throughout the whole of this order," he states, "as represented in the British Isles, a remarkable unity of organisation prevails. In all cases, save that of *Corydalis solida*, the main stem is a sympodium or pseudaxis, composed of binodal caulomeres, except in the basal region, where they are of a higher order, and often in the apical region also, where they become uninodal." The paper is illustrated by woodcuts. In addition the student of descriptive botany will find two papers by Mr. J. G. Baker: a monograph of the genus *Gethyllis* (with two plates), and a synopsis of the Cape species of *Kniphofia*, in addition to a continuation of his synopsis of the genus *Selaginella*; and the numbers are not wanting in other papers of interest in descriptive, systematic, and geographical botany.

THE number for October is an unusually interesting one. Mr. H. N. Ridley gives descriptions and figures of two recent additions to the British flora, both belonging to the Cyperaceæ, and both from Scotland: *Schænus ferrugineus*, L., and *Carex* *salina* var. *kattegatensis*, Fries. The discovery of the former species is especially interesting. Tne genus *Schœnus* includes between 60 and 70 species, of which two are natives of the northern temperate zone; all the remainder of Australia and New Zealand. Both of the northern species are now known in Britain.—Mr. J. G. Baker completes his monograph of *Selaginella*, including no less than 312 specie·.—In addition to smaller original papers the reprints include Mr. Carruthers' report on additions to the botanical department of the British Museum during 1884, and Mr. George Murray's valuable notes on the inoculation of fishes with *Saprolegnia ferax*, extracted from the annual report of the Inspector of Fisheries.

Rivista Scientifico-Industriale, August-September.—Transport and distribution of electricity by means of induced transformers: Gaulard and Gibbs' secondary generators (three illustrations), by Emilio Piazzoli.—Remarks on the objections raised against some of the author's theories in physics and electricity, by Prof. Carlo Marangoni.—On the emissive power of the electric sparks, by Prof. Emilio Villari.—On the true nitrous ethers of the alcohols, by Prof. G. Bertoni.—On the crustaceans of the province of Rome, by A. Statuti.

Bulletins de la Société d'Anthropologie de Paris, fasc. 2, 1885.—Report of Commission of Financial Administration of Society, by M. Dally.—Presentation, by M. Mortillet, of the numbers of the journal *L'Homme* for 1885, in which the question of a Tertiary man is discussed. M. Mortillet took occasion to explain at length his reasons for believing that there existed in the Tertiary age animals of sufficient intelligence to fabricate tools for themselves, and to make use of fire. M. de Nadaillac is unable to accept the opinion of M. Mortillet, and considers it impossible to affirm with any certainty either that the flints in question belong to the period to which they are assigned, or that they have not been deposited in the strata where they are found by the agency of running water, or of some of the great telluric disturbances of which unmistakeable traces are present in the beds at Thenay (Loir-et-Cher), which M. Mortillet characterises as Miocene.—M. D'Acy drew attention to the presence of numerous flints similar to those of Thenay which he and others had found among the Maçonnais deposits, and whose cracked and fractured surfaces differed in no way from the normal and natural character presented by the argillaceous flints ordinarily referred to the Tertiary ages.—On the historic significance of the Egyptian word "heter," horse, by M. Piétrement, who refutes the various arguments advanced in proof of the existence of the horse in Egypt before the invasion of the Hyksos, and endeavours to show that its introduction among the Egyptians was due to the so-called "Shepherd" invaders, who were of mixed Mongolian and Semitic origin.—Continuation of Dr. Fauvelle's treatise on "The Will," considered from an anthropological point of view.—On Beauty, by M. Delaunay.—Report of French missionaries' account of the Fuegians in 1884, communicated by Dr. Hyades.—On the Redskins in the Jardin d'Acclimatation, Paris, by Dr. Manouvrier, with craniometric and other measurements.—On the characteristics of a native of New Caledonia in the service of M. Moucelon, who explained some of the peculiarities of language and modes of counting prevalent among the people, and described their leading physical and mental characteristics. He remarked that the half-castes, born of white fathers and native mothers, are generally strong and prolific, while they show a tendency to revert to the character of the white type. Cannibalism, however, is not yet wholly eradicated amongst them.—On an anomaly of the humerus, by M. Chudzinski. This consists in a bony excrescence immediately below the deltoid, to which a bundle of muscular fibre is attached. The case, which is believed to be unique of its kind, appears to be one of atavism.—On an anomalous muscle in the hand, by M. Baudoin. Here the presence of a well-developed muscular fascia in the right hand of a man aged fifty, which simulated a part of the muscular development of the foot, may be similarly characterised as an evidence of atavism.—On a case of congenital hypertrophy of the parietals, by M. Topinard.—On supernumerary breasts, by Dr. Blanchard.—The etiology of elephantiasis, by M. Foley.—On the influences of heredity in deaf-mutes, by M. Drouault.—A case of a muscular anomaly of the fore-arm, by M. Chudzinski.—On sterility among the descendants of a white and a mulatto, by the Marquis de Saporta.—On certain crania from Lagoa-Santa, collected by Dr. Lund, and now at Copenhagen, with comparative analysis of a similar number of Californian crania, by M. Ten Kate.

Revue d'Anthropologie, tome 8ème, 3ème fascic., Paris.—On the weight of the cerebral lobes, according to Broca's register, by Dr. Philippe Rey. The data on which Dr. Rey's tables are based were obtained from 347 subjects, of which 231 were men and 116 women. On examining the means the figures yielded for the several lobes, without reference to sex or stature, it is found that while the total weight of the right hemisphere predominates over that of the left, the left frontal is heavier than the right, this difference amounting to 1·6 gr. on the total of 231 cases. This excess of weight of the left frontal had been noted by Broca, who believed it to be due to the influence of the third convolution. The right occipital is, on the other hand, 0·5 heavier than the left. The difference of weight for the entire anterior region between men and women amounts to 69·65 gr., which constitutes a large proportion of the general cerebral excess of weight in the male sex. The weight of both hemispheres is at its maximum between the ages of 25 and 35 years, although this period is generally reached earlier in women than in men, owing apparently to the more rapid evolution in the former of some one of the lobes. Loss of weight is most marked between 55 and 75 years, when it may amount to 62 grammes.—Anthropometric instructions for travellers, by Dr. Paul Topinard. The writer, after considering the true significance of the loosely-applied term "race," and pointing out the importance of accepting one uniform and fixed system of anthropometric measurement, proceeds to describe the nature and mode of application of the various instruments indispensable for the attainment of trustworthy and available results. These admirable instructions are rendered specially serviceable through the addition of numerous comparative tables, including a useful schematic representation of the means of the measurements obtained for the European male adult when taken in proportion with the mean stature, which is estimated at 100. This code of instructions ought to be in the hands of all travellers able and willing to contribute towards the general mass of our anthropological knowledge, and its translation into our own and other tongues would be a gain to science. Numerous diagrams illustrate the way in which the instruments should be used, and the positions of the body best adapted for the purpose of each special observation.—On atavism in man, by Dr. R. Blanchard. The author considers that as the greater number of the teratological conditions observable in man may be explained by the persistence of some embryonic condition which is normally of a transitory character, we must look to atavism for an explanation of such anomalies. Beginning with the cranium, Dr. Blanchard shows that microcephalus and analogous cranial deformities must be characterised as ancestral reversions, the mean cranial capacity of civilised races having demonstratively augmented within the last few centuries, while we find on passing down to the lower animals that the cranial capacity of the gorilla, or chimpanzee, which is more than five times less than the mean given for Parisians of the present day, is only slightly in excess of that observed in microcephalic subjects. After passing in review the various anomalies to be met with in the human anatomical system, and pointing out their analogues in the normal anatomy of the lower animals, he proceeds to the muscular system, in which the writer shows that supernumerary muscles occur three or four times in every hundred cases. This branch of the subject is, however, only briefly touched on in consideration of the exhaustive work of M. Testut bearing on the question, and to this the student is referred. Finally, after considering the comparative history of the development of the human fœtus, and of the embryo of some of the lower animals, the author concludes by drawing attention to the importance of studying the normal anatomy of the lower animals, more especially of reptiles, marsupials, and lemurians, if we desire to elucidate the origin and development of the various anomalies presented by the human organism.—On Broca's method of estimating the capacity of the cranium, by M. P. Topinard. The writer gives a categorical description of the instruments to be used and the steps to be followed in the process, together with tables showing the various results that had been yielded by Broca, Ranke, and others when lead, glass beads, or millet seed had been used as the agent for gauging the capacity.

SOCIETIES AND ACADEMIES

SYDNEY

Linnean Society of New South Wales, June 24.—The following papers were read:—Rough notes on the natural history of the Claremont Islands, by Gervase F. Mathew, R.N. Mr. Mathew gives an interesting account of the fauna and flora met with on these islands, in which he enumerates 23 species of birds and 20 species of *Lepidoptera*, of which 2 *Lycaenæ* are probably new. He also gives some notes on the habits of each species enumerated.—An afternoon among the butterflies of Thursday Island, by Gervase F. Mathew, R.N. Mr. Mathew gives an account of a few hours' ramble on Thursday Island, resulting in the capture of 48 species of diurnal butterflies. He gives a detailed description of the larva of *Ornithoptera pronomus*. He also makes brief mention of the flora and physical geography of the island.—New fishes from the Upper Murrumbidgee district, by William Macleay, F.L.S. Two new fishes are here described, and two others, probably new, are noticed. The new ones are a species of *Murrayia*, from the Murrumbidgee, near Yass, and a very blunt-headed species of *Oligorus* from the same locality. The two fishes alluded to as probably new are a species of *Gadopsis* from the Little River and a *Galaxias* from Yass River.—On a new *Diplocrepis*, by J. Douglas Ogilby. Mr. Ogilby describes, under the name of *Diplocrepis costatus*, a species differing considerably from *D. puniceus* of Richardson, and he points out that the fish is more nearly allied to the New Zealand genera, *Diplocrepis* and *Trachelochismus*, than to the Australian genera, *Crepidogaster*.—Jottings from the Biological Laboratory of Sydney University, by William A. Haswell, M.A., B.Sc., Lecturer on Zoology and Comparative Anatomy.—On a destructive parasite infesting the oyster. Specimens of diseased oysters from the Hunter River beds were found to have their shells perforated and destroyed by a small boring annelid—*Leucodore ciliata*—which, by burrowing through the substance of the shell, causes the disintegration of the valves and the death of the oyster.—On some recent histological methods and their application to the teaching of practical histology.—On the minute structure of *Polynoë*.

PARIS

Academy of Sciences, October 12.—M. Bouley, President, in the chair.—The President announced the death on October 6, at Jasseron (Ain), of the eminent histologist, M. Ch. Robin, Member of the Section for Anatomy and Zoology.—Memoir on the botanical work of the late M. Charles Edmond Boissier, who died at Valleyres, Canton of Vaud, on September 25, by M. P. Duchartre. Born at Geneva, in 1810, of a French Huguenot family, M. Boissier first devoted his attention to the Swiss Alpine flora. But he will be remembered chiefly for his explorations in the Iberian peninsula (Grenada, Sierra Nevada, &c.) in 1837, and in the Levant (Greece, Anatolia, Syria, Egypt, &c.) in 1842–46. The results of his labours in these botanical regions are embodied in his "Elenchus plantarum novarum minusque cognitarum quas in itinere hispanico legit" (Geneva, 1838); "Voyage botanique dans le midi de l'Espagne pendant l'année 1837" (Paris, 1839–45); and "Flora orientalis, sive enumeratio plantarum in Oriente a Græcia et Egypto ad Indiæ fines hucusque observatarum," five large volumes, 1867–1884.—On the neutralisation of the aromatic acids, by M. Berthelot. The results are here given of experiments made on mellic acid, $C_{24}H_6O_{24} = 342$; meconic acid, $C_{14}H_4O_{14}$, $3H_2O_2 = 254$, and acrylacetic acid, $C_4H_2O_2(C_6H_6O_4) = 114$.—On sundry phenols, by M. Berthelot. The author here passes from the study of normal phenol to that of its homologues, the cresylols and ordinary thymol, as well as the naphtols or phenols derived from naphtaline.—Note on the first volume of the *Annales de l'Observatoire de Bordeaux*, issued by M. Rayet, and presented to the Academy by M. Lœwy. Besides a full account of the foundation of the Bordeaux Observatory in 1871 and of the instruments employed in it, this volume contains all the magnetic and meteorological observations taken in 1880–81 and some of the results of the work begun in 1885 for the purpose of determining the co-ordinates of 23,000 stars in the Southern Hemisphere between $-15°$ and $-30°$, already observed by Argelander at the Bonn Observatory in 1850.—Effects of mildew on the vine as shown by a comparison of the plants successfully treated with a mixture of lime and sulphate of copper by M. Nath. Johnston in the Médoc district, with plants in the same district attacked by the disease and left untreated, by MM. Millardet and Gayon.—Observations on the nature of inverted sugar and of elective fermentation, by M. E. Maumené. Further experiments confirm the conclusion already arrived at that M. Leplay's theory of elective alcoholic fermentation is based on erroneous assumptions.—Note on the constant presence of *Amœba coli* in dysenteric secretions, by M. A. Normand.—Observations on Palisa's new planet 251, made at the observatory of Paris (equatorial of the west tower), by M. G. Bigourdan.—Observations of Brook's comet and of Palisa's new planet 251, made at the Observatory of Algiers with the 0·50 m. telescope, by M. Ramband.—Researches on vanadium: properties of vanidic acid, by M. A. Ditte.—Kinematic analysis of the locomotion of the horse by means of M. Marey's chronophotographic apparatus, five illustrations, by M. Pagès. In this paper the author explains and illustrates the trajectory and velocity of the foot and pastern in the three principal actions of the horse—the step, trot, and gallop.—Note on the internal phenomena of muscular contraction in the primitive striated fasces, by M. F Laulanié.—On the physiological action of the salts of lithium, potassium, and rubidium, by M. Ch. Richet. The mean toxic dose with the chlorides of these alkaline metals has been determined for the tench, frog, pigeon, rabbit, and some other organisms.—On the development of Fissurella, by M. L. Boulan. From a study of the biological evolution of this organism the author concludes that it is a true gasteropod, and cannot, therefore, be grouped with the order of worms; further, that the apparent symmetry of the adult Fissurella is, in reality, a disguised progressive asymmetry.—Influence of salt water on the development of the larvæ of the frog, by M. E. Yung. The tadpole perishes in three to twenty minutes in the water of the Mediterranean containing 4 per cent. of salts, and in a few hours in a solution of marine salts in the proportion of 1 per cent. But it may be adapted to this element by a gradual preparation through a progressive series of solutions from 2 to 8 per 1000.—On the apparent rotatory movement of balloons recorded by aëronauts, by M. G. Tissandier.—Memoir on the fermentation of bread-stuffs in connection with M. Aimé Girard's communication on this subject, by M. G. Chicandard.

CONTENTS

THURSDAY, OCTOBER 29, 1885

THE ANTI-CHOLERA INOCULATIONS OF DR. FERRAN

IN the spring and summer of the present year the public in Europe—lay and medical—have been greatly agitated by the exploits of a Spanish medical gentleman, who, during the cholera epidemic then raging in Spain, claimed to have discovered a means of preventing cholera. He was hailed as a great benefactor, and if his deeds had been equal to his professions, he would no doubt fully deserve to rank with Jenner, the greatest benefactor to mankind. But fortunately the medical world, at any rate the scientific medical world outside Spain, is not guided by the allegations of enthusiasts nor by wonder-doctors either. A Don Quixote, who discerns in a windmill giants, in a flock of sheep a squadron of the enemy's soldiers, may present points of interest to the psychologist: to the disciple of physiology and pathology he demonstrates an aberration of the visual nerve centres. I shall show that Dr. Ferran comes very near in rank, not to Jenner, but to his own illustrious countryman, the Knight of La Mancha.

The method of Ferran is practically this:—Ferran says that by a peculiar mysterious method of cultivation—which for a long while he was not going to divulge—he has succeeded in attenuating the action of the comma bacillus of Koch. In these cultivations the comma bacillus after very complex morphological changes, unnecessary to detail here, forms spores. Such cultures introduced in sufficient quantities into the subcutaneous tissue of animals (guinea-pigs) or man produce a disease which is a mild and abortive form of cholera; it manifests itself in local inflammation, and a general constitutional disturbance, febrile rise of the body temperature, headache, nausea, and sickness, and even diarrhœa. After a few days the person inoculated returns to his normal state. Persons once, twice, or thrice inoculated answer, or ought to answer, each inoculation with the said constitutional disturbance. Statistics collected by Ferran and his adherents in the places where these inoculations were practised, notably in Alcira, in and about Valencia, prove, so it is said, that the number of cholera cases and of deaths from cholera decreased in a conspicuous degree after these inoculations had been commenced, and also that those persons that had been inoculated remained almost impervious to cholera, while others not so inoculated fell victims to the plague in large numbers. In these assertions and practices several important questions are involved, each of which demands a direct answer, which ought to be favourable to this theory of Dr. Ferran.

First: Is the so-called cholera-bacillus, or Koch's comma-bacillus, found in the intestinal discharges of cholera patients, the *vera causa* of cholera?

Second: Does this so-called cholera-bacillus form spores, which when introduced into the living tissue germinate into the comma bacilli: in the subcutaneous tissue capable of producing only an abortive and mild form, but in the alimentary canal producing severe and malignant cholera?

Third: Do the cultivations of Dr. Ferran, when inoculated into the subcutaneous tissue, set up a disturbance which can be considered as an abortive form of cholera?

Fourth: Are persons so inoculated really protected or almost protected against an attack of real cholera; and do the statistics collected by Ferran and his adherents prove this?

(1) The first of these questions, it is obvious, forms the basis of the whole theory; for if the comma bacillus of Koch is not the real cause of cholera all the rest of Ferran's assertions, as far as cholera is concerned, fall to the ground. The claims of the comma bacillus of Koch to be accepted as the true cause of cholera, rests on very insufficient evidence: the epidemiological evidence as to the spread of cholera being dependent on soil and season, the anatomical evidence as to the comma bacilli being limited to the cavity of the cholera intestine, they being absent from the tissues and the blood, the misproportion existing between the number of comma bacilli present in the alimentary cavity, and between the severity and acuteness of the disease in many cases, and a number of other facts not necessary to mention here, prove to my mind that the comma bacillus is not the real cause of cholera. Add to this that Emerich of Munich vindicates this claim to be the real cause of cholera, not to the comma bacilli of Koch, but to small straight bacilli, probably identical with those seen and described by the English cholera Commission in India as constantly present in the alimentary canal of cholera patients, and for which bacilli I did not and cannot claim any real infective power; and further, that Emerich's view is backed up by no less an authority than Von Pettenkoffer himself. There is then at present an interesting contest going on between two rival bacilli: one, having Berlin for the head-quarters of its advocates, may be called the northern bacillus; the other, in Munich, may be called the southern bacillus. As to the actual facts, it seems to me the question is not whose claim is stronger, but whose claim is weaker.

(2) All except Ferran, acquainted practically with the comma bacillus in pure cultivations (Koch, Van Ermengem, myself, Mr. Watson Cheyne, Finkler, Emerich, Buchner, Klebs, and many others) are agreed that the comma bacillus in artificial cultivations never forms spores; having multiplied until all the nutritive material in the cultivation is exhausted, a period arrives when the comma bacilli degenerate and die; some undergo this long before the point of exhaustion is reached, others retain their vitality longer, but after weeks and months death has involved all the comma bacilli present in the cultivation. [An impurity accidentally present in the culture would effect this death of the comma bacilli in a much shorter period; in fact, in many instances, they would not have much chance of primarily reaching any considerable number.]

When this period has been reached, the culture becomes incapable of starting a new culture; and *vice versâ*: by this means the point of death of the bacilli present in the culture can be tested and accurately determined. I have a large number of tubes of pure cultivations of the comma bacilli, the nutritive medium being broth, or peptone and broth, or gelatine peptone and broth, or gelatine peptone and meat extract, or Agar-Agar peptone and broth, &c. In each of these media the comma bacilli thrive well and form copious growths. The cultures are pure, contain the comma bacilli only, as all sub-cultures from them yield again the comma bacilli, and comma bacilli only. Now the remarkable fact about such culture tubes is this: that after several months all life in them becomes extinct, as is proved by inoculating from them a series of tubes containing suitable nutritive material, no comma bacillus or any other bacteria making their appearance. I have ascertained this in a great many cases, and it is in perfect agreement with the experience of Koch and many other workers. This clearly proves that there are not present in such tubes spores of the comma bacilli, for, if the comma bacilli, like some other bacilli—*e.g.* bacillus subtilis of hay infusion, or bacillus anthracis, were capable of forming spores, such a total extinction of life could not take place; the spores, although, owing to exhaustion of nutritive material, incapable of germinating into bacilli while in the tube in which they were formed, would undoubtedly germinate when transferred into a fresh and suitable nutritive medium. This total extinction of life does occur not only in tubes in which the nutritive medium is in a fluid condition, but also in all Agar-Agar peptone broth tubes, this material, unlike gelatine, remaining in its solid state, however luxuriant the growth of the comma bacilli may be.

Dr. Ferran claims to have discovered means by which the comma bacilli can be made to produce spores. In his cultures he notices a number of peculiar things which he considers as antecedents to the formation of spores and as fully formed spores. But direct observations that these are really spores, that, like spores, they actually germinate into the bacilli, Dr. Ferran has not deemed it necessary to make. As a matter of fact those to whom Dr. Ferran has shown his specimens, in which these alleged spores were supposed to be present, failed to see them (see the Report of the French Commission headed by Dr. Brouardel; see also Dr. van Ermengem's Report).

The methods of examination and cultivation of bacteria perfected by Koch, which, owing to the thoroughly reliable results they yield, are now universally followed by all who wish to acquire correct ideas and a sound knowledge of the life-history, morphology, and activity of bacteria, have led those practically acquainted with the comma bacilli to the conclusion that they do not form spores. Dr. Ferran is of the contrary opinion; but, judging from the Report of the French Commission, and from that of van Ermengem and others, who have visited Ferran and seen him at work, it is pretty clear that this gentleman is not only unpractised in, but altogether unacquainted with the elements of technique necessary in bacterial investigations; more than this: according to a graphic description by the special correspondent of the *Times*, Dr. Ferran makes his cultivations in broth in a temporary laboratory, the kitchen of an untenanted house, reeking with the effluvia of an untrapped sewer opening into this kitchen. Dr. Ferran's cultivations have been examined microscopically by a Valencia Commission, who found that they contained a motley crowd of various kinds of bacteria; Dr. Chantemesse in a paper read before the Paris Académie de Médecine (see *Brit. Med. Journal*, Sept. 26, 1885) states that as the result of a microscopic examination of Dr. Ferran's cultures he found the fluid variable in its composition; sometimes it is a cultivation of impure comma bacilli, sometimes it contains masses of different micro-organisms, but the comma bacilli are barely present. Add to this that Dr. Ferran, as the special French Commission attested, possesses neither the skill nor uses the ordinary precautions and apparatus indispensable in investigations of this nature, and all Ferran's extravagant assertions as to the behaviour of the comma bacillus in cultivations, as to its peculiar power of forming spores, must be regarded as sheer nonsense.

3. Notwithstanding this deficiency of Ferran in his mode of preparing his so-called "vaccine," it might be said, and it has been said by Dr. Cameron in a powerful and very able article in the *Nineteenth Century* for August 1885, that by subcutaneously inoculating a cultivation of comma bacilli, no matter however impure and contaminated, *e.g.* such as were at Ferran's disposal, the effect is different from the one produced by introducing them into the alimentary canal. In the former case, *i.e.* in the subcutaneous tissue, they are planted in a soil not congenial to them, and their product is only an abortive form of cholera, whereas in the latter, *i.e.* in the cavity of the alimentary canal, they find a more suitable soil, a soil which is their natural breeding ground, and the result is virulent real cholera.

What Ferran by the inoculation of his cultures into the subcutaneous tissue of human beings actually did produce, is, according to a number of witnesses (see the letters of the special correspondent of the *British Medical Journal;* the evidence given in detail by the special correspondent of the *Times*, October 20, and a number of other independent witnesses, English and French), septic infection, the intensity of which, as might be expected, and as Ferran himself admits, depends on the quantity injected. This result, however, is not always produced, the injection being sometimes quite inert, notwithstanding the presence of the comma-bacilli in the "vaccine" fluid. In the very able letter by the special correspondent of the *Times* for October 20 we are informed that Dr. Ferran explained to this gentleman in detail that the culture fluid used for inoculation need not contain any comma bacilli at all, in order to produce the desired result; further, that the comma bacilli can be killed by boiling or otherwise, without impairing the efficacy of the fluid, and that therefore a chemical substance present in the culture fluid, and probably the product of the organisms, must be regarded as the active principle. While this latest assertion of Ferran clearly shows that he is profoundly ignorant of the theory and practice of protective inoculations, such as are employed by Chauveau, Pasteur, Koch, Gaffky, Arloing and Thomas, and many others in a variety of specific diseases (anthrax, some forms of septicæmia, fowl cholera, symptomatic charbon, &c.), and while it is in flagrant opposition to his own assertions of an earlier date, it also proves that the results obtained by Ferran by the inoculations of his "cholera vaccine" into the subcutaneous tissue of human beings harmonise well with the assumption that what he produces is simply septic poisoning, *i.e.* changes such as have been proved to follow the injection of certain chemical substances known as ptomaïnes, and produced by the growth and activity of putrefactive bacteria in media containing proteids. Brieger (" Die Ptomaine," Hirschwald, Berlin, 1885) has published a most important series of observations on the production, nature, and action of ptomaines, and has greatly enlarged our knowledge of this as yet obscure subject. The description of the symptoms observable on persons inoculated by Ferran (as given by a variety of independent witnesses and by Ferran himself), can leave little doubt that the result of these inoculations is septic poisoning, in severe cases dangerous phlegmon and ulceration, and even death. This is also the opinion of a number of medical men (Spanish, English, and French) who have had the opportunity of seeing and examining such persons, as will be seen from the Report by the Special Commissioner of the *British Medical Journal*, the Report by the Special Commissioner of the *Times*, the Report by the Special French Commission, and the Report of the Commission sent by the Spanish Government. Such being the case, the inoculations practised by Ferran and his coadjutors can have no possible prophylactic effect against cholera, even granting, for the sake of argument, that one mild attack of cholera protects against a second severe one, a question which is still *sub judice*, since some competent authorities maintain that such immunity, although holding good in a number of infectious maladies, does not apply to cholera.

4. Now, are persons inoculated by Ferran furnished with immunity against an attack of cholera? The statistics published by Dr. Ferran and his adherents on the marvellous effects of inoculation in Alcira, Valencia and other places, accepted by Dr. Cameron in his article above referred to, show us a picture of brilliant successes, favourably comparing and even surpassing the statistics of the effect of vaccination against smallpox. Those statistics collected by Ferran being endorsed by several medical men and other notabilities of the town of Alcira and elsewhere, Dr. Cameron cannot bring himself to regard as not revealing the truth; he cannot imagine that all these worthy people should conspire to pervert the truth and to prevent the truth from becoming known.

The correspondent of the *Times* in his letter, published October 20, gives a long list of places where the statistics published by the Ferranists are signed and stamped by the Alcalde of the place, the local judge, the priest, the resident doctors, and the notary; all duly signed and stamped. This Englishman, however, probably knowing what value to attach to the competency and veracity of all those worthies, examined the statistics for himself, and the result of his inquiry may be briefly summarised by saying that Dr. Ferran and his partisans have simply "cooked" those statistics. They have done these things: when a person who had been inoculated by Ferran did nevertheless become affected with cholera, and died of it, death was put down as caused not by cholera but by some other disease; false entries were made as to persons who, having been inoculated, nevertheless died of cholera, were not entered as having been inoculated; persons have been registered as having been "vaccinated" by Ferran, but on inquiry were found to have died of cholera several days previous to the alleged "vaccination."

Add to this the fact that in Alcira, for instance, the inoculations and their wonderful effects had not commenced until the population had abandoned the impure water supply; that in some places many of the inoculated persons belonging to the well-to-do classes (a fee being paid for the inoculation) were therefore less exposed to infection, and those statistics become a gross farce and a shameless imposture. And this is practically the opinion of the Special Commission sent by the Spanish Government; this Commission has reported altogether unfavourably on these inoculations, declaring them barren of all scientific value, dangerous inasmuch as persons inoculated and suffering in consequence from a form of septic poisoning become more susceptible to infection from cholera and other diseases, and further condemning them as of no value in giving immunity against cholera.

The fact that Dr. Ferran and his associates took payment for the inoculations—thousands of persons were inoculated and reinoculated in Valencia and elsewhere, for each inoculation a fee of from 5 to 12 francs being charged—gives to the whole business a very ugly look. The *Times* correspondent (*Times*, October 20) does not therefore fully express the real value of Dr. Ferran when he says that he (Dr. Ferran) "is the dupe of illusions, conceived in ignorance."

E. KLEIN

LIFE OF SIR WILLIAM ROWAN HAMILTON

Life of Sir William Rowan Hamilton, Royal Astronomer of Ireland. By Robert Perceval Graves, M.A., Sub-Dean of the Chapel Royal. Vol. II. pp. 719. With Portrait. (Hodges, Figgis, and Co.)

IN a former number of this journal it was our duty to notice the first volume of the life of the illustrious Irish mathematician. We have now to congratulate Mr. Graves on the completion of the second instalment of that great work which has evidently been to him a labour of love. This volume, like its predecessor, bears abundant testimony to the conscientious manner in which the author has sought to delineate a picture of Hamilton, told as far as possible by the letters from Hamilton to his friends and by extracts from his journal. We are again surprised at the extraordinary copiousness of the materials which were available.

The incidents in the life of Hamilton apart from his literary and scientific activity are but few. The last volume conducted us to the year 1832, when Hamilton was in his twenty-seventh year. We had there seen the troubled course of his two earlier love affairs, and at the outset of this volume we are introduced to the third with Miss Bayly, to whom he was married in 1833. His domestic happiness was in the course of years clouded over by the ill-health of his wife, though to the end he remained an attached husband, as she was an attached wife; two sons and one daughter were the issue of this union.

The reader of this work can hardly fail to be struck with the number and the worth of the friends to whom Hamilton was endeared; he possessed to a remarkable degree the power of transforming a casual acquaintanceship into a true and lasting friendship. His intimacy with Wordsworth has been already referred to, and was carried on by occasional letters and visits until the death of the poet. Among his other literary friends we may mention Maria Edgeworth, who writes to him (p. 384):—

"Take your head from the stars or from transcendental mathematics and come and enjoy Folly and Friendship."

There are also copious letters to and from Aubrey De Vere, Lord Dunraven, the Marquis of Northampton, and many others, including not a few to his intimate friend the author of the present work; one of these we would specially mention (p. 357), in which Hamilton sketches the obligations of true friendship. The scientific correspondence of Hamilton with many of the leading philosophers of the last generation occupies, as might have been expected, a large proportion of the volume.

At successive meetings of the British Association Hamilton was a well-known and a conspicuous figure. When the Association visited Dublin in 1835 he was but thirty years old, yet he had already attained a scientific renown which made him perhaps the most eminent man at that meeting. It was on this occasion that the Board of Trinity College entertained the distinguished visitors at a banquet. The guests had assembled in the venerable library of the University. The Earl of Mulgrave, then Lord Lieutenant of Ireland, called Hamilton to the centre of a little circle, and, after conferring upon him the honour of knighthood, said:—

"I but set the Royal, and, therefore, the national mark on a distinction already acquired by your genius and labours" (p. 158).

In speaking at the banquet subsequently, Whewell said, in language which the enthusiasm of the moment might perhaps excuse:—

"It was now one hundred and thirty years since a great man in another Trinity College knelt down before his Sovereign and rose up Sir Isaac Newton" (p. 159).

In the year 1842 Sir R. Murchison, then general secretary of the Association, writes to Hamilton as follows (p. 387):—

"Your letter of the 16th having crossed mine, *I am in despair* at your resolution not to visit Manchester; and in order to shake it if possible, even at the eleventh hour, I enclose you a letter from Herschel, whose resolutions were quite as firm as yours, and who yet has made them fly before Bessel. Think of this philosopher coming on purpose to see such men as Herschel, yourself, and two or three others, and finding Airy and Baily flown to Italy and Sir William Hamilton *lecturing* in Dublin!! Pray put off your class for a week. Make a noble effort and lay it all on Bessel's shoulders, and you will add to your glory."

On this occasion Hamilton had also the gratification of meeting the great mathematician Jacobi, who, after referring to Hamilton as the "Lagrange of your country," said (p. 388):—

"Provided that we give to the dynamical equations that remarkable form under which they have been presented for the first time by the illustrious Astronomer Royal of Dublin, and in which they ought to be presented hereafter, in all the general researches of analytical mechanics."

We also read how Hamilton was received at the Oxford meeting in 1847, in which, to quote his own words from a letter to the author, he says (p. 585):—

"It has several times happened to me to sit between Struve and Le Verrier (both of whom, somewhat to my surprise, and certainly beyond my deserts, assigned to me a high place among British astronomers in their speeches at the concluding meeting). And when I rose to give an account of the application of the calculus of quaternions to the theory of the moon on the Thursday of last week, and saw before me not only those two eminent foreign astronomers, but also Herschel, and Airy, and Adams, and Challis, besides Peacock and Whewell, and others scarcely less distinguished, I could not refrain from acknowledging it to be an alarming and almost an awful thing to speak on any subject of physical astronomy in the presence of such an audience."

Hamilton also records in an unsent letter the following, which refers to the same meeting (p. 585):—

"My friend Struve, of Russia, at Oxford, 1847, said: that, though I held the title of Royal Astronomer of Ireland, my astronomical brethren on the Continent would decidedly prefer my never looking through the telescope to my giving up or less ardently pursuing mathematics. 'You are,' he was pleased to say, 'our teacher.'"

Hamilton was for many years not only the most distinguished member of the Royal Irish Academy but also its president. Many interesting letters will be found in the volume relating to his election to this distinguished post. His rival, if so he can be called in what Hamilton describes as a "contest of generosity," was the late Provost Lloyd. Lloyd retired in favour of his friend, and Hamilton writes many letters, the character of which is fairly represented by one to Lloyd (p. 218), in which he disclaims

"Entertaining *even a thought* which could be construed into *treason* to our long and unclouded friendship, and that the part *you* have taken (while in some respects it adds to my pain) furnishes a new proof of the justice of the high opinion that I have ever entertained of you."

Hamilton discharged in the most exemplary manner the laborious duties of President for several years, until, as he writes (p. 510):—

"The day has at length arrived when I am to accomplish my desire of retiring from the chair of the R.I.A. How joyously, though not without a feeling of solemnity, I received the news of my being elected to the chair; how gladly now I resign it, yet not without a shade of that sadness which belongs to a farewell!"

The chief interest in this volume will be found in the account of the great invention of quaternions, with which the name of Hamilton will be for ever associated. His own appreciation of the importance of this achievement is shown in an extract from a letter to Prof. Lloyd in December, 1851 (p. 445):—

"In general, although in one sense I hope that I am actually growing *modest* about the quaternions, from my seeing so many peeps and vistas into future expansions of their principles, I still must assert that this discovery appears to me to be as important for the middle of the nineteenth century as the discovery of Fluxions was for the close of the seventeenth."

The account of the discovery which, after fifteen years of studious meditation, seems suddenly to have flashed upon Hamilton is told in an interesting letter written from his deathbed many years later to his son Archibald (August 5, 1865), p. 434:—

"On the 16th day of October, 1843, which happened to be Monday, and a council day of the Academy, I was walking in to attend and preside, and your mother was walking with me along the Royal Canal, to which she had perhaps driven; and although she talked with me now and then, yet an *undercurrent* of thought was going on in my mind which gave at last a *result*, whereof it is not too much to say that I felt *at once* the importance. An *electric* circuit seemed to close; and a spark flashed forth, the herald, as I *foresaw immediately*, of many long years to come of definitely directed thought and work, by *myself* if spared, and at all events on the part of *others*, if I should even be allowed to live long enough distinctly to communicate the discovery. Nor could I resist the impulse, unphilosophical as it may have been, to cut with a knife on a stone of Brougham Bridge, as we passed it, the fundamental formula with the symbols i, j, k;—namely, $i^2 = j^2 = k^2 = ijk = -1$, which contains the *solution* of the *problem*, but of course, as an inscription, has long since mouldered away. A more durable notice remains, on the council books of the Academy of that day—October 16th, 1843—which records the fact, that I then asked for and obtained leave to read a paper on *quaternions* at the *first general meeting* of the session, which reading took place accordingly, on Monday, November 13."

Among the most distinguished disciples of Hamilton is Prof. Tait, though *even he* has admitted that he has not read the whole of Hamilton's "tremendous volumes" (lives there indeed the man who has?). Another account of the discovery is found in a letter to Prof. Tait on October 15, 1858 (p. 435):—

"To-morrow will be the fifteenth birthday of the quaternions. They started into life full-grown on the 16th of October, 1843, as I was walking with Lady Hamilton to Dublin, and came up to Brougham Bridge—which my boys have since called Quaternion Bridge. I pulled out a pocket-book, which still exists, and made an entry, on which *at the very moment* I felt that it might be worth my while to expend the labour of at least ten or fifteen years to come. But then it is fair to say that this was because I felt a *problem* to have been at that moment *solved*, an intellectual want relieved which had haunted me for at least *fifteen years before*."

The unmathematical reader may naturally ask the nature of this notable discovery which Hamilton made at "Quaternion" Bridge.

It would seem that at this moment he solved the long-studied problem of the multiplication of directed straight lines, or vectors as he called them. Let a denote a straight line of determined length and direction. Let b denote another straight line at right angles to a, and radiating from the same origin; then the product ab denotes a third straight line from the same origin perpendicular to the plane of a and b; the product ba, however, denotes the perpendicular line on the other side of the plane, so that $ba = -ab$. This formula is eminently characteristic of the method, showing as it does that vector multiplication is non-commutative. It is, however, remarkable that the associative principle obtains in quaternions no less than in ordinary algebra; thus if a, b, c be three vectors, or more, generally quaternions, then $ab \times c = a \times bc$. This theorem, though *true* in quaternions, is still so far from being obvious that it implies the truth of an elaborate geometrical theorem.

If we could single out one point of special significance in the invention of quaternions it would be found in the *dual* interpretation of the symbol of a vector. Thus if the letter i denotes a vector or directed straight line of unit length, then the same symbol may also mean an operation of rotation through a right angle around the vector as an axis. In the formulæ of quaternions the symbols denoting vectors can be interpreted in this dual manner. A quaternion may be regarded as the operating factor which applied to one vector transforms it into another. This operation requires two quantities to specify the plane of the vectors—one to specify the angle between them and one the ratio of their lengths in all four quantities are required, whence the name quaternion.

An interesting letter (p. 536) to the Rev. John W. Stubbs, Fellow of Trinity College, dated October 19, 1846, gives a sketch of the points which Hamilton thought specially novel in his theory:—

"But did the thought of establishing such a system, in which *geometrically opposite factors*—namely, two lines (or areas) which are opposite IN SPACE give ALWAYS a *positive product*—ever come into anybody's head, till I was led to it in October, 1843, by trying to extend my old theory of algebraic couples, and of algebra as the science of pure time? As to my regarding *geometrical addition* of lines as equivalent *to composition of motions* (and as performed by the same rules), that is indeed *essential* in my theory, but *not peculiar* to it; on the contrary I am only one of many who have been led to this view of addition."

A few years later Hamilton commenced the delivery of lectures on quaternions in Trinity College. His own words are (p. 605):—

"It was on Wednesday, June 21, 1848, that I delivered my first lecture on quaternions to a very respectable audience, among the persons composing which were the Rev. George Salmon, Fellow of Trinity College, Dublin, and author of a lately-published treatise on Algebraic Geometry, and Arthur Cayley, Fellow of Trinity College, Cambridge, who first, except myself, has publicly used the quaternions."

These lectures, rewritten and greatly expanded, formed his first and classical volume—"Lectures on Quaternions." (Dublin, 1853.)

The publication of this work drew from Hamilton's many scientific friends cordial letters of congratulation. His old and intimate friend, Sir John Herschel, thus writes on July 21, 1853 (p. 681):—

"Now most heartily let me congratulate you on getting out your book—on having found utterance *ore rotundo* for all that labouring and seething mass of thought which has been from time to time sending out sparkles, and gleams, and smokes, and shaking the soil about you—but now breaks into a good honest eruption with a lava stream and a shower of fertilising ashes. I don't mean to say that there is not a good deal of cloud (albeit full of electric fire)—the good old 'stupendo e orgoglioso pino' of the fiery outbreak surrounding the bright jet, the true product—but the cloud clears as the wind drifts and leaves the hill conspicuous.

"Metaphor and simile apart, there is work for a twelvemonth to any man to read such a book, and for half a lifetime to digest it, and I am quite glad to see it brought to a conclusion."

The intercourse, both social and scientific, between Hamilton and Sir John Herschel gives many interesting pages to this volume. Thus, for instance, we find (p. 492) an account of a meeting between these philosophers at the house of their common friend, Dr. Peacock, the Dean of Ely. On Sunday they attended service in the Cathedral in company with Prof. James D. Forbes, and Hamilton recorded the incident in a sonnet which he recited to his friends. The next morning he received an acknowledgment in kind from Herschel. We quote here the two poems: that of Hamilton (p. 493) bears the title "In Ely Cathedral":—

"The sunshine, through the lofty window stealing,
Lit up that vast and venerable fane,
Ely's Cathedral, in dark clouds and rain
Wrapped lately, and shut up from joyous feeling:
In its soft progress all around revealing
Beauty or majesty unmarked before,
It shed its type of heavenly comfort o'er
Three kindred-kingdoms' sons together kneeling.
Oh, may that Church, Episcopal and pure,
One Mother of that kneeling company,
In essence one, in name and office three,
Mid outward storm and darkness still endure:
Be comforted of Christ in God's good time,
And share the sunshine of a heavenlier clime."

Herschel's sonnet in reply (p. 494) was handed to Hamilton the following morning:—

"ON A SCENE IN ELY CATHEDRAL

"The organ's swell was hushed, but soft and low
An echo, more than music, rang; when he,
The doubly-gifted, poured forth whisperingly,
High-wrought and rich, his heart's exuberant flow
Beneath that vast and vaulted canopy.
Plunging anon into the fathomless sea
Of thought, he dived where rarer treasures grow,
Gems of an unsunned warmth and deeper glow.
Oh! born for either sphere! Whose soul can thrill
With all that Poësy has soft or bright,
Or wield the sceptre of the sage at will
(That mighty mace which bursts its way to light).
Soar as thou wilt! or plunge—thy ardent mind
Darts on—but cannot leave our love behind."

We have introduced these verses not so much on account of the poetical merit they possess, which we confess appears to us to be but slight. They may, however, serve as samples of those poetical effusions with which these volumes teem—indeed they give the impression that there must be some occult sympathy between poetry and astronomy. It is well known that Romney Robinson was a poet, and though it does not appear that Sir George Airy had plunged into verse, yet when he and Hamilton were together at Parsonstown there was an amusing contest between the two Royal Astronomers as to which could repeat most English poetry. The present writer has heard this scene described by the late Earl of Rosse, who said that Sir G. Airy was admitted to have carried off the honours.

As an illustration of one of the less important mathematical labours of Hamilton we may mention his paper on the Hodograph, communicated to the Royal Irish Academy in 1846. This elegant conception is a curve whereof the radius vector to any point from the origin represents both in direction and in amount the velocity of a moving particle. Many interesting applications were made by Hamilton, and are referred to in correspondence with Whewell. A somewhat ludicrous incident in connection with the hodograph is recorded (p. 543). It appears that at the same meeting of the Academy in which the hodograph was discussed, Hamilton also exhibited Prof. Mädler's just published work on "The Central Sun." This precarious speculation was by the reporter injudiciously blended with the hodograph, and an astounding statement went the round of the papers asserting that Hamilton's wonderful calculus had succeeded in discovering the central point of the universe!

It is not, perhaps, generally known that the real discoverer of the hodograph was Bradley (see Rigaud's edition of Bradley's Memoirs, Oxford, 1832, p. 288). Bradley has there given a most elegant geometrical investigation of that circle related to elliptic motion which Hamilton afterwards named the hodograph.

The religious side of Hamilton's character demands a few words of notice. He was a member of the Establishment, and many passages show that he had the sympathies of a sound churchman. He seems to have been an admirer of Pusey, with whom he was also personally acquainted. We also find occasional reference to the midnight vigils with which he awaited the new year, and to the fasting which he sometimes practised for devotional reasons. We should imagine, however, that such exercises were but very occasional to a student so laborious yet so irregular as Hamilton.

He found time to be president of a local branch of the Society for the Propagation of the Gospel. He assumed the duties of a churchwarden, and vanquished Archbishop Whateley in a controversy on the orthodoxy of an inscription on the church window at Castleknock. At Whitsuntide we find him writing a dynamical theory of the ascension of our Lord, in which in mediæval fashion he proceeds to evaluate the *duration* of the phenomenon, which he demonstrates to have been less than the interval between Holy Thursday and Whit Sunday.

It is with evident pain that the biographer has felt himself compelled to record the one great failing of his illustrious friend. The excessive devotion of Hamilton to study and the engrossing nature of those mathematical reveries in which he indulged led to the formation of very irregular habits. He "too often found the dawn surprise him as he looked up to snuff his candles after some night of fascinating labour." The necessary hours for rest and refreshment being disregarded, he was led to the dangerous practice of an undue recourse to alcohol, and occasional intemperance was the consequence. Two or three scenes arising from this cause have been described in this volume. There is one which can hardly have been witnessed except by the biographer himself, but which his conscientiousness has compelled him to record. There is a second on a public occasion which caused the deepest grief to Hamilton's friends, one of whom called upon him with a kind remonstrance which was received by Hamilton in a manner worthy of his high character. There is also a third incident, perhaps the most painful of all, which illustrates the attempt of Hamilton to reform and the circumstances under which he relapsed.

We certainly have no intention of citing these passages in this place, for if torn from their setting in the life of this great man they would probably convey an exaggerated notion of the extent of his infirmity. We would rather record the words of Mr. Graves, where he says (p. 335):—

"It is mournful that what seems to have been an inconsiderate, and at first unconsciously indulged, defect in external regimen of life, for such in the inception was his infirmity, should avail to cast a shade over qualities so solid and so splendid as the moral and intellectual qualities of Hamilton."

We have still to look forward to the third and concluding volume of this important work. In it we are to read how Hamilton continued his stupendous labours which culminated in the appearance of his other great work, the "Elements of Quaternions." We are also promised that extensive correspondence with De Morgan, which will secure the attention of every lover of the "Budget of Paradoxes." At the close of our former notice we insisted on the duty which devolved on the University of Dublin of publishing in a collected form the mathematical writings of their illustrious son. This duty has not yet been discharged; let us hope that it will not be left to some foreign mathematician to undertake the work which it should be the glory of Trinity College to complete.

AN AGRICULTURAL NOTE-BOOK

An Agricultural Note-Book. By W. C. Taylor, Aspatria, Carlisle. (London: Longmans, 1885.)

IT is not often that note-books are published, and it is well. Notes are in their nature fragmentary, and disposed towards brevity, often lapsing into crudity. They are a sort of skeleton of imparted knowledge, or at least rather anatomical than living, moving, and breathing information. The least and the most that may be reasonably expected of them is that they should be correct. The small book which has just been published by Messrs. Longmans does not commend itself to our judgment. It is crude, fragmentary, and almost inarticulate or unintelligible. It purports to contain a body of teaching and of facts, but it really consists of disjointed sentences, the meaning of which it is often very difficult to gather. The grammatical construction of the sentences is also fearful and wonderful. To give an idea of this latest contribution to agricultural science, we select the opening passage, page 1, which reads as follows:—"The science of agriculture. Definitions and terms. Its definitions. Scientific truths taught by the practice of agriculture." "The practice of the farm teaching the science. The laws of agricultural science best learnt when thus taught, and lead to improvements in the application of science to farm practice." If this is a definition, much has been written in vain as to the difficulty of defining. It not only fails in definiteness, but is curiously involved, as well as untrue, for "the practice of the farm teaching the science" is an impossible and impracticable idea.

The word "its" before each paragraph of definitions and terms appears to bear reference to the general heading, "The Science of Agriculture," and cannot be supposed to bear a grammatical relation to "definitions and terms." Taking this view of Mr. Taylor's "notes," we read as follows:—

"Its character in the soil, as temper, will, and disposition. These to be noted: success of farmer depending much on his knowledge of above (sister sciences). *Hungry, sick, grateful, obstinate, kindly, tender*, &c."

We defy any one to make any sense out of these utterances, whether taken with or without their context.

Next we have an attempt at further amplification. Thus "1 HUNGRY—constantly in want of food." Now, be it remarked that the subject is *soils*, and we are told that a soil is "hungry, constantly in want of food." Also that it is "sick." Here is indeed confusion of metaphor and blind guiding with a vengeance. Only let readers of NATURE endeavour to picture to their minds a hungry and sick soil! No wonder that Mr. Taylor in the richness of his fancy can further enlarge upon its gratitude, tenderness, and kindliness. Page 1 would itself furnish ample matter for review. It is as full of difficulties as the Moabitish stone, although it might not so well repay deciphering.

Again we read: "Short supply of organic matter improved by adding clay, where practicable, and vegetable matter." While concurring with the last simply-given advice as remedying the fault in question, we deny that any amount of clay can help towards this end.

Turning p. 1, we come to p. 2, where we begin at the top as follows:—"3. TENDER.—Hard and baked. Improved by rain, drags and harrows at right time." This tender soil is then hard and baked, and it appears also that it is improved by certain natural and artificial agencies which we thought were not only and solely unfit for the amelioration of such tender, albeit hard and baked soils.

On the same page we are thus enlightened as to the primitive rocks:—"The primitive rocks differ from materials yielded by decay, which is accomplished by oxygen (O) and carbonic acid (CO_2), gases invisible and transparent. Both attack rocks and metals, however hard; seen in the mould-board of the plough reducing it (?) to a powder without noise. *Temperature* and *water*, other two *agents* acting on the *Traitor's iron* and *potash*, loosening particles from the hard rock." . . . . These agents are the *friendly helpers* to the farmer. The italics are Mr. Taylor's own. We are irresistibly reminded of Mr. Weg and Mr. Venus, those two "friendly movers" in "Our Mutual Friend."

Passing onwards through the dreary succession of sentences devoid of subject, predicate, or copula, we arrive at p. 12, where instruction is given upon the various component parts of soils. Here we find the following information regarding alumina:—"Alumina. (1) Present in the soil, but not in plant food. (2) Double silicates are (1) silicate of alumina, (2) (*a*) lime, (*b*) potash, (*c*) or of soda, (*d*) or of ammonia. (3) Order of compounds, $H_3N_1K_2CO_3$, Na_2CO_3. The higher favourite puts out a lower and unites with the silicate of alumina. (4) The powers of vegetable life command an influence over each and all the second-rank partners. (5) Performs work of outdoor servant. (6) Reconstructs broken-up partnerships. (7) Amidst the faithless, constant only she. (8) Acts as purveyor of food for the plant."

We leave this extraordinary statement of the eight duties of alumina in the soil to the judgment of any sound scientific man or agriculturist, asking only why young people should be subjected to teaching so completely misleading, erroneous, and unintelligible, on the plea that they are obtaining insight into the principles of agricultural science?

THE PREVENTION OF BLINDNESS

The Causes and the Prevention of Blindness. By Dr. Ernst Fuchs, Professor of Ophthalmology in the University of Liége. Translated by Dr. R. E. Dudgeon. 8vo, pp. 230. (London: Baillière, Tindall, and Cox, 1885.)

UNDER the title of "The Causes and Prevention of Blindness," Dr. Dudgeon has translated an essay, written by Dr. Fuchs, of Liége, under the conditions of a competition announced by the "Society for the Prevention of Blindness in London," and to which the prize of 80*l.* offered by the Society was awarded. The book may be described as containing a succinct exposition of the chief causes of blindness, and an endeavour to render them intelligible to non-medical readers; the object being to obtain the cooperation of the public in the removal of these causes, in so far as that desirable end may be attained by improved hygiene, and by a better knowledge of the most favourable conditions of ocular work.

The causes of blindness which may fairly be said to be thus remediable, even including under blindness high degrees of defective vision, are two in number—namely, the purulent ophthalmia of new-born infants, and the progressive short-sight which is not uncommon in schools. The former is a disease which might frequently be prevented, which is always curable if treated in good time, but which, if neglected, is almost certain to destroy the sight; and to neglect of its early stages among the poor, and in remote country districts, probably four-fifths of the blindness which occurs among children in this country may be ascribed. Several months ago the Ophthalmological Society of the United Kingdom, moved thereto by Dr. McKeown of Belfast, sent a deputation to the Home Secretary to call the attention of the Government to the dangerous character and the easy curability of this affection, and to urge that steps should be taken, through the instrumentality of the Registrars of Births, to diffuse a more general knowledge of the importance of early treatment. Partly through the opposition of the Registrar-General, the deputation met with no encouragement; and the information given by Dr. Fuchs is therefore as opportune as it is valuable, and might with great advantage be communicated to the poor by clergymen, schoolmasters, and others. It may be said, however, that many of his recommendations apply chiefly to countries in which the employment of midwives is more general than in England.

The progressive short-sight of the educational period is a matter which has lately attracted much notice in all civilised countries, and Dr. Fuchs has nothing to say concerning it which is original. He presents, nevertheless, a brief and convenient summary of the facts, and a good description of the methods of school lighting and fitting which are most to be commended. This part of his volume may be studied with great advantage by any teachers and managers to whom the more systematic treatises upon the subject are either unknown or inaccessible. The book contains one serious error, which, in the English version, has been slightly modified by a mistranslation. Dr. Dudgeon writes, with reference to the provision for instruction about eye diseases in the medical schools of Great Britain and Ireland—"There are eye departments in all the large hospitals, but as a rule no regular lectures on ophthalmology are delivered." The word rendered "ophthalmology" is in the original not "*ophthalmologie*," but "*augenheilkunde*," and the correct translation would be "the treatment of diseases of the eyes." On this subject, that is to say, upon so much of ophthalmology as has any direct bearing upon the duties of the medical practitioner, systematic lectures are delivered in every medical school in the United Kingdom; and it is difficult to believe that the translator could have been unacquainted with the fact. "Ophthalmology," of course, takes a much wider range, and embraces branches of optics and of physiology with which the practitioner, unless a specialist in eye disease, has neither time nor reason to concern himself.

OUR BOOK SHELF

Among the Rocks round Glasgow: A Series of Excursion-Sketches and other Papers. By Dugald Bell. Second Edition. (Glasgow: Maclehose, 1885.)

THIS volume furnishes a good example of what a busy man can do in his few intervals of leisure. The volume is mainly based on notes of excursions kept by the author while acting as secretary to the Glasgow Geological Society. It affords a fairly accurate idea of the geological structure of the country round about Glasgow, and of the principal features of interest which the rocks of the district present. The excursions extend as far as Stirling, take in the course of the Clyde and not a few districts on its banks. Many of the papers are pleasant reading; and even geological specialists may find something in the pages to interest and inform.

Three Martyrs of Science of the Nineteenth Century. Studies from the Lives of Livingstone, Gordon, and Patterson. By the Author of "Chronicles of the Schönberg-Cotta Family." (London: S.P.C.K., 1885.)

THE author of this volume tells the story of these three remarkable lives very pleasantly and instructively, more, however, from the religious than the scientific standpoint. A very fair account is given of the work accomplished by Livingstone in Africa, though the author does not seem to be quite aware of the value of the geographical work accomplished by Gordon on the Upper Nile.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Upper Wind Currents over the Equator

THE importance of an accurate knowledge of the general circulation of the atmosphere over the equator is so obvious and so little known that the following observations, taken on a voyage from Aden to Australia in February, 1885, will be of interest:—

Over the north-east monsoon, north of the line, the surface wind was east-north-east, while the low clouds came from due east. No high cirrus was ever seen.

In 2° N. lat. the surface wind lowest clouds came from N.N.E., the next layer of cirro-stratus from E. rather fast, while the highest cirri drove very slowly from E.S.E.

In about 1° S. lat. the surface came from N.W. (the N.W. monsoon), small flecks of low cloud from N.E., while some high cirri moved from E. at a moderate rate.

In 5° S. lat. the surface wind still blew from N.W., the lowest cumulus moved from N.N.W., the next layer of cirro-stratus from N., while a still higher layer of cirrus came slowly from E. or E.S.E.

In 10° S. lat. the surface wind came still from N.W., and the clouds at moderate altitude from S.E.

In the "Doldrums," which we only reached in 13° S. lat., the surface wind was from S. and the clouds from S.E.

After we entered the S.E. trade, while the wind came from S.E., the clouds drove from S., and when about 25° S. lat. the trade drew into E.; the clouds came from S.E.

The relation of upper to surface winds in the N.E. monsoon is just what might have been expected; but the discovery of an easterly current over the N.W. monsoon and of an upper current over the S.E. trade, more southerly than the surface wind, is not only altogether new, but also quite anomalous.

In Australia, and the Southern Hemisphere generally, the upper current over a N.W. wind is from about W. and over a S.E. wind from about E.

On my way home I ran a section across the Atlantic from Rio to Teneriffe, but the absence of cirrus prevented any satisfactory determination of the upper winds in that region.

The matter is, however, so important that I start again in a few days for the hurricane region of Mauritius, where I hope to observe one of these exceptional cyclones. Then I hope to repeat a section of the Indian Ocean between Mauritius and Bombay, and afterwards, if all goes well, to get some sections in the Pacific to see what the meaning of this curious discovery may be. RALPH ABERCROMBY

The Hellgate Explosion and Rackarock

THE statement in NATURE of the 15th inst. (p. 575) that rackarock is "blasting gelatine" or "nitroglycerine with compressed gun-cotton" is incorrect. Rackarock is simply powdered potassium chlorate, impregnated with an inexpensive oily combustible, such as coal-tar oil, and is one of my safety-explosives, which I discovered in 1870, patented in England, April 6 and October 5, 1871, and described more fully in the *Journal* of the Chemical Society for August, 1873, under the title: "On a New Class of Explosives, which are non-Explosive during their Manufacture, Storage, and Transport."

I am not responsible for the quaint name which the Americans have been pleased to give to my child.

As the so-called "rackarock" is not very sensitive or easy to explode, it requires a strong primer or detonator to set it off. This property, which I have fully discussed and particularly accentuated in my paper of 1873, explains why Gen. Newton, the Chief Engineer of the Hellgate mine, took the precaution of placing as a primer such a powerful charge (33 tons) of expensive dynamite on the cheaper charge of the potassium chlorate mixture (107 tons), a precaution carried here perhaps a little too far.

Still it is satisfactory to see that my safety-explosive performed the main part of the labour and rendered good service in the advancement of the works of peace. H. SPRENGEL

Savile Club, 107, Piccadilly

[We are very pleased to insert Dr. Sprengel's correction as to the composition of "rackarock." Up to the time of our notice about the explosion going to press the only information we could obtain was that it was the same substance as blasting gelatine, but with a less portentous name.—ED.]

An Earthquake Invention

IN your number for October 15 (p. 573) your numerous scientific readers will be interested to find a pretty long letter under the above heading from so able a seismologist as Prof. John Milne, of Tokio, Japan. Yet, his invitation notwithstanding, I must decline any discussion with *him*, either about my old letters which he refers to, or his own much changed opinion on their subject, since the occasion for my writing them occurred.

Those points, Mr. D. A. Stevenson, who is also invited, may, or may not, take up. My letters were impersonal, and dealt only with a British Association Report. I desire also to continue to keep them strictly to that, even to the very words of the particular Report as given forth to the world with all the usually unquestioned authority of that mighty Association, in their B.A. volume for 1884, p. 248, Section entitled "Experiments on a Building to resist Earthquake Motion."

On the Behaviour of Stretched Indiarubber when Heated

SOME time ago (NATURE, vol. xxv. p. 507) you permitted me to express a doubt as to the invariable success of an often-quoted experiment with cylinders of bismuth and iron, intended to illustrate some relations between specific heat and thermal conductivity.[1] I regret that I have made further progress along the evil road of scepticism. I should like, in fact, to ask whether it is absolutely true to say without qualification, as is done in many text-books, that india-rubber (when stretched) forms an exception to the general law that the volume of a body is increased when the temperature is increased. The usual form of the experiment supposed to prove this is well known: a piece of india-rubber tube or cord is stretched by a weight connected with a long light index-lever, and it is shown that when heat is applied the india-rubber gets decidedly shorter.

[1] Perhaps I may mention in passing that if lead is substituted for the bismuth the experiment succeeds perfectly, as theoretically it should do.

I have always had some hesitation in showing and explaining the result of the experiment in the above way, especially as I could not find any proof given that the contraction in length was not compensated, or more than compensated, by an expansion in other directions (like that of a worm in its creeping progress, or of a dry rope when wetted). I had, in fact, lately arranged an apparatus for determining the coefficient of expansion of india-rubber, whether positive or negative, when I found that the subject has been very fully investigated by Dr. J. Russner, of Chemnitz (see Carl's *Repertorium* for 1882, pp. 161 and 196).

His results are briefly these:—

(1) That india-rubber (of which several kinds were examined) has without exception a definite coefficient of expansion which is always positive; experiments made at temperatures varying from 0° to 53°·4 gave, for its value at 10°, 0·000657; at 30°, 0·000670.

(2) That india-rubber in a stretched state expands to the same extent as when it is not stretched. No point of minimum density was observed, such as Puschl supposed to exist.

(3) That the apparently anomalous behaviour of stretched india-rubber when heated is simply a case analogous to those of anisotropic crystals, which expand to different extents in different directions. Iceland spar, for instance, as Mitscherlich showed, actually contracts in a direction at right angles to its principal axis when heated, although its volume is, on the whole, increased.

Although ordinary india-rubber is, of course, isotropic, yet when stretched it becomes anisotropic, as may easily be shown by stretching a piece until it is semi-transparent, and placing it between crossed Nicols; the direction of the strain lying at an angle of 45° with the plane of polarisation. Distinct colours, as with a selenite film, will be seen, varying from red to blue with the amount of strain.

The fact that india-rubber becomes hot when stretched, and especially if stretched and allowed to contract several times in succession, may perhaps be accounted for by molecular friction. It would almost seem, then, that in the account given in many books the truth, as well as the india-rubber, has been slightly "stretched." H. G. MADAN

Eton College, October 23

The Resting Position of Oysters

IN carrying out a series of experiments on the artificial breeding of oysters in my private aquaria, I noticed that the young oysters born in the tanks rested on the flatter shell when they obtained a flat surface, such as a tile, to adhere to, but when I so arranged that they had irregular surfaces to deal with, such as little bundles of twigs, some adhered one way, and some the other. But where young oysters, nearly two years old, were moved from their original supports, and were compelled to find new ones, they selected the flat shell to rest upon in every instance, except where they were placed on sand, in which case they rested on the convex shell, in order apparently to avoid clogging the mouth of the shell with sand. Is it not possible from these observations that adult oysters vary their position according to the nature of the ground they are on. I have seen adult oysters on muddy ground lying on the convex shell, while where adhesion to a flat surface could be obtained, they were all on the flat shell, and pectens are dredged with Balani and other growths on the flat shell in some instances, and on the convex shell in others, principally, however, on the latter.

South Kensington Museum, October 23

The Value of the Testimony to the Aurora-Sound

I HAVE read with much interest the descriptions of this sound as given by Dr. Sophus Tromholt's correspondents in NATURE of September 24. I was, however, struck by the similarity of these descriptions to the well-known phenomena of *tinnitus* *aurium*, and it occurred to me that since a large number of persons have noises in the head—say one-half the entire adult population—it is probable that, when listening intently, a considerable number of observers heard the sounds of their own ears only. This is especially true of "sizzling," "hissing," and "buzzing" sounds.

If physicians affected with tinnitus are not careful to exclude the noises propagated in their own heads, they may discover many curious physical signs in the chests of their patients in making auscultatory examinations. SAMUEL SEXTON

The Red Spot on Jupiter

ON October 24, at 17h. 32m., this object was estimated exactly central on the planet. As seen with my 10-inch reflector, power 252, the spot was very plain, though the low altitude of Jupiter rendered the telescopic image far from good.

My impression is that this red spot is now decidedly more conspicuous than it was when I last saw it on July 8, and that during the ensuing opposition it will again attract general observation as one of the most prominent features of Jovian detail. This well-known marking has now been watched for more than seven years, and its present aspect leads to the inference that its existence will be indefinitely prolonged. We may therefore justly regard it as a lineament of singular permanency. Though its motion and appearance (*i.e.* tint) have been subject to considerable variation, there has been little, if any change in either the shape or size of the spot. The mystery regarding its origin and real nature may perhaps ultimately be revealed on the basis of renewed and more exact observation in future years. W. F. DENNING

Bristol, October 25

A Remarkable Sunset

WHILE out for a walk this afternoon I was struck by a peculiarity in the sunset which I do not remember to have seen noticed before. The sun set about 4.43 p.m., and there was the usual "after-glow." I began to notice this first about five o'clock; there was then in the west a large bank of cumulus cloud rather low down, above this was a brilliant lemon-yellow, very bright, and this was bounded by a broad arc of a pale pink, the latter fading away into the light blue of the sky. Very soon afterwards I noticed that the pink arc, instead of being continuous, was really made up of a series of beams of bright light, which pointed to the position of the sun. I counted these, and made out five bright rays at unequal distances apart; behind this (as it seemed) there were a few yellow cirrus clouds. A sunset like this I have often noticed before, but what followed is, I think, novel. The bright rays were slowly turning round like the spokes of a huge wheel moving in a direction contrary to the hands of a watch. I noticed also that the breadth between the bright rays altered, two of them seeming to almost coalesce. In about ten minutes' time one ray turned approximately through 90°, and a new ray brighter than the other appeared on the right. The altitude of a ray when vertical was from 30° to 40°, I should say. By 5.15 the rays became very faint and soon vanished, though above the dark bank of cloud I could detect a faint crimson-lake glow.

The day had been fine on the whole, except that there had been a little rain early in the morning, and a very heavy rain shower between 12.30 and 1 o'clock. The air was extremely clear, and the wind was blowing freshly from the west, or perhaps it was a bit north of west. It was blowing slightly from right to left across the line joining me to the sun.

This phenomenon of the pink rays revolving seems to be explained by the dark spaces being due to clouds which were being hurried along by the strong west wind. I should like to know if any one living in a line W.S.W. of Cambridge noticed broken masses of cumulus clouds this afternoon *overhead* between 5.0 and 5.15 p.m. Greenwich time. PAUL A. COBBOLD

Caius College, Cambridge, October 26

A Tertiary Rainbow

THE supposed tertiary rainbow about which I sent a note a month ago must have been a halo formed by ice crystals, as readers of NATURE will perhaps have inferred merely from the recorded distinctness of the colours. It did not occur to me that ice crystals would be found in a horizontal direction from here, over the hot plains of the Punjab on the evening of an August day. But I have since calculated the size of the tertiary rainbow and the order of colours in it, and the calculation leaves no doubt that the phenomenon must have been a solar halo, caused perhaps by a hailstorm over the plains.

Thaudiani, Punjab, Sept. 25 T. C. LEWIS

The Sense of Colour

IN the early English "Lay of Havelok the Dane" the following words occur:—

> "Also he wolde with hem leyke
> That weren for hunger *grene* and bleike."

Mr. Allan Cunningham in his interesting paper (p. 604) does not allude to this old use of the word green. Is it a solitary case? MARGARET HEATON

Belvedere, October 24

Stone Axes, Perak

A CURIOUS Malay superstition has come to my knowledge concerning these implements. They appear to be very rare out here, and those found are treasured by Malays as lucky things to have about the house. I have as yet only been able to procure two specimens. One of these I have described in a paper on the Sakaies read before the Anthropological Society in June last. This nearly resembles Fig. 55 in Dr. Evans' "ancient Stone Implements of Great Britain," and is made of a soft description of slate which can be scratched with the thumb-nail. The other is of a much harder description of slate almost like greenstone; it much resembles Fig. 76 of the same work. It is 7¾ inches long, 1⅝ inches wide at the widest end, which is sharpened, and 1½ inches wide at the other end, which is not sharpened. The faces are flatter than those figured by Dr. Evans and the sides perfectly squared. It is beautifully polished, but several depressions are left all over it, showing that it had originally been chipped out. The Malays call them Bâtu-lintarh—*i.e.* thunderstones—and account for their presence by saying that they are the missiles used by angels and demons in their continual warfare.

But the peculiarity of the superstition is this: the Malays aver that the soft implement which I have described has been made by an angel or a demon and buried in the earth to become hard and fit for use, and support their argument by saying that these objects have been found freshly made of clay and quite soft, buried in the earth, where they have lately been deposited by some angel or demon for a future time of battle. The Malays say that the bâtu-lintarh is hard to procure in this state, as it almost invariably drops to pieces. For this reason they do not value it much, and more particularly because it has never inflicted a wound. The hard polished celt which I have just described, however, they value very highly, because they say it has been used in the aërial warfare and has inflicted a wound on one or more of the combatants. They adduce this supposition from the fact of the several depressions left by the chipping out of the implement, and say that these marks were caused by its contact with the body of one of the demon combatants. This last idea is very closely connected with another Malay belief, and most probably took its rise from it. This belief is that if the blade of a kriss or spear is bent or in any way damaged, it has most certainly wounded if not killed a man or some wild animal, and is therefore proportionately of much greater value. A Malay who professes to be a good judge of a kriss will, if asked to appraise the weapon, invariably first glance along the blade to see if it is bent ever so slightly, and if it is he will most certainly add two or three dollars to its value because it has "m'nikam orang" (struck a man). I have very little doubt that if some of the fine limestone caves of this district were thoroughly examined, they would yield a rich harvest of anthropological material. A. HALL

Batu Gaja, Kiuta, Perak, September 6

Photographic Action on Ebonite

AT the back of one of the cases of lecture apparatus facing a north window in this laboratory, there happens to have been standing for six months or more an ebonite plate with a framed glass plate in front of it, the glass having a star-pattern done in little spots of tinfoil all over it. The thickness of the frame, say an eighth of an inch, separated the two plates from each other.

On taking them out of the case the other day I noticed the pattern on the glass clearly and sharply imprinted on the ebonite; every little circle well marked. Dust had been plentifully deposited on all parts not screened by the tinfoil spots, and the striking clearness of the impression was mainly due to this local absence of dust; but even on wiping off some of the dust the pattern could still be detected, owing to some difference of surface between the exposed and the shaded portions.

It evidently is another illustration of Prof. McLeod's observation of the effect of light on ebonite, the modified surface affording an easy lodgment for dust. In case there be anything more in the matter it is proposed to replace the same or similar plates, and observe at intervals.

EDWARD E. ROBINSON
Lecture Assistant to the Professor of Physics in University College, Liverpool

THE SLIDE RULE

It is a perpetual source of amazement to those who are familiar with this instrument that its use is not almost universal. People of every class have to make simple calculations, while those engaged in scientific work, in designing apparatus, or in invention perpetually cover sheets of paper with figures, all of which trouble and the loss of time which it involves might be saved by the intelligent use of a good slide rule, and yet, for reasons difficult to find out, the habitual use of this instrument is limited to a very small proportion of the calculating community.

Most people know that the scales are logarithmically divided—that is, that the distance between the divisions marked 1 and 10 being in imagination divided into 10,000 parts, the division marked 2 is at the 3010th of these parts, the division marked 3 is at the 4771st of these parts, and so on, 3010 being the log. of 2, 4771 the log. of 3, and so on; and further, that the spaces between these whole numbers are similarly divided into fractional parts, thus 1·1 is at the 414th of the imaginary parts and 1·01 at the 43rd of these parts, 414 and 13 being the logs. of 1·1 and 1·01. This is very generally known, but it is more generally believed that to use the rule involves so much thought and anxiety that it is far simpler to work out results in the usual way, or at any rate that the rule can only be of any real assistance when a great number of similar calculations have to be made; and further that, as the results to be obtained are not absolutely correct, that as an extreme error of 1, 1-10th, or 1-100th per cent. is possible, according to the nature of the instrument, it is not really to be trusted. These objections are easily answered. As soon as the slight difficulty of reading the rule has been overcome—a difficulty due to the fact that in ascending the scale the divisions become closer, so that if there is room for ten subdivisions between 10 and 11, there are only five between 20 and 21, and two between 40 and 41—a difficulty which once overcome never recurs—then the simpler calculations, such as multiplication, division, and simple proportion, can at all times without an effort or a thought be instantly performed, while those involving proportions in which some of the terms are squares, cubes, roots, sines, or tangents can, after a moment's reflection, be as easily completed, so that even in the case of single operations time is saved. It is true when many calculations of the same kind present themselves, especially if some of the terms in the series are identical, that the use of the rule is specially advantageous; but in any case mental labour and time are saved.

As to the probable accuracy of results obtained by the use of the rule, they are in general superior to the accuracy with which the figures which require reduction have been determined, or, if this is not the case, they are in general so nearly correct that the error is of no consequence. For instance, if the marks obtained by several examinees are to be reduced to correspond to a total of 100, the commonest rule, which gives an accuracy of 1-300th part, is sufficiently good; for the nearest whole number only, and the right order are all that are needed. It would be absurd to doubt the accuracy of the instrument because it cannot be trusted to give figures correct to one part in a thousand. Or, again, if the weight of a piece of metal has to be determined from its dimensions, a good rule trustworthy to 1 part in 1000 will in almost every case be more than good enough; for, even if the specific gravity of the material be known so truly, it is not often that the piece can be made so near the specified size that the discrepancy which may ultimately be observed will be due more to the error of the rule than to the inaccuracy of construction. In such a case it would be as absurd to discard the rule as untrustworthy as it is to use 7-figure logarithms for the calculations of an ordinary chemical analysis. There are cases, of course, where observations can be made with a degree of accuracy beyond that which is obtainable by any rule—for instance, determinations of mass, length, angles, and time can all be made with extraordinary precision. Where, then, uncertainty is not introduced by observations of another kind, where the entire precision to be obtained in any such observations may be expected in the result, as, for instance, in the determination of the refractive index of the glass of a prism, in such cases the slide rule is unsuitable, and tables of logarithms furnish the most obvious means of making the calculations. Or, again, when pounds, shillings, and pence are involved, a result correct to the nearest farthing is generally desired to make accounts come right, and so, unless the sums dealt with are moderate, the slide rule is again unsuitable. However, the calculation of interest furnishes a good example of proper and improper use of the rule in making calculations. If it is required to find what a certain sum (s) will be worth at the end of a year at so much (r) per cent., the result might be found from the proportion $100 : 100 + r :: s : x$. Here the amount x would be determined with an accuracy of say 1-1000th part, so that if 1000*l.* were involved, an error of 1*l.* might arise. This is an improper use of the rule. A greater degree of accuracy would be obtained by the proportion $100 : r :: s :$ the increase of s. Here the interest is found to the same proportionate accuracy, and so in such a case the greatest possible error could only be one shilling, if the rate is 5 per cent. This example, though obvious, is given because it corresponds exactly with cases that arise in the laboratory, where the rule, if used properly, is of service, but, if improperly, is useless.

Calculations involving only the simple arithmetical rules, when extreme accuracy is required, are best performed by the help of a table of logarithms, or with an arithmometer; in fact with an arithmometer a far greater degree of accuracy can be reached than with ordinary 7-figure logarithms, and though they are also suitable for calculations in which only three or four significant figures are required, their great size and expense compare unfavourably with the portability and cheapness of the rule, and, moreover, trigonometrical and logarithmic functions cannot be found with them. These machines are shown at the Inventions Exhibition by Tate and Edmonson, and are worth examining. There is another calculating machine close to Tate's, by which the interest on any sum at any rate per cent. for any time may be found to the nearest halfpenny in an incredibly short space of time, worthy of the attention of those who have to calculate interest. But, to return to the slide-rule, it is astonishing that an instrument like Gravet's, 10 inches long only, with which all calculations, arithmetical, trigonometrical, and logarithmic, can be worked out so easily and with an accuracy of from 1-500 to 1-1000, according to the nature of the calculation, should be so little used.

This is not the place to give instructions for using the rule, but an outline of the method is necessary to make it possible to compare the different makes, many of which are shown at the Inventions Exhibition.

With two similar scales of equal parts, as inches divided into tenths or centimetres divided into millimetres, it is possible to add numbers, or, conversely, to subtract numbers; thus, if the zero of one scale is placed opposite, say, 6·5 of the other, opposite every number n on the first will be found $n + 6{\cdot}5$ on the second, and so addition or subtraction could be performed, but there would be no advantage in so adding or subtracting. In the same way the slide of the ordinary slide rule is employed to add distances, but these distances do not correspond to the figures attached, but to the logarithms of those figures, and so the sum which is found by such an addition is not the sum of the figures apparently added, but their product. If the slide is placed at random, all the pairs of figures which are opposite to one another are in the same proportion, and the multipliers which will change either series into the other will be found on each scale opposite the divisions marked 1 on the other. It requires no great amount of memory to bear this in mind: however the slide may be set, those numbers which are opposite to one another are in the same proportion, *i.e.* have a common quotient, which may be found opposite any of the divisions marked 1; and yet this is all that has to be remembered in multiplication, division, and simple proportion. The two top lines of a slide rule are generally identical, and they are used for these simple operations; they are generally distinguished by the letters A and B. In general the bottom line of the slide, that is, the third altogether, is identical with the first two, and is labelled C. This arrangement is convenient, for it is possible to insert the slide upside down, in which case all numbers which are opposite one another on A and C have a common product, which may be found opposite any of the divisions marked 1. This furnishes the most ready mode of finding actual or approximate factors of numbers, and is of great use to those who have to calculate wheelwork; further, by the use of the inverted C line under the A line any harmonical progression can at once be read, and any number of harmonic means can be inserted between two quantities. The fourth line is generally made different from the others in that it is on double the scale, and it is then distinguished by the letter D. If the units of the C and D line are placed opposite one another, a table of squares and roots is formed, or if in any other position the squares of the numbers on D vary in the same proportion as do the numbers that are opposite to them on C. It is in calculations made on the C and D lines that so much time is saved, for proportions in which some of the terms are squares or square roots can be worked out as quickly and as accurately as those in which simple numbers only are employed. If the slide is inverted so as to bring the B line opposite to the D line, then the square of any number on D × the number opposite to it on B is constant. This product may of course be found in B opposite 1 in D. Cube roots, among other things, may be found in this way.

These four lines are all that are generally found in a slide rule; occasionally others are added: thus a line on one third of the scale of the D line (sometimes called an E line) will, with the D line, enable one to directly work proportions in which some of the terms are cubes or cube roots, but this is not often required. With the usual four lines all arithmetical processes, except addition and subtraction, can be performed. There are, however, rules in which on the back of the slide are scales in which the distances are log. sines or log. tangents of the angles marked, then these lines being placed against an ordinary A line so that 90° on the line of sines or 45° on the line of tangents is opposite 1 on the A line, a table of sines or tangents will be formed; and if the slide is placed in any other position, the sines or tangents of the angles denoted by any divisions on either of these special lines will vary in the same proportion as do the numbers which are opposite them on the A line. In those rules in which lines of sines and tangents are given there is generally a scale of equal parts in which the length of the D line is divided into 500 or 1000 parts. If this is placed opposite the D line, with the ends of the two scales opposite one another, a table of logarithms will be seen; thus the logarithm of any number on the D line will be found opposite to it on the scale of equal parts.

Having pointed out the chief uses of a slide rule, it will be possible to describe the differences in construction in the several varieties. The most simple possible form is the original Gunter's scale to be found on any sector. With this and a pair of dividers calculations may be made, for if the dividors are set to the distance between any two numbers, any other pair of numbers which are found by the dividors to be the same distance apart will be in the same proportion, or have a common quotient, just as a common difference would be found if a scale of equal parts were used. This, however, is troublesome; but if the same principle is applied to a scale in the circular form the result is much more convenient. In this case angular distance takes the place of linear distance, and a pair of arms which can be opened to any angle can be moved round, and every pair of numbers covered will bear to one another a constant proportion depending on the extent of the angle. This is the principle of some of Dixon's rules shown at the Inventions Exhibition, near the arithmometers. In the well-known pocket instrument, the calculating circle of Boucher, an instrument like a watch, one hand is fixed and one is movable, and the face is also movable. There is another instrument of the same kind, in which the scale is drawn on a helical line. Here the scale and one hand are movable, and there is one fixed hand. This, which is Prof. Fuller's spiral rule, is made and exhibited by Stanley. Circular instruments are also made, in which scales slide over one another, which are in this respect like the straight rules. There is more advantage in the circular form than appears at first. In the straight rules the A and B lines are each double, the first and second halves are identical; this repetition of the scale is required in order that, however the slide may be placed, the part of each opposite to the other may contain at least a complete scale of numbers. In the circular form, however, the beginning and end of a single logarithmic scale meet, and so the scale itself is its own repetition both above and below. For this reason the openness of the divisors in a circular instrument is the same as in a straight rule, of which the length is six times, instead of three times, the diameter of the circular line.

Of the two types of instrument—one in which one slide works against another, generally straight, sometimes circular, and the other in which there is no slide but only a line divided logarithmically with a pair of hands, which type is always circular—which may be called respectively the slide and the index types, each has certain advantages. The slide form is preferable, in that each setting of the slide furnishes a complete table of pairs of related numbers, as, for instance, of any English and foreign measure, of squares and roots on any scale, such as diameters and areas of circles, or of sines or tangents on any scale, so that, without moving the slide, any number of results may be read off, whereas with instruments of the index type the scale must be moved under the hands, or the hands over the scale, for each result. On the other hand, index instruments are more convenient than the usual slide rules in working out long expressions of the form $\frac{a \times b \times c \times d}{e \times f \times g}$, in which any of the terms may be squares, cubes, sines, or tangents, for the terms are taken alternately from the numerator and denominator and set in order with the fixed and movable hand until all are worked off, when the answer is found under the fixed hand. There is no necessity to observe any result till the process is complete; on the other hand, with slide instruments, each result of the form $\frac{a \times b}{e}$, $\frac{a \times b \times c}{e \times f}$, &c., must be read and set before it can be operated upon by the next pair of factors. In Gravet's rules, however, this disadvantage of the straight form is removed by the addition of a cursor or sliding index, which in other ways is a great comfort.

All instruments of the index type suffer terribly from parallax, owing to the hands being above the face, so that they do not in practice give the accuracy that from the length of scale upon them might be expected.

This is especially the case in small instruments: for instance, Boucher's calculating circle, made in the form of a watch, is probably divided so accurately that on that score an error of one part in a thousand does not exist; yet, owing to parallax, the practical limit is about 1-300. This instrument has, besides the ordinary line, one on a double and one on a treble scale for squares and cubes, a line of sines, and another of equal parts for logarithms.

The possible accuracy of any instrument depends upon the length of the scale included between 1 and 10, called the radius, and also upon the linear accuracy with which a setting or reading can be made; this is at least twice as great in slide as in index instruments. In order to obtain great accuracy various means have been adopted whereby a great length of scale is brought within a small compass. Among slide instruments are Prof. Everett's "Universal Proportion Table," published by Longmans, Green, and Co., and General Hannyngton's slide rule, made and exhibited at the Inventions Exhibition by Aston and Mauder. In these the slide is made in the gridiron form. In Everett's instrument there are twenty bars, the total length of which is about 13 feet; a scale of equal parts is also printed, so that logarithms can be read with it. In both of these instruments only simple proportions can be effected, unless special grids, divided on a double scale or trigonometrically, are provided. Far the most ingenious of all devices for obtaining a great length of radius in a comparatively short space is due to Mr. Beauchamp Tower, whose name is well known in connection with the spherical engine. His instrument is a slide instrument consisting of two tapes running side by side over equal and independent rollers, but the tapes have a half twist in them, so that they have each only one surface and one edge. In this instrument, made privately for his own use, each tape is about 12½ feet long, and as both sides of the tape are used the radius is about 25 feet, and therefore, as far as openness of scale is concerned, it is equivalent to a straight rule 50 feet long, while the instrument itself is only just over 6 feet in length.

Slide rules of the index class can have a great length of scale more readily employed than others. Thus Prof. Fuller's helical instrument has its radius equal to 42¼ feet, and is in openness of scale equivalent to a straight rule 85 feet long, while the box which contains it is only 17×3¾×3¾ inches inside measure. Dixon exhibits a special rule with the scale extending over 10 concentric circles, but with this form a less degree of accuracy is attainable when using the inner than when using the outer circle. Thus the inner circle is equivalent to a straight rule 30 feet long and the outer to one 60 feet long. There is an outer circle equally and logarithmically divided to find logarithms. In another of Dixon's instruments, similar in size and form, there is the same outer circle for proportions and logarithms, and a series of inner circles divided so as to give sines, cosines, tangents, cotangents, secants, and cosecants. Each of these is on a board 14 inches square. Rules with very extended scales do not in practice give results with an accuracy which is proportional to their length, though the working accuracy is very much increased. They have this advantage, that they can be worked to their limit with ease, while with a well-divided pocket rule the errors of construction are beyond the limits of vision, and so the calculator is apt to strain his eyes to get results as accurate as possible. For instance, results obtained by a good pocket-rule one foot long can be trusted to a thousandth part; at the same rate Prof. Everett's should be accurate to a thirteen-thousandth part, and Prof. Fuller's to an eighty-five thousandth part. In practice a four and a ten-thousandth part are their limits. Again, instruments with very extended scales have only room for one line, so that simple proportions only and logarithms are all that can be directly obtained from them. For general use in the laboratory or elsewhere where calculations of every kind have to be made, the straight form, on the whole, seems most convenient, because of its portability, the quickness with which it can be worked, the diversity of operations that it will directly accomplish, and the extraordinary accuracy in comparison with other forms of the results to be obtained. Far the best instruments of this type that the writer has yet seen are those made by Tavernier-Gravet, of Paris, already alluded to. They are different to those generally used in England in that the line in the slide which works against the D line is itself a D line, so that squared proportions have to be performed by the aid of the cursor. This form has the further disadvantage that the inverted slide cannot be used for finding factors, which is a great loss; on the other hand, the two lower lines may be used for simple proportions, and they will give a double accuracy. On the whole, the original pattern with an A, B, C and D line seems preferable. Of the straight rules shown at the Inventions Exhibition those made by Stanley exceed all the others in workmanship and they are equal in this respect to the Gravet rule. Among them are rules for special purposes, as Hudson's scales and Ganga Ram's rules. Hudson's scales, which are made in card, each having two slides, are a marvel of constructive skill. Dixon shows his "triple radius double slide rule," with which very complex operations may be readily performed. Heath shows a slide rule for converting sidereal to mean solar time, or the reverse, correct to about ·02 of a second, but this is not a slide rule proper, as the scales are not logarithmic.

There is entirely a different class of slide rule shown by Lieut. Thomson. In this there is, as usual, an A, B, and C line, but instead of the D line there is a "P" line, in which the distances, instead of being logarithmic, are logarithms of logarithms. By this instrument fractional powers may be found as readily as simple products or quotients. It has, however, this defect, that the scale converges so rapidly as the numbers ascend that high numbers can only be obtained with a proportionate accuracy far less than is possible with low numbers. It is one feature in the slide rule of ordinary construction that an error of reading of, say, 1-100th of an inch will produce the same proportionate error in any part of the scale. This rule for involution is shown in the straight and circular form. It is right to mention that the same thing exactly was invented by the late Dr. Roget and published by him in the *Phil. Trans.* of 1815.

No attempt has been made to give an account of every special form of rule that is made; those shown at the Exhibition and some other well-known forms, which well illustrate the different kinds of development, have been imperfectly described and the general principles on which all depend sufficiently explained to make evident the advantages of each type of instrument.

HOMING FACULTY OF HYMENOPTERA

IN connection with Sir John Lubbock's paper at the British Association, in which this subject is treated, it is perhaps worth while to describe some experiments which I made last year. The question to be answered is whether bees find their way home merely by their knowledge of landmarks or by means of some mysterious faculty usually termed a sense of direction. The ordinary impression appears to have been that they do so in virtue of some such sense, and are therefore independent of any special knowledge of the district in which they may be suddenly liberated; and, as Sir John Lubbock observes, this impression was corroborated by the experiments of M. Fabre. The conclusions drawn from these experiments, however, appeared to me, as they appeared to Sir John, unwarranted by the facts; and therefore, like him, I repeated them with certain variations. In the result I satisfied myself that the bees depend entirely upon their special knowledge of district or land-marks, and it is because my experiments thus fully corroborate those which were made by Sir John that it now occurs to me to publish them.

The house where I conducted the observations is situated several hundred yards from the coast, with flower gardens on each side and lawns between the house and the sea. Therefore bees starting from the house would find their honey on either side of it, while the lawns in front would be rarely or never visited—being themselves barren of honey and leading only to the sea. Such being the geographical conditions, I placed a hive of bees in one of the front rooms on the basement of the house. When the bees became thoroughly well acquainted with their new quarters by flying in and out of the open window for a fortnight, I began the experiments. The *modus operandi* consisted in closing the window after dark when all the bees were in their hive, and also slipping a glass shutter in front of the hive door, so that all the bees were doubly imprisoned. Next morning I slightly raised the glass shutter, thus enabling any desired number of bees to escape. When the desired number had escaped, the glass shutter was again closed, and all the liberated bees were caught as they buzzed about the inside of the shut window. These bees were then counted into a box, the window of the room opened, and a card well smeared over with birdlime placed upon the threshold of the bee-hive, or just in front of the closed glass shutter. The object of all these arrangements was to obviate the necessity of marking the bees, and so to enable me not merely to experiment with ease upon any number of individuals that I might desire, but also to feel confident that no one individual could return to the hive unnoticed. For whenever a bee returned it was certain to become entangled in the bird-lime, and whenever I found a bee so entangled, I was certain that it was one which I had taken from the hive, as there were no other hives in the neighbourhood.

Such being the method, I began by taking a score of bees in the box out to sea, where there could be no landmarks to guide the insects home. Had any of these insects returned, I should next have taken another score out to sea (after an interval of several days, so as to be sure that the first lot had become permanently lost), and then, before liberating them, have rotated the box in a sling for a considerable time, in order to see whether this would have confused their sense of direction. But, as none of the bees returned after the first experiment, it was clearly needless to proceed to the second. Accordingly I liberated the next lot of bees on the sea-shore, and, as none of these returned, I liberated another lot on the lawn between the shore and the house. I was somewhat surprised to find that neither did any of these return, although the distance from the lawn to the hive was not above 200 yards. Lastly, I liberated bees in different parts of the flower garden, and these I always found stuck upon the bird-lime within a few minutes of their liberation. Indeed, they often arrived before I had had time to run from the place where I had liberated them to the hive. Now, as the garden was a large one, many of these bees had to fly a greater distance, in order to reach the hive, than was the case with their lost sisters upon the lawn, and therefore I could have no doubt that their uniform success in finding their way home so immediately was due to their special knowledge of the flower garden, and not to any general sense of direction.

I may add that, while in Germany a few weeks ago, I tried on several species of ant the same experiments as Sir John Lubbock describes in his paper as having been tried by him upon English species, and here also I obtained identical results: in all cases the ants were hopelessly lost if liberated more than a moderate distance from their nest. GEORGE J. ROMANES

THE HEIGHTS OF CLOUDS

FROM the Upsala Observatory comes an account of fairly exact measurements of the heights of clouds during the summer of last year, and a very interesting publication it is. It appears that when the circumpolar expeditions were planned the Swedish Meteorological Observatory furnished their station at Spitzbergen with three theodolites, of a somewhat novel though simple construction, for the double purpose of observing the altitude of the aurora and that of clouds. The difficulty that has always been felt in such observations has been that of easy intercommunication between the different observers, so as to fix on the particular part of the cloud of which the height was to be measured. Thanks to modern invention this difficulty was got over by connecting each station with a telephone. The reported good results obtained at the circumpolar station—the publication of which, by the by, has not been done as yet—induced Herr Hildebrandsson, the director of the meteorological observatory at Upsala, to commence a set of similar observations there. On a couple of pillars, about 450 yards apart, and placed on an approximately north and south line, a couple of theodolites were erected, the stations being connected by telephones. The theodolites employed may be described as ordinary theodolites, the object glass of the telescope being replaced by a large open ring, across which were stretched a couple of cross wires, whilst the eye-piece consisted of a simple hole of 3mm. in diameter. When observing near the sun dark glasses would be placed in front of this orifice. As might be expected, there are several unavoidable errors in using these instruments, the principal of which are the uncertainty of an identical point in a cloud being measured at each station, and the want of synchronism of the observation—a very important point when clouds are travelling with any speed. The method of observation was somewhat laborious, and was as follows. The two observers, each at a theodolite, agreed as well as they could on the point in the cloud to be observed, and at a particular time, fixed upon in advance, brought the cross wires on this somewhat indefinite spot, and then read their instruments, noted the time of observation, described the cloud, and if possible sketched it. A second observation of the same point gave the direction and rate of motion of the cloud. Perhaps one of the most easily observed clouds is the cumulus, and we find from a table given that the probable error of observation is very considerable. Thus, in one whose height was calculated to be 1,639 metres, the probable error of one observation was 748 metres, and of the mean of 16 observations 187. Out of 101 observations the mean height of a cumulus was 1,690 metres, and the probable error of the mean 40

"Mesures des Hauteurs et des Mouvements des Nuages." Par N. Ekholm et K. L. Hagström.

metres. The labour to attain even such accuracy is very great. The surprise is that at Upsala they did not adopt a photographic theodolite such as is now, we believe, in daily use at Kew. In the Kew "nephographs," as they are called, the telescope is replaced by a camera, and the observations do not involve half the labour of eye-observations. For instance, when the two nephographs are in a fixed position the manipulations are simplicity itself. One observer telephones to the other the cloud whose height it is desired to ascertain. By means of a very simple pointer both direct their cameras to the cloud, having inserted a dry plate in position. The lenses are closed by shutters, both of which can be opened and then closed with any desired rapidity by an electrical arrangement from one station. The exposures are thus made simultaneously, and the photograph must include every point in the cloud. The position of the cloud is fixed by crossed lines etched on a glass plate which is in contact with the dry plate, and which always occupies the same position, and from these cross lines, which are impressed on the two negatives, any desired point is measured. The readings of the graduated circles of the nephoscope having been taken the height and distance of the cloud is readily calculated. It might be supposed that considerable errors might be made even with this arrangement as the solid angular distance included is somewhere about 55°, and the objects within this are impressed on a plate less than six inches square. As a matter of fact, such is not the case. Measurements of objects a couple of miles off, and at known distances from the observer, have been observed with an error of less than 1 per cent., a base of 250 yards having been used—an accuracy which is far greater than could be obtained by eye-observations when the object to be observed is uncertain in outline, and when there is no definitely fixed point to observe. It must not, however, be supposed that there are no difficulties in photographing clouds of every description. It requires, for instance, a keen judgment to hit off the exposure necessary to differentiate between the white clouds in the higher regions the pale blue sky against which they are projected. All such difficulties are to be overcome with practice. It is to be hoped that before long the Upsala Observatory will adopt such a plan as we have indicated, when the results they obtain will be even more valuable and be less laboriously attained than they are at present.

The following table gives the height of the different characters of clouds at Upsala :—

Stratus		625 metres.
Nimbus (lower)		1,115 „
„ higher		2,185 „
Cumulus and cumulo-stratus	top	1,690
	base	1,307
	mean	1,498
Lower alto-cumulus		1,988
Higher „ „		4,242
Cirro-cumulus		5,513
Cirrus		6,823

The authors point out that, according to their observations, apparently there are seven levels, each one occupied by a different species of cloud, viz. : 600, 1,100, 1,500, 2,000, 42-4,600, 58-6,600, and 80-8,600 metres ; and these levels agree with those deduced by M. Vettin of Berlin, who deduced them from a different mode of observation. There are several remarkable tables, some of which give the diurnal variation in the height of clouds, others the diurnal variation of the frequency of high clouds at Upsala during the summer, others again which discuss the question of the effect of the height of the barometer on the cloud masses. One of the most interesting sections of the memoir is that on the calculation of the velocity of wind at different heights from the movements of clouds.

On the whole, the Observatory at Upsala is to be congratulated on the step it has taken in making systematic observations of cloud heights and velocities. It is a matter of capital importance to meteorology that such should be undertaken in various localities, not only at or near the sea level, but also at as high altitudes as possible. Were the cloud levels, for instance, the same at all places, mountainous districts would be very much more cloud bound than we know is the case. Observations of clouds in the Alps show that the levels at which the different classes are to be found exceed the heights which are shown in the table above ; and it remains to ascertain not only the effect of barometic pressure on the levels, but also the disturbing effect caused by the elevations in the land. Such observations might well be added to the observatory at Ben Nevis, and no doubt some enthusiastic meteorologist would be willing to spend a summer in the Alps to make observations at a still higher station. Until work such as this is undertaken the subject can only be partially discussed on scientific grounds.

W. DE W. A.

THE RECENT TOTAL ECLIPSE OF THE SUN

WE have received the following communications :—

THE news that bad weather seriously interfered with the work of the Government Survey parties, sent to observe the eclipse of the 9th inst. from points on the centre line of totality, induces me to send you the accompanying incomplete sketch and hasty account by to-day's mail :—

I observed the eclipse from Tahoraite, the present southern terminus of the Napier-Wellington Railway, a point well within the belt of totality, but some forty miles north of the centre line.

I went, determined to concentrate my whole attention on the corona, and the corona alone—I did not even take my watch. My eclipse observations are therefore necessarily very incomplete.

After a stormy night (alternate showers of rain and hail, with a bitterly cold wind), day-dawn brought a clear sky ; but a heavy bank of clouds far away to the south boded no good to observers in that direction. The cold was bitter, and fresh snow lay very low down on the neighbouring hills.

The first contact occurred not long after sunrise, the atmosphere in the east being rather hazy, and the light *pale* (other observers say *ruddy*). At first the temperature of the air seemed to rise steadily, but when the sun's disk was a quarter obscured, it began to fall again, and as totality approached the cold became severe.

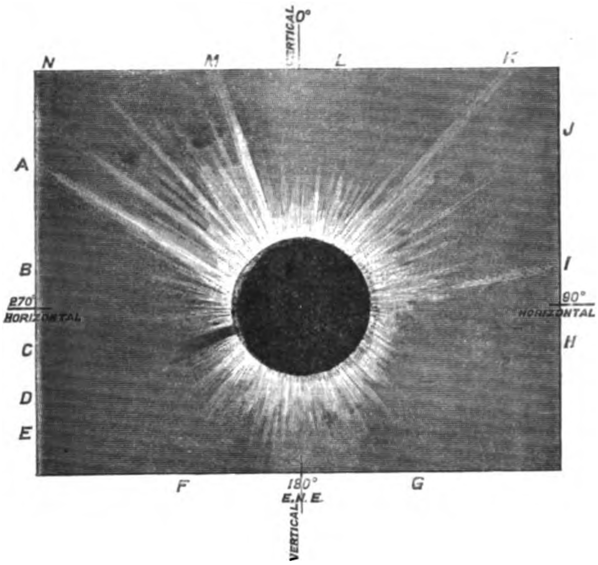
When the occultation of the sun had reached three-quarters, the so-called "livid" character of the light became very marked, and about ten minutes before totality a curious and tremulous play of light on the ground—like dark ripples or moving "marblings," if I may use the word, became apparent.

In order to keep my eyes as sensitive as possible to the faint light of the corona when it should become visible, I only watched the sun (through a telescope) for a few minutes after first contact, I then averted my gaze, and fixed it persistently on the dark-green bush surrounding the Tahoraite clearing. All I noticed during my hasty survey of the disk was two small and one large spot, the latter close to the limb at about 90° (see sketch), and surrounded by faculæ.

The moment "totality" occurred I turned my gaze towards the sun, and having previously, to save time, drawn disks on several pages of my pocket-book, I hurriedly took sketch after sketch of the shape of the corona, the rays of which were much better marked than I had been led to expect. My object in taking several sketches was to record any change in the position of the rays. I took five during the short time of totality, and their agreement is so clear as regards the number and relative position and length of the main rays, that it fully confirms the general impression left on my mind as to the fixity of this phenomenon.

I was just engaged in making a last estimate of the extent of the corona between 35° and 90°, when a cry arose from the bystanders, "Look at the red flame shooting out to the left!" I withstood the temptation, and observed the almost sudden disappearance of the corona on the reappearance of the sun. All I can therefore say of the red protuberance which attracted so much notice is that the emergence of the sun is blended in my mind with a vague and fleeting impression of a narrow streak of red light with a broad streak of white light outside it, between 200° and 290°, and almost symmetrically divided by the position of the dark rift in the corona.

An acquaintance who noticed the rift in the corona told me that the red flame shot out close to it. He described the shape of the flame as *ragged;* other intelligent observers compared it to a *sugarloaf;* the most intelligent



Corona as observed during solar eclipse of September 9, 1885, as seen from Tahoraite, North Island, New Zealand, about 40 miles north of centre line of totality:—A, 320°; longest ray, 2-3 diams. B, first contact about 285° (vague). C, Sun apparently reappears about 260° (vague). D, 250°; dark rift in corona. E, approximate position of large red protuberance which shot out just before close of totality. F, corona, ¾ diam., rather ragged. G, corona, ½ diam., regular. H, large sun-spot with faculæ close to the limb at time of first contact. I, 80°; 3rd longest ray, 1½ diam. J, between these two long rays corona extends nearly ¾ diam., with some longer rays. K, longest ray, 1¼ diam. L, corona, hardly ½ diam. M, 2nd longest ray, 1½-2 diams. N, between longest rays corona extends ¾ to 1 diam.; 2 long rays 1¼ diam. (N.B.—Corona alone was observed: relative position and lengths of rays reliable; absolute lengths to be taken with caution.)

of those I heard, to a *drop of water* hanging from an object. Other observers, again, stationed two miles off, saw, *not a red* but a brilliant *white* flame shoot out.

I leave these discordant statements and comparisons to be reconciled by other men.

During totality there was a considerable amount of diffused light around the sun. I am unable to state its extent or colour from personal estimate. Some of the bystanders called the colour pearl-grey; others, reddish; others, again, pale blue and white.

The colour of the corona itself seemed to me very pale bluish green.

The sketch I send you should explain itself. I will only mention that the angles are, of course, only estimated, the zero direction being the upper end of the vertical through the centre of disk.

The rift in the corona was very marked, and extended right down to the disk; it was very near to by far the longest of the rays. In conclusion there is nothing that the coronal rays remind me of so much as an auroral display.

N. A. Graydon

Hastings, Hawkesbay, N.Z., September 11

Mr. Henry Bedford, of All Hallow's College, Dublin, sends us a copy of the *Marlborough Express*, New Zealand, of Wednesday, September 9, 1885, giving an account of the eclipse as observed at Blenheim and other places in New Zealand.

The eclipse at Blenheim began at 6.30 a.m., and totality occurred at 7.25.

"The totality—if totality it was—could have lasted but a bare moment: for, to the untrained observer, it seemed that a patch of bright sunlight on the upper edge of it was never absent. It must, however, be remembered that Blenheim is on the very outer edge of the belt, and that the apparent duration of totality was so extremely short that, by an optical illusion, it might seem that sunlight was never totally obscured. The corona and sun's flames were plainly visible, and formed a spectacle which no mechanical contrivance can imitate, and no art can reproduce. Several stars in different quarters of the heavens—and particularly one about four sun's diameters below the eclipse—were seen, and the general appearance of the sky and of the shadows on the hill sides and in the water was that of early dawn. The eclipse was certainly a wonderful phenomenon, and almost as interesting to the non-scientific observer as to the man of science who viewed it in his observatory.

"Observations of the eclipse were taken in the cricket ground at Blenheim by Mr. Dobson, C.E., and ten instantaneous photographs were secured by Mr. W. H. Macey, the two gentlemen acting in conjunction. Mr. Dobson's observations were made by the telescope and theodolite, the powerful telescope belonging to Mr. Cullen of Mahikipawa having been erected in the cricket ground for the purpose."

At Wellington, by the time the total phase was reached the sun was sufficiently clear of clouds to give an uninterrupted view. As totality was reached the scene was most impressive, and as the darkness increased the western heavens became illuminated with a deep orange colour, shading off into the most delicate of yellows. A number of stars were plainly seen during the darkness. After about a minute and a half the sun again shone out, and gradually increased. Pigeons and birds began to fly about in a helpless fashion, and sought their roosts.

Dr. Hector reports:—"Heavy southerly squalls, with hail, spoiled the observations. We were at Dryertown, on the centre of the line, but got only partial glimpses. A pink patch surrounded the sun, and extended 15° from it, probably due to the same dust film in a high atmosphere that caused the sun-glows last year."

At Mastertton a heavy south-west gale with rain set in on the 8th, and the morning broke without any signs of clearing. Messrs. M'Kerrow and party, who had camped at the foot of Otahuao, proceeded to the top and fixed their instruments amid driving snow and hail. Just before totality the sky cleared, and all the phenomena were fairly visible. One photograph was taken before totality, three during, and one after. The corona was visible for fully a minute, encircling a ring of light radiating to a distance of about half a diameter of the sun. It was of a pale white colour, like the electric light; of uniform width, except at the sun's equator, where it slightly protruded, and was evidently of greater extent.

We have just received, by the dilatory method of a letter by post, an account of the preparations making and made for the due observation of the Total Solar Eclipse in September, up to within a fortnight of the event coming off; but no more. Our informant, the Venerable the Archdeacon Stock, of Wellington, New Zealand, was momentarily expecting two large auxiliary expeditions, one from Sydney, the other from Melbourne; and had been himself told off for corona work. But though brimming full of fine enthusiasm to do all that man could do in that department, he yet characteristically adds, "but how can we expect to see any of the more refined and minute features through all this Krakatão haze which the sun has still to shine through? In 1882, before that great volcanic eruption, we could see the comet of that year close up to the sun's limb; but now I am certain that nothing of the kind could be visible." C. P. S.

15, Royal Terrace, Edinburgh, October 21

NOTES

PROF. PASTEUR read on Monday evening to the Paris Academy of Sciences a statement, of which the following is the substance as telegraphed to the *Standard*:—M. Pasteur some time ago succeeded in rendering proof against rabies some sixteen out of every twenty dogs experimented upon. But to ascertain that immunity had really been given, he had to wait four months after the inoculation had taken effect. He therefore set himself to obtain virus of different degrees of strength, with the object of obtaining prompter and more certain results. This was effected by the following means:—A rabbit was inoculated with a fragment of tissue taken from the spine of a rabid dog. The incubation of the poison occupied fifteen days. As soon as the rabbit was dead a portion of its spinal marrow was in turn inoculated into a second rabbit, and so on until sixty rabbits had been inoculated. At each successive inoculation the virus became of increased potency, and the last period was not more than seven days. Having ascertained that exposure to dried air diminishes the virus, and consequently reduces its force, M. Pasteur supplied himself with a series of bottles containing dried air. In these bottles were placed portions of the inoculated spinal marrow of successive dates, the oldest being the least virulent, and the latest the most so. For an operation M. Pasteur begins by inoculating his subject with the oldest tissue, and finishes by injecting a piece dating from two days only, whose period of incubation would not exceed one week. The subject is then found to be absolutely proof against the disease. At the beginning of July a young Alsatian, named Joseph Meister, who had been severely bitten in several places by an undoubtedly rabid dog, presented himself at the laboratory. His case, left to itself, being considered hopeless by M. Pasteur, Prof. Vulpian, and other high authorities, the patient was submitted to the same series of inoculations that had been so successful on dogs. As a proof a series of rabbits were simultaneously subjected to the identical processes. In ten days thirteen inoculations were made with pieces of spinal marrow containing virus of constantly-increasing strength, the last being from the spine of a rabbit which had died only the day before. The youth thus operated upon by the successive administrations of weaker virus was made proof against the virus of the intensest strength. It is now 100 days since he underwent the last inoculation, and he is in perfect health. Those rabbits, on the contrary, which were at once inoculated with the strong virus, without first being rendered fit to receive it, became affected within the proper incubation period, and died with the usual symptoms. The first inoculation practised upon Meister was sixty hours after he had been bitten. M. Pasteur has, at the present moment, another human patient under treatment who was bitten a few days ago by a mad dog. M. Pasteur said it would now be necessary to provide an establishment where rabbits might always be kept inoculated with the disease. In this way there would constantly be a supply of spinal tissues, of both old and recent inoculation, ready for use. Before the sitting was adjourned M. Pasteur received an enthusiastic ovation from both the Academy and the public present.

THE annual meeting of the five academies forming the French Institute took place at two o'clock on October 24 in the large hall of the Institut; M. Bouguereau, President of the Academy of Beaux Arts was in the chair. The great prize delivered once every two years was awarded to Dr. Brown-Sequard, the well-known physiologist. M. Paul Bert had written a paper "On Vivisection," which was expected as a sequel to the delivery of the prize to Dr. Brown-Sequard, but it was not read for want of time. The annual banquet took place in the evening for the second time.

IT is rumoured that M. Goblet, the Minister of Public Instruction, proposes to return to the former organisation of the Institut, which was regarded as a universal self-electing body. Each class or special academy had not the privilege of choosing its own members as now, but of proposing a list of candidates to the whole Institut. The increased solemnity given to the annual and quarterly meetings, and the institution of banquets, are considered as preparatory to this important change.

M. BERTRAND, who was nominated member of the French Academy some months ago, will be received on December 10 next, at a solemn sitting, when he will read his inaugural address. It will be answered by M. Pasteur.

A VERY valuable addition has recently been made to the Science Collections now displayed in the Western Galleries at the South Kensington Museum of Science and Art. Mr. Rochfort Connor, of the Inland Revenue Department, has prepared a number of exquisitely finished pen-and-ink drawings of objects viewed with the microscope, often by the aid of very high powers. The collection, which covers two large screens in the rooms devoted to biology and geology, include drawings of insects and other minute forms of animals, and of various anatomical preparations from them, of curiosities of pond-life, and of the skeletons of many organisms, both recent and fossil. Among these last Mr. Connor's highly-finished representation of some of the more complicated forms of the Diatomaceæ, such as *Heliopelta* and *Coscinodiscus*, are especially worthy of admiration, though some of his drawings of Foraminifera, Bryozoa, and Sponge-spicules are scarcely inferior to these in delicacy of execution. These drawings represent, we understand, the leisure hours of a busy life-time, and their author is now engaged in a series of microscopic drawings illustrating the characters of food-products and their adulterants. A few of these are now exhibited as samples, and the series when complete cannot fail to be of great use to public analysts and others.

AT a meeting of the Brookville (U.S.) Society of Natural History, September 22 (according to *Science*), a committee was appointed to confer with the scientific associations, educational institutions, and with individuals throughout the State of Indiana, concerning the advisability of the formation of a State Academy of Science, and if thought advisable, to co-operate with such persons in favour of the formation of such an association. Free expression of opinion is called for by the committee, both as to the need of such an organisation and as to the best plan for its composition. It is now the plan to hold a meeting at Indianapolis between Christmas and New Year's day. It proposed that the organisation shall enable the citizens of Indiana who are engaged in scientific work to meet at certain times "for social intercourse, for the exchange of ideas, and the comparison of results of scientific studies." It would appear from the prospectus that the Academy would be a State society similar to the American Association.

SOME theoretical views on the detonation of meteorites have been recently offered by Signor Bombicci in the Royal Accademia dei Lincei. He supposes the detonation to be that of an explosive gas mixture, formed during the surface-heating of the mass in the atmosphere, and accumulating chiefly in the vacuous space left behind the mass in its very swift flight. The gas mixture is probably of oxygen and hydrogen, and it becomes detonant when the proportions are near those in which the gases form water. The oxygen may be supplied from the air; the hydrogen may come from the meteorite itself, which, having like porous bodies and fused metals, taken it up and condensed it in some region of space, sets it free again as it becomes very hot by friction of the air, and as an enormous difference of pressure arises between the front and the back part. But a portion (and perhaps the larger) of the detonating mixture may come from dissociation of the aqueous vapour in contact with the glowing and fused surface of the meteor. To the idea of an actual explosion of the meteorite by internal energy, Signor Bombicci objects that the ball must be shattered to the finest dust, and that fragments would not be coated with a crust. Sometimes meteorite stones remain quite whole in spite of the detonation. Haidinger's idea of the sound being due to air rushing into the vacuum behind the meteorite is thought improbable because the detonation takes place in very high layers of the atmosphere, where the air is much too rare; moreover the movement of the meteorite until detonation is a quite steady one. The character of the noise, and its repetition at intervals, also the shattering of the mass into fragments forming a cone of dispersion towards the earth all agree, in the author's opinion, with an explosion of gas behind the meteorite. Referring to another point, Signor Bombicci thinks that the earth has by virtue of its magnetism a selective action on cosmic masses; hence the universal presence of iron in meteorites.

MESSRS. A. AND C. BLACK will publish immediately a volume by Dr. Croll, F.R.S., entitled "Discussions on Climate and Cosmology," and also a new edition of "Climate and Time."

ACCORDING to the *Journal of Indian Art* the Government of India has decided to combine the duties of the Archæological Survey and those hitherto performed by the curator of Ancient Monuments. For this purpose India, exclusive of the Madras and Bombay presidencies, has been partitioned into three divisions, one of which has been placed under the control of Major Keith, who superintended the construction of the magnificent Gwalior gate which H.H. Maharajah Scindia has presented to the South Kensington Museum, and which will be a prominent ornament of next year's exhibition.

WE have received from Mr. Saville Kent, Superintendent and Inspector of Fisheries in Tasmania, a very encouraging report of operations for the year ending July 31, 1885. Much of the report is devoted to oyster fisheries, which Mr. Kent is endeavouring to develop on scientific principles. He has established hatcheries at various points, and a laboratory for experiments, and under his care the oyster ought to become an important industrial product in Tasmania. He also advises the encouragement of sponge fisheries. With regard to Salmonidæ, Mr. Kent concludes that no true salmon have yet been established in the lakes and rivers of Tasmania. The fish of large size which abound in the great lakes and other large sheets of water are really essentially the same as the Great Lake Trout or *Salmo ferox* of Great Britain.

IN the Report by the Board of Trade on their proceedings and business under the Weights and Measures Act for the past year, it is stated that the attention of the department has been called by the Corporation of Dublin to the necessity of providing a legal standard measure for testing steam pressure-gauges. In reference thereto regret has been expressed that at present the Standards Department has no power to do this. The question appears to be whether a pressure-gauge is a "measure" within the meaning of the Act. The testing apparatus proposed by the Corporation is a measurer of pressure applicable only for special use, and it belongs to a class of measuring instruments, as barometers, thermometers, &c., not directly provided for by the Act. In the report of last year an opinion was expressed that the time had now arrived when this country might, under proper conditions, join the International Convention on Metric Standards, and in September last Her Majesty's Government made known to the Comité International des Poids et Mesures at Paris that England was willing to join the Convention. This has now been done; and the Comité accepts the reservations of Her Majesty's Government as to the introduction of the metric system into this country, affirming that there is nothing in the articles of the Convention which implies any obligation on the part of a contracting State to attempt to modify the system of weights and measures legalised at the time in that State. The adhesion of England, therefore, is not to be regarded as any expression of opinion that the adoption of the metric system in this country would be desirable. A copy is attached to the Report of a Memorandum on Metric Standards intended for laboratory use; and also a copy of a scale of errors to be permitted on ordinary metric standards used in testing manufacturers' weights. Metric weights from 20 kilograms to 0·001 gram. to be used for the purposes of science and manufacture, or for any lawful purpose not being for the purpose of trade, have been verified for the local authority of Birmingham.

MR. CLEMENT L. WRAGGE, of the Torrens Observatory, near Adelaide, late of Ben Nevis, has been instructed by the Queensland Government to "visit and report as to the best means of establishing meteorological stations in Queensland, including the Cape York Peninsula and Torres Straits." Mr. Wragge, who lately returned to Brisbane from Northern Queensland, will commence his duties early this month, and proceeds shortly to Normanton in the Gulf of Carpentaria.

THE Institution of Mechanical Engineers met at Coventry yesterday, when the following papers were read:—On the construction of modern cycles, by Mr. Robert Edward Phillips, of London; on the distribution of the wheel load in cycles, by Mr. J. Alfred Griffiths, of Coventry; description of a hydraulic buffer-stop for railways, by Mr. Alfred A. Langley, of Derby.

THE aquarium at the Inventions Exhibition has lately received some valuable additions in the form of golden tench, American salmonidæ, and Italian carp, notwithstanding the fact that the Exhibition will shortly close. It is to be hoped that the exhibits from the Buckland Museum collection will be allowed to remain in the aquarium, where they appear to far better advantage than in their previous *locale*.

THE Ichthyological Museum now in course of formation at South Kensington has been lately enriched with further valuable specimens of fish. Amongst them are some prawns unique in size, measuring *twelve* inches long, which were presented by Mr. John S. Charles, of Lower Grosvenor Square.

THE *Scientific American*, in a recent issue, describes the tangent galvanometer constructed at Cornell University, from the designs of Mr. Anthony, the Professor of Physics, to meet the want of a standard instrument for the measurement of heavy currents, and for the direct calibration of the commercial instruments in use for measuring the currents employed in electric lighting, &c. For the measurement of heavy currents there are four circles, two 2 metres in diameter, and two 1·6 metres, mounted, according to Helmholtz's plan, at distances apart equal to their radii. The conductors forming these circles are copper rods, three-fourths of an inch in diameter. The needle is suspended by a silk fibre in a mass of copper, which serves as an effectual damper, and makes it possible to take readings very rapidly. By a peculiar arrangement of mirrors and telescope the deflections are read directly in angular measure on a circle 50 inches in diameter, to within three-tenths of a minute of arc. The copper conductors are mounted on a brass framework accurately turned and adjusted, and the dimensions are all known within one five-thousandth. For the measurement of small currents there are two circles, about 1·5 metres diameter, each having two conductors, and comprising altogether 72 turns of No. 12 copper wire.

THE indications of such an instrument of course depend upon the value of the horizontal intensity of the earth's magnetism, and without some means of determining this quantity in the place where the instrument stands, and at the time when a measurement is being made, no great accuracy is attainable. For making this determination, a coil a metre in diameter, consisting of 100 turns of No. 18 wire, is suspended, so that its centre coincides with the centre of the instrument by means of a single phosphor-bronze wire, which is itself attached to a torsion-head reading to ten seconds of arc. By the aid of this coil, observations may be taken at any moment for the determination of H by the method proposed by Sir William Thomson. The instrument is mounted in a copper building, from the construction of which all iron has been rigidly excluded. Several conducting wires connect the building with the dynamo and other rooms of the physical laboratory, 550 feet distant, and switches in the building serve to send the currents through the several coils of the galvanometer singly, in series, or in multiple arc, direct or reversed. By this means currents from 1 milliampere to 250 amperes can be accurately measured.

THE last number (Heft 33) of the *Mittheilungen der Deutschen Gesellschaft für Natur und Völkerkunde Ostasiens* contains a paper by Herr Hütterott on the Japanese sword, with numerous illustrations of the various forms. It describes the manner in which it is forged, how it reaches the extraordinary degree of excellence for which it is celebrated, in short the *technique* of the making of a Japanese sword in the feudal days. Herr Mayet concludes his account of a visit to Corea, the first part of which we have already noticed. Dr. Naumann, the director of the Geological Survey of Japan, and Japanese representative at the late Geological Congress at Berlin, communicated an extract from a report of his on the geological structure of the Japanese islands.

ONE-TENTH of the "Studentenschaft" at the Zurich University is now female. Twenty-nine young ladies study medicine, fourteen philosophy, and two political economy. Of the forty-five female students, fifteen are Swiss, and ten Russian.

THE after-sunglow has again at times been visible in Stockholm, from the middle of August to the middle of September, being distinct from the ordinary evening aurora.

A FURTHER telegram has just been received by the Russian Minister of War from Col. Prjevalsky, dated Osh, September 30—that is, the 12th inst., new style. Only the concluding passage has as yet been published by the Russian papers:—"August 14 (new style, August 26), Oasis of Tchira.—I have explored the Keria Mountains. We are now proceeding *viâ* Khoten and Aksu, and we shall arrive in Semiretchia towards the end of October. All is well."

THE spheroidal state of liquids has recently been made an object of study by Signor Luvini (*Il Nuovo Cimento*). A curious phenomenon was noticed when air was blown into the drop (to test the view that liquids in that state do not boil because they have lost their dissolved air). There arose bubbles often larger than the mass of liquid, and very persistent; they shared the movements of the drop and sometimes moved independently. Such bubbles were had in pure water, soapy water, alcohol, and ether, and would probably arise in all liquids. Sometimes they appeared only after the tube was withdrawn. Signor Luvini infers that liquids in the spheroidal state do not lose their dissolved air, or lose it very little. The author made arrangements for observing the spheroidal state under different air pressures, and he came to the conclusion that the temperature of each liquid in that state, under a given pressure, is very nearly equal to the least boiling temperature of the liquid under the same pressure.

WE have just received from the secretary, Mr. Charles Bailey, F.L.S., of Manchester, the reports of the Botanical Exchange Club for the years 1883 and 1884. For 1883 Mr. G. Nicholson acted as distributor, and 3735 specimens were received and divided out again amongst the members. In 1884 Mr. Arthur Bennett undertook the labour of distribution, and the number of specimens placed in circulation was 4371. The two reports contain a series of annotations by the distributors upon the more interesting plants which passed through their hands. For a considerable number of species new counties are registered. The most interesting additions to the British flora, of which they make mention, are a *Scutellaria*, intermediate between *minor* and *galericulata*, perhaps a hybrid, found by Mr. Nicholson in a place one would have thought likely to be thoroughly explored long ago—the shores of Virginia Water; *Potamogeton fluitans*, a pond-weed very difficult to recognise, found by Mr. A. Fryer in Huntingdonshire; and *Carex salina*, a boreal species known already in Scandinavia, Iceland, the Faroes, Nova Zembla, and North America, which has lately been discovered by Mr. Grant in Caithness. The Rubi of Britain want carefully comparing with those of the Continent, and Mr Arthur Bennett has done well to send the Club specimens to be verified by Dr. Foche, of Bremen, whose synopsis of the German Rubi has been taken lately by Hyman as a basis for his enumeration of the European forms in his most useful geographical conspectus of the European flora.

A CURIOUS calculation has been recently made by Signor Bartoli regarding the mean density of a body which should contain all the known elements in a solid state, either uncombined, or, if partly combined, each retaining the density belonging to it in the solid state. The author makes three suppositions—(1) the masses of all the substances equal; (2) masses such that the corresponding volumes are equal; (3) masses in ratio of the atomic weights. The corresponding mean densities he arrives at are 2·698, 7·027, and 5·776, and it is pointed out that the last value comes very near that got by Cavendish for the mean density of the earth, viz. 5·67; possibly an accidental agreement, yet interesting.

WE have received from Mr. Francis Day copies of two papers, on a subject on which he also read a paper at the Aberdeen meeting of the British Association. One is entitled "Notes on the Breeding of Salmonidæ," being observations on the fish cultural experiments being carried on at Howietown, and on experiments by the author himself at Cheltenham. The second, from the *Transactions* of the Linnean Society, is on the breeding of salmon from parents which have never visited the sea. This also describes the results of experiments at Howietown.

WE have received the report of the Council of the Leicester Literary and Philosophical Society for the past year. Various important additions have been made to the town museum; the work on the flora of Leicestershire, undertaken and edited by a botanical sub-committee, is now in the press, and will shortly be published; the resolution, adopted at the last general meeting of the society, for the promotion of science classes in the town has, owing to various circumstances, only been partially carried out. Two experimental classes, one for pure mathematics, the other for physiology, have been commenced, and have been attended with fair results. The reports of the various sections show a considerable amount of work done during the year.

Short abstracts of various papers read before the society are given in the *Transactions*.

A MISSION of thirteen youths, belonging to the best families in Cambodia, has arrived in Paris for the purpose of study. They have been placed under the care of M. Pavie, who has constructed a line of telegraphs between Siam and Cambodia. This is the first time since 1864 that Cambodians have come abroad for purposes of education.

THE additions to the Zoological Society's Gardens during the past week include a Vervet Monkey (*Cercopithecus lalandii* ♂) from South Africa, presented by Mr. George E. Crisp; a Malbrouck Monkey (*Cercopithecus cynosurus* ♂) from West Africa, presented by Miss Ethel O'Donoghue; a Kinkajou (*Cercoleptes caudivolvulus*) from Demerara, presented by Mr. John Carder; four Common Squirrels (*Sciurus vulgaris*), six Common Dormice (*Muscardinus avellanarius*), British, presented by Mr. Thomas Weddle; a Tennant's Squirrel (*Sciurus tennanti*) from Ceylon, presented by Miss Maude Bovill; two Vulpine Squirrels (*Sciurus vulpinus*) from North America, presented by Capt. E. E. Vaill; a Coypu (*Myopotamus coypus*) from South America, presented by Mrs. Amelia Appleton; a Robben Island Snake (*Coronella phocarum*) from South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; two Sly Silurus (*Silurus glanis*), European, presented by the Marquis of Bath, F.Z.S.; a Red Lory (*Eos rubra*) from Moluccas, an Alexandrine Parrakeet (*Palæornis alexandri*) from India, deposited.

OUR ASTRONOMICAL COLUMN

PERIODICAL COMETS IN 1886.—Of the now somewhat numerous list of comets of short period, two will be due at perihelion in the ensuing year:—(1) The comet Tempel-Swift, or 1869 III. and 1880 IV., which is likely to return under circumstances that will render observations impracticable, so far at least as a judgment can be formed without actual calculation of the perturbations. (2) Winnecke's comet, last observed in 1875, its track in the heavens near the perihelion passage in December 1880 not allowing of the comet being seen at that return; the perturbations may be very sensible during the present revolution: neglecting their effect, the mean motion determined by Prof. Oppolzer, for 1880, would bring the comet to perihelion again about August 24·5, under which condition its path would be as follows:—

	R.A. °	Decl. °	Distance from Earth
July 25·5	177·5	+10·2	1·17
Sept. 13·5	241·7	−24·9	0·98
23·5	246·1	−30·2	0·64
Oct. 3·5	264·8	−35·6	0·64
23·5	305·0	−36·0	0·77

The actual orbit of Winnecke's comet approaches very near to that of the planet Jupiter in heliocentric longitude 110°, at which point the comet arrives 720 days or 1·97 years before perihelion passage, the distance between the two orbits is then less than 0·06 of the earth's mean distance from the sun.

It is very possible, however, that the comet which may most interest astronomers in 1886 will be that observed in 1815, and known as Olbers' comet, which, according to the elaborate calculations of Dr. Ginzel, will again arrive at perihelion in December 1886. The most probable date that can be inferred from the observations of 1815, and the computation of planetary perturbations in the interval is December 16, but unfortunately the observations did not suffice to determine the mean motion in 1815 with precision, and consequently Ginzel found for the limits of the period of revolution 72·33 and 75·68 years, hence the comet may reach its perihelion many months earlier or later than the date given by calculation. Extensive sweeping ephemerides have been published, and it may not be too soon to direct attention to a search for the comet at the beginning of the next year, or as soon as the region in which its orbit is projected at the time can be advantageously examined.

A CATALOGUE OF 1000 SOUTHERN STARS.—Vol. iii. of "Publications of the Washburn Observatory" is to contain a catalogue of 1000 stars between 18° and 30° of south declination, formed by Rev. Father Hagen and Prof. Holden from the observations of Prof. Tacchini at Palermo during the years 1867–69, which were printed in the *Bulletino* of that observatory between April, 1867, and July, 1869, and with which Prof. Holden says he became acquainted through M. Houzeau's Vade-Mecum. The stars observed are from the 6th to the 9th magnitudes, and the magnitudes appear to have been very carefully noted, while it is remarked that the positions are excellent. They are reduced to the year 1850, but the mean epoch of observation of each star is appended. The copy before us is a reprint from the above-named volume. Tacchini's observations were made with the Palermo meridian circle fully described in the *Bulletino*.

ASTRONOMICAL PHENOMENA FOR THE WEEK, 1885, NOVEMBER 1–7

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on November 1

Sun rises, 6h. 56m.; souths, 11h. 43m. 40·9s.; sets, 16h. 31m.; decl. on meridian, 14° 35′ S.: Sidereal Time at Sunset, 19h. 15m.

Moon (two days after Last Quarter) rises, 0h. 13m.; souths, 7h. 20m.; sets, 14h. 14m.; decl. on meridian, 9° 37′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	7 57	12 22	16 47	18 25 S.
Venus	11 11	14 46	18 21	25 50 S.
Mars	23 54*	7 13	14 32	14 20 N.
Jupiter	2 55	9 9	15 23	2 2 N.
Saturn	19 45*	3 53	12 1	22 18 N.

* Indicates that the rising is that of the preceding day.

Phenomena of Jupiter's Satellites

The Phenomena of Jupiter's Satellites are such as are visible at Greenwich.

Saturn, Nov. 1.—Outer major axis of outer ring = 44″·0; outer minor axis of outer ring = 18″·9; southern surface visible.

Nov.	h.	
1	4	Mars in conjunction with and 4° 16′ north of the Moon.
3	7	Mercury at greatest distance from the Sun.
3	9	Jupiter in conjunction with and 0° 52′ north of the Moon.
7	21	Mercury in conjunction with and 6° 16′ south of the Moon.

THE SCOTTISH METEOROLOGICAL SOCIETY

AT the annual meeting of this Society the Report of the Council stated that thirty-eight new members had been added to the Society during the year, and the membership now numbered 698. A new station had been established on the island of Fidra, at the mouth of the Firth of Forth, and that observations had been made for the Society at San Gorge, Central Uruguay. A large number of naturalists and others had availed themselves of the facilities for research offered by the Scottish Marine Station during the summer, there being thirteen working at the laboratories at the present time. Communications were now going on between the Council and several influential gentlemen in Glasgow, which it was hoped would result in the establishment of a permanent station for marine research on the Clyde. Mr. H. N. Dickson, of the Marine Station, communicated the results of experiments and observations which, during the past two months, he had been conducting at Granton, with the view of collecting data from which to determine the corrections to be applied to the readings of thermometers exposed in the ordinary Stevenson screen, in use in many places over the world. Having referred to the errors to which the ordinary screen gives rise, consequent on the varying atmospheric motion and radiation, he proceeded to say that his investigation was carried on chiefly by means of improved screens designed by Mr. John Aitken of Darroch, and that the dew points from the dry and wet bulbs by Glaisher's tables had been compared with those given by a new form of hygrometer designed by Prof. Chrystal of Edinburgh University. As regards Mr. Aitken's screen, in some a fan was introduced in order to secure a proper and uniform circulation of air for the thermometers in all weathers; others were simply sunshades; one consisted of two thermometers, one of which was partially blackened; and another of a thermometer having its bulb inclosed in a tight-fitting silver sheath, highly polished. The construction of Prof. Chrystal's hygrometer was explained and a brief account given of the results either already arrived at or suggested during the investigation, and it was intimated the inquiry was to be resumed at the Ben Nevis Observatory during August and September. At this Observatory, the climate of which offers unique facilities for the prosecution of such inquiries, an instrument of novel construction would be added, which had been designed by Prof. Tait for hygrometric research. Prof. Ewing, of Dundee, then described the arrangements which had been made for commencing the proposed earthquake observations on Ben Nevis this summer. The investigation was to include earthquakes proper; earth movements of so very delicate a kind as to be totally indistinguishable without some form of instrumental assistance, which are conveniently called earth tremors; and there were what might be named changes of the vertical, or those tiltings which the earth's surface seemed to be constantly undergoing. The different seismometers to be employed at the Observatory were then described, and in illustration some of the more striking peculiarities of the earthquakes of Japan were referred to.

PROF. KIESSLING'S INVESTIGATIONS INTO THE ORIGIN OF THE LATE SUNSET GLOWS[1]

THE interesting and important experimental demonstrations lately made by Prof. Kiessling of Hamburg to illustrate the artificial formation of all manner of sunset effects are probably well known to meteorologists in general. The September number of *Das Wetter* contains a valuable series of comparisons tending to show that the conditions under which artificial glows were produced have actually existed whenever the remarkable sunset effects have made themselves prominent. The following abstract may prove of interest to those who do not receive the paper itself.

With regard to the "after-glow," or re-illumination, he suggests two explanations as possible:—(*a*) Simple reflection of the refracted rays essential to the formation of the ordinary sunset-glow (the *first* glow); or (*b*) direct diffraction by a second homogeneous haze at much greater elevation. He considers, however, that the calculated heights of the latter place it out of the question. To the former there are only two important objections, the chief one being the slight polarisation, so far as the very scanty records indicate. The observations are, however, exceedingly deficient. Still, Prof. Kiessling has to allow that they do not tell in favour of the proposed explanation. The other difficulty is the *position* of the glow. It presupposes a mirror-like surface, parallel to the earth, with the intermediate space unusually transparent, conditions at first sight very improbable at the altitudes under consideration. But Prof. Kiessling's own experiments, detailed at the end of his paper on "Die Dämmerungserscheinungen im Jahre 1883," have shown the possibility. In these he obtained results most remarkably similar to those requiring explanation, and by methods reproducing in a striking manner the conditions considered actually to exist in the atmosphere.

A warm, moist stratum of air being produced in contact with a cold stratum the resulting haze along the contact surface formed the site of diffraction phenomena, approaching those actually observed in ordinary brilliant sunsets according to the fineness of the haze particles, and also reflections reproducing the "after-glow."

The almost constant saturation of the cold upper strata in winter is indicated by observations at high-level stations and the persistent upper haze. Let a warm [cyclonic] current come beneath such a layer, then the fine haze at the surface of contact will have beneath it the peculiarly transparent atmosphere common to such conditions and requisite for the transmission of the resulting diffraction (and reflection) phenomena. This should be found to exist in *all* brilliant sunsets, Prof. Kiessling stating the following law:—*An intense purple glow, visible over a considerable area, may occur when, in close proximity beneath a lofty and highly-attenuated haze, there is formed an extensive stratum of air at considerably higher temperature.*

Although we cannot ever expect direct observations of temperature at the common surface producing the sunset glows, yet, as Prof. Kiessling shows, if we can prove that the warm undercurrent always accompanies sunset glows, the proof is practically complete. Such indications may be expected during the colder seasons in the form of abnormal vertical distribution of tempera-

[1] Ueber die Entstehung des zweiten Purpurlichtes und die Abhängigkeit der Dämmerungsfarben von Druck, Temperatur, und Feuchtigkeit der Luft *Das Wetter*, vol. ii. No. 9. p. 161.

ture, an *increase* instead of decrease at higher stations. He brings forward a long array of figures supporting this conclusion, especially for sunrise effects in 1883, as seen from Säntis (2467 metres), in North-East Switzerland, in the bend of the Rhine. Stations to the east—Munich (528 metres) and Hohen Peissenberg (994 metres) are taken for observations on temperature and relative humidity. The last place is about 35 miles south-west of Munich; both may be considered as beneath the sky region producing glows at Säntis. As *difference of temperature* is the most decisive comparison, his tables are here reduced to a series showing the difference of Hohen Peissenberg returns from Munich, in degrees Centigrade. In some cases one or two other returns are also added, reduced in like manner. *Normally*, allowing for difference of height, Hohen Peissenberg should register 2°·5 below Munich.

The final set of observations refer to some of the earlier afterglows. The greater anomaly with greater elevation (increases of 5°·2, 10°·6, 12°·2, and 17°·1 respectively in the figures given) is very suggestive. The reason of the non-agreement in May has already been stated.

Except the last, these observations refer to ordinary sunrise effects, but the only difference between them and the recent glows is considered to be that the latter occur by reflection at a higher level and in a more finely attenuated haze, thus giving the richer effects. The presence of such a haze with the glows was a matter of very common observation.

The question, of course, requires further consideration, especially with respect to observations of the recent glows. Besides this connection with a warm stratum of air, Prof. Kiessling finds another, almost as general, with barometric maxima, as was noticed with the similar phenomena in 1881.

Referring, in his concluding paragraph, to the connection of the glows with the Krakatoa eruption, Prof. Kiessling writes that the thousand or so records of their geographical distribution, now in his hands, "show a perfectly continuous spread of the anomalous glows, and of the diffraction phenomena of Bishop's Ring dating from August 26, 1883, and spreading from the Straits of Sunda as a centre over the tropical and temperate zones."

J. EDMUND CLARK

A CENTURY OF SCIENCE IN BENGAL

IT was a happy idea of the Council of the Asiatic Society of Bengal to commemorate the completion of a century of the Society's existence by publishing a review of the progress made and the services rendered to knowledge by the institution.[1] The idea of a learned society composed of Europeans in India studying the country and communicating to each other at periodical meetings the results of their researches, arose first in the fertile brain of Sir William Jones, who was judge in the Supreme Court at Fort William, and who delivered, on January 15, 1784, to about thirty members of the European community of Calcutta, a "Discourse on the Institution of a Society for Inquiring into the History, Civil and Natural, the Antiquities, Arts, Sciences, and Literature of Asia." As a result of this discourse, the "Asiatick Society," the parent of all such societies, was founded. Its motto, which is taken from Sir William Jones's discourse here referred to, is this: "The bounds of its investigations will be the geographical limits of Asia, and within these limits its inquiries will be extended to whatever is performed by man or produced by nature." After many vicissitudes it has just completed its hundredth year, and the record of its work forms the large volume just mentioned. This is divided into three parts: first, a history of the Society, by Dr. Mitra; its work in archæology, history, and literature, by Dr. Hœrnle; and the work in natural science, by Baboo P. N. Bose. The change which has come over the face of India in the course of a century could hardly be better marked than by the fact that two out of the three parts into which the volume is divided—one of these being on natural science—are written by native gentlemen. In the history of the Society we notice that in 1808 a resolution was proposed by Dr. Hare and seconded by Dr. Leyden (frequently referred to in Lockhart's "Life of Scott"), "that a Committee be appointed for the purpose of physical investigations, the collection of facts, specimens, and correspondence with individuals whose situations in this country may be favourable for such discussions and investigations." It was then agreed to provide two committees—one for science, the other for literature; twenty years later, in 1828, a committee was appointed "to promote geological researches, working under the rules then in force for the Physical Committee," and at the same time the published *Transactions* of the Society were divided into two parts, one devoted to physical, the other to literary subjects. Nearly twenty years later the whole of the work of the Society was delegated to six committees, one having charge of zoology and natural history, another of geology and mineralogy, and a third of meteorology and physics. The establishment of a museum did not occur to the founder, but curiosities were constantly coming in from members, and in 1796 it was proposed to give these a suitable house. In 1814 Dr. Wallich proposed the formation of a museum, and offered duplicates from his own collections, as well as his services in arranging it, and a museum was accordingly started. The story of the growth of the various sections of the Natural History Museum is told by Dr. Mitra. On the whole it is one of great progress, although financial difficulties beset the museum at first. But as soon as the Society became able to pay for scientific curators all went well. In 1865 the Society's zoological, geological, and archæological collections were made over to the Government of India for the public museum in Calcutta. A writer in the *Calcutta Review*, speaking of the Society's exertions for the establishment of the national museum, said: "Had it done nothing else to promote science during the last ten years, it would have entitled itself to the gratitude of posterity for the vigour with which it has prosecuted to success a project fraught with so much public usefulness." The earlier volumes of the Society's *Transactions*, published under the title "Asiatick Researches," created a sensation in the literary and scientific world in Europe. A French translation was speedily published, with notes on the scientific portions by no lesser hands than Cuvier, Lamarck, Delambre, and Olivier. Of the work of the Society in preserving Sanskrit MSS., in translating and publishing various works from the native languages, and other valuable services to literature, Dr. Mitra speaks at length. Amongst the publications, apart from the papers, we notice many of scientific interest, such as catalogues of various sections of the museum, of the mammals and birds of Burmah, of Indian lepidoptera, besides translations of numerous works of Hindoo science. In summing up at the conclusion of his historical sketch the benefits conferred on India and the world by the Society during its hundred years of existence, Dr. Mitra sums up its scientific work (apart from papers, and published volumes above referred to) thus: "It got up an archæological and ethnological museum of considerable extent, a geological museum rich in meteorites and Indian fossils, and a zoological museum all but complete as regards the avifauna of India."

The long review of the work of the Society in natural science is, as already mentioned, written by Baboo Bose. His method is to take the various branches of science in succession, such as mathematical and physical science, geology, zoology, botany, geography, ethnology, and chemistry, and to describe under sub-heads the papers on these subjects contributed to the *Transactions* of the Society, together with a brief biographical sketch of the more celebrated or prolific authors. At the end we get a classified index of all the scientific papers, an alphabetical list according to the author's names being given at the conclusion of the first part. Amongst the latter we notice many whose names are familiar as contributors to NATURE. In the early years of the Society, and down to 1828, the scientific contributions to the Society's *Proceedings* were almost wholly connected with some branch of pure or mixed mathematics, for most of the men who went out to India, especially in the scientific branches of the military service, had been well grounded in this subject. The section on the investigations into the mathematical science of the Hindoos is of great interest. Sir William Jones put before the Society from the outset the object of studying these sciences, and he set the example himself, but the initial difficulty was to find any native capable of assisting him. Baboo Bose records that, although ample stipends were offered by Sir William Jones to any Hindoo astronomer who could name in Sanskrit all the constellations which he would point out, and to any Hindoo physician who could bring him all the plants mentioned in Sanskrit books, he was assured by the Brahmans whom he had commissioned to search for such instructors, that no Pundit in Bengal even pretended to possess the knowledge he required. Geology and mineralogy flourished in the Society from the commencement, while zoology was at first unduly depressed and discouraged owing

[1] "Centenary Review of the Asiatic Society of Bengal, 1784 to 1883." Published by the Society, Calcutta. Thacker, Spink, and Co., 1885.

to the aversion of Sir William Jones to zoological studies, and it was only about 1828 that the papers of Dr. Falconer, Col. Tickell, and others began to occupy an important position on behalf of zoology in the Society's transactions. With Indian botany, geography, and ethnology are connected many names of world-wide fame. With regard to chemistry, it may be said practically there is no chemical research in the Society's publications. Chemistry, as Baboo Bose explains, can only be studied in the laboratory, and until recently India had but few laboratories, and few competent men with leisure to devote to the subject. A curious statement, by the way, creeps into the account of Mr. Piddington, who studied Indian storms, and gave an account of every cyclone in the East between 1839 and 1851. Baboo Bose says his experience was most varied, and then quotes the following from some unnamed source :—"He was one of the few who escaped from the massacre of Amboyna." Now, as the massacre of Englishmen by the Dutch Governor of Amboyna took place in 1622, Mr. Piddington, if he was observing storms in India in 1850, could hardly have been in the Eastern Archipelago two centuries and a quarter previously. Many other portions of this volume, such as the chapters on coins, on ancient Indian alphabets, on the study of the languages and literature of India, and on the study of Indian antiquities, are of deep interest, but we have confined ourselves to the chapters on natural science.

The dominant feeling produced by an examination of this volume is one of satisfaction that so much has been done by this single society towards investigating the past and the present of (or, in the words of Sir William Jones, "man and nature in") our great dependency. For the most part this has been done by private individuals, but on more than one critical occasion the directors of the East India Company, in accordance with their generous traditions, came to the aid of the Society with large contributions; otherwise there appeared no way out of the difficulty except the dissolution of the Society and the abandonment of the works in which they were engaged. If this were the place it would be interesting to compare this method of practically leaving everything to private initiative, with that adopted by the French in Indo-China, of the Government undertaking a series of literary, artistic, and scientific investigations through competent specialists into a new possession. Notwithstanding the great and marked success of the Asiatic Society of Bengal, the French plan has advantages which cannot be overlooked.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—Among the more noticeable Natural Science Courses this term are Prof. Dewar's on Dissociation and Thermal Chemistry; Prof. Newton's, on Evolution in the Animal Kingdom; Dr. Gadow's on Human Embryology; Dr. Vines's, on the Physiology of Plants; and Prof. Macalister's, on the Peripheral Nervous System.

Prof. Hughes is lecturing on Methods of Geological Surveying; Dr. R. D. Roberts, on Principles of Geology; Mr. Marr, on Elementary Stratigraphy; Mr. T. Roberts, on Palæontology; and Mr. Hawker, on Elementary Petrology; all at the Woodwardian Museum.

Prof. Roy is lecturing on General Pathology, and also conducting a Practical Course in Morbid Anatomy and Histology.

Prof. Stokes is lecturing on Hydrodynamics; Prof. Cayley, on Higher Algebra; Prof. Darwin, on Orbits and Perturbations; Mr. Glazebrook, on Waves and Sound; Mr. Hobson, on Planetary Theory; Mr. Macaulay, on Theory of Structures; and Mr. Forsyth on Abel's Theorem. Numerous other courses on higher mathematics, open to the University, are being given by college lecturers.

We are glad to notice that Mr. A. Sheridan Lea, M.A., Lecturer on Physiology, and formerly Scholar, of Trinity College, has been elected to a Fellowship at Gonville and Caius College. Mr. Lea's work in connection with Prof. Michael Foster's "Text-Book of Physiology" is well known. Mr. Lea was placed in the First Class in the Natural Science Tripos in 1875, and has since been continuously engaged in the University teaching of Physiology.

Dr. S. Richemann has been appointed assistant to Prof. Dewar, Jacksonian Professor.

Messrs. E. W. Hobson and A. R. Forsyth are appointed Moderators, and Mr. C. H. Prior Examiner, for the next Mathematical Tripos.

King's College offers a Vintner Exhibition of 70*l.* per annum for Natural Science. The examination begins on December 10.

St. John's College offers several scholarships, exhibitions, and sizarships for competition on December 10. Candidates may offer any of the subjects of the Natural Sciences Tripos except Mineralogy, and may be elected on the ground of special proficiency in one only. Particulars will be furnished by the tutors.

A joint examination for Natural Science Scholarships at Emmanuel, Christ's, and Sidney Sussex Colleges will be held on January 5, 1886, and following days. The subjects are Chemistry, Physics, Elementary Biology, Geology, and Mineralogy. Further particulars will be given by the tutors of either college.

Out of the 875 freshmen whose names have appeared in the preliminary lists, about 104 have announced their intention of studying medicine in the University. A few more may be added when the results of the October Previous Examination are known. The Anatomy School is attended by over 130 students, for whom an exceptionally abundant supply of dissecting material is in hand. The Demonstration Lectures have to be repeated from lack of room; indeed, the necessity for increased accommodation in this department is becoming extremely urgent.

LONDON.—We have received a circular stating that "In view of the adjourned extraordinary meeting of Convocation (of London University) to be held on Tuesday, November 3, a number of graduates met on Wednesday last to consider the proposed scheme for the establishment of a Teaching University for London. As the result of their deliberations it was thought desirable that attention should be called to some of the more striking objections to the proposed scheme; and that, having regard to the grave importance of the questions to be submitted to the members of Convocation affecting the very existence of the University as at present constituted, they should be especially requested to attend on Tuesday next, and to give their support to Mr. Bone's amendment, to *receive* the report submitted by Lord Justice Fry, without *adopting it* '*in bloc*.' Should this amendment be carried, the following resolutions, expressing what is believed to be the feeling of the majority of the graduates, will be moved:—(1) 'That Convocation, whilst affirming the general principles of the desirableness of bringing the teachers and the examiners of the University into closer relationship with one another and with the Senate, and of modifying the constitution of the Senate in accordance with the previous recommendations of Convocation, and without giving to the teachers an undue share of representation on the governing body of the University, refers back the scheme to the Special Committee for further consideration.' (2) 'That the number of members on the Special Committee be increased by one-half.'"

SOCIETIES AND ACADEMIES

SYDNEY

Linnean Society of New South Wales, July 29.—The following papers were read:—A monograph of the Australian sponges, part 5, the Auleninæ, by R. von Lendenfeld, Ph.D. Several sponges from various localities in the Australian region have been included by the author in this new sub-family, the members of which are characterised by a very peculiar structure not met with in any other sponges. The new sub-family *Auleninæ* is placed in the family Spongidæ, and consists of the two new genera Aulena and Halme, with three species in all. The anatomy and histology of these is accurately described and illustrated by numerous plates. The Auleninæ form honeycombed or complicated reticulate structures; the cavities form a kind of vestibule and are simple in Halme, where an outer lamella surrounds the whole sponge, or subdivided into numerous small compartments, as in Aulena, where no outer lamella exists. Into the system of Vestibule-Lacunæ both the inhalent and the exhalent canals of the sponge open. The skeleton of Halme is composed of thick main fibres rich in sand, thin, simple and clean connecting fibres, and a hard cortex of sand cemented with spongiolin. The skeleton of Aulena is very peculiar. It consists of a regular network of fine horny threads in the joining points of which large sand grains are found. In the membranes of the Vestibule-Lacunæ of this genus nervous elements, sensitive and ganglia cells have been discovered by the author. These and many other histological details are described in the paper, which dwells also on the morphological significance of these interesting new sponges.—On a sponge destructive to oyster-culture in the Clarence River, by R. von Lendenfeld, Ph.D. In this paper the author describes a new sponge, *Chalinula coxii*, which appeared some years ago on certain oyster beds in the Clarence River, and destroyed some of them completely.—Note on the Glacial period in Australia, by R. von Lendenfeld, Ph.D. The author draws attention to some further evidence of ice action in the Mount Lofty group near Adelaide, where some glacier-polished Siluro-Devonian rocks, with very well preserved striæ, have been discovered and photographed.—Jottings from the biological laboratory of Sydney University, by William A. Haswell, M.A., B.Sc., F.L.S., &c., Lecturer on Zoology and Comparative Anatomy. This paper contains (1) some notes on an Australian species of Bonellia, which seems scarcely to differ from the European species, *Bonellia viridis;* and (2) some observations on aquatic respiration in fresh-water turtles.—On the supposed Glacial epoch in Australia, by Capt. F. W. Hutton, F.G.S., &c. The author discusses the phenomena which have been adduced as evidence for the former existence of a Glacial epoch in Australia, and shows that they are susceptible of a different interpretation. He distinguishes between a Glacier epoch, such as has occurred in New Zealand, in which, owing to various local, but only local, causes, ice-fields prevailed over much larger districts than at present, and a Glacial epoch, such as has been demonstrated in the Northern Hemisphere, which is the result not of variations caused and limited by local circumstances, but of alterations universal or cosmical in character. The Glacier epoch in New Zealand is regarded as anterior to the Glacial epoch of the North.

Paris

Academy of Sciences, October 19.—M. Bouley, President, in the chair.—Remarks on the 209th volume of the "Connaissance des Temps" for the year 1881, presented to the Academy on behalf of the Bureau des Longitudes, by M. Faye.—Note on the establishment of a laboratory in the Institute for the measurement of the photographic plates obtained during the transit of Venus in 1882, by M. Bouquet de la Grye. Arrangements have been made, by means of which it is hoped that the calculations and measurements relating to 700 plates will be completed in fifteen months.—Note on the Dinoceratidæ discovered by Mr. Marsh in the Eocene formations of Wyoming, United States, by M. Albert Gaudry. These huge pachyderms, which seem most to resemble the European Coryphodon described by M. Hébert, are specially remarkable for the characteristic horny protuberances on the frontal region, whence their name (δεινός, terrible, and κέρας, horn). The skull is also distinguished by its small size, in this respect resembling that of a reptile, as well as of several other mammals of the Lower Tertiary epoch.—On the birational geometrical transformations of the *n* order, by M. de Jonquières.—Note on the fifth part of the topographical map of Algeria, presented to the Academy on behalf of the Minister of War, by Col. Perrier. This part comprises the six divisions of Jebel-Filfila, Bone, Wed-Guergur with Cape Rosa, Menerville, Medeah and Mostaganem to the scale of 1 : 50,000.—Note on the sub-lacustrine ravines of glacial streams, by M. F. A. Forel. During his recent surveys of Lakes Constance and Geneva, M. Hörnlimann has discovered that both the Rhine and the Rhone continue their course under the lacustrine waters through deep ravines excavated beneath the respective submerged deltas. That of the Rhine has been traced for a distance of four kilometres and to a depth of 125 metres below the lake, while that of the Rhone may be followed for over six kilometres from the mouth of the river with a depth varying from 200 to 230 metres.—On the origin and classification of meteorites, by M. Stanislas Meunier. The author discusses the objections urged against his views on the nature and classification of meteoric bodies, by M. Brezina in the "Meteoritensammlung des Mineralogischen Hofkabinets in Wien," Vienna, 1885.—On the latitude of the observatory of Bordeaux, by M. G. Rayet. The mean latitude of this establishment, whose longitude was determined in 1881 at 11m. 26·444s. W., is found to be 44° 50′ 77″·23.—On the integrals of total differentials of the second species, by M. E. Picard.—Questions relating to a bundle of plane cubic figures, by M. P. H. Schoute.—On the torsion of prisms, by M. Marcel Brillouin.—Description of a new apparatus for measuring electric currents (one illustration), by M. F. de Lalande. This apparatus, for which the name of "electric areometer" is proposed, dispenses with a permanent magnet, the source of so much error in other appliances, is highly sensitive and practically unaffected by changes of temperature, while its readings are unmodified by the neighbourhood of metallic bodies or even of powerful magnets.—On the theory of the transmitting electromagnetic telephone, by M. E. Mercadier.—Note on the electrolysis of the salts, by M. Ad. Renard.—Combination of the neutral carbonate of magnesia with the bicarbonate of potassa, by M. R. Engel.—On the adulteration of olive oil intended for consumption by the addition of sesame cotton and other oils extracted from seeds, by M. A. Audoynaud. The bichromate of potassa and nitro-sulphuric acid are proposed as reagents for determining the presence of these substances.—On certain peculiarities in the development of the teeth of the cachalot (spermaceti whale), by M. G. Pouchet.—On the process of development of *Epicauta verticalis*, by M. H. Beauregard.—On the part supposed to be played by the living tissues of wood in the ascension of the sap in large plants, by M. J. Vesque. The author contests the opinion of those physiologists who hold that it is impossible to explain by the aid of purely physical forces the ascension of water in plants over 10 metres high.—On a waterspout observed at Shanghai on August 21, by M. Martial.—Account of the same waterspout, by M. Marc Dechevrens.—Description of M. Buisson's new rifle, by Gen. Favé. For this weapon it is claimed that it can be fired from five to ten times in a minute by troops charging the enemy without stopping an instant to re-load. As many as a hundred rounds may be fired off in this way.
